In a multicentre trial, 139 patients were randomized in a double-blind manner to dronabinol 2.5 mg or placebo twice daily for 6 weeks. Appetite and nausea improved significantly with dronabinol compared to placebo, with a trend to weight gain and improvement in mood and performance status. However, there was a significantly higher frequency of central nervous system adverse events with dronabinol compared to placebo (Beal et al., 1995).

Megestrol acetate

In a multicentre trial, 271 patients were randomized in a double-blind manner to MA 100, 400, or 800 mg, or placebo daily for 12 weeks. Maximum weight change, percentage of patients gaining at least 5 lb and mean change in lean body mass were significantly greater in the group that received MA 800 mg daily, compared with the group that received placebo. Also, perception of well-being, change in caloric intake and improvement in appetite were significantly greater in this group (Von Roenn et al., 1994).

In another multicentre trial, 100 patients were randomized in a double-blind manner to MA 800 mg or placebo daily for 12 weeks. Changes in caloric intake, protein intake, weight, fat mass, and well-being scores significantly favoured MA. There were no differences between groups in lean body mass, performance status and survival (Oster et al., 1994).

Thalidomide

In a multicentre randomized double-blind study, 104 men received either thalidomide 100 mg, thalidomide 200 mg, or placebo daily for 8 weeks. Weight gain in the thalidomide 100 mg group but not the 200 mg group was significantly different from the placebo group. More patients had dropped out of the 200 mg group due to adverse events, the most common of which was rash. No differences were seen in body composition, caloric intake or tumour necrosis factor alpha levels (Kaplan et al., 2000).

Amino acids

A single-centre trial was undertaken to determine whether glutamine supplementation and select antioxidants could satisfy an increased glutamine requirement and thus reverse body cell mass loss in patients with AIDS. Twenty-six patients were randomized in a double-blind manner to glutamine 40 mg with selected antioxidant nutrients or placebo orally daily for 12 weeks. Glutamine-treated patients had a significantly greater increase in body cell mass and body weight compared to control patients (Shabert et al., 1999).

In another single-centre trial, 58 patients were randomized in a double-blind fashion to arginine 14 g, glutamine 14 g and hydroxyl beta-methylbutyrate 3 g or placebo daily for 8 weeks. The amino acid-treated group gained significantly more weight and lean body mass compared to the placebo group (Clark et al., 2000).

Multiple agents

In a multicentre, open-label trial, 52 patients were randomized to dronabinol 2.5 mg twice daily, MA 750 mg daily, the two agents together, or the dronabinol plus MA at a lower dose of 250 mg daily for 12 weeks. Patients who received MA at the higher dose gained significantly more weight than those who didn't. There were no differences between arms with respect to performance status, quality of life, mood, hunger, or adverse events (Timpone et al., 1997).

Forty patients were randomized in a multicentre study to MA 800 mg daily or oxandrolone 10 mg twice daily for 2 months in an unblinded manner. Weight, BMI, fat, and lean body mass increased significantly in both groups, with no differences between groups (Mwamburi et al., 2004).

A multicentre, randomized, double-blind trial was undertaken in 79 men who received MA 800 mg daily plus testosterone 200 mg or placebo every two weeks for 12 weeks. Both groups experienced increased weight, lean body mass, and fat mass, but there were no differences between groups in magnitude or composition of weight gain (Mulligan et al., 2007).

Chronic obstructive pulmonary disease
Anabolic steroids

In a single-centre trial, 230 patients with moderate to severe COPD who were admitted to an inpatient pulmonary rehabilitation programme were randomized to placebo intramuscularly every 2 weeks for four doses, placebo injections plus nutritional supplementation, or nandrolone (50 mg for men and 25 mg for women) intramuscularly every 2 weeks for four doses plus nutritional supplementation. The injections were given in a double-blind manner. Patients in both groups that received nutritional supplementation experienced significant weight gain compared to those in the placebo group. However, patients who did not receive nandrolone gained fat mass, whereas those who also received nandrolone gained fat-free mass. Maximal inspiratory pressure improved significantly in both treatment groups at 4 weeks, but was sustained only in combination group at 8 weeks (Schols et al., 1995).

In a single-centre, randomized, double-blind trial, 23 male patients with stable COPD received testosterone 250 mg intramuscularly plus stanozolol 12 mg or placebo orally daily for 27 weeks. Both groups received daily inspiratory muscle training from weeks 9 to 18, and exercise training on a cycle ergometer from weeks 18 to 27. Lean body mass increased from baseline in the anabolic steroid group, but was not significantly different from the placebo group. Both groups demonstrated increased maximal inspiratory pressure, which was greater in the anabolic steroid group but not significantly different from the placebo group. There were no significant changes in 6-minute walking distance or maximal oxygen consumption in either group. No adverse effects were apparent (Ferreira et al., 1998).

In a single-centre, randomized, double-blind trial, 63 male patients with stable COPD received nandrolone 50 mg or placebo on days 1, 15, 29, and 43. All patients participated in an 8-week inpatient pulmonary rehabilitation programme. Patients who were depleted in fat-free mass received oral nutritional supplements. Treatment with nandrolone resulted in a significantly greater increase in fat-free compared to placebo. Physical functioning improved in both groups, without differences between groups. Health status as measured by the St George's Respiratory Questionnaire improved in the nandrolone group but not in the placebo group, although the difference between groups was not significant. In a post hoc analysis, patients on oral glucocorticoids who received nandrolone had a significantly greater improvement in maximal inspiratory pressure compared to the placebo group. Also, peak workload improved to a significantly greater extent compared to the placebo group (Creutzberg et al., 2003).

Fifty-three men with stable COPD and serum testosterone at the lower range of normal were randomized to the following groups: (1) placebo without resistance training, (2) testosterone 100 mg weekly without resistance training, (3) placebo with resistance training focused on muscles of ambulation, and (4) testosterone with resistance training. The interventions lasted for 10 weeks, and the drug component was double-blind and placebo-controlled. Patients receiving testosterone demonstrated a significantly greater increase and decrease in lean body mass and fat mass, respectively. The increase in lean body mass tended to be greater in testosterone-treated patients who received resistance training versus those who didn't, but the difference was not significant. Measures of leg strength and fatigability improved significantly in all three active intervention groups compared to the non-intervention group, with the greatest improvement seen in the group that received both testosterone and resistance training. There was no increase in respiratory muscle strength or whole-body exercise endurance in any group (Casaburi et al., 2004).

A single-centre randomized double-blind trial was undertaken in 29 male ambulatory patients with stable moderate to severe COPD who were not participating in a pulmonary rehabilitation programme. Patients received testosterone 250 mg or placebo intramuscularly every four weeks for 26 weeks. No changes were seen in pulmonary function, respiratory symptoms, mood, disability scores or body weight. Fat-free mass increased and sexual function improved in the testosterone group, with a significant difference from the placebo group. No adverse effects were noted (Svartberg et al., 2004).

In a single-centre randomized double-blind trial, ambulatory patients with stable severe COPD who were not participating in a pulmonary rehabilitation programme received nandrolone (50 mg in men and 25 mg in women) or placebo every 2 weeks for 16 weeks. The study was terminated after interim analysis of results of first 16 patients showed no differences in any nutritional, functional or quality of life outcomes (Sharma et al., 2008).

Megestrol acetate

In a multicentre trial, 145 patients were randomized to MA 800 mg or placebo daily for 8 weeks in a double-blind manner. The MA group gained significantly more weight compared to the placebo group. The weight gain was determined to be fat mass. $PaCO_2$ decreased and PaO_2 increased significantly in the MA group compared to the placebo group, consistent with stimulation of ventilation. There were no differences between groups in respiratory muscle strength. Distance walked in 6 minutes and dyspnoea score were significantly worse with MA compared to placebo, but body image and appetite scores were significantly better (Weisberg et al., 2002).

Growth hormone

A single-centre randomized double-blind trail was conducted in stable COPD patients attending an inpatient pulmonary rehabilitation programme. Sixteen patients received either rhGH 0.15 IU per kg or placebo subcutaneously daily for 3 weeks. The rhGH group demonstrated significant advantages in lean body mass and resting energy expenditure compared to the placebo group. No differences were seen in body weight, caloric intake, respiratory or peripheral muscle strength, maximal power during incremental exercise, dyspnoea, or mood.

Six-minute walking distance was significantly worse in rhGH-treated patients (Burdet et al., 1997).

Polyunsaturated fatty acids (PUFAs)

A single-centre, randomized, double-blind trial was undertaken in 102 stable COPD patients admitted to an inpatient pulmonary rehabilitation centre. They received a PUFA blend 9 g or placebo daily for 8 weeks. All patients who were nutritionally depleted also received liquid nutritional supplementation. PUFA-treated patients showed significantly greater increase in peak workload and duration of submaximal bicycle ergometry test, compared to placebo-treated patients. No differences were apparent in body composition, muscle strength or lung function (Broekhuizen et al., 2005).

Agents under investigation

Current trials in progress and investigational new agents can be found at <http://www.clinicaltrials.gov>. Current investigations appearing under the search term *anorexia* encompassed continuing interest in progestational agents at various doses/combinations with other therapies, as well as new agents including atypical neuroleptics (olanzapine, mirtazapine), creatine, as well as various herbal preparations. Trials appearing under the search term *cachexia* encompassed further elaborations within current drug classes (e.g. ghrelin, synthetic ghrelin, small molecule ghrelin receptor agonists), multimodal therapeutic strategies as well as new agents especially muscle-specific agents (selective androgen receptor modulators, antagonists to myostatin) and monoclonal antibodies to interleukin 1α and interleukin 6.

Conclusion and future perspectives

At the present time there is a basis to adopt a proactive approach to screening, assessment and early intervention for involuntary weight loss in cancer cachexia. There are clinically useful evaluations and the efficacy of a number of treatments has been established in randomized clinical trials. A future goal will be to further improve surveillance, especially the development of more clinically practical ways of assessing body composition so that losses of lean body mass and skeletal muscle may be detected early. A number of investigational new drugs are appearing in phase I–III clinical trials and these are targeted at stimulation of appetite in the hypothalamus as well as skeletal muscle anabolism. These agents provide further promise of slowing down or reversing weight loss and functional loss. Investigations of nutrient requirements are required to define the unique needs of patients with cachexia syndromes and underpin the development of nutritional recommendations or nutritional support products.

Common symptoms and disorders: skin problems

Skin problems in palliative care

Patricia Grocott, Georgina Gethin, and Sebastian Probst

Introduction to skin problems in palliative care

Skin problems are prevalent in patients with advanced disease who are receiving palliative care. Nursing aspects include the management of skin breakdown and wounds together with related symptoms, and promoting patient comfort and dignity, thereby enhancing the quality of life of patients and families. Palliative wound care encompasses the nursing care of patients, of all ages, with a weakened skin barrier together with the management of wounds caused by advanced and intractable diseases and conditions.

Framework for palliative wound care practice

Palliative wound care acknowledges the psychosocial impact of wounds on the individual concerned, their family and friends, and also their clinicians. It is driven by patient and family goals, which are integrated with three wound management components to reduce the impact of wounds on all concerned:

◆ management of palliation of the underlying cause of the wound

◆ management of wound-related symptoms

◆ management of the wound and peri-wound skin.

These components will be illustrated in this chapter in relation to good skin care, pressure ulcers, and fungating malignant wounds.

Palliative wound care patients

As with other aspects of palliative care, there is a concern that patients should not be labelled 'palliative' unless their situation warrants this. That said, the components of palliative wound care we propose are essentially components of appropriate patient care, which could complement curative wound care protocols. The difference between curative and palliative wound care, in our view, has more to do with goal setting and outcome measures than radically different clinical interventions. For example, palliative wound care goals include the management of odour, exudate, bleeding, pain, and the maintenance of an intact dressing system, which are interim goals towards wound healing by secondary intention (Dealey, 2012). Wound healing may also be achievable, demonstrated by Maida et al. (2012) in their survey of patients in a regional palliative care programme in Canada. The potential for complete healing of pressure ulcers of grade II and above, skin tears, and diabetic and venous ulcers increased the longer the

patients lived. Deep pressure ulcers, arterial wounds, and malignant wounds, however, did not heal (Maida et al., 2012).

The following are examples of skin damage and wounds in palliative care:

◆ pressure ulcers

◆ moisture lesions

◆ skin tears

◆ dry irritated skin

◆ malignant fungating wounds

◆ fistulae

◆ blistering skin conditions, for example, epidermolysis bullosa, bullous pemphigoid.

Patients' experiences of living with wounds

A cluster of qualitative research studies demonstrate the profound impact that wounds have on patients, carers, and professionals. Nurses have described caring for patients with this condition as an intense and unforgettable experience (Alexander, 2010). Patients reported an overwhelming sense of vulnerability of living within a body that cannot be trusted or one that was continually changing (Piggin and Jones, 2007). Patients also described delaying seeking medical help as they were feeling a sense of shame and blame (Lund-Nielsen et al., 2011) until their situations became unmanageable. Their problems included unpleasant wound odour, wound pain, bleeding and/or itching, as well as other fears related to being diagnosed with advanced cancer.

Uncontrolled wounds are distressing and burdensome for patients and families (Probst et al., 2012) and are linked to a poorer quality of life (Lo et al., 2012). Uncontrolled wound exudate and odour lead to a loss of self-confidence and progressive social isolation. For some this extends to keeping the wound a secret from family members (Probst et al., 2013). The concept of the unbounded body, depicting the erosion of physical boundaries and progressive spiritual loss, is used by researchers to explain patients' experiences of living with uncontrolled wounds (Lawton 2000; Probst et al., 2013).

Lawton (2000) observed that body boundaries could be reinstated, and individuals could regain a sense of control and well-being, with local wound management and continence interventions. Lund-Nielsen (2005) has demonstrated the positive impact of systematic approaches to dressing and managing fungating wounds, as has Grocott (2000). However, the systems evaluated by Grocott (2000) were experimental and have not been

commercialized. Probst et al.'s (2012, 2013) study, which included family members who were also carers, indicates that there is an ongoing struggle to contain advanced malignant wounds with currently available products, together with a lack of coherent professional advice and guidance on wound care interventions.

With regard to another condition giving rise to palliative care needs—epidermolysis bullosa (EB)—Grocott et al. (2013) have demonstrated the burden of skin and wound care on the individuals with this condition and their carers. A shared problem between people with EB and those with fungating wounds is the mismatch between the size and shape of EB and fungating wounds, and current dressings, which are designed to cover individual discrete wounds. Pre-sized and shaped dressings need to be patch-worked across extensive wounds, and are inherently unstable.

With regard to the management of symptoms such as malodour, which will be discussed further in the section of this chapter on symptom management, evidence from a recent international survey indicates that a myriad of interventions to control this very distressing symptom are not found effective (Gethin et al., 2014). A linked explanation of these findings may be that there is a similar mismatch between the size and scale of the wounds, the malodour problem, and the presentation of commercially available preparations for managing the source of the malodour. The fact that clinicians resort to unlicensed use of licensed materials (e.g. crushing metronidazole tablets into a hydrogel to line a large necrotic cavity) and the use of shaving foam and cat litter to absorb and mask odour, are evidence of desperate measures.

To overcome the limitations of current dressings in providing adequate and stable coverings for extensive wounds, Grocott et al. (2012, 2013) have worked in partnership with adults with EB, their carers, a designer, and a manufacturer to find solutions for whole-body wounds, based on the EB experiences. This research has resulted in dressing retention garments, which have been commercialized through international health services supply chains (Grocott et al., 2013a). A next stage of this research is to develop body-wrap disposable dressings for use with the dressing retention garment in a two-layer system.

Clinical assessment, decision-making, and evaluation

Clinical assessment, routine documentation, and evaluation are particularly important in palliative wound care where the evidence base is not established. Regarding the assessment of palliative wounds, five assessment scales have been identified: the Toronto Symptom Assessment System for Wounds, the Schulz Malignant Fungating Wound Assessment Tool, the Wound Symptoms Self-Assessment Chart (WOSSAC), the TELER System, and the Hopkins Wound Assessment Tool (Haisfield-Wolfe, 1999; Naylor, 2002; Maida et al., 2009; Grocott et al., 2011). Five 'core' symptoms are assessed by all the scales, these include odour, pain, exudate, itching, and bleeding. WOSSAC and TELER also include psychosocial aspects and impact on daily life. The structures of the five scales vary in the number of items used, their measurement, as well as in their mode of application. These scales can help clinicians to assess wounds and derive interventions in a systematic way, thereby improving professional practice and patient outcomes.

Patients with a weakened skin barrier: good skin care

General skin problems in advanced disease are largely attributable to skin that is weakened by the effects of chronic disease and ageing, performance status, multiple co-morbidities, and the iatrogenic effects of treatments, such as systemic glucocorticoid use (Maida et al., 2012). If the many factors that predispose palliative care patients to skin problems are taken into account it may be possible to mitigate their effects. Nursing care is clearly not able to prevent and resolve all the problems of advanced disease, for example, immobility and anorexia. However, dedicated interventions to prevent morbidity resulting from these problems, for example, pressure ulcers, skin tears, and dry skin conditions, may be possible.

Good skin care aims to maintain and replenish the skin by cleansing, hydrating and moisturizing, and protecting. If the patient's skin is to remain intact and free of distressing symptoms, knowledge and skill is required in the selection and use of skin cleansers, creams, and barrier products, together with dedicated and consistent care (Voegeli, 2012).

Skin cleansing

It is well recognized that the use of soap and water to clean the skin, with paper and cloth towels to dry the skin, can strip the skin of natural oils. The high alkaline content of soaps can alter the pH and the protective acid mantle of the skin. This disturbs the balance of normal skin flora, thereby reducing its protective function against colonization by pathogenic bacteria, which enter the body through breaks in the weakened skin (Voegeli, 2012).

A number of skin cleansers are available that are formulated to minimize alteration of skin pH and maximize the protective function of the skin. These products come in the form of emulsions, foams, and sprays. Some of the preparations also include a barrier product.

Moisturizing and hydrating

Moisturizing products such as emollients are designed to maintain or increase the hydration of the skin by trapping moisture under the barrier provided by the emollient itself. The choice of a lotion or an ointment depends on patients' preferences. Ointments take time to be absorbed into the skin and can leave a greasy feel, whereas lotions are rapidly absorbed. Ointments can also interfere with the action of disposable pads for the management of incontinence, as discussed later.

Protecting

Barrier products, such as barrier creams, have some effect on hydrating and moisturizing the skin, but their main function is to form a thin layer on the skin surface to protect the skin from excoriating body fluids. They need to be replenished whenever the skin is cleaned.

Pressure ulcers and moisture lesions

There is an extensive literature on the prevention and management of pressure ulcers, including clinical guidelines, which can be drawn on to guide pressure-relieving strategies and local wound management. There is also increasing recognition that

excessive moisture, maceration, and excoriation cause skin breakdown in patients who are not mobile and also suffer from continence problems (European Pressure Ulcer Advisory Group and National Pressure Ulcer Advisory Panel (EPUAP and NPUAP), 2009, 2010). Pressure ulcers and moisture lesions can coexist if each predisposing risk factor is not managed optimally.

The focus in this section is to put general principles of pressure relief, prevention, and management of moisture and excoriating skin damage, and ulcer management into the context of palliative wound care.

Prevention of pressure ulcers is inextricably linked with treatment. When pressure damage occurs, interventions that relieve pressure need to be put in place, together with additional measures to manage broken skin and wounds, including:

◆ pressure relief and management of any friction or shear forces

◆ good skin care

◆ wound management

◆ continence and fistula management.

Pressure damage prevention

Assessment of patients at risk of pressure damage is an important aspect of prevention. The use of risk assessment tools needs to be combined with clinical judgement and patients' preferences. The Hunters Hill Marie Curie Centre risk assessment tool has been developed specifically for palliative care patients who are, in the main, at considerable risk of developing pressure ulcers (Chaplin, 2010). Patients require regular repositioning on pressure redistribution devices (mattresses, seating), regardless of the quality of the device. Repositioning is also essential to maintain movement in joints, to help prevent contractures and pain from immobility, and for psychological reasons. The frequency of position change will be based on assessment of risk, the general condition of the patient, and the equipment being used.

Skin condition is the best indicator of how often position changes need to occur. This is assessed by lightly pressing an area of skin on which the patient was lying prior to turning. The skin should go white (blanche) and then return to its normal colour. The time taken to return to normal should be no longer than twice the length of time for which the finger pressure was applied. A fixed red mark that does not fade within 20 minutes after pressure has been relieved is indicative of pressure damage, loss of tissue viability, and varying degrees of skin breakdown and ulceration (EPUAP and NPUAP, 2009).

Patients with no evidence of pressure damage simply require good skin care and ongoing monitoring. However, pressure ulcers can still occur in spite of rigorous assessment and monitoring, and the use of first-class pressure-relieving devices for beds and chairs.

The development of a pressure ulcer is understandably distressing for patients, families and clinicians. Once an ulcer is established, care and management revolve around pressure relief, local wound management, including the management of moisture, and symptom management.

The nature and stage of the damage dictates treatment interventions together with curative or palliative goals. Pressure ulcers comprise devitalized tissue following interruption of the blood supply. The management plan will be guided by whether the aim is to heal the wound or to palliate. Strategies for healing and palliation are discussed in the section on local wound management and symptom control, using the conceptual framework of wound bed preparation (WBP). See Table 11.1.1.

Prevention of skin damage from moisture

Moisture lesions can be confused with sacral pressure ulcers, because of their location. However, the skin damage is associated with body fluids (urine, faeces, sweat) as opposed to pressure and shear (Bianchi, 2012). If the patient also has a pressure ulcer, the exudate from the ulcer will contribute further to the moisture damage unless it is managed effectively with local wound management strategies. In conjunction with good skin care, interventions to prevent and manage moisture lesions include the management of urinary and faecal incontinence with the following medical devices (EPUAP and NPUAP, 2009).

Disposable pads and close-fitting underwear or self-seal nappies

The pads are based on baby nappy technology and comprise a fluid handling system (super absorbent and gelling material with hydrophobic skin contact layer) designed to wick the urine away from the skin and contain it within the pad. Faecal matter will remain on the skin side of the pad. It is essential to change soiled pads as soon as possible to maintain patient dignity and also skin integrity.

Urinary catheters

Catheters may be used on an intermittent basis, by self-catheterization, or an indwelling catheter may be used on longer-term basis whereby the urine is collected into a drainage bag. Patients may find catheterization preferable to the use of pads; the choice needs to rest with the patient.

Anal or stoma bags

A variety of bags are available to collect faeces and fistula fluid. The practicality of using these is very dependent on the position of the anus, stoma, or fistula, the amount and consistency of the effluent, and the ability to get a good seal around the anus, stoma, or fistula, otherwise there will be leakage. This will not only embarrass the patient but also cause skin damage. Further discussion on the management of fistulae is provided in the section on fungating wounds and in Chapter 8.4.

Faecal management systems

These systems are based on the principles of a closed catheter system, whereby a flexible tube is inserted into the anus and the faeces are drained into a collection bag. Again their use will be based on an individual decision with the patient and carefully supervised by practitioners experienced in the use of these devices. Consideration needs to be given to the positioning of the patient to avoid blocking the drainage tube. Faecal management systems have been found to be helpful in situations where there is high faecal output and also a risk of cross infection, with *Norovirus* and *Clostridium difficile*, for example (see Chapters 4.12 and 10.3).

Fungating malignant wounds

Fungating malignant wounds are caused by tumour infiltration of the skin and its supporting blood and lymph vessels. The tumours may be locally advanced, metastatic, or recurrent. Unless they can be treated by single or combination anti-cancer treatments, there

Table 11.1.1 TIME, wound bed preparation, a range of potential nursing interventions, methods, and generic products for palliative wound care

TIME	Wound bed preparation: palliative nursing interventions	Methods and generic products for palliative wound care
TISSUE **Necrotic**	Debride the necrotic tissue	Autolytic debridement: hydrogel dressings Biological debridement: larval therapy Mechanical debridement: ultrasound and water irrigation devices Surgical and sharp debridement: scalpel, scissors, forceps by trained tissue viability nurse or surgeon Chemical debridement: active dressings: medical grade honey Enzymatic debridement: collagenase agents (European Wound Management Association (2013ab)
	Consider promoting and maintaining dry scab in the following circumstances: 　　Life expectancy is short 　　Multiple wounds over the body 　　Head and neck wounds	Apply astringent antiseptics: potassium permanganate (see Box 11.1.1)
Granulating	Promote and protect fragile granulating tissue	Apply semi-occlusive, non-gauze-based dressings: foam dressings with a low adherent wound contact layer
Epithelializing	Protect epithelializing tissue	Apply low-adherent moisture conserving primary dressings: soft silicone-based atraumatic dressings
INFECTION and/or INFLAMMATION	Debride the dead tissue which harbours bacteria, *unless scab formation is indicated* Apply antimicrobial dressings and solutions to remove bacteria	Select an option from the TISSUE debridement section above Select from the range of antimicrobial dressings: medical grade honey; polyhexamethylene biguanide (PHMB) impregnated dressings (European Wound Management Association, 2013a)
Moisture	Use dressing products to remove exudate from the wounds, without allowing the wound to dry out and stick to the dressings If wound has very high fluid output and dressing changes are a burden to the patient, consider topical negative pressure devices. These need to be used by trained personnel and with caution to prevent the potential for bleeding, particularly if applied to fungating malignant wounds (Ford-Dunn 2006)	Two-layer dressing system: low adherent primary dressing and secondary absorbent or super-absorbent pad Alginate or methylcellulose dressings with secondary absorbent or super absorbent pad Low-adherent foam dressings Topical negative pressure device
EDGE	**E**dge of wound epithelializing to cover granulation tissue **E**dge of wound free of non-viable tissue and debris in non-healing wounds	Monitor outcomes from the above to achieve optimal condition of wound edge in healing and non-healing wounds

Source: Data from Leaper DJ et al., Extending the TIME concept: what have we learned in the past 10 years?, *International Wound Journal*, Volume 9, Supplement 2, pp.1–19, Copyright © 2012; Ford-Dunn, S, Use of vacuum assisted closure therapy in the palliation of a malignant wound, *Palliative Medicine*, Volume 20, Issue 4, pp.477–78, Copyright © 2006 and F. Gottrup et al., (Ed.) *Antimicrobials and Non-healing Wounds: Evidence, controversies and suggestions*, EWMA Document, MA Healthcare Ltd, London, UK, Copyright © 2013, http://ewma.org/english/publications.html

is the potential for massive skin damage. This occurs through a combination of tumour growth, loss of local blood supply, consequent loss of tissue viability, and local infections. The dead tissue is colonized by anaerobic and aerobic bacteria, which are associated with malodour, exudate, and potential for further tissue damage.

Fungating tumours present with proliferative tissue growth, progressing to ulceration as and when the blood supply to the area is interrupted. The wounds can be full thickness, also extending into adjacent structures, most notably muscle.

Diagnosis is based on histological assessment and the treatment aim is to control tumour growth, control bleeding, and promote wound closure whenever possible. Fungating tumours that are sensitive to conventional anti-cancer treatments can be resolved. Unfortunately tumour recurrence with fungation is not uncommon. Without treatment, fungation can extend catastrophically and is associated with significant co-morbidity (Grocott et al., 2013b).

Commonly available treatment options include surgery, radiotherapy, photodynamic therapy, immunotherapy, and systemic treatment of the primary cancer with chemotherapy (see Chapter 12.3). Whilst these treatments may to an extent be successful, their burden to the patient can be considerable and the likelihood of the resultant of fungating lesion healing is relatively low.

Advances in palliative treatments, however, offer the potential to manage cutaneous and subcutaneous metastases, for example, electrochemotherapy (ECT). This physical drug delivery system, using electroporation to deliver low doses of non-permeant or poorly permeant chemotherapeutic agents (bleomycin and cisplatin) directly into the tumour cells, is demonstrating positive palliative outcomes, regardless of tumour aetiology. Standard operating procedures for administering ECT have been validated (Marty et al., 2006). There is growing evidence of favourable patient outcomes in terms of complete and objective responses with minimal and transient side effects, such as mild erythema

localized to the treatment site, acceptability to patients, and the ability to re-treat if the problem recurs. Symptom management with ECT (bleeding, exudate, odour) is also reported (Matthiessen et al., 2012; Teissié et al., 2012).

Without curative or palliative treatment, fungating wounds advance relentlessly. The nursing management of these wounds is complex, requiring a range of specialist skills such as stoma care, continence care, lymphoedema management, nutrition and parenteral feeding, symptom control, and local wound management (see Chapters 4.12, 11.1, 11.3).

Local wound management

Wound dressings and devices in conjunction with symptom management can significantly relieve the physical and psychosocial problems, and the overall impact of a wound. However, as already discussed, there are limitations in the performance of dressing systems currently available for the extensive wounds that fall within the remit of palliative care.

Local wound management is determined by the location, size, and shape of the wounds together with presenting problems. Current practice in wound care, including the manufacturing focus for wound dressings, is substantially based on the theory of moist wound healing (Winter, 1962). This theory explains the profound influence on epithelialization of restricting the evaporation of water from the wound surface. It does not explain the management of advanced, exudating wounds (Grocott, 2000).

Tissue hypoxia in pressure ulcers and fungating wounds is a significant factor in local wound management because of the consequential dead tissue, exudate, and odour. The activity of anaerobic bacteria, which proliferate in these hypoxic conditions, combined with facultative aerobic species is attributed to the characteristic symptoms of malodour and another distressing symptom, profuse exudate. Exudate production is also attributed to bacterial enzymes (proteases) and their role in the autolytic processes of tissue breakdown and liquefaction together with local oedema and lymphoedema (Ford-Dunn, 2006).

WBP is a framework to guide and structure a local wound management strategy that is increasingly adopted in clinical care together with the acronym, TIME (Leaper et al., 2012). TIME summarizes the four components of WBP and requires assessment and monitoring of the following:

◆ **T**issue management

◆ **I**nfection and inflammation management

◆ **M**oisture balance

◆ **E**dge of wound in terms of how this advances inwards to cover the broken area.

Table 11.1.1 illustrates the components of WBP and TIME applied to palliative wound care, together with a diverse range of possible local wound management strategies, for example, wound debridement or preservation/promotion of a dry scab. The application of such strategies should be based on individualized assessment of needs.

Essentially, WBP is a framework for managing the local wound environment including clinical signs of bacterial overload, infection, the state of wound tissue, exudate, and the peri-wound skin. The rationale underpinning WBP is that if healing is the goal, the wound bed needs to be free of bacteria and harmful enzymes that may delay healing. If palliation is the goal, clearance of dead tissue and management of bacterial overload can reduce odour, exudate, and damage to the peri-wound skin.

Correction of cellular dysfunction and cellular imbalance refers to a number of factors including cell senescence and the overexpression of proteolytic enzymes. Enzyme imbalance can apparently be corrected with advanced wound products such as topical proteinase modulating agents. However, dysfunction at the cellular level is challenging to address in practical and measurable ways, and the evidence base for the effectiveness of these agents, which are costly, remains weak.

WBP emphasizes the removal of dead tissue (unless preservation of natural scab is indicated) and the control of symptoms such as exudate and odour.

Debridement of dead tissue

Dead tissue is unsightly and a focus for bacteria. Bacteria metabolize dead tissue and the by-products of this metabolism are malodorous. This is a natural autolytic process of dead tissue removal. A number of methods have been advanced to speed the removal of dead tissue. These include surgical, larval, enzymatic, and mechanical methods (European Wound Management Association, 2013b).

Debridement in long-term wounds will need to be repeated. Therefore careful attention needs to be paid to the choice of method, so that it minimizes side effects and is acceptable to the patient. In addition, the clinical gains to the individual patient need to be assessed critically. For example, patients with extensive wounds covered with scabs may not benefit from debridement if life expectancy is short and the consequent exudate profuse. In these circumstances, the aim will be to maintain a dry wound environment.

The use of medical-grade honey dressings to debride and deodorize a range of extensive, complex wounds, including fungating lesions, has been reported (Molan, 2005). For some patients, the introduction of honey into a wound can be painful, attributed to the osmotic pull exerted by the honey on fluid and tissues within the wound. The pain may be transient as the honey liquefies. However, for some patients this symptom is intolerable and alternative debriding agents such as hydrogels or iodine preparations will be indicated. Because honey promotes autolysis, the devitalized tissue is liquefied and separated from the wound bed. This exudate has to be contained with wound dressings otherwise the patient experiences a further unpleasant problem or the aggravation of an existing problem. The management of exudate is discussed further in the following section, as is the use of honey in the section on malodour.

Exudate

Without control of exudate the physical and psychosocial impact of a wound is compounded by leakage, soiling, frequent dressing changes or re-padding, peri-wound maceration, and odour. Effective control of exudate substantially reduces the wound management problems, and patients can regain a degree of independence and control over their daily lives.

As previously mentioned, there are circumstances when maintaining a dry scab over the wound is the kindest option for the patient. If a complete scab cannot be achieved or maintained, and if the wound surface can be dried to slow the rate of volume of

Box 11.1.1 Case example: patient with a large, exuding, fungating wound of the face

The patient had an aggressive facial cancer, which resulted in a large crater in the centre of her face. The crater was lined with dry dead tissue. The dead tissue started to liquefy causing exudate to dribble down her face, and into her mouth. The wound management goal was to dry the wound to a scab, and to minimize the intrusion of dressing changes. Potassium permanganate-soaked[a] gauze dressings were applied, and left for 20 minutes. They were removed and a permeable silicone foam dressing was applied to line the cavity, to prevent dressing adherence, and to allow free passage of air to the wound to maintain the scab. Until scab formation was achieved, the potassium permanganate-soaked dressings were applied twice a day. Thereafter they were applied as needed. This dressing protocol was simple and quick to apply, and achieved the goal of scab formation to minimize the distress caused by uncontrolled exudate.

[a] Potassium permanganate solution is an astringent antiseptic that can dry broken skin that is oozing fluid. The solution can stain the skin and nails and therefore needs to be used with care (Palliativedrugs.com (2014).

exudate produced, the wound may be manageable, and the patient may not be subject to the distress and embarrassment that a wet wound can generate (McManus, 2007) (see Box 11.1.1).

Fistula management

The management of fluid from fistulae is particularly challenging with immense variation in presentations between patients. A fistula is an abnormal track that communicates between two hollow organs. An enterocutaneous fistula is a connection between a hollow organ and the skin. There are multiple causes of fistulae. For example, they may develop as a complication of surgery, infection, radiotherapy, and progressive malignant disease.

The nursing care of patients with fistulae follows substantially the principles of stoma care. These principles are:

◆ Prevention of skin excoriation with barrier products.

◆ Collection of effluent in closed stoma devices or wound manager devices.

◆ Management of odour in a closed device; the use of odour-neutralizing sprays when bags are emptied and changed.

◆ Nutrition and fluids to maintain a balance between intake and loss, which may require enteral or parenteral feeding.

◆ Supportive care to protect the patient's sense of self, autonomy, and ability to socialize (see also Chapter 4.12).

The location and advancement of the fistula can preclude the application of a stoma device. Clinicians are challenged in these circumstances to find novel approaches to manage the lesions. Custom-built solutions need to be found using stomahesive pastes and hydrocolloid dressings to which a drainage bag(s) can be attached. Alternatively it may be possible to fit silicone mesh dressings over a fistula. The dressing, which can be left *in situ* for 3–4 days unless clogged with debris, can assist in directing the flow of fluid into a super absorbent pad with a waterproof backing, which also assists with preserving the integrity of the skin,. The pads will need to be fixed with an adhesive, waterproof tape, or film to avoid leakage. Given that the pads will need to be changed several times a day, when heavily soiled, the skin under the adhesive needs to be protected with repeat applications of a barrier product.

Management of wound-related symptoms

Symptom management measures are both systemic and local. The measures focused on in this chapter are predominantly linked to local wound management. The key issue here is that the management of advanced wounds is complex and requires an interdisciplinary approach. The patients need to be referred to palliative care teams who have specialist knowledge and expertise in the art and science of symptom control.

Symptoms specifically related to the wound include pain, soreness and irritation from excoriated skin conditions, pruritus, odour, spontaneous bleeding, and haemorrhage. Frequently more than one problem needs to be managed at a given time. For example, it is well known that wounds can bleed, be malodorous, and painful. If the wounds become infected, problems of pain, odour, and bleeding are exacerbated, the wound extends, and the frequency of dressing changes increases, including the amount of product required. Accurate diagnosis and treatment can reduce the severity of the problems to all concerned.

Pain

The causes of pain may be multiple, and include emotional factors. Pain associated with pressure ulcers and fungating wounds is generally of a mixed aetiology. Patients can experience stinging, burning, aching, and sharp pain, depending on the size, position, and nature of the wound. Some will have no pain at all, others just at dressing changes, whilst some will have constant pain.

Pain management requires careful assessment, administration of combinations of drugs, monitoring of pain levels, and emotional support (see Section 9).

Analgesia can be given systemically and/or locally. For pain at dressing changes, a short-acting analgesic can be administered and repeated if the dressing change is lengthy.

The local application of analgesia for pain from damaged and ulcerated skin, such as topical opioids, is not supported by high-quality studies. Opioids were considered to act systemically until receptors were identified in inflamed peripheral tissues. A systematic review of the evidence to support the use of topical opioids concluded that the evidence does not provide clear, detailed recommendations for clinical practice. For example, the evidence is lacking in terms of the wounds that are most suitable, the choice of opioid, the carrier, the starting dose, titration, or interval of administration (LeBon et al., 2009). Concerns about the systemic uptake of opioids may be allayed by a small experimental study by Ribeiro et al. (2004) who found that when applied topically to ulcers, morphine was not absorbed unless the ulcer had a large surface area. They concluded that the analgesic effects are likely to be mediated locally, not systemically (Ribeiro et al., 2004).

Current published literature on the prescribing and use of topical opioids is based on individual case reports and small randomized controlled trials involving patients with a variety of painful wounds. In the face of this lack of research, a concentration of

morphine: hydrogel 1:1000 (0.1%) has been adopted as normal practice, as suggested in the literature (Graham et al., 2013). We have observed that the wetness of the wound environment can result in the gel sliding off the wound. Frequency of dressing changes and replacement gel must therefore increase commensurately.

Soreness and irritation from macerated and excoriated skin conditions

As indicated earlier in the section on good skin care, exudate and body fluids cause predictable and inevitable damage to the skin in the form of inflammation, pruritus, and progressive damage to the tissues. The interventions indicated earlier are applicable to the prevention and treatment of maceration and excoriation from exudate in relation to pressure ulcers and fungating wounds. To maintain skin integrity, interventions need to cover the area of skin that is vulnerable, repeating the process at dressing and pad changes.

Cutaneous pruritic irritation

This form of irritation is quite distinct from the irritation caused by maceration. It is a creeping, intense itching sensation attributed to a number of diseases and disorders, such as cholestatic liver disease and tumours. Inflammatory breast disease with cutaneous infiltration is a particular example. Pruritus can be extremely disabling and difficult to treat. It is generally not responsive to antihistamines. It is worth considering non-pharmacological interventions. For example, the intensity of pruritus can be diminished with the use of transcutaneous electrical nerve stimulation (TENS). The application of TENS is worked out according to receptor sites in the skin and involves a degree of trial and error. It is therefore important to involve experts in the administration of this treatment, being careful not to raise patients' expectations (see Chapter 9.9). In addition, drawing on research into the management of pruritic dermatological conditions, personal clothing, and bed linen that wicks away heat and moisture can help to dampen this very debilitating symptom (Senti et al., 2006).

Malodour

The impact of malodorous wounds on patients, carers, and health-care professionals is quite profound (Gethin, 2011). Indeed, strong environmental odours have been shown to be related to increased levels of stress and negative mood (Avery Hoton et al., 2009). Wound odour has been described as 'repulsive', 'that stinking thing', 'rotten', and, in the absence of treatment strategies, some patients resort to a range of measures including decreasing fluid intake in an attempt to manage this problem (Lo et al., 2008; Probst et al., 2012, 2013).

The causative agents in malodour include a mixture of volatile agents produced by aerobic and anaerobic bacteria together with a mixture of amines and diamines such as cadaverine and putrescine that are produced by the metabolic processes of other proteolytic bacteria (Thomas et al., 1998). More recently, dimethyl trisulphide (DMTS) (a compound also emitted from vegetables and some microorganisms) has been identified as a source of odour in fungating wounds (Shirasu et al., 2009). In addition, dead tissue also provides a source of malodour. While agents such as metronidazole, charcoal, aloe vera, and honey have been reported to decrease malodour there is no consensus or guidelines to manage this distressing symptom.

A survey aimed to determine, from an international perspective, those measures that clinicians currently use to manage and assess malodorous wounds, revealed the significance of the problem and also the lack of effective strategies to combat the odour (Gethin et al., 2014). In all, 1444 clinicians from a range of disciplines and specialties across 36 countries participated. Results reveal a lack of strategies to assess and manage malodour as only 12% currently assess odour, yet 83% report this as being a major problem for both the patient and caregiver. A total of 3671 words were suggested to describe odour and seemed to represent repulsion to malodour with words such as 'offensive', 'pungent', 'foul', 'putrid', and 'rotten' being among the most commonly cited.

The following systemic and topical approaches are the most commonly used to attempt to deal with malodour.

Systemic antibiotics

These are used to reduce bacterial colonization and thereby to control the offensive odour from volatile metabolic end-products. One of the limitations of systemic antibiotics is the increasing incidence of antibiotic resistance. A further limitation is their side effects which may be debilitating.

Topical antimicrobials

Topical agents, such as metronidazole gels and the silver impregnated dressings, are alternatives to the systemic route, though they tend to be more expensive than systemic antibiotics (European Wound Management Association, 2013a). There are practical issues around the application of topical agents and dressings to extensive wounds to achieve sufficient inhibitory concentration of the active ingredients of the agents to deodorize. The issues include the size of the wounds and a lack of tissue penetration to bacteria located below the surface. In addition, the site of the wound may limit the efficacy of topical gels, which are absorbed into dressings and pads. Perineal wounds are an example of wounds that are particularly difficult to manage. Although metronidazole is widely used (Gethin et al., 2014) there is a lack of guidelines or consistency in the method and strength of application. A recent systematic review of topical agents, which included metronidazole, to control odour of malignant fungating wounds identified ten studies of which only two were controlled studies (da Costa Santos et al., 2010). Of these, the sample size was small ($N = 11$) and the method of topical application differed across all studies. The review highlighted the need for further research to determine the optimal method and strength of application to achieve odour control in malignant fungating wounds.

Debridement of dead tissue

The rationale for removal of dead tissue is covered in the section on local wound management and Table 11.1.1.

Adsorption of volatile malodorous chemicals by charcoal cloth

Activated charcoal dressings act as filters to absorb the volatile malodorous chemicals from the wound, before they pass into the air. They must therefore be fitted as a sealed unit or the volatile malodorous chemicals simply escape into the air. Air-tight charcoal garments may overcome this limitation when the wounds are extensive or sited in body curves which are difficult to dress. In addition, charcoal is inactivated if it becomes wet, therefore the dressings need to be applied as the outer dressing, and changed if wet (Hampton, 2008). Charcoal dressings are the second most

frequently cited dressing for management of malodour but it is recognized that more methodologically refined studies are required to raise the level of evidence and grade of recommendation for use (da Costa Santos et al., 2010).

The case report by Ford-Dunn (2006) illustrates the benefits of a topical negative pressure system to combat malodour and manage exudate in a malignant wound

Infection

As with other interventions in palliative wound care, the aim is to provide maximum comfort and minimum distress to the patient. If a wound is showing no signs of improvement, and the patient's condition is sufficiently good to allow for wound healing, heavy bacterial colonization and infection may be root causes. Signs of local infection, such as advancing redness of the skin with heat, are sufficient to consider the wound infected, and to initiate topical antimicrobial dressing products.

It may not be necessary or indicated to take a wound swab if the patient's prognosis is short, particularly if they are unable to take oral antibiotics. Systemic medication of proven sensitivity to the culture from the wound swab is otherwise indicated for the management of infection as bacteria have invaded local tissues. Topical agents can additionally help to reduce the microbial load on the wound, and assist the management of exudate and odour.

The role of wound dressings in infected wounds is threefold:

- to contain the infection and prevent contamination to and from the wound
- to keep anti-microbial agents in contact with the wound
- to contain exudate and odour.

Some of the advanced dressings such as silver-impregnated products can be left *in situ* for several days as they are designed to release the active antimicrobial agent over a specified time period. The manufacturers' guidance assists decisions around frequency of changes when using these products. Exudate levels will, however, dictate the frequency of changes required on an individual basis (European Wound Management Association, 2013a).

Bleeding

On rare occasions tumours will erode a major vessel, causing a fatal bleed. These situations are extremely distressing to witness and manage. Death will normally occur within a few minutes and the patient will lose consciousness some time before that.

Attention to the following can reduce the incidence of more minor bleeding at the dressing changes:

- dressing application and removal techniques
- maintenance of humidity at the wound/dressing interface
- cleaning techniques.

Particularly for fungating wounds, when capillaries are visible on the surface, mechanical damage and bleeding can occur with fibrous materials such as alginates. Alternative non-fibrous systems include silicone wound contact dressings with dressing pads, or gel sheets. In addition, radiotherapy may be used palliatively to control spontaneous bleeding from eroding blood vessels. Additionally, through observation, Gehl and Geertsen (2006) have identified an antivascular or blood-stemming effect of ECT on bleeding tumours, with almost immediate effect and no regression (Gehl and Geertsen, 2006). It is therefore important to have contacts with oncology centres for rapid patient referrals for effective control of bleeding.

Topical measures such as adrenaline 1:1000 are also applied. Surgical haemostatic sponges are alternative, practical emergency measures for controlling fast capillary bleeding though they appear expensive on a unit cost basis. Sucralfate suspension is also advocated by palliative care specialists as an off-licence, cost-effective alternative.

Conclusion

Palliative wound care can be complex and is best addressed using an interdisciplinary approach, drawing on colleagues who can contribute specific knowledge, skills, and experience to problem-solve for the patients. The mainstays of palliative wound management comprise treatment of underlying causes wherever possible, local wound management, and symptom control. These are crucial to the physical and psychological well-being of the patients and families. There remain significant limitations in the evidence to underpin palliative wound care interventions. In addition, the design and presentation of medical devices for palliative wound care need to take into account the extensive nature of the skin damage and wounds that occur as a result of advanced disease.

11.2

Pruritus and sweating in palliative medicine

Mark R. Pittelkow, Charles L. Loprinzi, and Thomas P. Pittelkow

Introduction to pruritus and sweating in palliative medicine

Itching (pruritus) and sweating (perspiration, diaphoresis) are physiological functions of the skin that normally serve human existence well. Itching is the sensory input arising from the skin and mucous membranes that alerts man to potentially harmful insults from physical, chemical, and biological sources. The reflex of scratching is closely linked to the perception of itch, and in most situations functions effectively as an aversive motor response to relieve the sensation and protect the skin. Similarly, sweating is a well-developed and finely coordinated sudomotor response designed to regulate body temperature and prevent hyperthermia.

However, both pruritus and sweating have the potential to function aberrantly and develop into pathological conditions that create significant suffering and morbidity. Since these skin responses encompass both normal and abnormal functions, effective treatments to alleviate or eliminate the pathological component are challenging. In this chapter we provide a practical overview of the normal function and pathophysiology of pruritus and sweating, and offer a variety of therapeutic options and general comforting measures for patients experiencing these maladies.

Pruritus

Terminology

Itch and pruritus are terms used to describe both physiological and pathological sensory perception. Itch is a distinctive and common cutaneous sensation that arises from the superficial layers of the skin and mucous membranes. It is often fleeting, and the sensation may pass relatively unnoticed since the reflex action of scratching is largely involuntary and typically relieves the temporary discomfort.

Itch (itching, itchy, or itchiness) and pruritus (from the Latin *prurire*, to itch) are generally considered to have equivalent meanings. Itch and related descriptions such as 'terrible itching' are terms commonly used by the patient to convey this distinctive symptom. However, subtle differences in the terminology of itch and pruritus have evolved in the medical literature. In this respect, the terms itch and pruritus have been used to characterize the spectrum of unique cutaneous sensations ranging from the physiological response to severe pathological symptoms (Winkelmann, 1961; Winkelmann and Muller, 1964; Gilchrest, 1982; Denman, 1986; Bernhard, 1994). Physiological itch is the short-lived cutaneous response to the usual events of living, while pruritus is more closely associated with pathological itch (Winkelmann and Muller, 1964; Bernhard, 1994). Use of the term pruritus represents the symptomatic level or quality of itch that is defined as an intense cutaneous discomfort occurring with pathological change in the skin or body and eliciting vigorous scratching.

The definition of pruritus or itch is subjective and not entirely precise. Although the general sensation is well known and implicitly understood, many patients with more severe symptoms assimilate itch with various other discomforting or unpleasant sensation. The term itch frequently encompasses a range of descriptive or qualifying terms such as tickle, prickle, pins and needles, burning, stinging, chafed, raw, aching, and even 'painful' sensations (Bernhard, 1994).

To avoid confusion and to focus on the palliative medicine perspective, the terms itch and pruritus are used interchangeably to describe this pathological symptom. Patients experiencing pruritus may develop this symptom only mildly and transiently, or itching may be so severe and unrelenting that it preoccupies and completely disrupts their daily existence. It must be recognized that itch or pruritus is variable in its perceived quality and intensity. As with pain, the perception and tolerance of pruritus and the response to this sensation depends significantly on the individual's physical and emotional states, the functional level of activity, adaptive coping mechanisms, and the overall outlook. Attempts to develop questionnaires that assess severity of pruritus have been developed based on modified pain questionnaires (Yosipovitch et al., 2001). These quantitative measuring tools will be useful to better standardize symptoms and treatment responses.

Anatomy and physiology

Pruritus is a discrete sensation and a primary sensory modality arising from the activation and integration of cutaneous sensory neural receptors, afferent pathways, and central nervous system processing centres (Paus et al., 2006) (Fig. 11.2.1). In the past, itch
Fig. 11.2.1 Pathway for transmission of itch sensation. The C fibres terminate in substantia gelatinosa. Spinothalamic relay axons cross and ascend contralaterally at the spinal level of entering sensory neurons. Larger-diameter A fibres and other interneuronal and central pathways may modulate signalling information.

was considered to be a low-threshold form or submodality of pain based on various clinical and experimental observations. Both pain and itch are induced by noxious stimuli and therefore are designated 'nociceptive'.

A prevailing theory was that itch and pain were related sensations that differed only in the strength of the stimulus, with itch being a response to a weak stimulus and pain being elicited by a stronger stimulus. Further investigation of pain and pruritus not only revealed similarities but also clearly demonstrated the distinctive differences between these two sensations. Recent research has conclusively demonstrated that itch and pain are represented by distinct nerve fibres. Itch neurons are specific type C fibres in skin, each having a wide innervation territory, thin axon, and very low conduction velocity (Schmelz et al. 1997). The central neural pathway for itch has also been recently localized to spinothalamic lamina I neurons that are selectively sensitive to histamine (Andrew and Craig, 2001).

Many definitions of pruritus specifically include the reflex action of scratching. Scratching illustrates the distinctive sensation of pruritus, and the scratching reflex is routinely elicited and intimately coupled to itch. Scratching is regarded as a protective reflex, much as withdrawal (flexion) and guarding are comparable reflexes in response to painful stimuli.

Pruritogenic stimuli

Pruritus is induced in skin by various stimuli. Both exogenous and endogenous factors have the capacity to elicit itch (Hägermark, 1992; Wallengren, 1993). Most experimental and spontaneous triggering factors are mediated via the exogenous or external route. Cutaneous sensory nerves which convey the pruritic signal become activated through the application of either physical or chemical stimuli to the skin (Fig. 11.2.2). Many physical stimuli induce pruritus, including pressure, thermal stimulation, low-intensity electrical stimulation, formation of suction blisters, and epicutaneous application of caustic substances.

Chemical stimuli include histamine, proteases, prostaglandins, and neuropeptides (Pauset al., 2006). Delivery of histamine to the upper layers of skin by injection or iontophoresis has been a quantitative and reproducible method of examining pruritus experimentally. Histamine is also secreted in skin by mast cells. It acts directly on free nerve endings in skin.

Proteases such as trypsin, chymotrypsin, papain, and kallikrein have the ability to induce pruritus when injected into skin. For example, the spicules of the plant cowage (*Mucuna pruriens*) contain an endopeptidase. These fine spicules are an active ingredient of itching powder and induce an itching sensation when they penetrate into the epidermal layers or dermoepidermal junction of skin. Other natural proteases produced in cells and tissues of the body or by microorganisms such as bacterial or fungal microflora of the skin also have the potential to induce pruritus.

Mediators of pruritus

The nerve fibres that conduct signals representing itch are located predominantly at the epidermal–dermal junction and have free endings extending into the epidermis (Wallengren, 1993). The afferent sensory neurons that mediate these separate stimuli are distinct subsets of pruritogenic fibres (Dhand and Aminoff, 2014). Many of these nerve fibres contain neuropeptides such as substance P, neurokinin A, and calcitonin gene-related peptide (Fig. 11.2.2). Other neuropeptides contained in nerves deeper in the dermis and located around blood vessels include vasoactive intestinal peptide and neuropeptide Y. Substance P, which is the best-characterized pruritogenic neuropeptide, is a sensory transmitter of nociception. It is localized to sensory nerve endings in the skin and is abundant in the prevertebral ganglia, the dorsal roots of the spinal cord, and the brain. Administration of substance P intrathecally causes intense scratching that can be blocked by an antagonist. Nerve fibres containing substance P appear to transmit direct synaptic sensory impulses for the itch sensation.

Capsaicin, an alkaloid derived from the common pepper plant, is a well-known stimulant of erythema and pain when applied to mucous membrane or skin. It depletes substance P from the sensory nerves and excites the type C polymodal nerve fibres conveying pain. However, after initial stimulation, capsaicin blocks C fibre conduction and mediates neuronal toxicity which eventually decreases fibre density. These activities of capsaicin have stimulated the use of this agent for the treatment of pruritus (Bernstein, 1992).

Neuromediators directly influence vascular permeability and erythema (Fig. 11.2.2). They also activate release of other mediators such as interleukins, prostaglandins, bradykinin, serotonin, and histamine from infiltrating leucocytes and tissue-localized mast cells. Together, these neural and cellular mediators induce the sensation of itch, augment local activation of inflammatory responses that often accompany itch, and create areas of hyper-responsiveness around the primary stimulus zone for itch. For example, the phenomenon of 'itchy skin' (alloknesis) may be due to regional hyper-responsiveness as well as a lowering of the threshold to itch stimuli at the level of the spinal cord. Additionally, neuromediator release is probably augmented through antidromic nerve stimulation.

Cutaneous neural input

Human skin is supplied principally by nerve fibre networks composed of A and D myelinated fibres and thin type C
Fig. 11.2.2 Stimuli of itch in skin or at peripheral and central neural sites. External or endogenous (systemic) routes of activation trigger nerve fibre stimulation in the skin and the release of neuropeptides including substance P (SP), neurokinin A (NKA), and calcitonin gene-related peptide (CGRP). These mediators trigger inflammatory cells in the skin to release histamine (H), bradykinins (BK), serotonin (S), interleukins (IL), and prostaglandin E_2 (PGE-2). Vascular permeability, inflammatory cell infiltration, and nerve stimulation are evoked by stimuli.

unmyelinated fibres. Afferent type C fibres include C mechano-receptors, cold thermoreceptors, C polymodal, and C itch noci-ceptors. Itch is primarily conveyed by the C itch fibres which represent approximately 15–20% of unmyelinated nerve fibres in skin. The remaining polymodal C fibres constitute about 80% of all afferent C fibres (Fig. 11.2.1). The exact location and unique identity of the itch receptor is unknown, but it is likely resides in free nerve endings.

Itch, therefore, is separate from the slow, aching, dull, or burning pain that is conducted by type C polymodal fibres (Winkelmann, 1988; Handwerker et al., 1991). Myelinated A delta nociceptors conveying sharp pain also have been iden-tified. Physiological and pharmacological studies have shown that separate independent sensory channels conduct itch and pain stimuli. The latency between stimulation and onset of the sensation of pain coincides with the relatively low rates of conduction (2 m/s) by the neurons that serve these sensory functions. Itch fibres have very slow velocities of 0.5–0.7 m/s (Schmelz et al., 1997; Andrew and Craig, 2001). Some inves-tigators have suggested separating 'itch' into the 'pricking' sensation carried by myelinated fibres and the 'burning' sen-sation conveyed by unmyelinated fibres. This classification of sensations correlates with the two different systems of sensa-tion described by Head (Head, 1905) in 1905 as the epicritic or specific well-defined sensation that mediates spontaneous itch and the protopathic or diffuse poorly localized sensation that conveys the perception of itchy skin. On the basis of cur-rent scientific knowledge pain and itch are largely separable cutaneous sensations. However, there is evidence of secondary neuron interactions with 'itch-specific' fibres being suppressed by coactivation of pain nociceptors using agents such as capsaicin.

In addition to the external or exogenous pathway for initia-tion of the itch sensation, there is considerable clinical evidence for the endogenous activation of pruritus (Winkelmann, 1961; Winkelmann and Muller, 1964; Gilchrest, 1982; Denman, 1986; Bernhard, 1994) (Fig. 11.2.2). The endogenous route for stimula-tion of pruritus represents a major and clinically relevant pathway; however, it is poorly understood. The potential sites of stimulation (the peripheral nervous system, the spinal cord, and/or the cen-tral nervous system), the inciting agents and mediators, and the relative overlap of exogenous versus endogenous activation path-ways remain to be clearly delineated and applied effectively in the clinical setting. The systemic or endogenous stimuli for itch have been only partially characterized, and the biochemical causes for pruritus associated with a spectrum of systemic illnesses, includ-ing metabolic disease, organ failure, and various malignancies, continue to be ill-defined and vexing problems. One recently identified and novel endogenous mediator is lysophosphatidic acid which is markedly elevated in cholestatic pruritus and is an intense pruritogen when injected into the skin (Oude Elferink et al., 2011).

Several substances have been shown to mediate different or opposing effects on itch when tested experimentally. Their activi-ties depend on the route of administration and their specific responses at the peripheral, spinal cord, and/or central nerv-ous system levels. These observations support the concept of itch as a neural message that is interpreted in the context of sig-nal reception, transmission, and modulation at each level of the nervous system.

Opioid and serotonergic mediators

Opioids are one example of substances that exert separate and potentially disparate responses in modulating the transmis-sion and perception of itch and pain at different levels of the nervous system (Lowitt and Bernhard, 1992; Bernhard, 1994). Uncovering the existence of central opioid receptors led to the discovery of encephalins, endogenous pentapeptides that bind to

these receptors. Opioids are powerful analgesics that mimic the effects of encephalins. However, opioids mediate both excitatory and modulatory effects on pruritus at several levels. At the spinal level, encephalins released from short spinal interneurons and opioids stimulate an inhibitory presynaptic signal transmitted to primary afferents that modulates secondary transmission of itch. However, within some regions of the central nervous system, opioids directly trigger itch. Clinically, intrathecal or epidural morphine has been known to induce localized or generalized itching. At the peripheral level within skin, opioids stimulate mast cell degranulation and release of histamine which produces itch. Furthermore, based on the recent identification and characterization of itch-specific primary nerve fibres, opioids may induce itching by blocking the painful stimuli that suppress activity of central itch neurons.

Central activation of itch by opioids appears to play a dominant role in some diseases, since opioid antagonists have been shown to exert significant antipruritic effects (Lowitt and Bernhard, 1992; Bergasa et al., 1995). The parenterally administered opioid antagonist naloxone inhibits induction of itch following histamine injection of skin. Pruritus of cholestatic liver disease (primary or secondary biliary cirrhosis) can be dramatically reduced with naloxone or the oral antagonist nalmephene (Khandelwal and Malet, 1994; Paus et al., 2006).

Serotonergic compounds are another group of agents that modulate effects on pruritus primarily at the peripheral level, although receptors for serotonin are present in the peripheral and central nervous systems. Cutaneous injection but not intravenous infusion of a serotonergic agonist increases the scratching reflex in animals. Peripheral serotonin receptors in humans are presumed to play a role in the mediation of pruritus. Temperature-dependent pruritus experienced by patients with polycythaemia vera may be stimulated by serotonin. Serotonin reuptake inhibitors, specifically paroxetine, have recently been reported to be useful for treatment of polycythemia vera-related pruritus (Diehn and Tefferi, 2001). Of potential clinical significance, generalized pruritus of hepatic cholestatic disease and chronic renal insufficiency have been relieved dramatically with intravenous administration of the type 3 serotonin (5-HT_3) receptor antagonist ondansetron (Schworer and Ramadori, 1993; Radereret al., 1994). However, other recent placebo-controlled studies have refuted this finding in uraemic pruritus (Ashmore et al., 2000). Nonetheless, opioid and serotonin receptor antagonists have revealed the complex mechanisms involved in transmitting signals for pruritus at the peripheral and central nervous system levels.

Pathogenic correlates in management of pruritus

The similarity of the symptoms of exogenous and endogenous forms of pruritus has prompted empirical use of similar treatment measures for both types of conditions. Frequently, however, effective therapy for pruritus caused by one condition is not particularly beneficial for pruritus of another cause. Also, treatments that ameliorate or relieve pruritus induced by exogenous agents have limited or minimal effects on alleviating pruritus of endogenous cause. This is probably related to the site and mode of activity of these treatments and their limitations in targeting the receptors, mediators, or central neural pathways that control expression of endogenous versus exogenous pruritus.

The nuclei of the afferent C itch and polymodal nerves reside in the dorsal root ganglia and axon extensions that synapse in the dorsal horn of the substantia gelatinosa (Fig. 11.2.1). Secondary neurons cross the spinal cord to the contralateral spinothalamic tract of the venterolateral quadrant before ascending to the thalamus. Lamina I of the spinothalamic tract contains type C itch fibres (Andrew and Craig, 2001). There is also evidence in animals that pathways in addition to the anterolateral system can transmit pruritogenic stimuli. Both the ventral posterior inferior nucleus and the ventral periphery of the ventral posterior lateral nucleus of the thalamus contain itch fibres projecting from lamina I (Andrew and Craig, 2001). The synaptic neurons within the thalamus project to the somatosensory cortex of the postcentral gyrus. Scratching is the spinal reflex in response to itching but also has input from higher neural centres.

Perception of itch has the potential to be modulated at the level of the spinal cord and, probably at other levels, by additional neural input as described for pain by Melzack and Wall (1965). The description of 'a gate control system that modulates sensory input from the skin before it evokes pain perception' can also be applied to the perception of itch.

A fibre impulse conduction is self-regulated by a negative feedback pathway that tends to dampen continued firing. It also interrupts summation of sensations of itch and pain conveyed by the C itch and polymodal fibres. The 'gate' has the ability to control neural transmission. Gate closure is envisaged to produce inhibition at the spinal cord level such that stimulation of A fibres by scratching would induce or enhance inhibition of conduction. Although the gate-control theory has been intensively evaluated and revised over the past three decades and its operational functionality has been challenged, practical application based on this theory appears to have been made in the control of pain and itch using transcutaneous electrical nerve stimulation (Carlsson et al., 1975; Monk, 1993).

Clinical evaluation and treatment of pruritus

The clinical approach to pruritus can present a considerable diagnostic as well as therapeutic challenge. To formulate a simple clinical strategy for diagnosis and treatment of pruritus, pathological itch can be classified as primary or secondary (Table 11.2.1). Secondary pruritus is caused by either dermatological or systemic disease (Winkelmann, 1961; Winkelmann and Muller, 1964; Gilchrest, 1982; Bernhard, 1994). Pruritus can be further separated into localized and generalized forms based on the location and extent of body surface involvement. In most cases, localized pruritus is due to cutaneous infections or other regionalized expressions of dermatological disease. As a comprehensive classification to better understand the wide ranging causes and interventions for pruritus, The International Forum for the Study of Itch (<http://www.itchforum.net>) has adopted these broad categories: dermatologic, systemic, neurogenic, and psychogenic (Yosipovitch and Bernhard, 2013).

Generalized or diffuse pruritus typically presents more troublesome symptoms for the patient and a greater challenge for the physician. Diffuse pruritus is usually related to a dermatological or systemic disorder affecting the entire skin surface. However, even pruritus which is generalized or diffuse exhibits symptoms that may be accentuated and localized to certain regions of the body, and these symptoms may fluctuate, migrate, or extend over time.

Table 11.2.1 Pruritus: causes, distribution, and classification

Aetiology	Distribution	Classification
Primary	Localized	Dermatologic
Idiopathic	Generalized, diffuse	Systemic
Essential		Neurogenic
Secondary		Psychogenic
Dermatological		
Systemic		

Primary pruritus

Primary or idiopathic pruritus is identified in the majority (> 70%) of patients where dermatological disease (secondary pruritus) has been excluded as a cause for itching (Paul et al., 1987). Idiopathic pruritus may be fairly limited in extent and intensity. Symptoms can be reasonably controlled by conscientious skin care and topical soothing measures. However, other cases of primary pruritus prove to be quite extensive, severe, and chronic. The diagnosis of primary pruritus is established following a thorough medical and dermatological evaluation to exclude secondary causes of itching.

Evaluation and management of idiopathic pruritus is frequently a frustrating experience for the patient and physician as possible causes and beneficial treatments are sought. When no clear aetiology is delineated, both the patient and physician may experience disappointment. With severe idiopathic pruritus, there is also lingering uncertainty whether an occult disease, particularly malignancy, may eventually be uncovered. However, several clinical studies have shown that only a small percentage of patients referred to dermatologists for generalized pruritus will develop a malignancy during follow-up evaluation (Kantor and Lookingbill, 1983; Paul et al., 1987). The majority manifest haematological malignancies, particularly lymphomas, and therefore periodic clinical surveillance is warranted. However, the duration and severity of chronic primary pruritus may be sufficiently debilitating for palliative intervention and the identification of effective therapies to become the principal goals.

Secondary pruritus—dermatological

Secondary pruritus is associated with a variety of disorders including both dermatological and systemic diseases (Boxes 11.2.1 and 11.2.2). For example, contact dermatitis is a common characteristic skin disease that has itching and scratching as its hallmarks. Box 11.2.1 lists the major dermatological entities that are accompanied by pruritus. Some disorders, such as scabies, insect bites, folliculitis, and allergic contact dermatitis, are caused by exogenous agents that elicit pruritus. Other conditions, including atopic dermatitis, bullous pemphigoid, lichen planus, psoriasis, and urticaria, are endogenously mediated inflammatory skin conditions that exhibit variably intense symptoms of pruritus.

The mechanisms that induce itching have been partially characterized for some of these disorders. Specific inflammatory cell types, such as mast cells, lymphocytes, and eosinophils, play important roles in the pathogenesis of specific diseases and the

Urticaria, dermographism
Xerosis (asteatosis).

---

development of pruritus. Neuropeptides, cytokines, and proteases, among other mediators, are the main cellular products initiating pruritus (Fig. 11.2.3). These mediators probably act in addition to specific neurotransmitters which directly convey a pruritogenic signal to the itch receptor. Treatment of the specific skin condition and elimination of any offending exogenous agent(s) typically alleviate the symptoms of pruritus. When dealing with pruritus which may be skin related, it is crucial to identify and classify any primary skin lesions and obtain appropriate skin sample specimens or skin biopsies. This information is often very helpful in establishing a diagnosis. The correct diagnosis and appropriate therapy for dermatological disorders should be sought through specialist consultation and is well described in standard dermatology textbooks.

Cutaneous diseases which cause pruritus should not be overlooked. For example, unrelenting pruritus caused by scabies infestation, sometimes lasting for months to years, has been mistakenly attributed to concurrent malignancy. Other cutaneous infections, irritant or allergic contact dermatitis, or autoimmune blistering diseases such as bullous pemphigoid have been repeatedly observed to develop during the course of malignancies or other systemic illnesses. By recognizing that pruritus is due to a supervening dermatological condition, prompt and appropriate treatment can be instituted and the skin disease and pruritus both resolve. Therefore the periodic evaluation and re-evaluation of the causes of idiopathic or poorly controlled pruritus may uncover new information that will significantly benefit total patient care and improve overall comfort.

Box 11.2.2 Systemic disorders associated with pruritus

Biliary and hepatic disease:

    Biliary atresia

    Primary biliary cirrhosis

    Sclerosing cholangitis

    Extrahepatic biliary obstruction

    Cholestasis of pregnancy

    Drug-induced cholestasis

Chronic renal failure—uraemia

Drugs:

    Opioids

    Amphetamines

    Cocaine

    Acetylsalicylic acid

    Quinidine

    Niacinamide

    Etretinate, Acitretin

    Other medications

    Subclinical drug sensitivity

Endocrine diseases:

    Diabetes insipidus

    Diabetes mellitus

    Parathyroid disease

    Thyroid disease (hypothyroidism, thyrotoxicosis)

Haematopoietic diseases:

    Hodgkin's and non-Hodgkin's lymphoma

    Cutaneous T-cell lymphoma (mycosis fungoides, Sézary's syndrome)

    Systemic mastocytosis

    Multiple myeloma

    Polycythaemia vera

    Iron-deficiency anaemia

Infectious diseases:

    Syphilis

    Parasitic

    HIV

    Fungal

Malignancy:

    Breast, stomach, lung, etc.

    Carcinoid syndrome

Neurological disorders:

    Distal small-fibre neuropathy

    Stroke

    Multiple sclerosis

    Tabes dorsalis

    Brain abscess/tumours

    Psychosis, psychogenic causes

Delusions of infestation (parasitosis).

Some dermatological conditions provide instructive lessons on the aetiology and limitations of managing pruritus. For example, prurigo nodularis is a distinctive pruritic dermatosis that can be chronic and is often recalcitrant to therapy (Doyle et al., 1979). The symptom of pruritus appears to play a more central role in the pathogenesis and propagation of this disease and there is increasing evidence that the primary form has a neurogenic aetiology. The pruritus of prurigo nodularis largely localizes to the nodular lesions that appear to develop and become more prominent as a result of scratching. Cutaneous nerve elements are accentuated and aberrantly located within the epidermis and dermis within the lesions and are often difficult to block effectively or eliminate. These factors probably account for the refractory nature of the condition to various treatments. Clinical and therapeutic observations on prurigo nodularis potentially have aetiological and practical relevance to non-dermatological disorders that are associated with pruritus since some of these conditions may also be quite refractory to many therapeutic measures directed at alleviating the itch.

Secondary pruritus—systemic

Pruritus is a feature of a broad range of systemic diseases (Box 11.2.2). For some diseases, specific medical or surgical treatment provides cure of the illness and pruritus. However, with many of the chronic systemic diseases, patients may survive for long periods with adequate control of the illness. Unfortunately, pruritus often continues to be a major symptom and may cause considerable morbidity. Several excellent reviews have recently been published that examine the criteria and evidence to recommend various skin directed or parenteral agents for treatment of pruritus due to various systemic (systemic or neurogenic) causes (Weisshaar et al., 2012; Xander et al., 2013).

Topical antipruritic agents

A variety of topical medications have been developed through the years to provide symptomatic relief of itching (Arndt et al., 1995; Devers and Galer, 2000). Many of the active ingredients have long been known to ease the symptoms of itch. A list of the common therapeutic antipruritic lotions, creams, and gels, together with their active ingredients, is given in Table 11.2.2. Topical medications are not convenient to apply to the entire body surface on a routine basis, but even patients with more generalized pruritus often have localized areas of accentuated itching that are more troublesome to control. Therefore topical agents have a role in treating both regionalized accentuation of generalized pruritus and localized itching.

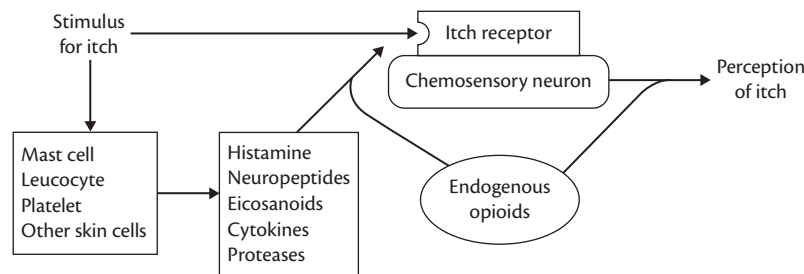
Phenol in dilute solution (0.5–2%) alleviates pruritus by anaesthetizing cutaneous nerve endings. Phenol is potentially neurotoxic and hepatotoxic, and should be avoided in pregnancy and in


Fig. 11.2.3 Factors mediating itch: direct or indirect activation of itch receptor by specific pruritogens. The itch signal is transmitted to a chemosensory neuron which is activated and conveys perception centrally in the nervous system. Endogenous opioids, among other factors, modulate pruritogenic signals.

Table 11.2.2 Topical antipruritic agents

Preparation	Active ingredient
Dodd's lotion	Phenol, glycerine, zinc oxide
Lerner's lotion	Ethyl alcohol, glycerine, zinc oxide
Salol	Phenol, acetylsalicylic acid
Sarna®	Menthol, camphor, phenol
Schamberg's lotion	Menthol, phenol, zinc oxide
Topic gel	Benzyl alcohol, ethyl alcohol, menthol, phenol
Wibi lotion	Menthol
Crude coal tar 3–10% solution	Crude coal tar
Caladryl®	Diphenhydramine, calamine, camphor
Pramosone®, Prax®	Pramoxine
Quotane®	Dimethisoquin
EMLA™	Lignocaine, prilocaine
Lignocaine patch	Lignocaine
Zonalon®	Doxepin
Zostrix®	Capsaicin

Source: data from Fransway, A.F. and Winkelmann, R.K., Treatment of pruritus, *Seminars in Dermatology*, Volume 7, Number 4, pp. 310–25, Copyright © 1988.

infants under 1 year of age. Menthol and camphor relieve itching by counter-irritant and anaesthetic properties. Menthol (typically 0.25–2%, but can be as high as 16%) produces a cool sensation, and camphor (typically 1–3%, but can be as high as 9%) exerts similar effects. Zinc oxide, coal tars, calamine, glycerine, and salicylates also have been used in many preparations with reported benefit, although their specific modes of action have not been elucidated.

Pramoxine hydrochloride is a topical anaesthetic similar to dyclonine that has been used as the sole ingredient or has been compounded with hydrocortisone or menthol and is available as an aerosol, foam, cream, gel, or lotion. Newer anaesthetic prescription medications include EMLA™ cream, a combination of the caine drugs lignocaine (lidocaine) and prilocaine which are absorbed transcutaneously and produce anaesthesia as well as abolish itch. Lignocaine patches (Lidoderm®) are also available that can be applied to problematic pruritic areas (Devers and Galer, 2000). Combinations of amitriptyline (1–2%) and ketamine (0.5–5%) compounded for

topical application in solutions, gels, and creams have been shown to possess significant antipruritic and dysaesthesia-relieving activities when applied topically (two to five times daily) to limited (< 10%) body surface areas (Poterucha et al., 2013a, 2013b). Doxepin has been demonstrated to be effective in relieving the itch of skin disease and may be useful for pruritus of various aetiologies. Capsaicin has been reported to be effective in localized neurogenic pruritus of various causes and has demonstrated benefit in other conditions accompanied by itch. Initial applications of the medication produce burning sensations and other discomfort. The patient must be alerted to these sensations and coaxed to continue if sustained use is planned and benefit is to be obtained.

Systemic therapies and other treatments

A plethora of systemic medications and various other modalities have been used in the treatment of pruritus (Winkelmann and Muller, 1964; Gilchrest, 1982; Winkelmann, 1982; Denman, 1986; Fransway and Winkelmann, 1988; Lorette and Vaillant, 1990). These agents are organized and listed in Box 11.2.3 according to their standard pharmacological activities. On examining this list, it becomes apparent that no drug has ever been successfully developed, tested, and produced exclusively or even primarily for pruritus. This fact alone reveals the potential difficulties that are encountered in the pharmacological treatment of chronic and severe cases of pruritus. All too frequently, patients requiring palliative relief from intractable itching are subjected to trials of various medicines in an attempt to discover which one 'works best' for them. With persistence and luck, a particular drug or modality can be identified that offers benefit and has tolerable side effects. Combinations of systemic and topical agents often seem to provide the best relief. Clinical experience has also shown that certain medications or treatment modalities seem to provide more consistent benefit for specific types of secondary pruritus, as is the case for ultraviolet B (UVB) phototherapy and the pruritus of chronic renal failure. Unfortunately, few controlled clinical studies have ever been conducted on the palliative management of pruritus, and a well-developed and simple clinical management strategy does not exist. Therefore, as outlined above, the practical aspects of establishing the probable cause(s), selecting a treatment, and assessing its benefit, side effects, and potential risks must all be addressed routinely as part of the process of providing palliative care for the patient with pruritus. In addition, several simple measures can be adopted to give patients and their skin some relief from the anguish of itching and the injury of scratching.

Box 11.2.3 Pruritus therapies

Anti-inflammatory agents
 Corticosteroids
 H_1, H_2, H_3 blocking agents
 Salicylates
 Cromolyn
 Thalidomide
Vasoactive drugs
 α-blockers
 β-blockers (e.g. propranolol)
Central and peripheral nervous system agents
Anaesthetic agents:
 Lignocaine etc.
 Propofol
 Ketamine
Antidepressant agents (tricyclic, SSRI(34)):
 Neuroleptic agents
 Tranquillizing agents
 Sedatives
 Opioid antagonists (naloxone, naltrexone, nalmephene)
 Serotonin antagonists (ondansetron)
Analgesic (non-conventional, voltage-gated calcium channel)
Neurokinin receptor antagonist agents:
 Aprepitant
GABA agonists-voltage-gated calcium channel modulators:
 Gabapentin
 Pregabalin
Sequestrants:
 Cholestyramine
 Charcoal
 Heparin (IV)
Miscellaneous
Disease-specific drugs and therapies:
 Cholestatic disease (Jones and Bergasa, 2000): rifampicin, methyltestosterone ursodeoxycholic acid, partial external biliary diversion (Fransway and Winkelmann, 1988; Ghent and Carruthers, 1988; Whitington and Whitington, 1988; Gregorio et al., 1993)
 Uraemia: erythropoietin, parathyroidectomy, ultraviolet B phototherapy (Gilchrist et al., 1977; Hampers et al., 1986; Marchi et al., 1992)
 Polycythaemia vera: α-interferon (Finelli et al., 1993), paroxetine (Diehn and Tefferi, 2001)
 Neurofibromatosis (neurofibroma): ketotifen (Riccardi, 1993)
Phototherapy: ultraviolet A, ultraviolet B, photochemotherapy (PUVA) (Gilchrist et al., 1977; Fransway and Winkelmann, 1988)
Transcutaneous nerve stimulation (Carlsson et al., 1975; Monk, 1993)
Plasma exchange, apheresis (Fransway and Winkelmann, 1988)
Acupuncture (Fransway and Winkelmann, 1988)
Psychotherapy, biofeedback, relaxation techniques (Fransway and Winkelmann, 1988).

Pruritus of malignancy

Itching associated with malignancy presents special challenges and dilemmas. It can be among the most severe and recalcitrant forms of secondary pruritus. Patients with malignancy-associated pruritus represent a significant percentage of those requiring palliation, and many may manifest this symptom at some time during their illness. However, the frequency, chronicity, and severity of pruritus associated with malignancy and its response to treatment are difficult parameters to determine, and they have not been examined systematically and reported in the literature. For example, the percentage of patients for whom the symptoms of itching have been relieved by primary treatment of the malignancy versus those who have benefited from symptomatic therapies has not been defined in this population of patients. As a result, a single, specific, and effective treatment plan for pruritus of malignancy is not available.

Symptomatic skin care

Patients with itching of malignancy may manifest different types of pruritic skin lesions that warrant individualized therapies. Many patients will demonstrate excoriations due to scratching and injury of the skin from fingernails or other implements (brushes etc.). Other patients show discrete papular, crusted, or excoriated lesions more characteristic of prurigo. As a routine, close trimming and filing of sharp edges of fingernails as well as wearing cotton gloves, if necessary, are initial steps to minimize further skin injury. Tepid (not too warm or too hot) baths are usually soothing and temporarily relieve the itch. Patients often relate that a hot bath or shower feels more relaxing and offers symptom relief, but the itch is worse afterwards due in part to vasodilation and the accentuated neural response of cutaneous heating. Immediately following the bath and a light towelling, the patient or caregiver should lubricate the skin with a fragrance-free, cream-base emollient containing phenol or menthol if this is found to be beneficial. Applying a cream results in better maintenance of skin hydration and lessens the chance of further aggravation of pruritus from xerosis. Wearing clothing that is loose fitting, less irritating (e.g. avoid wools), and minimizes heat retention and sweating (e.g. avoid synthetics) can also be helpful in lessening the frequency and intensity of itch. Cotton fabric clothing usually meets these requirements.

For patients with numerous excoriations and crusting due to scratching, application of tap water wet dressings (or cotton long underwear soaked in water) to the affected areas several times daily for 1–2 h provides temporary relief and hastens healing of injured skin. A low- to medium-potency corticosteroid cream containing 1–2.5% hydrocortisone can be applied to the skin prior to the wet dressings for topical anti-inflammatory action. A more potent corticosteroid such as triamcinolone 0.05–0.1% in a cream base can be used for 7–10 days as needed on an intermittent basis, but prolonged use should be avoided to prevent atrophy and bruising of the skin, secondary skin infections, or hypothalamic–pituitary–adrenal suppression.

Oral corticosteroids

Various systemic anti-inflammatory agents are useful in the management of pruritus. Oral corticosteroids often improve the symptoms of itching for patients with primary or secondary pruritus. In many patients, the specific activity is unknown. The corticosteroid may inhibit release of pruritogens, inflammatory factors, or neuromediators, or it may block pruritogen activity or alter its metabolism. As with topical steroids, prolonged use has significant adverse side effects. However, in cases where the duration

of treatment is limited, an oral corticosteroid can provide much sought relief of itching.

Antihistamines

Antihistamines are another class of agent that offers benefit in treatment of itching. More than 30 different antihistaminic compounds of at least six different classes are available over the counter or by prescription. Although antihistamines provide minimal benefit for some patients with problematic itching such as that associated with Hodgkin's disease, obstructive jaundice, or uraemic pruritus, they have a good safety profile and should be used at full dose to attempt amelioration of pruritus. For example, pruritus is an early manifestation of HIV infection, and antihistamines, sometimes at high dosages, are used to control symptoms. Studies have shown superior efficacy of sedating over low-sedating antihistamines for relieving itch. Low-sedating antihistamines (e.g. fexofenadine, cetirizine, and loratadine) should be reserved for the histamine-mediated whealing disorders that are accompanied by pruritus. Longer-acting antihistamines with central nervous system sedation are preferred for control of itch. These include chlorpheniramine, diphenhydramine, clemastine, hydroxyzine, and cyproheptadine. Agents of different classes should be tried if an antihistamine of one class is not effective. Sometimes, combination of agents from different classes is efficacious when a single agent is ineffective.

Other drug therapies

Cromones and thalidomide are anti-inflammatory agents that have been reported to be useful in pruritus associated with several different types of chronic or malignant disease. Disodium chromoglycate improves the flushing and pruritus of systemic mast cell disease (Soter et al., 1979). It also has been reported to improve the pruritus of Hodgkin's disease when other therapies have failed (Leven et al., 1979). Thalidomide has been found to relieve the intractable pruritus and development of skin lesions in prurigo nodularis (Winkelmann et al., 1984). More recently, thalidomide (100 mg/day) was found to produce significant relief of uraemic pruritus (Silva et al., 1994). This drug is used primarily in the treatment of leprosy reactions and graft-versus-host disease. Because of its neuropathic and teratogenic side effects, thalidomide is not routinely available for prescription. However, selected patients who require only a limited course of therapy and can be monitored regularly may be candidates for thalidomide when an alternative medication is sought.

Many drugs have effects on the peripheral or central nervous system, and some of these agents have been found to be very useful in the treatment of itching from many causes. Anaesthetic agents administered by the intradermal, intravenous, or intra-arterial routes have effects similar to topical anaesthetics in blocking sensory input and transmission, including the sensation of pruritus. Parenteral lignocaine (200 mg in 100 mL saline by an intra-arterial line) alleviates refractory pruritus in hepatic cholestasis and chronic renal failure (Tapia et al., 1977; Levy and Catalano, 1985). Hypotension, cardiovascular effects, seizures, and psychosis are possible side effects. Recently, the anaesthetic sedative propofol, used at subhypnotic doses (15 mg) daily when itch was most severe or by continuous infusion at 1–1.5 mg/kg/hour, produced significant reduction in pruritus due to cholestatic disease of pancreatic neoplasia, hepatic and bile duct metastasis, cholangitis, and primary biliary cirrhosis (Borgeat et al., 1993,

1994). A rapid onset of action within 5–10 minutes was observed. Propofol also relieves pruritus from spinal morphine administration, and it is postulated that propofol blocks effects of opioid-like pruritogens at the spinal level (Borgeat et al., 1992). Parenterally administered agents such as lignocaine, propofol, and naloxone are of relatively limited use in chronic pruritus. However, if acute severe episodes of pruritus become incapacitating, these agents can often provide much sought relief and re-establish some measure of symptom control.

Antidepressant drugs, including doxepin, amitriptyline, nortriptyline, and imipramine, have antihistaminic effects as well as psychoactive and analgesic properties that make them useful in the management of various pain and itch states. Serotonin reuptake inhibitors such as paroxetine have demonstrated significant activity in controlling recalcitrant types of pruritus, especially secondary to polycythemia vera (Diehn and Tefferi, 2001), as well as various other advanced cancers (Zylicz et al., 1998). Neuropathic pain with protopathic features of diffuse burning itch as well as the sensation of pain is improved by chronic antidepressant treatment (Willner and Low, 1993). These medications may also benefit patients with pruritus where depression appears to be playing a role in the prominence or severity of symptoms Fried, 1994). Neuroleptic medications, including pimozide and haloperidol as well as risperidone, drugs useful in the management of delusions of infestation (parasitosis), may play a therapeutic role in some clinical situations. Although not indicated for the primary treatment of organic pruritus, these agents may be useful when patients exhibit delusional ideation in conjunction with their disease process. Treatment improves the symptoms of psychosis and diminishes the mental fixation on pruritus (Fried, 1994).

Sedative medications such as diazepam have been shown to be ineffective in reducing experimental itch, although mechanically induced pruritus was eliminated with this agent (Hagermark, 1975; Lorette and Vaillant, 1990). Sedatives in conjunction with other antipruritic agents appear to offer greater relief if the patient is experiencing anxiety as part of the chronic pruritic reaction. In addition to the sedative effects of antihistamines such as hydroxyzine, doxepin, and diphenhydramine, specific anxiolytic agents, including buspirone, clomipramine, and benzodiazepines such as alprazolam, can be used when anxiety appears to be playing a role in magnifying the symptoms of pruritus. Long-term treatment with benzodiazepines should be avoided as there is a risk of habituation (Fried, 1994).

The opioid and serotonin antagonists, as reviewed earlier, have been found to be very effective in selected types of chronic pruritus. The opioid antagonists have been evaluated most extensively in the clinical setting of pruritus of cholestasis where they show significant benefit in symptom relief (Jones and Bergasa, 1990; Bergasa et al., 1995). Naloxone must be administered parenterally. Naltrexone and nalmephene are orally active agents which may be useful as longer-term therapeutic agents for chronic pruritus. Some studies have clearly demonstrated benefit for cholestatic pruritus (Jones and Bergasa, 2000), though randomized, blinded, and placebo-controlled studies in uraemic pruritus seem to indicate no significant improvement in symptoms (Pauli-Magnus et al., 2000). Serotonin (5-HT) antagonists are few in number and less well evaluated in pruritus. However, the 5-HT$_3$ receptor antagonist ondansetron shows promise as the first in a new class of agents to alleviate the symptoms of generalized pruritus in

patients with cholestasis and chronic renal failure (Schworer and Ramadori, 1993; Raderer et al., 1994), although recent studies have refuted its efficacy in uraemic pruritus (Ashmore et al., 2000).

Gabapentin and the newer analogue, pregabalin are anticonvulsant drugs with analgesic activity but with no appreciable anti-inflammatory activities. These novel agents have recently been shown to bind to the alpha 2- delta-1 subunit of the voltage-dependent calcium channel and mediate analgesic properties in the brain and spinal cord levels. Both agents have activity in neuropathic pain, and recent clinical evidence indicates effectiveness in pruritus due to uraemic states as well as other types of primary and secondary pruritus, including pruritus following burn injury.

Sequestrants such as cholestyramine or charcoal administered orally or heparin administered by intravenous infusion have been reported to be helpful in the treatment of obstructive biliary pruritus (Fransway and Winkelmann, 1988). Cholestyramine was also observed to improve itching in polycythaemia vera and uraemia. These treatments may be useful as adjuvant or alternative therapies during the management of chronic pruritus due to these diseases.

A variety of miscellaneous therapies are listed in Box 11.2.3, which also includes additional disease-specific medications reported to benefit chronic pruritus and other treatment modalities such as phototherapy, transcutaneous nerve stimulation, plasma exchange, and acupuncture. Pertinent references reporting the benefit of specific therapies are cited for each modality. For example, several medications and physical modalities have been found to relieve the pruritus of chronic renal failure. Despite our lack of knowledge regarding specific pruritogenic factors and their expression and activity in chronic renal failure, UVB phototherapy often provides symptomatic relief. UVB phototherapy is well tolerated, has few side effects, and can be administered at many dermatological practices or regional clinical phototherapy centres. A combination of narrow-band UVB and crotamiton has been reported to alleviate pruritus of metastatic breast carcinoma to the skin (Holme and Mills, 2001). Erythropoietin and thalidomide have been reported to improve uraemic pruritus. Interferon-α and rifampicin have been found to be effective for polycythemia vera and malignant cholestatic pruritus, respectively (Price et al., 1998; Lengfelder et al., 2000). Parenteral lignocaine is typically reserved for severe recalcitrant episodes of pruritus in uraemic patients unresponsive to other measures.

The multitude and variety of medications and sundry other therapeutic modalities reviewed in this chapter attest to the magnitude, severity, and chronicity of pruritus. All these drugs and therapies have been successful, to some extent, in ameliorating or abolishing this troublesome symptom. In managing the symptom of pruritus as well as the disease, it behoves the physician to make the best possible assessment of the specific physical and emotional factors that may be contributing to the intensity and character of a patient's problem of itch. With reassurance, flexibility, creativity, persistence, and a demonstrated concern by the physician, most patients will find relief and comfort.

Sweating

Anatomy and physiology

Sweating is a physiological sudomotor response of skin that has pathological counterparts. Abnormalities of sweating can be classified in terms of quantitative or qualitative dysfunction. From the perspective of palliative care, the most troublesome sudomotor symptoms relate to inappropriate or excessive sweating which occurs as part of malignant disease or its treatment. To understand the aetiological factors contributing to abnormal sweating and its palliative management, the anatomy and physiology of the peripheral and central thermoregulatory systems of the human are presented and reviewed.

Sweating or perspiration is a unique function of the skin of humans and apes that allows evaporative heat loss and regulation of body temperature in a hot environment or during physical exertion. Other mammals must pant, seek a cooler location, rest, or splash the skin with water to lower body temperature thermally. The crucial function and efficiency of sweat production is witnessed in individuals with the inherited disorder anhidrotic ectodermal hypoplasia who are unable to rely on evaporative heat loss through sweating. Physical inactivity, a cool ambient environment, or wetting the clothing or skin with water substitutes for sweating in order to achieve thermoregulation. Another group of persons particularly susceptible to the adverse consequences of thermal stress are young infants and the sedentary elderly who fail to sweat sufficiently and are also more likely to develop and succumb to hyperthermia.

Temperature regulation

Sweating is an important component of the elaborate thermoregulatory system of humans that is shown diagrammatically in Fig. 11.2.4 (Ogawa and Low, 1992). The hypothalamus integrates inputs from central and peripheral thermoreceptors with the efferent response mechanisms, particularly sweating. The two types of thermosensitive neurons, warm-sensitive and cold-sensitive, are located in the preoptic and anterior hypothalamus (POAH). Warm-sensitive neurons respond to a rise in peripheral body temperature and are more abundant than cold-sensitive neurons which are activated by a decrease in peripheral temperature.

Body temperature is sensed at several crucial sites within the body, including specific thermoreceptors in the skin, spinal cord, and brainstem as well as thermal responses from the abdominal viscera. The POAH integrates thermal information from these sites and others in the body. Body temperature appears to be regulated to match a set-point. An abnormal upward shift of the set-point is believed to be the mechanism for production of fever. Additional control of the central thermoregulatory centre is mediated at several other sites in the brain with projections to the POAH, including the midbrain reticular formation, the raphe nucleus, the amygdala, the hippocampal formation, the sulcal prefrontal cortex, and the medial forebrain bundle. Thermoregulatory control of the hypothalamus can be modified by higher brain activity such as sleep, mental stress, and emotional excitement.

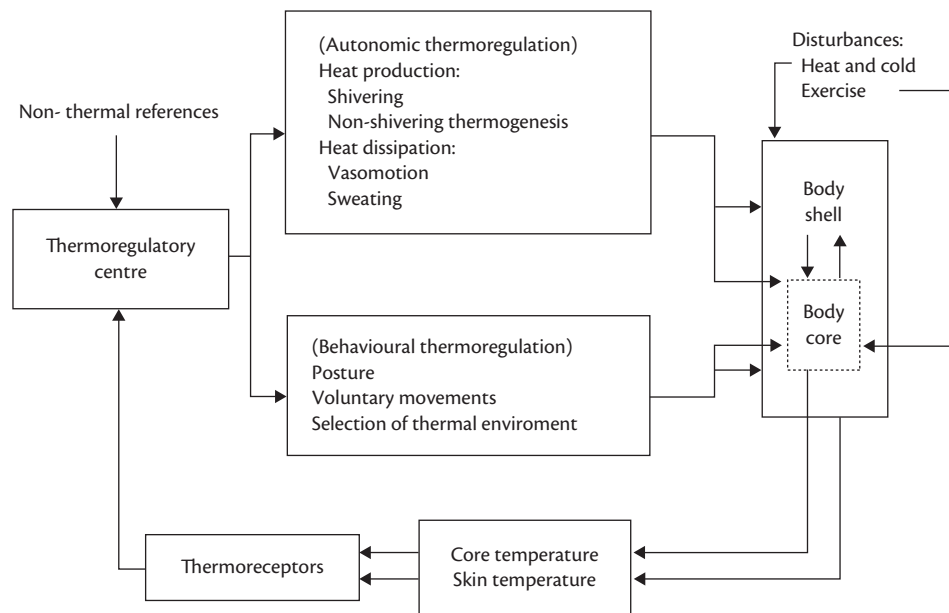
Hypercapnia, plasma osmolality, intravascular volume changes, and dehydration also alter the body temperature and set-point. Chemical mediators, including neurotransmitters such as catecholamines and acetylcholine and the eicosanoid prostaglandin E, play central roles in the control of normal thermoregulation as well as in the expression of fever. Hypothalamic peptides, including thyrotropin-releasing hormone, bombesin, neurotensin, adrenocorticotropic hormone, and vasopressin, are also important in the modulation of central thermoregulation.


Fig. 11.2.4 The human thermoregulatory system.

Autonomic control

The afferent input and efferent responses of thermoregulation are complex but are intimately coupled and controlled by both peripheral and central mechanisms (Fig. 11.2.5). The main thermoregulatory response affecting vasomotion and sweating is mediated through the autonomic system. The cutaneous vasculature is innervated mainly by adrenergic vasoconstrictor nerve fibres. Vasodilation and constriction are coordinated with sweating responses and interact to control blood flow and dissipate or preserve body heat. Sympathetic efferent pathways descend from the hypothalamus through the brainstem to the spinal cord and the preganglionic neurons. From here the fibres exit the cord and enter the sympathetic chain. Postganglionic sympathetic axons innervate sweat glands, blood vessels, and pilomotor muscles in skin. Eccrine glands are innervated by cholinergic fibres. Sweating is produced by both thermal and mental stimulation of eccrine glands, but the distribution and inciting factors causing the sudomotor response are different. Thermal sweating results from excess temperature that is perceived by the body. A local thermal stimulus will generate a uniform sweat response over the body surface while sparing the palms and soles.

The palms and soles show a baseline sweat pattern in the waking state, and mental excitement and stress will increase the rate. This response is called mental sweating. Mental sweating is controlled by the cerebral neocortex limbic system as well as by the hypothalamus. Thermal and mental sweating have some overlap in their central control but are also coordinated independently. General body surface sweating can be affected by various mental stresses. Mental sweating may augment or depress the thermal response of sweating over the body surface, but always increases sweating of the palms and soles. Axillary and, in some individuals, forehead sweating have a lower threshold to stimulation and are often active when there is no thermal sweating elsewhere.

Thermal sweating normally occurs uniformly over the body. Various factors, including body position, exercise, dehydration, sweat gland blood flow, ambient humidity, gender, and age, have also been shown to exert significant effects on the distribution, rate of production, activation thresholds, and other functional aspects of sweating. These factors must be taken into consideration in determining whether sweating responses are physiological or pathological.

Hyperhidrosis

In considering the palliative aspects of sweat dysfunction, most patients are typically bothered by hyperhidrosis (excessive sweating) or the distinctive symptom of nocturnal diaphoresis (night sweats) (Lea and Aber, 1985). A variety of underlying disorders contribute to localized or generalized hyperhidrosis (Table 11.2.3). Hyperhidrosis can be further classified as primary or secondary. It also should be appreciated that it may be a compensatory response to anhidrosis at other body sites. Therefore the cause of hyperhidrosis should be determined if possible, and attempts should be made to alleviate underlying abnormalities that may induce pathological states of excessive or insufficient sweat production.

Clinical evaluation

Determination of sweating abnormalities can be based on the clinical history and examination, or on more comprehensive evaluations such as thermoregulatory sweat testing or specific measurements such as quantitative sudomotor axon reflex tests (QSART) (Fealey, 1992). QSART measures the pattern of sweat response and discriminates whether abnormalities in sweat production are pre- or postganglionic. Postganglionic abnormalities demonstrate alterations in the QSART while disturbances at the preganglionic level typically spare QSART function.

Thermoregulatory sweat testing assesses the integrity of the peripheral and central sympathetic sudomotor pathways
Fig. 11.2.5 Autonomic thermoregulatory sweat pathways: afferent and efferent limbs integrating temperature sensation and sudomotor response.

Fealey et al., Thermoregulatory Sweating Abnormalities in Diabetes Mellitus, pp.617–628, Copyright © 1989 Mayo Foundation for Medical Education and Research, with permission from Elsevier, http://www.sciencedirect.com/science/journal/00256196.

(Fealey, 1992). Thermal stimulation is achieved by raising the skin temperature and the central or core body temperature. An environmentally controlled cabinet that warms the ambient air temperature to 45–50°C and also heats the skin with infrared lamps is used to raise central (oral or tympanic membrane) temperature and skin temperature to levels that stimulate sweating. Sweating on the skin surface is visualized with a special indicator powder containing iodinated corn starch, iodine solution, or alizarin-red-containing corn starch and sodium carbonate. Reduced or absent sweating can be delineated clearly (Fig. 11.2.5), and the distribution and extent of sweat loss is useful in further characterizing potential pathological abnormalities of the pre- or postganglionic pathways (Fig. 11.2.6) or the end organ, that is, the sweat glands (Fig. 11.2.7).

Disruption of the sympathetic chain or white rami produces localized loss of sweating as can be seen with a Pancoast tumour involving the apical lung (Fig. 11.2.6). In contrast, irritation of the sympathetic chain by encroachment of a neoplasm such as bronchial carcinoma, mesothelioma, or osteoma may also produce ipsilateral hyperhidrosis (Walsh et al., 1976).

Stroke rarely causes contralateral hyperhidrosis if large infarcts affect both the superficial and deep cerebral structures. Basilar artery strokes have been known to produce focal symmetrical sweating.

Generalized or regionalized hyperhidrosis

Generalized hyperhidrosis occurs with various systemic diseases, including endocrine disorders, menopause, infections, lymphomas and other cancers, carcinoid syndrome, and drug withdrawal (Fealey, 1992). Endocrine disturbances observed to cause excessive sweating include acromegaly, diabetes mellitus, diabetes insipidus, hypopituitarism, hypoglycaemia thyrotoxicosis, and phaeochromocytoma. Drugs reported to cause hyperhidrosis include opioid analgesics such as morphine, diamorphine, methadone, butorphanol, and pentazocine, antidepressants such as fluoxetine, aciclovir, and naproxen. If patients experience significant symptoms of sweat excess as a result of a particular medication, switching to an alternative drug may provide significant relief. Although the mechanism producing hyperhidrosis is not clearly understood and may be different for each of these causes,

Table 11.2.3 Hyperhidrosis

Localized hyperhidrosis	Generalized hyperhidrosis
Essential (primary)	*Systemic illness*
Neurogenic:	Phaeochromocytoma
Spinal cord disease	Thyrotoxicosis
Peripheral neuropathy	Hypopituitarism
Cerebrovascular disease (stroke)	Diabetes insipidus
Intrathoracic neoplasms or masses	Diabetes mellitus
Unilateral circumscribed	Acromegaly
Cold-induced	Hypoglycaemia
Associated with cutaneous lesions	Carcinoid syndrome
Gustatory	Menopause
	Tuberculosis
	Lymphoma
	Endocarditis
	Angina
	Malignancy
	Nocturnal
	Episodic
	Medication-induced

Fig. 11.2.6 Anhidrosis (light-coloured areas) of the right head, upper trunk, and upper extremity due to a right-sided Pancoast tumour. Distal sweat loss is due to peripheral neuropathy.
Reproduced from Fealey, R.D., The thermoregulatory sweat test, pp. 217–29, in Low, P. A. (Ed), *Clinical Autonomic Disorders: Evaluation and Management*, Little Brown, Boston, USA, Copyright © 1992, with permission from Lippincott Williams & Wilkins.

a downward shift of the set-point of the POAH could stimulate inappropriate sweating.

The patient may confuse excessive regionalized sweating with generalized hyperhidrosis. Compensatory hyperhidrosis may occur within normal sweat-producing areas of the skin in response to anhidrosis that involves other areas of the skin. The patient may not notice the loss of sweating, but, rather, experiences discomfort from the exaggerated sweating response. In this case, detection of the underlying cause of the loss of sweating would guide further treatment and appropriate management for symptomatic hyperhidrosis.

Treatment of sweating

The management of hyperhidrosis is based on identifying the primary cause underlying the abnormal sweat response as well as eliminating any potential aggravating factors that may further augment sweating. Primary hyperhidrosis will not be considered in the discussion of the palliative management of sweating. A variety of therapies offer benefit in treatment of primary hyperhidrosis but are not usually applicable to management of secondary hyperhidrosis (White, 1986). For primary localized hyperhidrosis, endoscopic thoracic sympathectomy or botulinum toxin injections into the affected skin regions are the most popular therapies (Heckmann et al., 2001; Vallieres, 2001).

Hot flushes

Hot flushes are a prominent cause of excessive sweating in patients with cancer. A detailed discussion of the proposed pathophysiological mechanisms for this problem is outside the scope of this chapter, but can be found elsewhere (Casper and

Yen, 1985; Charig and Rundle, 1989; Quella et al., 1994). Hot flushes classically occur in menopausal women and are associated with oestrogen depletion. Breast cancer survivors are not exempt from this clinical problem; in fact, they are more at risk for several reasons. First, adjuvant chemotherapy given to premenopausal women can frequently result in premature ovarian failure with all the sequelae of oestrogen-depletion problems; second the commonly used anti-oestrogen, tamoxifen, causes hot flushes as its most common toxicity; third, commonly used aromatase inhibitors also cause hot flushes; and fourth, general clinical practice has been to deny hormone replacement therapy to these women because of theoretical concerns that oestrogen replacement might harm them.

Given that breast cancer is a commonly diagnosed cancer whose incidence is rising, particularly among younger women, and that hot flushes are a very common clinical problem, what therapeutic options are available? Potential options can be grouped into two classes: hormonal and non-hormonal. Non-hormonal options will be considered first.

Non-hormonal treatment options for women

Twenty-five years ago, the most common non-hormonal treatment option for treating hot flushes was Bellergal®. This is a mixture of phenobarbital and belladonna alkaloids. Review of studies, however, show minimal suggestions of efficacy for hot flushes (Bergmans et al., 1987).

Clonidine is the next non-hormonal agent that was studied and utilized for hot flushes. Well-conducted, placebo-controlled trials demonstrated that it reduces hot flushes more than does a placebo (Goldberg et al., 1994; Pandya et al., 2000). However, it only reduces hot flushes by about one hot flash per person per day, on average. It is also associated with toxicities, such as dry mouth, constipation, and sleeping troubles. Thus, it is not very useful for most women.

In the 1990s, data became available looking at the newer antidepressants as agents to decrease hot flushes. A placebo-controlled clinical trial looked at venlafaxine in a dose-finding study (Loprinzi et al., 2000). This demonstrated that venlafaxine, at a target dose of 75 mg per day (with an initiation dose of 37.5 mg per day), decreased hot flushes by about 60% from baseline, compared to a 27% reduction with a placebo arm. This agent does cause some toxicities, with nausea and vomiting being the biggest problem. In 5–10% of patients this is severe enough to prevent continuation of this medication. In the rest of them, however, the nausea generally abates with continuation of the drug for longer than one week.

Multiple additional antidepressants have been studied, illustrating that paroxetine (Stearns et al., 2000, 2003, 2005), desvenlafaxine (Deecher et al., 2006, 2007; Speroff et al., 2008; Archer et al., 2009), citalopram (Barton et al., 2003, 2010), and escitalopram (Defronzo Dobkin et al., 2009; Freedman et al., 2011; Freeman et al., 2011; Carpenter et al., 2012) can decrease hot flushes to a similar degree as does venlafaxine. Fluoxetine and sertraline appear to also reduce hot flushes, but to a less substantial degree than is seen with venlafaxine and paroxetine (Loprinzi et al., 2002; Suvanto-Luukkonen et al., 2005; Kimmick et al., 2006). An individual patient pooled analysis confirmed that the available randomized trials demonstrated that antidepressants does decrease hot flushes (Loprinzi et al., 2009b).

There is concern that some of these antidepressants should not be used with tamoxifen as it interferes with an enzyme (CYP 2D6) which is utilized to convert tamoxifen to its active metabolite, endoxifen (Stearns et al., 2003). This concern was first noted with paroxetine. Fluoxetine also appears to be a strong inhibitor of CYP 2D6. Venlafaxine and citalopram have not been considered to be strong inhibitors of this enzyme, but are the topic of current investigation.

Subsequent to information regarding antidepressant use, data became available demonstrating that gabapentin also reduces hot flushes. At a target dose of 900 mg per day, it reduces hot flushes by about 50–60% (Guttuso et al., 2003; Pandya et al., 2005). An individual patient pooled analysis confirmed that the available randomized trials demonstrated that gabapentin does decrease hot flushes (Loprinzi et al., 2009b). An additional placebo-controlled trial demonstrated that a related agent, pregabalin, also decreases hot flushes to a similar degree (Loprinzi et al., 2010).

A recent trial compared the use of venlafaxine versus gabapentin in breast cancer survivors, in a randomized cross-over trial. This study revealed that the women preferred venlafaxine over gabapentin at a 2:1 ratio (p = 0.01) (Bordeleau et al., 2010).

There are other non-hormonal agents that have been studied, such as black cohosh and vitamin E, that do not appear to be very efficacious (Barton et al., 1998; Pockaj et al., 2006).

Hormonal agents

Soy products have been examined in multiple placebo-controlled clinical trials. The bulk of the information available suggests that soy is not very helpful for reducing hot flushes (Quella et al., 2000). There have been some studies which have reported positive results and, eventually, further investigation might define some soy product that does help hot flushes. Nonetheless, until this has been done, soy phytoestrogens should not be recommended as therapy for hot flushes.

Progestational agents, however, do clearly decrease hot flushes. A placebo-controlled trial examined 40 mg/day of megestrol acetate versus a placebo (Loprinzi et al., 1994b). This demonstrated an approximately 85% reduction of hot flushes, with low doses of megestrol acetate, results similar to what would be expected with oestrogen therapy. These results were replicated by an independent study group, which also supported that 20 mg/day was an effective dose (Goodwin et al., 2008). A subsequent clinical trial compared oral megestrol acetate to intramuscular medroxyprogesterone acetate (MPA) (Bertelli et al., 2002). Both of these agents appeared similarly advantageous, with a suggestion that the MPA was slightly better. Another trial compared a single intramuscular dose of MPA to continuous oral venlafaxine. MPA reduced hot flushes more substantially then did venlafaxine (Loprinzi et al., 2006).

There are hypothetical concerns with regards to the use of low doses of progestational agents in women with breast cancer (Loprinzi et al., 2006). There are some data to suggest that it might promote breast cancer growth, while there are other data suggesting that it might actually have antitumor activity. Many oncologists have been concerned about giving this therapy to women with a history of breast cancer, especially hormonal receptor positive breast cancer.

Oestrogen also decreases hot flushes by approximately 80–90% (North American Menopause Society, 2004) but increased concerns were raised with combined hormonal therapy (oestrogen plus progesterone) with the publication of the Women's Health Initiative (Rossouw et al., 2002). This therapy increased the risk of breast cancer and increased the risk of cardiovascular trouble, including thromboembolic problems. This raised concern for the use of this therapy, both in women with breast cancer and women without a history of breast cancer. A subsequent Women's Health Initiative trial reported on the use of oestrogen therapy alone (without a progestational agent) in women who had had a hysterectomy (Anderson et al., 2004). In this situation there was no increased risk of breast cancer, with a suggestion that there was actually a decreased incidence of breast cancer in women receiving Premarin®, when compared to the placebo group. There are mixed reports with regards to the safety of oestrogen use in women with a history of breast cancer (Vassilopoulou-Sellin et al., 1997, 1999, 2002; Dew et al., 1998; Col et al., 2001). All in all, oestrogen is frequently not utilized in patients with a history of breast cancer because of the concerns noted above.

Another group of cancer patients who suffer from hot flushes are men who have had androgen ablation therapy for prostate cancer. Hot flushes affect approximately 75% of such men and can be a very substantial problem (Charig and Rundle, 1989; Quella et al., 1994). Noting that there have not been near as many hot flash trials performed in men, as there have been in women, it has been proposed, as a general principle, that hot flash treatment in women can relatively well provide direction for what works in men (Loprinzi and Wolf, 2010).

Nonetheless, some hot flash studies have been done in men. A placebo-controlled trial demonstrated that clonidine does not appear to decrease hot flushes in men (Loprinzi et al., 1994a, 1994b). A randomized, placebo-controlled, dose-finding, double-blinded clinical trial evaluated gabapentin for treating hot flushes in men, reporting results similar to what has been observed in women (Loprinzi et al., 2009a; Moraska et al., 2010). Additionally, pilot trials support that venlafaxine and paroxetine appear to help hot flushes in men as well as it does in women (Roth and Scher, 1998; Quella et al., 1999; Loprinzi et al., 2004). Lastly, low-dose megestrol acetate alleviates hot flushes in men as well as it does in women, with about an 85% reduction in hot flushes. It should be noted that megestrol acetate has occasionally been associated with rising prostate-specific antigen concentrations, however (Burch and Loprinzi, 1999; Sartor and Eastham, 1999). Therefore, it is reasonable to try one or more of the non-hormonal agents first, saving progestational agents for patients who do not get relief from non-hormonal agents.

Treatment of other causes of sweating

Another cause of sweating is related to fever. Sweating is a physiological response to fever, and documented fevers that elicit diaphoresis either during or following the episodes need to be investigated and treated appropriately. Sweating can be a prominent clinical problem in patients with advanced cancer who have tumour fever. Antipyretic agents such as aspirin and paracetamol (acetaminophen) appear to reduce fever by resetting the POAH set-point, and these agents improve symptoms, including sweating, that are associated with fever. At times, however, patients with tumour fever are relatively asymptomatic while they are febrile, but they may perspire and chill during defervescence. A simple solution to this problem is to discontinue antipyretic medications. Asymptomatic fever may continue but symptomatic periods of defervescence decrease. Another method of treating tumour fever is to use non-aspirin-containing non-steroidal anti-inflammatory drugs (NSAIDs) such as naproxen. These drugs can be remarkably successful in alleviating tumour fevers and associated sweating (Chang and Gross, 1984; Tsavaris et al., 1990; Chang and Hawley, 1995). While the efficacy may cease after a period of weeks or months, switching to another NSAID may again induce defervescence (Tsavaris et al., 1990).

Sweating may be a chronic and prominent concern for many patients who do not have any malignancy or infectious aetiology. Even in patients with malignancy, where antipyretic therapies have either been instituted or discontinued to attempt symptom relief, diaphoresis may continue to be a major symptom. Various medications, including H_2-antagonists, have been tried empirically in attempts to provide relief. Although a specific mechanism of action is not well defined and documented clinical trials are lacking, clinical experience has indicated marked benefit from cimetidine (400–800 mg twice daily) in both idiopathic and malignancy-associated sweating. Whether other newer H_2-blockers exhibit a better or worse clinical response is not known.

Thalidomide is another medication that may exert significant benefit in reducing sweating as well as improving other symptoms and syndromes of advanced cancer, such as cachexia, nausea, and insomnia (Peuckmann et al., 2000). Both low-dose (100 mg orally every night) and high-dose (300 mg twice daily) thalidomide have been reported to improve sweating in the majority of affected patients (Deaner et al., 2000; Eisen, 2000). Thalidomide has been shown to reduce tumour necrosis factor-α production as well as modulate other interleukins and cytokines. Besides peripheral neuropathy, severe constipation, headache, cutaneous eruptions-skin sloughing, and oedema have been reported. However, the relative safety of the drug in advanced cancer favours judicious use. Other medications to be considered for management of excessive sweating in general as well as night sweats include thioridazine, nabilone, mirtazapine, desloratidine, and benztropine (Mold et al., 2012). It is hoped that improved therapies will follow as the peripheral and central neural controls of sweating become better understood.

Lymphoedema

Vaughan Keeley

Introduction to lymphoedema

Lymphoedema is a chronic oedema developing as a result of failure of the lymphatic system to drain fluid and other substances, such as proteins, from the tissues. It typically affects the limbs but can involve any part of the body.

The management of all types of lymphoedema is largely palliative in nature in that there are no surgical or other treatments which offer a cure for the problem in the vast majority of cases.

This chapter will focus on oedema associated with advanced cancer and other diseases, encountered towards the end of life with some reference to cancer treatment-related lymphoedema, as this may also be present in people with advanced disease. Further details on cancer treatment-related lymphoedema are available in the online appendix of this chapter.

Although the literature on this topic remains sparse (Beck et al., 2012), there is a growing recognition of the problem (Towers et al., 2010). The International Lymphoedema Framework (ILF) (a charity established to aim to improve the management of lymphoedema and related disorders worldwide) recently published a 'position document' on 'The Management of Lymphoedema in Advanced Cancer and Oedema at the End of Life' (ILF, 2010).

Physiology of chronic oedema

Tissue fluid formation

The amount of fluid in the tissues depends upon the balance between fluid entering by capillary filtration and that leaving by lymphatic drainage. Under normal circumstances the two are balanced and there is no oedema. If capillary filtration exceeds lymphatic drainage, then oedema develops (Levick and McHale, 2003).

Capillary filtration and lymphatic drainage

The amount of capillary filtration depends upon the so-called Starling forces across the capillary wall:

- the hydrostatic pressure gradient across the capillary wall which tends to push fluid out of the capillary
- the colloid osmotic (oncotic) pressure due to plasma proteins which tends to draw fluid into the capillary.

The net effect of these opposing forces, together with the permeability of the capillary wall, will determine the rate of flow out of the capillary. Fluid within the tissue (interstitial) space then drains away via the lymphatics. The flow into the lymphatics will depend upon similar forces.

The previous understanding of capillary filtration and re-absorption as described by Starling, whereby fluid is filtered out of the arteriolar end of the capillary and a large proportion reabsorbed in the venous end of capillary, is no longer felt to be true in the steady state for most capillary beds (Levick and Michel, 2010). In the new model, in most capillary beds, once fluid has entered the interstitial space, it is drained away via the lymphatics only and not via re-absorption into the veins. This emphasizes the central role of lymphatics in maintaining tissue fluid homeostasis and in oedema formation. The old model is still found in most medical text books but the new concepts are being increasingly recognized.

The flow along the lymphatics is dependent upon a number of factors:

- an intrinsic 'pumping' effect of smooth muscle within the walls of larger lymph vessels, the direction of flow being determined by valves
- extrinsic compression of the lymphatics by skeletal muscle activity, similar to that which enhances venous flow
- fluid is re-absorbed from the lymphatics into the veins in lymph nodes, such that the flow in efferent lymph vessels is less than in the afferent vessels which carry lymph to the lymph nodes.

Oedema formation

Oedema occurs when capillary filtration exceeds lymphatic drainage. This can occur in a number of circumstances:

1. Failure of lymphatic drainage (lymphoedema)—this can result from:

- mal-development of the lymphatics (primary lymphoedema)
- damage to the lymphatics from surgery, radiotherapy, infection, trauma, and cancer (secondary lymphoedema)
- malfunction of the lymphatics due to reduced extrinsic compression by skeletal muscles in conditions resulting in immobility, for example, paraparesis (this causes a mixed aetiology oedema as there will also be reduced venous drainage, which leads to increased capillary filtration).

2. Increased venous pressure (causing increased capillary hydrostatic pressure and capillary filtration rate) in:

- deep vein thrombosis (DVT) and post-thrombotic syndrome
- chronic venous hypertension secondary to varicose veins
- heart failure,
- chronic immobility (see above).

3. Hypoalbuminaemia (resulting in increased capillary filtration as the plasma colloid osmotic pressure is reduced), for example, in:

  ♦ advanced cancer

  ♦ advanced liver disease

  ♦ nephrotic syndrome.

Oedema in advanced cancer

In the oedema of advanced cancer, the swelling can have a particularly complex aetiology which may include:

♦ lymphatic damage due to treatment or malignant lymphadenopathy

♦ venous obstruction due to extrinsic venous compression by tumour or by intrinsic obstruction by thrombosis or tumour, including that of large veins such as the superior vena cava or inferior vena cava

♦ hypoalbuminaemia

♦ lymphovenous malfunction due to immobility (dependency oedema)

♦ general fluid retention due to drugs, for example, corticosteroids.

Clinical features

General features of chronic oedema

In lymphoedema, the oedema which is soft and pitting initially becomes firmer and pits less easily. This is due to the accumulation of adipose tissue and fibrosis, which arises from a chronic inflammatory process (Brorson and Svensson, 1998; Daroczy et al., 2003).

By contrast, in chronic venous oedema, chronic lipodermatosclerosis is a common finding along with ulceration. There is a loss of subcutaneous tissue with fibrosis which typically distorts the shape of the leg causing the 'inverted champagne bottle' appearance (Mortimer and Burnand, 2004).

In conditions with mixed aetiology, the skin and subcutaneous changes can also be mixed.

Skin changes of lymphoedema

Although these changes are characteristic of lymphoedema, they are more typical of longstanding chronic lymphoedema and are usually not seen in oedema which develops in association with advanced cancer due to the time course of development (see later). They may, however, be present in patients who have previously developed cancer treatment-related lymphoedema or those with other long-term conditions leading to immobility.

At first the skin appears normal or a little stretched but again with time various changes occur.

Typical skin changes in lymphoedema include the following:

♦ Skin thickening.

♦ Hyperkeratosis: build-up of the horny layer of the skin.

♦ Lymphangiectasia: dilated lymph vessels which appear on the skin surface like small blisters, which if damaged can leak lymph (lymphorrhoea).

♦ Papillomata: these skin lesions are similar to lymphangiectasia but also contain fibrous tissue, giving them a firmer consistency; they often occur in groups producing a cobblestone-like appearance to the skin.

♦ Increased skin creases: these can become very deep in severe particularly around the joints swelling causing deformity of the limb.

♦ Chronic inflammation: this leads to erythema of the skin and can be similar to the chronic lipodermatosclerosis seen in venous disease.

♦ Stemmer's sign (usually positive): this is the inability to pick up a fold of skin over the proximal phalanx second toe in lymphoedema of the leg and reflects the skin and subcutaneous tissue changes described above. In normal toes Stemmer's sign is negative, that is, one can pick up a fold of skin at the toe base.

These skin changes are usually more obvious in leg lymphoedema than in the arm but can occur anywhere.

Pain

The limb often feels heavy and the skin stretched or tight. Patients may experience pain which is often described as an ache, tightness, or heaviness rather than a severe sharp pain (Badger et al., 1998). Typically, the pain is worse when the swelling is worse such as towards the evening in active patients with leg lymphoedema. In addition, the weight of the limb can cause pain at its root typified by shoulder pain in patients with arm oedema.

Impaired mobility/use of limb

Lymphoedema can impair the use of a limb by the weight of the swelling making it more difficult to move or by causing stiffness due to firm swelling around the joints. This is particularly problematic in the leg with stiffness of the ankle joint resulting in restricted contraction of the calf muscles and thus impairment of the muscle pump which would normally aid venous and lymphatic flow. This in turn exacerbates the swelling.

Psychological aspects

Many patients experience significant distress as a result of their lymphoedema (Woods, 2000). This may include alteration of body image, loss of independence, loss/change of employment, and difficulty in finding suitable clothes and shoes to wear.

Frid et al. (2006) found that for those in the late stages of cancer, the impact of oedema was worsened due to feelings of hopelessness, disgust, and social isolation.

Specific situations

Advanced breast cancer

Oedema in advanced breast cancer can be particularly distressing. It can occur as a result of recurrent disease in the axilla, when it may be associated with a brachial plexopathy which, by causing paralysis of the arm, can exacerbate the swelling.

In addition, metastatic cancer can develop in the skin of the chest wall (cancer en cuirasse) and upper arm. This tends to obstruct the skin lymphatics and may cause gross oedema of the arm with the skin becoming tense, stretched, and fragile. In these circumstances the limb can become useless, heavy, and painful. The fingers and hand can become deformed and may look like a 'boxing glove'. The skin can break, leading to profuse lymphorrhoea and predisposing to infection and ulceration (Fig. 11.3.1).

The extreme nature of the oedema in this situation is probably explained by the combination of damage to the deeper lymphatics by surgery, radiotherapy, and possibly tumour and damage to the superficial skin lymphatics by tumour. It is believed that the

Fig. 11.3.1 Severe skin changes in a lymphoedematous leg.

superficial lymphatics act as a collateral system of drainage when the deeper system is damaged, a process exploited by the compression and massage techniques used in the treatment of lymphoedema. When these are blocked by tumour, the collateral routes are no longer available so severe oedema develops. There may be additional factors such as extrinsic compression of the axillary vein which can contribute to the swelling.

Advanced pelvic and abdominal cancer

Gross oedema of the legs, genitalia, and abdomen can occur in patients with advanced pelvic and abdominal cancers.

The clinical features may include:

- soft, pitting or firm oedema of the leg(s)
- stretched, shiny, fragile skin
- lymphorrhoea
- ulceration
- genital oedema—scrotal and penile or vulval
- pitting oedema of the abdominal wall
- ascites
- dilated veins on the abdominal wall in inferior vena caval obstruction
- Stemmer's sign may be negative.

There may be no skin changes typical of chronic lymphoedema, unless there has been a preceding treatment-related oedema.

Gross oedema can severely restrict mobility. Patients may be unable to walk, climb stairs, get up from a chair, or lift their own legs on to their bed. This may exacerbate existing problems resulting from the muscle weakness of advanced cancer.

Patients may find the appearance of their limbs and genitalia difficult to cope with. Furthermore, in men, penile oedema may lead to problems with micturition and sexual function. It may be difficult to insert a catheter per urethram, if needed, so sometimes a suprapubic catheter is necessary.

The oedema can be part of a 'pelvic syndrome' which includes other symptoms such as neuropathic pain, bladder spasms, fistulae, haemorrhage, and malodorous discharge (Sanz and del Valle, 2007).

Facial oedema in advanced head and neck cancer

Previous treatment of head and neck cancer with radiotherapy and neck dissections can cause lymphoedema, commonly in the submental region. However, with recurrent disease, extensive soft oedema may develop. This can include the whole face and eyelids. This can result in the inability to open the eyes particularly first thing in the morning when the oedema is at its worst due to gravitational effects if the individual has been lying down in bed during the night. Speech and swallowing can also be affected.

End-stage heart failure

Peripheral oedema is a usual feature of chronic heart failure but may be extensive and include ascites in severe cases. Immobility contributes to the oedema. Sometimes as the heart failure worsens and hypotension develops, there can be a slight improvement (as capillary filtration is reduced). Hypoalbuminaemia can also contribute to worsening oedema.

End-stage renal disease

'Fluid overload' is a feature of end-stage renal disease even with dialysis. Hypoalbuminaemia secondary to proteinuria can contribute to the oedema, as can immobility.

End-stage respiratory disease

In this situation, right heart failure (cor pulmonale), immobility, and hypoalbuminaemia from anorexia/cachexia may contribute to oedema formation. Patients who sleep in a chair at night due to dyspnoea are particularly prone to dependency oedema of the legs.

End-stage liver disease

Venous hypertension due to fluid retention caused by hyperaldosteronism and portal hypertension with ascites, hypoalbuminaemia, and immobility cause oedema in advanced liver disease.

End-stage neurological disease

Immobility is the main contributing factor in this situation. Typically as the neurological condition progresses, oedema increases as a result of deteriorating mobility.

Investigations

In the palliative care setting the diagnosis is usually clear, but factors which can contribute to the clinical picture of oedema, such as coexisting heart failure, need to be considered. In patients with advanced cancer, investigations may aid the consideration of palliative treatments such as chemotherapy/radiotherapy (see below) or help to determine the prognosis and thereby, guide management.

Investigations which may be helpful in the assessment of oedema in palliative care can be seen in Table 11.3.1.

The choice of any investigations will depend upon the initial clinical assessment.

Other tests may be necessary to confirm that it is safe to carry out planned compression treatments by assessing the ankle brachial pressure index (ABPI), Doppler wave form examination, or arterial ultrasound studies to investigate possible peripheral vascular disease.

Treatment

General principles

The current management of lymphoedema and other chronic oedema is largely based upon a combination of physical techniques:

- compression
- massage

Table 11.3.1 Assessment of oedema in palliative care

Investigation	To assess
Blood tests	
Full blood count	Anaemia
Urea and electrolytes	Renal function
Liver function tests	Hepatic disease
Plasma proteins	Hypoalbuminaemia
Brain natriuretic peptide	Heart failure
Ultrasound examinations	
Venous system	Venous disease, incompetence, thrombosis
Abdomen	Intra-abdominal disease
Axilla/breast	Axilla/breast cancer recurrence
Computed tomography/ magnetic resonance scans	Extent of malignancy

- exercise
- skin care.

This approach is known by various terms including decongestive lymphoedema therapy (DLT) and combined decongestive therapy (CDT).

Although there is evidence that the combination of these techniques is effective in reducing the volume of limb oedema and the incidence of cellulitis in chronic lymphoedema (Ko et al., 1998), there are few reports on the effectiveness of each component (Badger et al., 2004). As a consequence, an international consensus approach has been taken to produce a guidance document, *Best Practice for the Management of Lymphoedema* (Lymphoedema Framework, 2006).

Compression

Compression is a key component of management. It is provided in a number of ways: bandaging, elastic compression garments, and intermittent pneumatic compression pumps.

Multilayer lymphoedema bandaging

This technique comprises a series of layers of bandage applied to a swollen limb, which creates a graduated compression with the pressure reducing from the distal to proximal part of the limb.

Compression bandages need to be applied by skilled trained practitioners as, if incorrectly used, they may cause damage to the skin and subcutaneous tissues.

They are particularly useful for the initial management of lymphoedema to reduce swelling and improve limb shape before applying an elastic compression garment. They are also used if there is broken, ulcerated, or fragile skin and for the control of lymphorrhoea.

In patients with oedema of advanced cancer and lymphorrhoea, a modified lower-pressure 'palliative bandage' can help control symptoms of heaviness and leakage (Crooks et al., 2007).

Elastic compression garments

Graduated elastic compression garments are used in the long-term management of lymphoedema and other chronic oedemas. They are available 'off the shelf' or 'made to measure' and in a number of different strengths of compression and materials. They may, however, not be suitable for people with extensive oedema in advanced disease, particularly those with fragile skin.

Intermittent pneumatic compression pumps

Although the use of intermittent compression pumps had largely 'gone out of fashion' in the management of lymphoedema in the United Kingdom, interest is being regained with the development of more sophisticated devices. These multichamber devices inflate in a sequential fashion and provide a massage effect from the distal part of the limb to the proximal, said to mimic manual lymphatic drainage (MLD) (see following section).

Massage techniques

Manual lymphatic drainage

This is a technique of light superficial massage which improves lymphatic drainage. It is carried out by trained professionals as part of a programme of management, usually combined with other modes of treatment, particularly compression.

It seems to be particularly useful in the management of midline oedemas such as breast, trunk, genital, and head and neck oedema and where there is swelling at the root of an oedematous limb. These are all areas where it is difficult to create effective compression garments.

MLD is said to be contraindicated in acute cellulitis, severe heart failure, renal failure, hypertension, ascites, superior vena caval obstruction, around primary tumours, and metastases (Badger et al., 2004). In the latter, it is considered theoretically possible that MLD facilitates metastatic spread (Godetter et al., 2006). However, in the oedema of advanced cancer, MLD may be helpful in providing symptomatic relief (Pinell et al., 2008). In this situation, it seems reasonable to use MLD if the benefit is likely to outweigh the risks and the patient gives informed consent.

Simple lymphatic drainage

This is a technique based upon MLD but which patients and carers can be taught to apply themselves. Again there is little research evidence for its effectiveness but many patients find it helpful. It is usually carried out daily and the patient or carer needs to be motivated to do it regularly.

Skin care

The aim of skin care is to maintain the integrity of the skin and minimize the risk of infection. The routine use of moisturizers is recommended for all patients, with oilier preparations being used if the skin is particularly dry or doesn't respond to simple preparations (e.g. aqueous cream).

Other conditions such as eczema and tinea should be treated appropriately.

Exercise

Muscular activity is known to improve lymphatic and venous drainage. However, for patients with advanced disease, opportunities for exercise are likely to be limited.

Outcome measures

The conventional outcome measure of the treatment of lymphoedema of the limbs is an improvement in limb volume. Limb

volumes may be measured by a tape measure method or an opto-electronic device such as the Perometer®. In the former, a series of circumferences is measured along the limb and these are converted into a calculated volume.

In patients with oedema in advanced cancer, the aims of treatment are not usually focused on volume reduction and therefore other measures of symptom improvement such as the relief of pain and improvement in mobility and quality of life may be more relevant.

Other treatments

Drug treatments also have little place in management. Diuretics such as frusemide (furosemide) seem to be ineffective in lymphoedema although they may have a place where there is also fluid retention where heart failure is a component.

Skin taping (e.g. kinesio tape) is increasingly used in the management of lymphoedema, particularly mid-line oedema. This tape is believed to stimulate lymph flow as the skin moves against it. There is little research evidence for its use.

Management of oedema in advanced cancer

The general principles of symptom management in palliative care can be applied to oedema in advanced cancer:

◆ determining the underlying cause(s)

◆ considering potentially reversible factors including psychosocial issues

◆ deriving treatment options, taking into account likely prognosis

◆ ensuring the burdens of treatment do not outweigh the benefits

◆ enabling patients and their carers to make an informed decision.

Potentially reversible factors and their treatment are summarized in Table 11.3.2.

Details of a number of these approaches can be found elsewhere in this book or in a textbook of general medicine. Some factors, for example, hypoalbuminaemia are difficult to reverse.

Corticosteroids can sometimes be helpful in relieving lymphatic and extrinsic venous obstruction. It is usual to give a trial of high-dose steroids, for example, dexamethasone 6 mg twice daily for 1 week to assess effectiveness. After this the drug can either be discontinued if ineffective or 'down-titrated' to the minimum effective dose, balancing benefit against unwanted effects.

Table 11.3.2 Potentially reversible factors in oedema of advanced cancer and their management

Factor	Possible management
Anaemia	Blood transfusion
Ascites	Paracentesis
Fluid-retaining drugs	Discontinue if possible, consider diuretics
Superior vena caval obstruction	Metal stent, corticosteroids and radiotherapy, chemotherapy
Inferior vena caval obstruction	Corticosteroids, stent insertion
Heart failure	Diuretics, digoxin, angiotensin-converting enzyme inhibitors, beta blockers
Lymphadenopathy	Corticosteroids, consider anticancer treatment

If there are no reversible factors or the unwanted effects of treatment outweigh the benefits, then a purely symptomatic approach may be necessary. This may include:

◆ analgesia

◆ skin care

◆ modified, supportive bandaging for comfort or controlling lymphorrhoea

◆ shaped tubular bandage, for example, tubigrip if unable to tolerate an elastic compression garment

◆ support and positioning, for example, the use of a Lancaster sling to support a paralysed swollen arm with a brachial plexopathy

◆ passive movements to help reduce stiffness

◆ gentle massage techniques (MLD, SLD)

◆ aids to mobility and function.

The skin is often very fragile in patients with advanced disease and the oedema can be very extensive so the physical management techniques described previously need to be modified accordingly. (For details see ILF (2010) and Crooks et al. (2007).) The aim of treatment is comfort rather than limb volume reduction.

Compression techniques should be used with care in those with extensive oedema in advanced cancer, particularly those with hypoalbuminaemia. In this situation, in our clinical experience, oedema can be displaced to other areas, for example, from the legs to the trunk/genitalia.

Some patients, for example, those with advanced breast cancer, may have associated fungating lesions. If a compression bandage is applied to an oedematous arm with an ipsilateral fungating breast lesion, there may be an increase in any discharge from the lesion. This can be distressing for patients and it is important to warn them about this possibility.

Further details on the management of fungating and other wounds in oedema of advanced disease can be found in the ILF position document (ILF, 2010).

Needle drainage of oedema

There has been renewed interest in the physical drainage of oedema fluid in patients with advanced cancer. A good symptomatic response has been reported in eight patients with severe oedema using subcutaneous needles draining into a closed bag system (Clein and Pugachev, 2004). No patients developed an infection but the median survival was only 2 weeks. There would normally be concerns about introducing needles into a lymphoedematous limb because of the risk of infection and worsened swelling. However, this technique may have a place in selected patients with advanced cancer, a short prognosis and severe symptomatic oedema which has been unresponsive to other conventional approaches.

Oedema in non-cancer advanced disease/end-of-life care

There is little in the literature which describes the specific management of oedema in advanced cardiac, renal, respiratory, hepatic, and neurological disease. The general approaches described above are appropriate but specific techniques such as the use of diuretics in heart failure need to be considered (see Chapter 15.3).

Evidence base for treatments in palliative care

A recent systematic review of the evidence for various treatment modalities in the palliative care of cancer-related lymphoedema

(Beck et al., 2012) confirmed the paucity of large well-designed studies. There were no randomized controlled trials found, with most reports relating to case studies of needle drainage, MLD, DLT, compression and kinesio taping. All were rated as 'effectiveness not established' by the reviewers.

Complications of lymphoedema and their treatment

Cellulitis

Clinical features

Patients with lymphoedema are more prone to developing cellulitis in the affected limb (Mortimer and O'Donnell, 2003).

The typical clinical presentation is the onset of flu-like symptoms which may include malaise, fever, myalgia, nausea, vomiting, and headaches. This usually precedes symptoms in the affected limb which can include pain, redness, and increased swelling. On examination, the patient may have a red, warm, tender swollen limb or part of the limb. There may be lymphangitis, lymphadenitis, and in severe cases the skin may blister and desquamate in places. In very severe cases, this may progress to necrotizing fasciitis.

This classical presentation is, however, not seen in a number of patients who may have a variety of different rashes in the affected limb and variable systemic symptoms.

There may be evidence of a likely portal of entry of infection, for example, a scratch or cut, insect bite, skin cracking due to tinea pedis (athlete's foot), an ingrowing toenail, dermatitis, etc. However, in many cases there is no obvious source. It has been postulated that in some cases the infection arises at a distant site, for example, tonsillitis.

The cause of most of these infections is believed to be beta haemolytic streptococci but it is not easy to prove this with swabs or blood cultures. Indeed, the degree of uncertainty as to the aetiology of these episodes has led to them also being known as 'acute inflammatory episodes'. Some episodes may be inflammatory rather than infective but because of the often rapid progression of symptoms which can result in hospital admission for intravenous (IV) antibiotics, it is usual practice at present to treat them as infective.

The differential diagnosis includes acute DVT, acute inflammatory skin conditions such as eczema, and acute lipodermatosclerosis arising from acutely increased venous pressure.

The propensity to develop these infections is believed to be related to a local immune paresis in lymphoedematous limbs, as normally functioning lymphatics are an essential part of the local immune response to infection (Mallon et al., 1997).

Management

Antibiotic treatment is aimed at the beta-haemolytic *Streptococcus*. Many patients who present early can be managed with oral antibiotics and rest at home but some with severe cellulitis may need to be admitted to hospital for IV antibiotics, either at presentation or if their condition progresses despite appropriate oral antibiotics.

There is no research evidence at present as to the best antibiotic regimen but a group of clinicians in the United Kingdom has produced a 'consensus' guideline (British Lymphology Society and the Lymphoma Support Network 2013).

The recommended antibiotics are

- For management at home:
  - Amoxicillin 500 mg 8-hourly (or erythromycin 500 mg 6-hourly if allergic to penicillin).
  - Clindamycin 300 mg 6-hourly—if not responding satisfactorily to amoxicillin after 48 hours
  - Flucloxacillin 500 mg 6-hourly may be added if there is a suspicion of a staphylococcal infection, for example, folliculitis, crusted dermatitis.
  - Antibiotics should be continued for at least 14 days or until signs of inflammation have resolved.

- For management in hospital:
  - Flucloxacillin 2 g 6-hourly IV.
  - Clindamycin 600 mg 6-hourly IV—if penicillin allergic or if poor response to flucloxacillin after 48 hours.

Antibiotics can be changed to the oral route when temperature is normal for 48 hours and the inflammation is much resolved. NB Local hospital antibiotic guidelines determine the choice of regimen.

It is worth taking swabs from any area of broken skin but the results may be unhelpful. Blood tests (white cell count, erythrocyte sedimentation rate, and C-reactive protein) may be helpful in monitoring progress as is marking and dating the edge of the rash/erythema.

Bed rest seems to improve the rate of recovery. Compression garments used to treat the lymphoedema may need to be removed temporarily because of discomfort but, ideally, this should be for as short a time as possible. Massage should be avoided in the acute episode.

In end-of-life care, the appropriateness of the use of oral or IV antibiotics in symptom relief should be considered.

Lymphorrhoea

Lymphorrhoea is the leakage of lymph from an oedematous limb through defects in the skin. It can result from direct trauma, for example, cuts and abrasions, or from rupture of cutaneous lymphangiectasia or papillomata.

The leakage can be quite profuse and distressing for patients. Any damage to the skin is also likely to increase the risk of infection and therefore lymphorrhoea should be treated promptly.

Lymphorrhoea is best treated by the application of a compression bandage with absorbent padding but the compression applied may need to be modified in patients with fragile skin, for example, in advanced cancer (Anderson, 2003). The bandage may need to be changed several times per day to begin with because of 'strike through' but often the leakage can be sealed within a few days. However, in some situations, particularly with severe oedema and skin breakdown, the leakage may be persistent and require prolonged bandaging.

Conclusions

Although in some countries, for example, the United Kingdom, a number of palliative care services treat people with all types of chronic oedema, the most commonly encountered forms in the palliative care setting are those related to cancer treatments and those associated with advanced disease, especially cancer, towards the end of life.

Currently, the standard treatment usually involves a combination of physical treatments (DLT or CDT). However, this usually needs to be adapted in advanced disease, ensuring that realistic outcome goals are set and that the burden of treatment does not outweigh the benefit. The conventional holistic palliative care approach is important in this as in the management of other symptoms.

SECTION 12

Issues in populations with cancer

The oncologist's role in delivering palliative care

Nathan I. Cherny and Stein Kaasa

Introduction to the oncologist's role in delivering palliative care

The division of cancer care into initial primary anti-tumour therapies followed by hospice or palliative care for patients who have progressive disease is anachronistic (World Health Organization, 1990). Since the goals of medical oncology extend beyond the reduction of tumour burden and the deferral of death and incorporate a quality of life dimension, there is need for a continuum in patient care in which both primary therapies and palliative interventions are integrated according to the clinical circumstances of the patient. For most patients, it is the oncologist who assumes the role of the physician primarily responsible for the provision and coordination of cancer care. This role is enormously challenging (Box 12.1.1) and it demands a wide range of cognitive, clinical, and interpersonal skills and a readiness to work collaboratively with professionals from other disciplines including palliative care.

Traditionally, the study and practice of medical oncology has focused on the development and implementation of anti-cancer therapies. By virtue of these endeavours, along with measures to provide for early diagnosis, substantial improvements in long- and short-term survival have been achieved for a number of cancers such as the germ cell tumours, lymphomas, early-stage breast and colorectal cancer, and the leukaemias. More sobering, however, are the observations that the cure rate for cancer remains less than 60% and that cancer continues to account for over 25% of all adult deaths (Siegel et al., 2012). Many patients are not cured, and for them the issues regarding the quality of their remaining time are critical, irrespective of the clinical course of their illness or the duration of survival.

Palliative and supportive care in medical oncology

Recommendations on the integration of palliative medicine and medical oncology

An expert committee of the World Health Organization on cancer pain and palliative care has emphasized the need for the integration of efforts directed at maintaining the patient's quality of life in all stages of cancer treatment (World Health Organization, 1990). This report emphasized that factors causing patient distress exist from the time of diagnosis and that supportive and palliative interventions are needed concurrently with efforts to control the underlying cancer. This holds true for patients undergoing curative, life-prolonging, and palliative anti-cancer treatments. This approach has been widely endorsed by numerous national and professional bodies (Foley and Gelband, 2001; National Institute for Clinical Excellence, 2004; Smith et al., 2012; Greer et al., 2013).

The National Comprehensive Cancer Network (NCCN) Clinical Practice Guidelines in Oncology (NCCN Guidelines®) emphasize the importance of palliative care as part of comprehensive cancer care:

> Palliative care is a special kind of patient- and family-centered health care that focuses on the effective management of pain and other distressing symptoms, while incorporating psychosocial and spiritual care according to the patient/family needs, values, beliefs, and cultures. The goal of palliative care is to anticipate, prevent, and reduce suffering and to support the best possible a quality of life for patients and their families, regardless of the state of the disease or the need for other therapies. Palliative care begins at diagnoses and should be delivered concurrently with disease-directed, life-prolonging therapies and should facilitate patient autonomy, access to information, and choice. Palliative care becomes the main focus of care when disease-directed, life-prolonging therapies are no longer effective, appropriate, or desired. Palliative care should be initiated by the primary oncology team and then augmented by collaboration with an interdisciplinary team of palliative care experts. (National Comprehensive Cancer Network, 2014)

In recent years the importance of this integration has been emphasized by several randomized studies involving patients with advanced cancer that demonstrated that integrating specialty palliative care with standard oncology care leads to significant improvements in quality of life and care and possibly survival (Jordhoy et al., 2001; Brumley et al., 2007; Gade et al., 2008; Bakitas et al., 2009; Temel et al., 2010; Zimmermann et al., 2012).

Supportive or palliative care: defining terms

There has been much confusion regarding the definitions of supportive care and palliative care. The most widely accepted formal definition of palliative care, which was drafted by two oncologists (Neil MacDonald and Eduardo Bruera), is that of the World Health Organization (World Health Organization, 2002, 2007). It states:

> Palliative care is an approach that improves the quality of life of patients and their families facing the problem associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and

- Psychological symptoms.

treatment of pain and other problems, physical, psychosocial and spiritual. Palliative care:

- provides relief from pain and other distressing symptoms;
- affirms life and regards dying as a normal process;

- intends neither to hasten nor postpone death;
- integrates the psychological and spiritual aspects of patient care;
- offers a support system to help patients live as actively as possible until death;
- offers a support system to help the family cope during the patient's illness and in their own bereavement;
- uses a team approach to address the needs of patients and their families, including bereavement counseling, if indicated;
- will enhance quality of life, and may also positively influence the course of illness;
- is applicable early in the course of illness, in conjunction with other therapies that are intended to prolong life, such as chemotherapy or radiation therapy, and includes those investigations needed to better understand and manage distressing clinical complications.'

The European Society of Medical Oncology (ESMO) has adopted pragmatic definitions that distinguish supportive and palliative care and emphasizes the discrete sub-entity of end-of life care. According to these definitions, supportive care aims to optimize the comfort, function, and social support of the patient and their family at all stages of the illness. Palliative care is care that aims to optimize the comfort, function, and social support of the patient and their family when cure is not possible. Although the clinical scenarios suggested by these definitions obviously overlap, it is the context of incurability, with all of its implications for the patent and family, that grounds palliative care as a special entity. Supportive care is needed by every patient continuously; palliative care focuses on the special needs of patients who are either incurable or who have a very low likelihood of cure.

From this perspective, 'end-of-life care' or 'terminal care' is defined as palliative care when death is imminent (Fig. 12.1.1). End-of-life care acknowledges that the intensity of physical, psychological, existential, spiritual, and family issues may be magnified by the patient's approaching death.

Ultimately, however, the distinction between supportive care and palliative care is largely semantic, and it should be emphasized that the terms are used differently by various specialists across countries (Cherny, 2009). Regardless of the definition, the fundamental reality is that patients with cancer, and their families, may express unmet physical, psychosocial, or spiritual needs at any point during the course of the illness. These needs require specific interventions that aim to reduce distress, enhance coping, or otherwise improve the individual's quality of life (Cherny, 2009).

The oncologist's role in palliative care

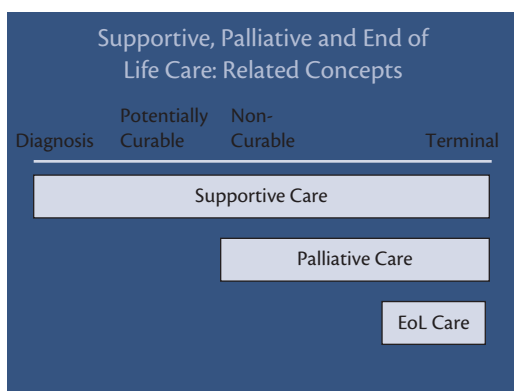
Both the American Society of Clinical Oncology (ASCO) (Smith and Schnipper, 1998; Ferris et al., 2009; Smith et al., 2012) and ESMO (Cherny et al., 2003) have policy statements outlining the responsibilities of medical oncologists in the care of patients with incurable cancer and the integration of oncology and palliative care. ASCO states that it is the oncologist's responsibility to care for their patient along a continuum that starts at the moment of diagnosis and extends throughout the course of the illness. In addition to appropriate anti-cancer treatment, this includes symptom control and psychosocial support during all phases of care, including the last phase of life (Smith and Schnipper,


Fig. 12.1.1 Trajectories of illness.

1998; Ferris et al., 2009). The ESMO policy statement reiterates these points and defines the role of the oncologist in palliative care (Box 12.1.2).

The oncological management of advanced cancer

The judicious use of disease modifying treatments can potentially prolong survival and improve comfort and function. As treatment options become more varied, complex and expensive, the balancing of benefits and burdens in considering these primary treatment options is becoming increasingly challenging (Markman, 2003; Harrington and Smith, 2008). Decision-making must take into account a range of relevant issues, including goals of care, likelihood of benefit, likelihood of harm, and the desires, beliefs, and understanding of the patient and family (Hairon, 2008). Addressing the relative roles of disease-modifying approaches requires familiarity with key concepts of patient benefit, quality of life, and risk/benefit analysis (Detmar et al., 2002). When the therapeutic index of anti-tumour therapies is diminished and the likelihood of benefit is outweighed by either the risk or the burden of the treatments, it is the oncologist who must help steer the patients and the family to a care programme that focuses on symptom management and other efforts to reduce suffering, help coping, maintain quality of life, and prepare for the end of life (see below) (Harrington and Smith, 2008; Cheng et al., 2013; Schenker et al., 2014).

Communication with patients and family members

Given the complexity of the goals of care, patient and family expectations, and the range of therapeutic options, communication with patients and their families is a critical element of the oncologist's role in caring for patients with incurable cancer. Communication is challenging and requires patience and refined interpersonal and counselling skills to facilitate effective, informed decision-making.

A variety of communication tasks usually are undertaken by the oncologist. The diagnosis, prognosis, and treatment options must be explained and this may involve discussions about the potential risks and benefits of treatment options, the role of palliative care, and the necessity for discontinuing anti-tumour therapies when appropriate. In performing these tasks, oncologists need the skills to deal with intense emotions, highly distressed patients, and family members with fears, anger, and anticipatory grief.

Box 12.1.2 ESMO policy regarding the role of the oncologist in the provision of supportive and palliative care

1. The Medical Oncologist must be skilled in the supportive and palliative care of patients with cancer and in end-of-life care.

2. The oncologist must address the need for an appropriate medical nursing and para-medical infrastructure to address the special needs of these patients and their families.

3. It is the responsibility of the medical oncologist to assess and evaluate physical and psychological symptoms of patients under their care and to ensure that these problems are adequately addressed.

4. The delivery of high-quality supportive and palliative care requires cooperation and coordination with physicians of other disciplines (including radiotherapy, surgery, rehabilitation, psych-oncology, pain medicine and anaesthesiology, palliative medicine, etc.) as well as with paramedical clinicians (including nursing, social work, psychology, physical and occupational therapy, chaplains, and others).

5. In the care of dying patients the medical oncologist must:
   - Respect the dignity of both patient and caregivers
   - Be sensitive to and respectful of the patient's and family's wishes
   - Use the most appropriate measures that are consistent with patient choices
   - Make alleviation of pain and other physical symptoms a high priority
   - Recognize that good care for the dying person requires quality medical care, but also entails services that are family- and community-based to address, for example, psychological, social, and spiritual/religious problems.
   - Offer continuity (the patient should be able to continue to be cared for, if so desired, by his/her primary care and medical oncology providers)
   - Advocate access to therapies which are reasonably expected to improve the patient's quality of life and ensure that patients who choose alternative and non-traditional treatments not be abandoned
   - Provide access to palliative care and hospice care
   - Respect the patient's right to refuse treatment, as expressed by the patient or an authorized surrogate
   - Respect the physician's professional responsibility to discontinue some treatments when appropriate, with consideration for both patient and family preferences
   - Promote clinical and evidence-based research on providing care at the end of life.

The management of the complications of cancer

Oncologists must be expert in the evaluation and management of the complications of cancer and anti-cancer therapies. Some common complications are listed in Box 12.1.3.

Evaluation and management of physical, psychosocial, and spiritual disturbances

Patients with advanced cancer commonly have multiple symptoms and other sources of suffering. To address their needs, oncologists must be expert in the evaluation and management of the common physical symptoms, including pain, dyspnoea and cough, fatigue, nausea and vomiting, constipation, diarrhoea, insomnia and itch. In addition, psychological and existential distress is common and oncologists must be prepared to assess and help manage the varied sources of these concerns.

There is extensive evidence suggesting that cancer patients' informational and emotional needs are commonly underestimated and that depression, in particular, is often undetected or undertreated (Breitbart et al., 2000; Pereira and Bruera, 2001; Hotopf et al., 2002; Rhondali et al., 2012). Many patients who develop psychological distress do not spontaneously disclose these problems (Maguire, 2002). There is a notion that 'good patients' don't complain. Furthermore, cancer patients may believe their emotional response to be an inevitable reaction to having a cancer diagnosis. Paradoxically, the most distressed patients may be least likely to acknowledge or discuss their emotional concerns (Greenley et al., 1982).

Oncologists ought to be familiar with the assessment of common psychological problems, such as anxiety, depression, delirium, suicidality and desire for death, death anxiety, and anticipatory grief (Passik et al., 1998; Holland, 2003; Rhondali et al., 2012). Where possible, they should be familiar with anxiolytic and antidepressant pharmacotherapy and they should work closely with mental health clinicians to help address these issues.

Ensuring a care continuum

Abandonment and discontinuity of care are a cause of great distress to cancer patients (Back et al., 2009). As the physician typically responsible for the primary care of the major medical problems faced by the patient, the oncologist should ensure that the patient has an ongoing and adequate care plan, particularly as the role for anti-tumour therapies diminishes and the patient approaches the end of life.

Interdisciplinary cancer care

The needs of patients with advanced cancer are too complex to be cared for by any one person. In the setting of advanced cancer, the oncologist must work with an interdisciplinary team to build a care plan around the individual needs of the patient and family (Borneman et al., 2008; Viola et al., 2009). In addition to other oncological and medical subspecialists, interdisciplinary cancer care often will involve collaboration with social workers, mental health professionals, chaplains, physical therapists, occupational therapists, speech therapists, palliative care clinicians, and others.

Palliative care research

Quality of life research has had important impact on the evaluation of oncological interventions and the quality of life is a now widely accepted clinical outcome worthy of evaluation (Minasian

Box 12.1.4 Common ethical issues in the care of patients with advanced cancer

◆ Ethical issues related to disclosure of diagnosis and prognosis

◆ Ethical issues in decision-making: paternalism, autonomy, informed consent

◆ Ethical issues relating conflicts of interest

◆ Ethical issues when patients refuse or demand treatment

◆ The right to adequate relief of physical and psychological symptoms and its implications

◆ Consent: informed, uninformed

◆ Ethical issues at the end of life:
  • sedation for refractory symptoms
  • hydration and nutrition at the end of life
  • Do not resuscitate orders
  • use of invasive palliative approaches, that is, nephrostomy or dialysis.
  • foregoing treatment
  • euthanasia, assisted suicide.

---

et al., 2007). Oncologists should be familiar with some of the methodologies involved in the measurement of pain (Caraceni et al., 2002) and other physical and psychological symptoms, such as dyspnoea (Bausewein et al., 2007), fatigue (Stein et al., 2004; Wu et al., 2006), nausea and vomiting (Aaronson et al., 1993), depression and anxiety (Moorey et al., 1991; Maher et al., 1996; Fossa and Dahl, 2002), and desire for death (Chochinov et al., 1995). Though most oncologists will not conduct palliative care research, appreciation for the strategies used to study quality of life and its component domains is important, even if only to assist in judging the level of evidence for the interventions that may be applied to address sources of distress.

Ensuring sound ethical practice

Patients with advanced and incurable illness are in a vulnerable position and there are multiple ethical issues that arise in their care. Medical oncologists must be familiar with common ethical problems that arise (Box 12.1.4) and the ethical principles that assist in their resolution.

Transitioning oncology patients to palliative care

In the setting of far advanced and increasingly refractory cancer, one of the most challenging aspects of the oncologists role is to help patients and their families deal with the transitioning to care that is increasingly focused on palliation rather than disease modification (Schofield et al., 2006). Talking to patients and families about dying and palliative care is not easy, especially when patients and/or families want to continue aggressive therapy (Neff et al., 2003; Matsuyama et al., 2006; Otani et al., 2011). This transition to increasingly palliative care is a stressful experience; for many patients it implies impending death and it often triggers fears of

helplessness and abandonment by the medical profession. One can diminish the trauma of this process by gradually introducing palliative care as a legitimate and important focus of care at an earlier stage of the disease trajectory alongside efforts to modify the natural history of the disease This approach recognizes that with disease progression, treatment goals will evolve from seeking a cure, to control of disease and complications, maintaining physical functioning and quality of life, and ultimately to symptom control.

When to raise the issue

In general, it is preferable to introduce the concept of palliative care as care focused on optimizing the quality of life and introducing access to a multidisciplinary team early after the diagnosis of advanced cancer (Morita et al., 2004). This approach is widely supported by data derived from patients and their family members (Hagerty et al., 2004, 2005). Discussion of this kind need to include a review of the information needs and desires of the patient.

The setting

Sensitive discussions of this kind should be carried out in a supportive private environment and patients should be encouraged to invite their significant others to be present. Where possible the place should be a quiet, comfortable, and private location, and adequate uninterrupted time should be available for questions and discussion, and the patients should be encouraged to invite their significant others to be present (Butow et al., 1996; Ptacek and Eberhardt, 1996).

Assess patients' information needs

As a starting point it is important to evaluate the patient's understanding of his/her illness and their understanding of the goals of the treatments that they have undergone until this point. Open-ended questions can be used to evaluate how the patient is coping physically and emotionally and regarding major concerns. Patients' information needs vary greatly and one wants to find the balance between delivering information necessary for understanding and decision-making and an 'assault of truth' whereby patients are given more information than they want or desire (Clayton et al., 2005c).

Several studies have shown that a small proportion of people do not want a lot of information (Sapir et al., 2000; Hagerty et al., 2004; Clayton et al., 2005c). A survey of 126 metastatic cancer patients (Hagerty et al., 2004) found that 33% wanted to discuss 'dying and palliative care services' when first told cancer had spread; 19% said in the next few consultations; 33% said later, upon (their) request; 11% said never; and 10% were unsure. Almost half wanted the oncologist to initiate the discussion, 20% wanted the oncologist to check first if the patient wanted to know, and 24% wanted the oncologist to address the issue only if the patient asked. For some patients, there will be a 'necessary collusion' in which these issues will not be addressed forthrightly, but rather with the passage of time and evolution of the disease (Groopman, 2005; Helft, 2005).

Talking about prognosis

In these dialogues it is common for patients to ask questions about prognosis. The motivation underlying queries about prognosis are not always clear. Whereas many patients want information about their anticipated future so they can plan accordingly, others are

seeking reassurance that things are not so serious or hopeless. It is important to try to understand the patient's motive in seeking this information.

In discussing prognosis, clinicians often describe median survival data or 5-year survival data. Median survival information can be particularly misleading as it is a point descriptor that does not describe interindividual variability, which may be great. Similarly, 5-year survival data may not give adequate information about true anticipated likelihood of survival. If, indeed, prognostic information is required, the following principles are useful (The Michigan Physician Guide to End-of-Life Care, 2001; Clayton et al., 2005a):

1. *Be honest*. If you don't know, say so. It may be useful to describe a worst case and a best case scenario.

2. *Use averages*. 'One third of people will still be doing well a year from now and half will live about 6 months. However, you are unique and I don't know exactly what course this disease will take.'

3. *Emphasize the limits of predictions*. 'No one can really be sure what this will mean for you as an individual. We can't predict surprises and it is prudent to make plans both for the best, but also to cover options if things don't go well.'

4. *Commit to non-abandonment*. Reassure the patient you will continue to care for him or her, whatever happens.

5. *Caution patients and their families that unexpected events can happen*. Suggest that it is worth while to get their affairs in order so they won't be totally unprepared if something unexpected does happen. 'Let's hope and work for the best but, at the same time, prepare for things in case the situation does not go as well as what we hope for.'

6. *Avoid nihilism*. Never tell a patient 'There's nothing more that can be done' or ' Do you want everything done?' There is ALWAYS something to be done. Though chemotherapy may have a higher likelihood of harm than help, there is still much that must be done to help the life yet to be lived. Discuss what can be done to make it better (and what might make it worse).

7. *Initiate end of life planning*. Sensitively bring up the important subject of advance care planning

Discussing anti-tumour therapies when cure is not possible

It is intrinsically difficult to tell a patient and their family that there is no treatment that offers the possibility of cure (Otani et al., 2011). Despite progress in non-curative anti-tumour therapies in some conditions, in many diseases the potential benefit of therapy is small and when benefit is derived, it is often of short duration. Many patients in this setting undertake sometimes burdensome treatments based on exaggerated expectations of potential treatment benefits (Weeks et al., 1998). In counselling such patients it is important to outline treatment options including those that do not involve potentially burdensome anti-tumour treatments. As well as presenting potential benefits

of anti-tumour therapies, it is appropriate to discuss the likelihood of help and of harm.

Situations in which cure is not possible are heterogeneous. In some instances, such as metastatic breast, colorectal cancer, ovarian or small cell lung cancer, there may be a moderate to high likelihood of prolonging survival. In other situations, such as gastric or pancreatic cancer and most of the soft tissue sarcomas, substantial survival prolongation is less likely. In the latter situations informed consent requires that patients understand the limited likelihood of benefit and patients should almost always be offered the options of palliation without chemotherapy or the option of participating in an experimental therapy (if one is available).

These recommendations are supported by the findings of a study of the recordings of the initial oncological consultations of 118 cancer patients with incurable disease. Analysis of these consultations found that whereas 84.7% of patients were informed about the aim of anti-cancer treatment, that their disease was incurable (85%) and about life expectancy (58%), only a minority of consultations included discussion of an alternative to anti-cancer treatments (44%), discussion on the impact of anti-cancer treatment on quality of life (36%), or an offer of management choice (30%) (Gattellari et al., 2002). In only 10% of consultations did the oncologist check the patient's understanding.

Introducing palliative care options

After indicating that further curative treatment has a low chance of being effective and that the aims of the treatment are disease control and optimizing quality of life, the clinician should introduce the option of effective palliative treatment options to help improve the quality of life. For patients wishing to continue disease-modifying treatments, it needs to be explained that this is not an 'either/or' choice, but rather a situation in which the best care will incorporate a balanced approach between the two parallel strategies.

Maintaining hope

Being told that a cancer cannot be cured is devastating for most people and in this setting patients believe it is crucial that doctors help them find some way of maintaining hope as well as giving them honest information about their disease (Clayton et al., 2005b). Indeed, many patients and their families are avoidant of discussions about prognosis or curability for fear that the discussion may undermine or destroy hope.

Hope has been defined as an expectation that there will be a positive outcome in the future (Nunn, 1996). Commonly, however, it is associated with unrealistic expectations. Magical thinking and hope for miracles are a transcultural phenomenon and, in the context of a poor prognosis, it is not necessarily inappropriate for a patient to hope for a cure even if it is highly unlikely, but messages of hope from health professionals should focus on more realistic events, such as long periods of remission, response to treatments and excellent symptom control. Strategies that successfully promote appropriate hope may make a critical contribution to discussing the transition from curative to palliative care.

Deliberately fostering false hope of a cure, when a cure is not possible, may hinder patients and their family from making appropriate treatment and lifestyle decisions in order to make the best use of their remaining time together. Hence, it is critical that the messages of hope provided to patients are appropriate.

In a survey of 156 patients with advanced and incurable illness (Hagerty et al., 2005), doctor behaviours that augmented hope included offering the most up-to-date treatment (90%), appearing to know all there is to know about the patient's cancer (87%), and saying that pain will be controlled (87%). The majority of patients indicated that the doctor appearing to be nervous or uncomfortable (91%), giving the prognosis to the family first (87%), or using euphemisms (82%) would not facilitate hope.

Qualitative data derived from interviews with patients and their caregivers (Clayton et al., 2005b) revealed several hope enhancing themes: (1) emphasize what can be done (particularly control of physical symptoms, emotional support, care and dignity, and practical support), (2) explore realistic goals, and (3) discuss issues related to day-to-day living. Dr Joanne Lynne suggests making seven commitments to patients (Lynn, 2000):

1. You will have the best of medical treatment, aiming to prevent exacerbation, improve function and survival, and ensure comfort.

2. You will never have to endure overwhelming pain, shortness of breath, or other symptoms. Symptoms will be anticipated and prevented when possible, evaluated and addressed promptly, and controlled effectively. Severe symptoms—such as shortness of breath—will be treated as emergencies. Sedation will be used when necessary to relieve intractable symptoms near the end of life.

3. Your care will be continuous, comprehensive, and coordinated. You and your family can count on having certain professionals to rely upon at all times and on an appropriate and timely response to your needs. The transitions between services, settings, and personnel will be minimized in number and made to work smoothly.

4. You and your family will be prepared for everything that is likely to happen in the course of your illness. If necessary you will receive supplies and training needed to handle predictable events.

5. Your wishes will be sought and respected, and followed whenever possible. You will be given information about the available choices and you will be encouraged to be an active participant in decision making. You will have the right to refuse treatments.

6. We will help you and your family consider your personal and financial resources, and we will respect your choices about the use of your resources.

7. We will do all we can to see that you and your family will have the opportunity to make the best of every day. We are committed to treat you as a person, not a disease. What is important to you is important to us as part of the care team. We will endeavor to respond to your physical, psychological, social, and spiritual needs as well as those of your family. Indeed we will be there to support your family throughout this period and after your death.

Logistical considerations in provision of oncological palliative care

Oncology, hospice, and palliative medicine—the division of labour

The integration of oncological care and palliative care requires familiarity with a range of therapeutic options, appropriate patient evaluation, and a collaborative therapeutic relationship with the patient and other members of an interdisciplinary care team. Care planning and goal setting may be facilitated by considering the natural history of cancer in five phases (Box 12.1.5). The changing status of the patient along this continuum influences the coordination and implementation of palliative interventions.

The medical oncologist is almost always the coordinating health-care provider during the first three phases: the diagnostic work-up, attempts at curative therapy, and the phase of ambulatory palliative care, during which the patient continues to attend the cancer clinic. During the latter phase, community-based nursing and medical providers are often introduced to provide additional services outside of the health-care institution and in anticipation of diminished mobility. A large majority of cancer patients live at home during most of the course of the illness. Programmes to extend palliative care services into the home are widely available. Oncologists should familiarize themselves about the existing programmes, refer patients appropriately, and provide continuity of care. In the United States, home-based end-of-life care often is provided by a certified hospice programme. In the US version of hospice, the oncologist can choose to remain the physician of record throughout the period of end-of-life care, or can become a consultant (Schonwetter, 1996).

During the fourth phase, when the patient has advanced illness and may not be ambulatory, and during the fifth, end-of-life care, new decisions often are required about the site of care and level of help required by the patient and family. Patients may be treated at home, in a nursing home, in an inpatient palliative care facility such as a hospice residence, or if indicated, an acute care hospital. Decisions regarding the site of care are influenced by the nature and severity of the prevailing clinical problems, the extent of home-based medical and nursing resources, the availability of community facilities, the goals of care, and patient preference (Hinton, 1994a, 1994b).

The role of the oncologist during these latter phases is determined by similar considerations. In some instances, the oncologist will remain the primary provider of palliative care until the patient dies. In other instances, there should be a smooth transition of care as other services play a progressively greater role and the oncologist becomes a supportive figure. By maintaining

---

Box 12.1.5 Five phase in the natural history of cancer

1. Diagnostic: ambulatory or inpatient
2. Curative primary therapy
3. Ambulatory palliative therapy
4. Sedentary palliative therapy- interactional
5. Sedentary palliative therapy- non-interactional.

continuity in care, the oncologist can ensure that cancer-related issues are adequately addressed and also can limit concerns about abandonment that can magnify patient and family distress (Quill and Cassel, 1995).

Models of care

There is no one best way for oncologists and specialist palliative care services to work together. Rather a number of different models have been developed (Greer et al., 2013):

Sequential care model

In this model the patients is cared for by the oncology service as long as there is potential benefit in disease-modifying treatment. When it is clear that there is no further benefit to be derived from this treatment, the responsibility for the patient's ongoing care is transferred to the palliative care service. Of course, the palliative care service may be consulted earlier, when the patient is under primary oncological management, and similarly, should anti-tumour interventions be required (such as palliative radiotherapy) when the patient is being followed primarily by the palliative care services, expert oncological consultation is available. In this model of care, end-of-life care is coordinated by the palliative care service.

The advantages of this model of care are that it is characterized by clear delineation of responsibility. It enables the oncologist to focus on the dominant aspects of his professional tasks and allows him to fulfil his obligations to provide palliative care and continuity of care by a process of benevolent transfer of primary responsibility to a palliative care team. Successful implementation if this model requires close cooperation between the oncology and palliative care services, good communication to minimize patient feelings of abandonment, and timely referral of patients.

Oncologist-based palliative care

In this model, the oncologist assumes the role of coordinating care and providing both anti-cancer and palliative care services, thus seeing the patient through from diagnosis until death (Cherny, 2003). This approach emphasizes the importance of the oncologist/patient relationship and the notions of continuity of care and non-abandonment. Oncologists undertaking this approach need to be highly skilled in palliative care and in interdisciplinary care, including interaction with a palliative care support team. Even oncologists who are highly skilled in palliative care may sometimes benefit from expert input and this should be sought when difficult problems arise.

The major advantage of this approach is its emphasis on continuity of care. The success of this model is dependent on the level of palliative care skills and sophistication of the oncologist, and his/her ability to balance competing intellectual and practical interests. This approach is augmented by having a strong relationship with a care team, including a palliative medicine expert for backup in difficult cases.

Concurrent model

In this model, patients with advanced cancer are jointly cared for by both oncology and palliative medicine specialists in a similar way that medical, surgical, and radiation oncologists traditionally work together (Meyers et al., 2004). The relative role of the oncology or palliative medicine physician is determined by the prevailing problems and, indeed, case management responsibilities may be handled by either and are usually determined by the circumstances of the patient.

This model emphasizes the duality of advanced cancer care and the need for continuity of care, both with regard to disease modification and palliative care. Successful implementation of this approach requires close cooperation and open communication between oncology and palliative medicine clinicians. This approach is strongly supported by data demonstrating improved patient outcomes (Jordhoy et al., 2001; Brumley et al., 2007; Gade et al., 2008; Bakitas et al., 2009; Temel et al., 2010; Zimmermann et al., 2012).

Palliative care delivery in major cancer centres

A survey of 142 cancer centres in the United States found that the overwhelming proportion of centres had palliative care services, but in many cases these services were very limited in their scope (Hui et al., 2010). Although this penetration is also seen in Canada, the United Kingdom, and Australia, integration of palliative care and oncology is the exception rather than the rule in many other parts of the world.

Beyond minimal requirements (Box 12.1.6), ESMO has developed an incentive programme to recognize centres that demonstrate a high level of integration between medical oncology and palliative care (Cherny et al., 2010). To be eligible for accreditation as a 'designated centre' 13 criteria must be met (Box 12.1.7). These criteria set a gold standard for integration. As of 2014, 174 centres across Europe, North America, Asia, and the Middle East have been accredited with achieving this level of care. Processes for the development of integrated services in major cancer centres have been described (Bruera and Sweeney, 2001; Walsh, 2001; Hydeman, 2013; Marchetti et al., 2013).

Box 12.1.6 Proposed minimal requirements for palliative care in cancer centres

1. Cancer patients receiving active therapy in cancer centres, especially those with advanced cancer, should be routinely assessed regarding the presence and severity of physical and psychological symptoms and the adequacy of social supports.

2. When inadequately controlled symptoms are identified they must be evaluated and treated with the appropriate urgency (depending on the nature and severity of the problem).

3. Cancer centres must provide skilled emergency care of inadequately relieved physical and psychological symptoms.

4. Cancer centres must ensure an ongoing programme of palliative and supportive care for patients with advanced cancer who are no longer benefited by anti-tumour interventions.

5. Cancer centres should incorporate social work and psychological care as part of routine care.

6. When patients require inpatient end of life care, the cancer centre staff either provide the needed inpatient care or arrange adequate care in an appropriate hospice or palliative care service.

Box 12.1.7 Criteria for optimal supportive and palliative care in a cancer centre

1. The centre provides closely integrated oncology and palliative care clinical services.

2. The centre is committed to a philosophy of continuity of care and non-abandonment.

3. The centre provides high-level home care with expert back-up and coordination of home care with primary cancer clinicians.

4. The centre incorporates programmatic support of family members.

5. The centre provides routine patient assessment of physical and psychological symptoms and social supports and has an infrastructure that responds with appropriate interventions in a timely manner.

6. The centre incorporates expert medical and nursing care in the evaluation and relief of pain and other physical symptoms.

7. The centre incorporates expert care in the evaluation and relief of psychological and existential distress.

8. The centre provides emergency care of inadequately relieved physical and psychological symptoms.

9. The centre provides facilities and expert care for inpatient symptom stabilization.

10. The centre provides respite care for ambulatory patients for patients unable to cope at home or in cases of family fatigue.

11. The centre provides facilities and expert care for inpatient end-of-life care and is committed to providing adequate relief of suffering for dying patients.

12. The centre participates in basic or clinical research related to the quality of life of cancer patients.

13. The centre is involved in clinician education to improve the integration of oncology and palliative care.

The development of palliative care services requires appropriate resource allocation for staffing, physical space, and necessary supports. Thought should be given to the development of processes such as joint meetings to facilitate good integration between oncology and palliative care services. Tumour boards for patients with advanced cancer, radiology conferences, and interdisciplinary psychosocial conferences to discuss challenging cases, afford excellent opportunities to forge collaborative working relationships and balanced discussion.

Where oncological palliative care is delivered in the cancer centre

Since most patients with advanced cancer receive a trial of therapy in an ambulatory office-based setting or radiotherapy centre, the incorporation of onsite palliative care assessment and intervention programmes provides an excellent opportunity to assess the need for palliative interventions, and to address physical or psychosocial needs.

With the changing patterns of oncological care delivery, oncology inpatient wards increasingly are occupied by patients needing symptom control or terminal care (Salminen et al., 2008) and the administration of palliative care has become a major part of inpatient oncology care (Ferris et al., 2009).

In some inpatient and outpatient settings, palliative care consultation services can help deliver specialist palliative care in a manner similar to other consultation services. When a patient is admitted to the hospital, this service can assist oncologists by providing expert back-up in the management of difficult cases. Back-up of this type may take the form of advice, direct participation in management, or sometimes in the transfer of case management. Palliative care consultations can have major impact on physician education and practice among oncologists (Hanson et al., 2008; Weissman et al., 2008; Zhukovsky et al., 2009).

Dedicated acute inpatient palliative care units, if available, can provide a high level of expertise in palliative interventions, such as symptom control, and comprehensive end-of-life care (Mercadante et al., 2008; Albanese et al., 2013; Eti et al., 2014). Oncologists can admit patients to acute palliative care units in hospitals for symptom evaluation and management, respite, management of treatment complications, or terminal care.

Barriers to coordination between oncology and palliative care

Different cultures of care

It has been pointed out that palliative care and oncology have substantially different histories and cultures of care (McKenzie, 1998). These differences may account for some of the difficulties sometimes encountered in integration of these approaches. Whereas palliative care grew out of the hospice movement, which tends to the physical and emotional needs of patients and their families rather than focusing on the diseases themselves, modern oncology has developed out of the specialist biomedical model with a strong emphasis on addressing the disease processes with view to cure patients or to prolong their lives. Whereas interdisciplinary care is inherent to palliative care, in oncology despite the growing prevalence of multidiscipline clinics and tumour boards, the concept of the 'patient care team' has not yet been universally adopted. Indeed, the ESMO survey of oncologist practice in the management of incurable cancer patients indicates that it is relatively underdeveloped and uncommon (Cherny and Catane, 2003).

Delays in referral for palliative care consultations

Very often the timing of referrals to specialized palliative care services, including palliative care units, inpatient hospices, and home-based palliative care programmes, is very delayed until patients have a very severe symptom burden or, often, until patients are close to death (Cheng et al., 2005; Ferrell, 2005; Morita et al., 2005). In a survey of bereaved family members of cancer patients (Morita et al., 2005), half of the respondents regarded the timing of referrals as late or very late, and indeed the median admission period was less than 1 month (22 days), and approximately 20% of the patients died within 1 week. The reasons for this are complex: persistent beliefs that palliative care has an alternative philosophy of care incompatible with cancer therapy, beliefs that providing palliative care is the oncologist's role, lack of knowledge about locally available services, oncologist and patient reluctance

to address issues implying incurability, optimism that third- or fourth-line salvage treatments will prolong survival or improve quality of life, fears that a palliative care referral will undermine hope or shortens the patient's life, and insufficient in-advance discussion about preferred end-of-life care with physicians (Morita et al., 2005; Schenker et al., 2014). Oncologists sometimes express reluctance about palliative care referrals for fear that anti-tumour treatment strategies will be challenged (often by palliative care clinicians with limited familiarity with oncological care strategies) or that the patient will be 'stolen' (Cherny and Catane, 2003; Ferrell, 2005; Schenker et al., 2014; Von Roenn et al., 2013).

Another reason for delayed referral is the oncologist's failure to recognize the deterioration in the patient's clinical course. There are data to suggest that oncologists are commonly overoptimistic and overestimate survival substantially (Christakis and Lamont, 2000). Indeed, a meta-analysis of the 13 available studies showed that cancer physicians tended to overestimate prognosis by at least 30% (Glare et al., 2003). To add to this, when patients request information about prognosis, many physicians consciously overstate the prognosis even beyond their own (inflated) estimate (Lamont and Christakis, 2001).

Abandonment

Unfortunately, when a patient's disease reaches an advanced stage, a point at which symptom management becomes more necessary, some oncologists relinquish their role in the care of the patient because radiotherapy and chemotherapy have nothing more to contribute (Dias et al., 2003). Sadly, it is not uncommon to hear patients relate that the oncologist said that 'there is nothing further can be done'. In many cases, not only is there no continuity of care, but in many cases, palliative care options are not presented. For some patients, situations of this ilk undermine hope and the desire to live (Kissane et al., 1998).

Territoriality

There is anecdotal evidence that professionals in various disciplines looking after patients with cancer may never meet one another, and oncologists, family physicians, and palliative care specialists often do not appreciate the challenges other physicians face (McKenzie, 1995, 1998). The survey of European oncologists revealed that many oncologists believe that palliative care colleagues do not understand cancer care at a level sufficient to render informed advice, and a small proportion of oncologists feel that palliative care physicians will 'steal' patients (Cherny and Catane, 2003).

Palliative care education for oncologists

Current shortcomings in oncologist education

In 1998, the ASCO performed a large-scale survey of US oncologists about their experiences in providing palliative care (Emanuel et al., 2000; Hilden et al., 2001). The survey questionnaire consisted of 118 questions. A total of 3227 oncologists responded. There were no significant differences between the percentages of medical, radiation, surgical, or paediatric oncologists who responded as a proportion of their representation in ASCO. In this survey, the most frequent sources of palliative care education were trial and error during clinical practice (90%), from colleagues during clinical practice (73%), from a role model during oncology fellowship training (71%), and from a traumatic experience with a patient. The ASCO survey found that the oncologists did not obtain adequate information from their colleagues and role models, despite reporting these people as the most frequent educational resource: 81% said they had inadequate mentoring or coaching in how to discuss poor prognosis, 65% said they received inadequate information about controlling symptoms, and less than 10% thought all of their formal training during medical school, internships, residency, and fellowship combined was 'very helpful'.

In a 2004 survey, ASCO trainees rated end-of-life education less highly than their general fellowship training. They viewed their attendings as more expert in non-end-of-life care than in terminal care. Of those who had performed bone marrow biopsy, feedback on this technique was more likely to have occurred than feedback on an end-of-life discussion (73% vs 56%; p = 0.0006). Regarding pain management, 94% of fellows felt prepared to manage pain in the dying, 75% assessed pain in their patient who died most recently, 41% were explicitly taught when to rotate opioids, and only 30% performed an opioid conversion correctly (Buss et al., 2007).

In a survey of ESMO members regarding their involvement in palliative care, 42% of respondents reported that they had not received adequate training in palliative care during their residency. This finding is consistent with previously published data regarding the training of medical oncologists in the management of cancer pain (Larue et al., 1995; Gerrard et al., 1999; Sapir et al., 1999), communication skills (Baile et al., 1997; Fallowfield and Jenkins, 1999), and palliative care (Gerrard et al., 1999; Gilewski, 2001). In response to the statement 'most medical oncologists I know *are* expert in the management of the physical and psychological symptoms of advanced cancer', more respondents disagreed (41.8%) than agreed (37.5%). This finding suggests that most oncologists have a low assessment of their colleagues' readiness to manage the physical and psychological symptoms of advanced cancer, a perception that is consonant with the findings regarding training.

Curricular requirements of ASCO and ESMO

There is universal recognition for the need to provide training in palliative care for all oncologists. This has been incorporated into the 'Global Core Curriculum in Medical Oncology' that was developed and endorsed by ASCO and ESMO (Hansen et al., 2004) and in the ESMO document describing the core elements of oncology training in palliative and supportive care (Cherny et al., 2003).

In 2010, the ESMO palliative care working group and the ASCO task force on palliative care made a joint submission for the revision of the palliative care content of the Global Core Curriculum in Medical Oncology. These recommendations are presented in Box 12.1.8. These recommendations distinguish between three levels of desired proficiency:

1. *Expert*: refers to a high level of academic and practical knowledge. At the completion of training, oncology graduates should be expert in the oncological management of advanced cancer, the management of complications of cancer and the evaluation and management of physical symptoms of cancer and cancer treatment.

2. *Skilled*: refers to effective clinical competence. This level of proficiency is required for communication with patients and family members.

The palliative care role of the oncologist

It is the oncologist's responsibility to care for their patient along a continuum that starts at the moment of diagnosis and extends throughout the course of the illness. In addition to appropriate anti-cancer treatment, this includes symptom control, psychosocial support and the coordination of services to provide continuity of care and family support during all phases of care, including the last phase of life.

Interdisciplinary care

Trainees should be aware that the management of patients with advanced cancer will usually require close cooperation with clinicians of other disciplines including nurses, social workers, anaesthesiologists, palliative care clinicians, psychologists, psychiatrists, chaplains, rehabilitation, physical therapy, occupational therapy, speech therapy and dietitians.

Trainees should be skilled at interdisciplinary care planning and coordination. They must be familiar with the roles of clinicians from other disciplines and indications for referral of requests for assistance.

The oncological management of advanced care

Medical oncologists must be expert in the appropriate selection and use of anti-tumour therapies as palliative techniques when cure is no longer possible. They should be familiar with key concepts of patient benefit, quality of life and risk/benefit analysis.

Pain

Trainees must be expert in the assessment and management of cancer pain.

1. Pain assessment: trainees should be skilled in the comprehensive assessment of pain from cancer and its treatment. They should have an understanding of the use of pain scales. They should understand the mechanisms and pathophysiology of cancer pain syndromes, understand the concept of 'total pain,' and be familiar with the clinical features of the full range of cancer pain syndromes and the diagnostic approaches to identify them.

2. Pharmacotherapy: trainees should have an understanding of the pharmacology and toxicity of non-opioid and opioid medications commonly used in the management of cancer pain. They should be experienced in the initiation of analgesic therapy, monitoring patients for adequacy of pain relief and titration of analgesics. They must be skilled in the evaluation and management of opioid adverse effects such as constipation, nausea and vomiting, drowsiness, confusion and myoclonus. Trainees should be familiar with the use of adjuvant analgesics for the management of neuropathic, visceral and bone pain. They must be familiar with approaches to the management of breakthrough pain

3. Primary therapies: trainees must be familiar with the role of primary anti-cancer treatments for the relief of pain, including the roles of radiotherapy and surgery. Specific examples include the role of radiotherapy and/or surgery in the setting of spinal cord compression and impending fractures.

4. Difficult pain syndromes: Trainees must be familiar with the range of options available to patients with difficult or refractory pain syndromes including the indications for experts consultations with a pain or palliative medicine specialist, invasive or neuroablative procedures and sedation as an option of last resort for dying patients with refractory pain.

Symptom evaluation and management

Trainees should be familiar with the use of scales to evaluate common physical symptoms in patients with cancer. The trainees should be expert in the evaluation and management of common symptoms including dyspnea, nausea and vomiting, constipation, diarrhea and cancer related fatigue.

1. Dyspnea: trainees should be familiar with the differential diagnosis of dyspnea in the patient with advanced cancer. Trainees should be able to identify potentially remediable causes and be familiar with specific treatment modalities. Trainees should be familiar with the use of opioids for the management of symptomatic dyspnea.

2. Nausea and vomiting: trainees should be familiar with the differential diagnosis of nausea and vomiting in the setting of advanced cancer and be able to identify potentially remediable causes. Trainees should have an understanding of the mechanism of action of antiemetics and their appropriate use for symptom control.

3. Constipation: trainees should be familiar with the factors that contribute to constipation in patients with advanced cancer. Trainees should be able to distinguish constipation from bowel obstruction. Trainees should be familiar with approaches to prevent constipation, provide supportive counseling and prescribe rational pharmacotherapy for the treatment of constipation.

4. Cancer-related fatigue: trainees should be familiar with the factors that contribute to fatigue in patients with advanced cancer and the expected occurrence and duration of treatment-related fatigue. Trainees should be able to identify potentially remediable causes and recommend appropriate pharmacologic and supportive approaches for fatigue.

Box 12.1.8 Continued

5. Diarrhea: trainees should be familiar with the differential diagnosis of diarrhea in patients with advanced cancer. Trainees should be able to identify potentially remediable causes and identify patients at high risk for obstruction. Trainees should be familiar with treatment strategies for the various causes of diarrhea in patients with advanced cancer. In particular, trainees should be familiar with treatment strategies for chemotherapy- and radiation therapy-induced diarrhea and neutropenic enterocolitis.

6. Delirium: trainees should be familiar with the differential diagnosis of delirium in patients with advanced cancer. Trainees should be able to identify its medical causes. Trainees should be familiar with treatment strategies for the various causes of delirium in patients with advanced cancer and with the symptomatic management of delirium with antipsychotic medications.

7. Anorexia/cachexia and starvation: trainees should be able to differentiate between starvation and cancer cachexia. They should be familiar with the pathophysiology of cancer cachexia with the phases or early cachexia, cancer cachexia and refractory late cachexia. They should be able to formulate rational therapeutic plans for patients with starvation syndromes and cancer cachexia, recognizing the potential benefits, limitations of benefit and risks of the various treatment options.

Management of the complications of cancer

Trainees must be expert in the evaluation and management of the complications of cancer including:

1. Bone metastases: indications for radiotherapy and surgery, the role of biological treatments, radiopharmaceuticals and the use of bisphosphonates.

2. *CNS metastases, brain and leptomeningeal metastases: indications for steroids, surgery, radiotherapy, and shunts. Use and limitations of intrathecal or systemic chemotherapy.*

3. Neurological dysfunction: primary, metastatic, paraneoplastic and iatrogenic.

4. Liver metastases and biliary obstruction: management of obstruction including percutaneous and endoscopic stenting.

5. Malignant effusions pleural, peritoneal and pericardial. Trainees should be skilled at paracentesis and thoracocentesis. They should be familiar with the role of surgical approaches including percardiocentesis, pericardial window, shunts, and pleuradhesis.

6. Obstruction of hollow viscera: esophagus, airways, gastric outlet, small and large bowel, ureters. They should be familiar with medical management of bowel obstructions and the indications for surgical, radiotherapeutic and gastroenterological approaches to esophageal, bowel and ureteric obstruction.

7. Metabolic consequences of cancer: hypercalcemia, hyponatremia, renal failure.

8. Anorexia and cachexia: dietary counseling, the use of appetite stimulants, the role of enteral and parenteral feeding.

9. Hematologic consequences: anemia, neutropenia, thrombocytopenia, clotting diathesis.

10. Sexual dysfunction.

Communication

Trainees must be skilled in effective and compassionate communication with cancer patients and their families. Specific skills include:

1. Explaining diagnosis and treatment options.

2. Disclosure of diagnosis.

3. Defining goals of care.

4. Explaining issues relating to prognosis.

5. Explaining the potential risk and benefits of treatment options.

6. Counselling skills to facilitate effective, informed decision-making.

7. Explaining the role of palliative care and it relevance in all phases of the illness trajectory.

8. The care of distressed family members: fear, anticipatory grief, bereavement care.

9. Convening and leading of family meetings.

10. Discussing transitions in care; e.g., initiation of hospice, discontinuation of chemotherapy.

Palliative rehabilitation

Trainees must be aware that palliative cancer care aims to improve function as well as comfort and that rehabilitation may have an important part in optimal care, even for patients with incurable disease. Trainees should be familiar with the role of rehabilitation in patients with deficits in speech, swallowing, breathing, cognition and all forms of motor function.

Box 12.1.8 Continued

Cultural competence

Trainees should be familiar with the impact of culture on the management of patients with cancer. Trainees should be able to discuss specific cultural-based preferences with patients and their families. Trainees should appreciate the need for cultural sensitivity. Trainees should be familiar with the need for individual assessment of patient's desire for disclosure and full participation in decision-making processes.

Evaluation and management of psychological and existential symptoms of cancer

Trainees should understand the psychosocial influence of cancer. Trainees should be aware of available resources and recognize when intervention is indicated at all stages of disease. Trainees should appreciate the spiritual conflicts associated with the diagnosis and treatment of cancer. Trainees should learn to recognize adaptive and maladaptive behavior in coping with disease. Trainees should recognize acceptable coping mechanisms by patients and families within the context of the cancer diagnosis.

Trainees should be familiar with the indication and uses of psychotropic drugs.

Trainees should have knowledge of the bereavement process.

Trainees should have an appreciation of the physician's personal coping.

Trainees must be familiar with the evaluation and management of the common psychological and existential symptoms of cancer including:

1. Distress
2. Anxiety
3. Depression
4. Demoralization
5. Loss of dignity
6. Delirium
7. Suicidality, desire for death and requests for euthanasia or assisted suicide
8. Death anxiety
9. Anticipatory grief
10. Uncertainty

Self-care

1. Trainees should recognize the factors that contribute to burnout and compassion fatigue.
2. Trainees should be able to differentiate depression from burnout.
3. Trainees should develop a plan for self-care that includes recognizing and monitoring for symptoms of burnout, addressing symptoms if they occur, maintaining work-life balance and seek consultation if the symptoms are progressive or severe.

End-of-life care

1. Advanced care planning: Trainees should be equipped to discuss advanced care planning with patients with advanced and incurable illnesses and their family members.
2. Communication: Trainees should be skilled in the effective and empathic communication of impending death with patients and their family members. Trainees should be able to discuss discontinuation of antineoplastic therapies, transitions in care, the anticipated clinical course, signs and symptoms of imminent death and the strategy to ensure optimal patient comfort as well as family support
3. End-of-life care planning: Trainees should be aware that it is the responsibility to ensure that care planning is undertaken interpersonally, or by another member of the interdisciplinary team. They should be aware of options for end-of-life care including home-based care, inpatient care and hospice care and should be able to help negotiate care preferences with the patient and their family.
4. Non-abandonment: Trainees should be aware that many patients and families are concerned that their oncologist will abandon them at the end of life and should be aware of the need to maintain availability and support.
5. Symptom management: Trainees must be familiar and skilled in the management of common symptoms at the end of life including pain, dyspnea, delirium, death rattle, and anguish. Trainees must be familiar with the identification of refractory symptoms and indications for, and use of sedation in the management of refractory symptoms at the end of life.

Box 12.1.8 Continued

Ethical issues in the management of patients with cancer

Trainees must be familiar with common ethical problems that arise in the management of advanced cancer and ethical principles that assist in their resolution. They should be familiar with:

1. Ethical issues related to disclosure of diagnosis and prognosis.

2. Ethical issues in relation to decision-making: autonomy, relational autonomy, indications for paternalism, assessment for decision-making capacity, surrogate decision-making, principles of shared decision-making

3. The right to adequate relief of physical and psychological symptoms and its implications.

4. Consent: informed, uninformed.

5. Ethical issues at the end of life: sedation for refractory symptoms, hydration and nutrition at the end of life, DNR, use of invasive palliative approaches; i.e., nephrostomy or dialysis.

6. Ethical issues related to foregoing treatment.

7. Ethical issues relating to requests for euthanasia or assisted suicide.

Palliative care research

Medical oncologist must be familiar with palliative care research methodologies that are applicable to patients with advanced cancer including:

1. Quality of life research.

2. Pain measurement and research.

3. Measurement of other physical and psychological symptoms: dyspnea, fatigue, cachexia, nausea and vomiting, depression and anxiety, and desire for death.

4. Needs evaluation.

5. Decision-making research.

6. Psychosocial research.

7. Care delivery research; particularly with reference to integrating oncology in palliative care

8. Palliative care audit.

---

3. *Familiar*: is the lowest level of required competence. It refers to familiarity with core concepts to the level of being able to adequately evaluate the patient, initiate basic therapy, and communicate with clinical experts. At the completion of training, oncology graduates should be familiar with evaluation and management of psychological and existential symptoms of cancer, interdisciplinary care of patients with advanced cancer, palliative care research principles, ethical issues in the management of patients with cancer, and strategies to identify and prevent burnout.

Educational materials for oncologists

Remarkably, despite the frequent role as primary care provider to cancer patients with advanced illness, oncologists are not a regular target audience for educational materials on palliative care. Nonetheless, special educational materials have been developed and should be widely promoted. Among these materials are the following:

ESMO Handbook of Advanced Cancer Care: this is a small practical handbook developed and distributed by ESMO, written by oncologists and clinicians working with cancer patients, outlining major issues in palliative care as they apply to the cancer patient. It addresses a wide range of issues in decision-making, physical, and psychological management issues.

Evidence-based clinical guidelines: in the United States, both the NCCN (<http://www.nccn.org>) and the National Cancer Institute (NCI; <http://www.cancer.gov/cancertopics/pdq/supportivecare>) have developed online resources to deliver up-to-date, evidence-based guidelines for elements of palliative care. The NCI's supportive care subsection of the PDQ includes monographs covering common physical and psychological symptoms in patients with advanced cancer. The NCCN Guidelines® offer a thoughtful evidence-based approach to several aspects of supportive and palliative care for cancer patients. The guidelines on 'Palliative Care and Distress Management' are particularly commended (<http://www.nccn.org/professionals/physician_gls/f_guidelines.asp#supportive>).

EPEC-O: ASCO, in collaboration with the National Cancer Institute and EPEC (Education for Physicians in End-of-Life Care), has developed a curriculum in end-of-life care specific

to oncologists. This well-developed programme aims to equip oncologists with the attitudes, knowledge, and skills to provide the best possible palliative care for their patients. The educational materials, which are available on DVD includes three plenary sessions and 32 PowerPoint presentations with background information for the instructors. The multimedia materials make excellent use of trigger films to stimulate discussion and to highlight important points.

Optimizing Cancer Care—The Importance of Symptom Management Vols I and II: these are curricular materials that have been published and marketed by ASCO. This is a well-developed (but expensive) educational resource that covers 29 supportive care topics, including effective communication, and physical and psychological symptom assessment and management. It uses an array of teaching tools—treatment scenarios, annotated slides, algorithms, and a table of medications.

Initiatives to improve oncologist understanding and involvement in palliative care

Oncology conferences: there is an encouraging trend to greater incorporation of palliative care content in major oncology meetings. Additionally, many of the international and national oncology organizations now organize conferences and workshops on palliative and supportive care issues.

Incorporation of palliative care issues in major oncological journals: journal content of the major oncological journals reflects, to some degree, professional priorities. Although all of the major oncological journals cover palliative care issues to some degree, they remain marginalized issues in most of the journals. Of the major oncology journals, the outstanding exception is the *Journal of Clinical Oncology*. In addition to publishing more than 600 reports of clinical trials in the area of palliative care and quality of life, it created a new section in 2000, which is entitled 'The Art of Oncology: When the Tumor Is Not the Target' and focuses on issues of patient–physician communication, ethical decision-making, and symptom control in the management of advanced cancer.

Working towards the future

The advancement of medical oncologist awareness, knowledge, practice, and research in palliative medicine will require an elevation of the relative priority of palliation as a goal of cancer care. This, in turn, will need to be reflected in resources allocation, programme development, and clinical practice.

Palliative medicine as an oncological subspecialty: there is a need for more oncologists with advanced training in palliative medicine. The prevalence of patients in need of this sort of specialty service suggests that each department would benefit from at least one oncologist with palliative medicine expertise. For the medical oncologist, an enhanced familiarity with palliative medicine can extend the clinician's therapeutic repertoire, diminish the stress of caring for patients who have incurable cancer, improve patient outcomes, and provide new avenues for clinical research and reward (Epstein and Morrison, 2012).

Elevating the priority of palliation: this process requires a paradigm shift at all levels of the cancer medicine infrastructure. Given the current infrastructure for career development and resource allocation for clinical and research programmes in medical oncology, initiatives such as those undertaken by ASCO and ESMO are needed to raise the priority of palliative medicine.

Development of clinical programmes: individual institutions must be encouraged to develop expert services to provide a clinical service and role models, and to conduct clinical and basic research in the palliative care of cancer patients. Services should incorporate clinical resources to address problems related to physical and psychological symptoms.

Research: palliative medicine opens a vast array of potential research questions. Symptom palliation, ethics, communication, coping needs, emotional and spiritual care, and the palliative effects of primary antineoplastic therapy are all valid research directions for oncologists. The clinical trials expertise that currently exists in the oncology community should be used to address specific symptom control problems (such as dyspnoea, nausea, and delirium) or complications of cancer (such as neoplastic plexopathies, or bowel obstruction).

The individual clinician: every oncologist can focus their attention on the palliative needs of their own patients. Practice guidelines, journals, consultants, and other resources are available to help address these issues. Physicians can remind themselves, their colleagues, and students to think about physical and psychological symptom control and patient supports at all stages of the illness and not just in the terminal phase. Oncologists can develop relationships with local hospice organizations to ensure close cooperation and smooth transition with continuity of care for patients referred for hospice care. Those involved with teaching can emphasize the evaluation and management of physical and psychological symptoms, communication skills, attitudes, and the care of dying patients.

Conclusion

The integration of palliative medicine and medical oncology, in practice and in education, can provide a better standard of patient care, reduce the risk of oncologist burnout, and increase the likelihood of patient family and physician satisfaction. There need be no gulf between these disciplines and only together do they represent truly comprehensive cancer care. The realization of this fusion will require the participation of individual clinicians, programme directors, and the policymakers for cancer centres, professional organizations, and the health-care regulatory authorities. It is a logical next step in the evolution of medical oncology.

Disease-modifying therapies in advanced cancer

Dirk Schrijvers

Introduction to disease-modifying therapies in advanced cancer

Diagnosis of cancer can be in an early or advanced stage. The stage at diagnosis depends on several factors such as the region where the patient is living (more advanced disease in developing countries); the health-care system and the implementation of screening programmes; patient factors such as cancer awareness, beliefs, and financial resources; and cancer-related factors such as visibility (ulcerations) and early physical complaints (e.g. bleeding and pain).

If a patient is diagnosed with advanced-stage disease, the possibilities of treatment and the outcome of treatment depends on several factors such as the health-care resources, knowledge and attitudes of both the professional health-care giver, the patient, and the non-professional caregiver, the availability of different treatment modalities (e.g. surgery, radiotherapy, and medication) and the type of cancer.

In regions with sufficient health-care resources, disease-modifying therapies can be proposed to the patient in combination with palliative care.

Aims of therapy

When an advanced-stage cancer is diagnosed and health-care resources are available, a disease-modifying therapy might be considered. Before discussing such a treatment, it is important that the patient is informed about his or her condition to participate in the decision process.

Different aims of therapy can be postulated in patients with advanced disease, depending on their condition and wishes and the disease itself.

If the condition of the patient is very weak (e.g. Eastern Cooperative Oncology Group Performance status ≥ 3) the likelihood of benefit from anticancer treatment is limited and in many instances treatment should be withheld because it may compromise well-being without contributing to improved quality or duration of survival. Several instruments have been developed to determine the frailty of a patient (Luciano et al., 2010) and expected toxicity (Extermann et al., 2012) in relation to treatment and the patient should be evaluated before any diagnostic and treatment procedure to avoid unnecessary examinations and harm to the patient.

If the condition of the patient permits, an anticancer treatment may be proposed. The aim of the treatment may be curative or palliative. Even in patients with advanced disease, treatment may be given with the aim of curing (= curative intent) the patient with certain cancer types (Box 12.2.1) while for other conditions, cure is not an option and anticancer treatment can be given to improve or stabilize the quality of life and sometimes prolong life (= palliative treatment).

The aim of the treatment should be clearly explained to the patient and the caregiver(s) with information regarding acute and late side effects to ensure that the patient can make an informed decision and consent to the proposed treatment plan.

Disease-modifying therapies in advanced cancer

Surgery

While in the past, surgery was mainly used in patients with localized disease or with palliative intent (e.g. derivations), it now has a place in the treatment of patients with advanced disease to achieve cure or better disease control. It has an important impact on treatment outcome in combination with other treatment modalities and the treatment proposal should be discussed beforehand in a multidisciplinary team.

Local disease

Even in patients with advanced disease, the removal of the primary tumour can be used to influence the course of the disease.

In a treatment with *curative intent*, surgery on the primary tumour is standard practice in patients with metastatic testicular cancer (e.g. orchiectomy), ovarian cancer (e.g. removal of both ovaries together with all peritoneal disease), and metastatic thyroid cancer (total thyroidectomy) and improves treatment outcome.

The beneficial effect of removing the primary tumour in *palliative setting* has also been shown in certain tumour types:

- In patients with metastatic renal cell carcinoma, nephrectomy can result in the disappearance of lung metastases and in patients treated with interferon, prior nephrectomy improves overall survival. This improved survival might be the result of deprivation of angiogenic factors secreted by the primary tumour (Karam and Wood, 2011).

- In patients with breast cancer (Pérez-Fidalgo et al., 2011; Hartmann et al. 2014) and colorectal cancer (Verhoef et al., 2011) there is limited data to suggest that removal of the local tumour may have a beneficial effect on survival.

> **Box 12.2.1** Advanced stage cancer that can be treated with curative intent
>
> Chemotherapy:
> - acute lymphoblastic leukaemias (children)
> - acute myeloid leukaemia
> - choriocarcinoma
> - high-grade non-Hodgkin's lymphoma
> - Hodgkin's disease.
>
> Combination of chemotherapy and surgery:
> - breast cancer
> - germ cell tumours of testis and ovary
> - colorectal cancer
> - epithelial ovarian cancer
> - Ewing's sarcoma
> - osteosarcoma
> - rhabdomyosarcoma
> - Wilms' tumour.
>
> Combination of chemotherapy and radiotherapy:
> - anal cancer
> - cervical cancer
> - head and neck cancer
> - lymphoma
> - non-small cell lung cancer
> - small-cell lung cancer.

Regional disease

Lymph node invasion has a prognostic role in most tumours and determines subsequent adjuvant treatment in many tumour types. In some tumour types (e.g. intermediate and high-risk endometrial cancer (Neubauer and Lurain, 2011), malignant melanoma (Rager et al., 2005), non-small cell lung cancer (Bakir et al., 2011), and bladder cancer (Brunocilla et al., 2011)), lymph node dissection and removal of all involved lymph nodes contributes to a better overall survival.

Distant metastatic/recurrent disease

Surgery is also used more frequently in patients with synchronous and/or metachronous metastatic disease and selected patients with solid tumours can be cured by complete resection of metastases if the primary tumour is controlled.

- In some patients with *lung* metastasis, metastasectomy can be considered if the primary tumour is controlled, no extra-thoracic lesions are present with the exception of hepatic lesions that can be resected completely, metastases are technically resectable, and the general and functional risks are acceptable (Hornbech et al., 2011). Long-term survival has been reported after metastasectomy of lung metastases in patients with testicular cancers, osteosarcoma, soft tissue sarcoma, renal cell carcinoma, and colorectal cancer (Hornbech et al., 2011).

- While curative resections of *liver* metastasis have been reported in patients with colorectal cancer, its value in other tumour types (e.g. breast cancer and melanoma) has not been clearly demonstrated (Zani and Clary, 2011).

- Resection of solitary *brain* metastasis in combination with whole-brain irradiation of different tumour types has also been reported to be beneficial in patients with a good performance status (Scoccianti and Ricardi, 2012) resulting in improved function and duration of survival.

- Metastasectomy of painful lesions in the adrenal gland and bone may improve comfort but there is no evidence of improved survival.

Radiotherapy

External beam radiotherapy is another local treatment modality that has a place in the treatment of patients with advanced cancer (see Chapter 12.4). It is indicated in the palliative treatment of metastatic lesions causing symptoms such as pain due to bone metastasis or compressive complications by metastatic disease (e.g. pathological enlarged lymph nodes, brain metastasis). In addition to its palliative effects, radiotherapy has also an impact on disease outcome and overall survival in selected (loco-regional) advanced cancers.

- In patients with extensive disease *small cell lung cancer*, combination of loco-regional radiotherapy with chemotherapy improves local control and survival compared to chemotherapy alone (Jeremic et al., 2010). In patients with extensive disease small cell lung cancer and a response to chemotherapy, prophylactic whole-brain irradiation leads to a significant reduction in symptomatic brain metastases and improved survival (Slotman et al., 2007).

- Radiotherapy has also a role in the multimodality treatment of patients with *solitary brain metastasis* and the combination of surgery and whole-brain radiation improves tumour control at the original metastatic site and in the brain overall when compared to surgical resection alone (Scoccianti and Ricardi, 2012).

- In patients with loco-regional recurrent *head and neck cancer*, re-irradiation of the head and neck region with or without chemotherapy can induce long-time disease control although toxicity can be excessive.

While radioactive isotopes have been used in the control of painful diffuse bone metastases in palliative care setting, some isotopes are able to modify the course of metastatic disease. In patients with *thyroid cancer*, radioactive iodine has been used to control metastatic disease; Yttrium (^{90}Y)-edotreotide (Reiners et al., 2011) improves symptoms and survival in patients with metastatic *carcinoid tumours* (Bushnell et al., 2010), and radium 223 is able to improve survival in castration-resistant *prostate cancer* patients and bone metastasis only (Parker et al., 2011). Microspheres labelled with ^{90}Y are being tested in the local treatment of primary and metastatic *liver malignancies* (Uthappa et al., 2011).

Medication use

Several drugs are used in the treatment of cancer and are classified as (anti)hormones, cytotoxic or chemotherapeutic agents, targeted agents, and immunomodulatory drugs.

(Anti)Hormones

Some cancers are hormone sensitive and their biological behaviour can be modified by hormonal manipulations.

Breast cancer

In 70% of breast cancers, oestrogen and/or progesterone receptors are present and these tumours can be treated with hormonal manipulations in adjuvant and metastatic setting to modify the course of the disease. In oestrogen receptor (ER)-positive postmenopausal women with loco-regional disease, treatment with aromatase inhibitors and/or anti-oestrogens (e.g. tamoxifen) improves disease-free and overall survival. Postmenopausal women with ER-positive metastatic disease without prior endocrine therapy or with a previous treatment with tamoxifen should be offered an aromatase inhibitor. In pre- or perimenopausal women with ER-positive tumours not previously treated with hormonal therapy, tamoxifen and ovarian suppression should be offered as first-line treatment while ovarian suppression should be added to women previously treated with tamoxifen at disease progression (National Institute for Health and Clinical Excellence, 2009). When starting (anti)hormonal treatment, side effects (e.g. hot flushes, arthralgia, second tumours, and osteoporosis) should be taken into account for selection of the hormonal therapy.

Endometrial cancer

Endometrial cancer is considered to be a hormone-driven cancer. A trial of hormonal therapy may be helpful to palliate symptoms (Kokka et al., 2010).

Prostate cancer

Prostate cancer is usually a hormone-sensitive tumour that can be influenced by hormonal manipulations. In patients with advanced prostate cancer, androgen deprivation therapy (ADT) by orchiectomy, luteinizing hormone-releasing hormone agonists or antagonists, and diethyl-stilbestrol has a high likelihood of inducing a remission, thus delaying progression, relieving and preventing complications, and palliating symptoms effectively.

The timing of starting ADT should be individualized. Although immediate ADT at diagnosis significantly reduces disease progression and the complication rate compared with deferred ADT at the time of symptomatic progression, it does not induce a clear survival benefit. Side effects of ADT are sexual dysfunction, hot flushes, osteoporosis with fractures, metabolic syndrome, and cardiovascular morbidity and mortality (Heidenreich et al., 2012). Hormonal manipulations are also effective in patients who have developed castration-resistant prostate cancer and an overall survival benefit has been shown with abiraterone acetate, a cytochrome 17-complex inhibitor that completely inhibits testosterone production in all tissues as well as some newer anti-androgens.

Thyroid cancer

Patients with advanced differentiated thyroid cancer may benefit from L-thyroxine treatment at doses that suppress serum thyroid stimulating hormone (TSH) levels. TSH is thought to increase tumour growth but the optimal reduction of TSH concentration to reduce tumour recurrences and improve survival is unknown. Aggressive TSH suppression is indicated in patients with high-risk disease or recurrent tumours, whereas less aggressive TSH suppression is reasonable in low-risk patients (Biondi and Cooper, 2010). Side effects of high-dose L-thyroxine include cardiovascular (e.g. arrhythmia, heart failure, hypertension, myocardial infarction, palpitation, and tachycardia), central nervous system (e.g. anxiety, emotional lability, fatigue, fever, headache, hyperactivity, insomnia, irritability, and nervousness), gastrointestinal (e.g. abdominal cramps, appetite increased, diarrhoea, vomiting, and weight loss), neuromuscular (e.g. muscle weakness and tremor), and skeletal (e.g. decreased bone mineral density,) complications.

Neuroendocrine tumours

Low-grade neuroendocrine tumours may be treated with somatostatin analogues (e.g. octreotide or lanreotide) to improve symptoms such as flushing and diarrhoea and influence disease evolution (Grozinsky et al., 2008) and in patients with metastatic enteropancreatic neuroendocrine tumours progression-free survival (Caplin et al., 2014).

Cytotoxic agents

Cytotoxic agents interfere with cell cycle processes and have been used since the 1940s in the treatment of early and advanced cancer. Patient selection is of utmost importance since the therapeutic index between activity and toxicity is very narrow. Most of these treatments induce severe acute and sometimes late side effect that have to be taken into account when deciding on the use of chemotherapy.

In the curative setting, cytotoxic agents are mostly used in combination schedules and/or with other treatment modalities (e.g. surgery, radiotherapy). In high-risk patients with local or loco-regional disease their aim is to improve cure rates. Adjuvant chemotherapy with curative intent is given in patients with breast, colorectal, non-small cell lung, or testicular cancer while chemoradiation is used in locally advanced cervical, anal, and head and neck cancer. In patients with advanced metastatic cancer such as testicular cancer, germ cell tumours, non-Hodgkin and Hodgkin lymphoma, and certain haematological malignancies, chemotherapy can be given with curative intent (Box 12.2.1).

In most patients with advanced disease, the aim of chemotherapy is not cure but disease control to improve quality of life or sometimes overall survival. In several tumour types, chemotherapy is able to improve overall survival and quality in life when given as first-line treatment. In a number of tumour types, second- and even third-line chemotherapy is able to influence cancer evolution positively compared to best supportive care or standard treatment (Table 12.2.1).

Targeted agents

Due to a better insight into processes involved in carcinogenesis, a group of drugs targeting specific pathways has been developed and is used in the treatment of cancers. These drugs are able to induce tumour responses in previously treatment-unresponsive disease and have a disease-modifying potential in patients with specific dysregulations of a pathway. Although they are considered to be specific, they induce toxicities that, although different from those due to chemotherapy, are a burden for the patient or can be life-threatening.

One of the first agents in this group was imatinib and this drug changed the disease evolution of patients with gastrointestinal stromal tumours (GIST) and chronic myeloid leukaemia. There were few treatment options for these patients to induce long-term remission and the use of imatinib acting as a blocker of the

Table 12.2.1 Improved quality of life and/or survival with an anti-cancer therapy compared with best supportive care/placebo/standard treatment in randomized trials in patients with advanced solid cancers

Tumour type	First-line therapy	Second- and third-line therapy
Adrenal cortex	Mitotane[a]	
Bladder	Platinum-based + gemcitabine	Vinflunine[b]
Breast	(Hormones, sequential chemotherapy) Doxorubicin + docetaxel; taxane + trastuzumab[c]; aromatase inhibitor + trastuzumab; liposomal doxorubicin	Docetaxel[b], capecitabine + docetaxel; trastuzumab[c], T-DM1**, exemestane + everolimus
Carcinoid	Somatostatine analogue + interferon α	
Colorectal	Fluoropyrimidine-based[b], irinotecan-based + cetuximab, oxaliplatin-based + cetuximab, fluoropyrimidine-based + bevacizumab; oxaliplatin-based + panitumumab***, capecitabine	Irinotecan-based[b], cetuximab***; irinotecan-based + panitumumab***; panitumumab***[b], capecitabine-based, regorafenib
Gastric	5-fluorouracil-based; platinum-based + docetaxel; fluoropyrimidine-platinum + trastuzumab[c], capecitabine-based	
Gastro-intestinal stromal tumour	Imatinib[f]	Sunitinib[b], regorafenib[e]
Head and neck	Platinum-based + Cetuximab Platinum-based + docetaxel	
Kaposi sarcoma	Liposomal doxorubicin	Liposomal doxorubicin
Liver	Sorafinib[b]	
Melanoma	Interferon α, interferon α + bevacizumab, vemurafinib, dabrafenib + trametinib	Ipilumumab[b]
Mesothelioma	Platinum + pemetrexed	
Non-small cell lung	Platinum-based[b]; platinum-based + docetaxel; platinum-based + bevacizumab; platinum-based + pemetrexed gefitinib[d]; erlotinib[d]	Docetaxel[b]; pemetrexed, erlotinib[b]/gefitinib[b], crizotinib[g]
Ovary	Platinum-paclitaxel-based, platinum-paclitaxel-based + bevacizumab	Topotecan; liposomal doxorubicin
Pancreas	Gemcitabine[b]; gemcitabine + erlotinib	
Pancreatic neuroendocrine tumours	Somatostatin analogues + sunitinib[b]; everolimus[b]	
Prostate*	Docetaxel + prednisone*, abiraterone acetate	Abiraterone acetate[b], cabazitaxel, enzalutamide, radium-223
Renal cell	Interferon α, interleukin, sunitinib, pazopanib[b]; temsirolimus	Sorafinib[b], everolimus[b]; pazopanib[b]
Small cell lung	Platinum-based	Topotecan[b]
Thyroid—medullary	Vandetanib[b]	

[a] phase II study; [b] placebo-controlled or best supportive care only; [c] HER-2 overexpressing tumours; [d] activating epidermal growth factor receptor tyrosine kinase mutations; [e] Ras wild type; [f] castration-resistant prostate cancer.; [g] alk mutation.

mutated protein BCR-ABL was able to turn these difficult-to-treat and fatal diseases into chronic conditions.

Bosutinib is also a drug that interferes with this system.

Other agents targeting *independency of growth signals* have been used to treat several tumour types. The epidermal growth factor receptor (EGFR) can be influenced by monoclonal antibodies (e.g. cetuximab and panitumumab) or tyrosine kinase inhibitors (e.g. gefitinib, erlotinib, and afatinib) in patients with advanced disease. They are currently used in the treatment of metastatic cancers such as non-small cell lung cancer, head and

neck cancer, and colorectal cancer. Some of these medications are used in combination with cytotoxic agents and patient selection should not only be based on specific mutations but also according to the patient's frailty. Common side effects are skin toxicity and diarrhoea.

Another target influencing tumour growth is HER-2. Trastuzumab, a monoclonal antibody against HER-2 is used in combination with chemotherapy to treat advanced breast and gastric cancer while the dual tyrosine kinase inhibitor lapatinib is used as single agent in metastatic breast cancer. Cardiotoxicity

is of major concern and combination with cardiotoxic chemotherapy is contraindicated.

In malignant melanoma, 50% of patients have an activating mutation in the serine/threonine-protein kinase *B-raf* gene (BRAF) and inhibition of mutated B-raf protein by vemurafenib or dabrafenib leads to an overall survival benefit in this group of patients. Trametinib is a MEK protein kinase inhibitor that is registered for the treatment of patients with unresectable or metastatic melanoma with a BRAF V600 mutation.

Angiogenesis is another important target. Several medications against parts of the process of angiogenesis are used. They comprise interference with hypoxia-inducible factor, a transcription factor, by influencing the mTOR pathway (e.g. everolimus, temsirolimus); the vascular endothelial growth factor (VEGF) that induces angiogenesis (e.g. bevacizumab and aflibercept); and the VEGF receptor (e.g. sorafinib, sunitinib, pazopanib, and axitinib). This group of drugs is active against renal cell carcinoma, (neuro) endocrine tumours, colorectal, breast, and ovarian cancer with improvement of progression-free and overall survival. The main side effects are hypertension, thrombotic events, proteinuria, and bleeding.

Other pathways have been discovered (e.g. evading growth suppressors, resisting cell death or apoptosis, enabling replicative immortality, activating invasion, and metastasis) and many drugs are being explored to influence these pathways and improve patient outcome.

Immune system modulatory drugs

The immune system is an important factor in the control of cancer and medication interfering with this system has shown activity in patients with advanced cancer.

High-dose interleukin-2 is used in selected patients with malignant melanoma and renal cell carcinoma. The activity is difficult to predict but some patients reach a durable response. However, toxicity is impressive (e.g. 71% grade 3–4 hypotension; 52% chills, 34% confusion, 42% rash, 67% diarrhoea, and 43% dyspnoea with 24% pulmonary congestion).

Interferon is used in patients with advanced hairy cell leukaemia, lymphoma (follicular), malignant melanoma, and AIDS-related Kaposi's sarcoma. Again, systemic toxicities can be serious.

In patients with malignant melanoma, immune modulation by ipilimumab, a monoclonal antibody against the immune modulatory antigen CTLC-4, can induce durable responses with manageable skin and liver toxicity. Several drugs interfering with the programmed death receptor system on immune modulatory T cells are being tested and expected to be active in patients with solid tumours.

Oncological literacy

Palliative care clinicians do not need to be cancer experts. However, high-level integration between oncological care and palliative care requires familiarity with contemporary approaches to disease modification that can improve patient well-being. Palliative care clinicians ought to be familiar with web-based resources to access contemporary updates of standard oncological treatments for the diseases that they are encountering, especially when involved with upstream or early intervention palliative care programmes. Excellent web-based guidelines are available from the National Comprehensive Cancer Network (NCCN; <http://www.nccn.com>), the US National Cancer Institute (NCI; <http://www.cancer.gov/cancertopics/pdq>), the European Society for Medical Oncology (ESMO Guidelines) (<http://www.esmo.org/Guidelines-Practice/Clinical-Practice-Guidelines>) and eviQ Cancer Treatments Online (<http://www.eviq.org.au>).

Conclusion

In oncology, many new treatments have been introduced that have changed the dismal and short prognosis in patients with advanced disease. While some patients with advanced disease can be cured, the use of these treatments in patients with advanced non-curable disease is often beneficial. However, patient selection is of utmost importance and treatment decisions should be taken in a multidisciplinary team. It is important that these patients are evaluated by an oncologist to give them the best information on their disease and the possible interventions, so that patient and caregivers can make an informed decision about further treatment and care.

12.3

Radiotherapy in symptom management

Peter J. Hoskin

Introduction to radiotherapy in symptom management

The majority of cancer patients, particularly those with common tumours such as lung, breast, and prostate, require radiation therapy one or more times during the course of their disease. More than 40% of radiation treatments are given with palliative intent for control of local symptoms (Willams and Drinkwater, 2009).

General principles of radiotherapy

Radiobiology

Radiotherapy uses ionizing radiation to damage DNA. The most frequently used forms of ionizing radiation are X-rays produced from an X-ray machine or linear accelerator and gamma rays produced from a radioactive source. Biologically, these have identical effects. Particle radiation also is sometimes used, particularly electrons for superficial treatments and beta particles from systemic radioisotopes. Proton therapy is not indicated in palliative treatments.

Radiation causes both direct and indirect damage to DNA. Direct damage includes base deletions and breaks in the DNA chain, and indirect damage results from toxic free radicals produced from the interaction between radiation and water molecules in the cell. Indirect damage is the more important cause of cell death, which may occur from either reproductive failure or apoptosis following derangement of cell regulatory mechanisms. When very high single doses (> 10 Gy) of radiation are delivered, damage to endothelial cells occurs and the resulting interruption in blood flow may be another mechanism for cellular injury.

In clinical practice, radiation is delivered to maximize tumour cell kill whilst minimizing normal tissue damage by exploiting differences between normal and malignant cells. Cancer cells are less able than normal cells to repair 'sublethal' radiation damage, and differences in repair capacity account, in part, for variation in radiosensitivity. Factors that influence response other than repair capacity include oxygenation (hypoxic cells are relatively radioresistant), the number of cells actively dividing (cells in certain phases of the cell cycle are more sensitive than others; non-cycling cells are relatively radioresistant), and the rate of repopulation within the tumour. These parameters of repair, re-oxygenation, repopulation, and redistribution within the cell cycle, are the fundamental influences on the cellular response to radiation.

Palliative versus radical radiotherapy

The aim of radical radiotherapy is complete eradication of tumour cells within the treated volume, which must encompass the entire extent of the tumour. This must be done in a manner that also minimizes long-term normal tissue damage. In contrast, the aim of palliative radiotherapy is the control of symptoms with minimum associated acute radiation reaction.

These two very different aims result in different philosophies in the delivery of radiation. To minimize normal tissue damage during radical radiotherapy, the radiation dose is built up by delivering treatment on a daily basis over several weeks. In this way, high doses of radiation close to, or beyond, those tolerated by surrounding normal tissues can be given. Conventional treatment schedules deliver a single dose of radiation, often called a fraction, on a daily basis, Monday to Friday. This treatment may be accelerated, that is, given two or three times a day over a relatively shorter period, to produce greater tumour damage by reducing the opportunity for tumour repopulation. Treatment acceleration is limited by the increase in the acute reaction of normal tissue. *Hyperfractionation*, which delivers the total dose in an increased number of fractions over the same period dividing the usual daily dose into two or three smaller doses, may be employed to deliver higher doses with greater sparing of normal tissues.

Although fractionated and hyperfractionated radiotherapy requires 6–8 weeks and is arduous for the patient, it is justified when cure is the aim. For patients with limited life expectancy, however, more pragmatic schedules are appropriate. Sixty to 80% of tumour cells are killed by the first one or two radiation doses, and when the intent of treatment is palliative, this initial effect may be more than adequate for long-term symptom control. Indeed, in some scenarios, for example, metastatic bone pain, symptom response is independent of tumour shrinkage. Most palliative radiotherapy can be delivered in one or two treatments and rarely is it necessary to extend a course of treatment beyond 1–2 weeks. The delivery of short, relatively low-dose schedules results in less acute reaction and a minimal risk of late damage to normal tissues within the expected life span of the patient.

Radiotherapy in clinical practice

The most common type of radiotherapy is external beam irradiation (Table 12.3.1). In a modern radiotherapy department, most treatments are performed by a linear accelerator (Fig. 12.3.1) and comprise high-energy X-rays or an electron beam for superficial

Table 12.3.1 Types of external beam radiotherapy

	Energy	Source	Depth of penetration	Clinical use
Superficial X-rays	50–150 kV	X-ray tube	5–10 mm	Surface skin tumours
Orthovoltage X-rays	250–500 kV	X-ray tube	15–30 mm	Surface tumours
				Superficial bones, e.g. ribs, sacrum
Electrons	4–20 MeV	linear accelerator	15–70 mm	Surface tumours
				Superficial bones, e.g. ribs, sacrum
				Lymph nodes
Megavoltage X-rays	4–25 MV	linear accelerator	3–20 cm	Main source of radiation beams for sites other than above
Gamma rays	2.5 MV	cobalt source	5–10 cm	All sites except superficial skin

Clinac® Accelerators: Clinac 23EX with MLC-120 and PortalVision™

lesions. Alternative means to deliver radiation—brachytherapy and systemic radioisotopes—are used in specific circumstances. In brachytherapy, the radioactive source is placed directly onto or within the area to be treated (Table 12.3.2). Systemic radioisotopes target a specific tissue or pathophysiology, for example, radioiodine for thyroid cancer and strontium for bone metastases.

To direct radiation as accurately as possible to the tumour whilst minimizing exposure to normal tissue requires a systematic process that defines the treatment volume and optimal technique. This is called 'planning' and includes the following steps:

◆ Immobilization: it is necessary to immobilize the patient when small movements could result in the irradiation of critical structures, for example, the eye. Although a simple technique, such as sandbags, may suffice, more complex treatments may require a plastic shell with an individualized face mask.

Table 12.3.2 Isotope use in brachytherapy

Intracavitary	Iridium	Intrauterine
	Cobalt	Intravaginal
		Endo-oesophageal
		Endobronchial
		Endorectal
Interstitial	Iridium	Tongue, floor of mouth
	Cobalt	Buccal mucosa
		Breast
		Anal canal
		Vulva/vagina
Surface (Mould)	Iridium	Skin
	Cobalt	Penis

◆ Treatment volume localization: superficial lesions can be easily defined on examination but deep-seated tumours require radiographic localization. Although computed tomography (CT) scanning, which enables accurate three-dimensional reproduction of the anatomical region of interest, is now used for most planning situations, plain radiography with a treatment simulator is sufficient in many common palliative scenarios, such as bone metastases or a primary lung tumour. The simulator is an X-ray machine identical to the therapy machine in its geometric specifications and movement, which emits a diagnostic X-ray beam and produces an image of the proposed therapeutic beam.

◆ Dosimetric planning: once the volume has been defined, the means of treatment delivery is determined. For simple treatments, such as those for bone metastases, a single beam or two opposing beams to treat a block of tissue will be all that is required. For internal volumes, more complex, three- or four-field arrangements may be optimal. Even more complex planning, which may employ intensity-modulated radiotherapy (IMRT) or stereotactic techniques, is required in some situations, such as treatment close to the spinal cord, retreatments close to critical organs, and treatment of oligometastases (fewer than three metastases) when higher doses may be considered.

◆ Verification: the defined beam arrangement must be checked on the patient before treatment delivery. Beam position may be checked by imaging on the treatment machine using the megavoltage treatment beam, or on modern linear accelerators, using integrated kilovoltage CT imaging. With simple superficial fields, clinical measurement and observation are adequate. Accurate documentation of the beam position with indelible marking of defined skin entry points on the patient will facilitate this and ensure accurate day-to-day reproducibility when more than one fraction is to be given

A linear accelerator produces high-energy radiation at a rate of around 1 Gy per minute. This means that most treatments, even those using large single fractions in the palliative setting, last for only a few minutes. There are no accompanying symptoms provided the patient is comfortable at the outset. Many patients require help in achieving the required position and lying still during treatment. Unfortunately, many patients experience discomfort related to immobilization, the use of hard wooden flat couch, and the need for staff to leave the patient isolated whilst radiation delivery is taking place. The judicious administration of an analgesic or anxiolytic drug prior to treatment always should be considered.

Side effects of radiotherapy

The side effects of radiotherapy are categorized into two groups based on their timing relative to the radiation exposure. Acute effects occur during treatment and may persist for several weeks. Late effects are rarely seen before 9 months after treatment and the risk of a late complication continues indefinitely. The common clinical manifestations of acute and late radiation toxicity are shown in Table 12.3.3.

Acute toxicity is due to loss of epithelial cells. This results in skin erythema or desquamation, and depending on the site of treatment, oropharyngeal mucositis, oesophagitis, cystitis, or gastrointestinal irritation. Repair of the denuded surface with new epithelial cells occurs once treatment is completed, provided that the underlying stem cell population has not been damaged irreparably. Recovery usually occurs within a period of a few days or weeks. On rare occasions, however, there may be persistent damage, which is termed 'consequential damage'. This most often occurs in vulnerable sites, such as the back or the lower leg, where skin healing appears less efficient. Poor healing after radiotherapy may also be seen where there is secondary infection or trauma, and it is these events that predispose to the rare occurrence of radionecrosis.

Late effects cause of treatment-related loss of function and even mortality in patients receiving radical radiotherapy. For every tissue a 'tolerance dose' is defined, up to which late damage is not expected in the 'normal' population. One of the reasons for the complex planning systems which have evolved for radiation delivery is the strenuous effort required to avoid exceeding these doses whilst delivering effective doses to nearby tumour. Unfortunately there are genetically predisposed individuals to radiation damage where even a conventional tolerance dose may result in late damage.

Late radiation injury is due to vascular damage, specifically progressive endarteritis obliterans. This results in closure of small blood vessels and potential tissue ischaemia. Although the clinical

Table 12.3.3 Acute and late effects of radiation

Site	Acute effect	Late effect[a]
Skin	Erythema	Atrophy, fibrosis
	Desquamation	Telangiectasia
		Necrosis
Gastrointestinal tract	Nausea, anorexia	Stricture
	Vomiting	Telangiectasia, bleeding
	Diarrhoea	Perforation
		Malabsorption
		Chronic enteritis, colitis, proctitis
Bladder	Sterile cystitis	Reduced volume
		Telangiectasia, bleeding
		Urethral or ureteric stricture
		Fistula
Oral cavity Pharynx	Mucositis	Mucosal atrophy
	Dry mouth	Telangiectasia, bleeding
	Taste loss	Dental caries
		mandibular necrosis
Lung	Pneumonitis	Fibrosis
Central nervous system	Transient demyelination (Lhermitte's sign)	Myelitis
		Necrosis
		Local oedema
Eye	Keratitis	Cataract
		Entropion or ectropion
		Dry eye

[a] In most patients only minor late effects are seen. These are minimized by reducing the dose of radiation delivered to sensitive structures with the treated region to known safe 'tolerance' doses. Late effects are not expected after palliative radiotherapy.

manifestations may be relatively minor, such as the commonly observed appearance of skin or mucosal atrophy or telangiectasia, more serious consequences may occur. In the pelvis, the bowel or bladder may be damaged, resulting in fibrosis and bowel perforation or fistula formation between the bladder, bowel, or vagina. In the central nervous system, there is very limited ability to repair damage and catastrophic necrosis may occur if dose limits are exceeded.

Management of radiation side effects

Acute side effects are common and management is focused on relief of symptoms whilst allowing the affected area to heal. Mild skin reactions require no active treatment. Local applications are generally best avoided. Desquamation will rarely if ever be seen after palliative doses. The use of topical preparations such as gentian violet is to be discouraged, and talcum powder and proprietary creams containing metallic salts should be avoided at all costs during treatment as these can enhance the reaction. Starch powder, as found in proprietary baby powders, may be helpful in keeping the surrounding skin dry and comfortable.

Nausea during irradiation to the abdomen or pelvis usually responds to antiemetic therapy such as metoclopramide 10 mg 6–8-hourly, ondansetron 8 mg twice daily, or granisetron 2 mg daily. If antiemetics are ineffective, a small dose of a corticosteroid such as prednisolone 10–30 mg daily may be valuable. Prophylactic therapy may be helpful. For example, single radiation doses given to the lumbar spine or pelvis produce an exit dose of radiation to the abdomen, and a prophylactic regimen of dexamethasone 8 mg and ondansetron 8 mg or granisetron 2 mg given 30 minutes before treatment is effective in avoiding severe symptoms.

Radiation-induced acute diarrhoea may respond to a low residue diet, avoiding fruit and other fibre-containing foods. When required, loperamide or codeine phosphate on a regular basis three to four times daily is helpful.

Radiation cystitis is more difficult to ameliorate. The use of an alpha blocker such as tamsulosin may be helpful when there is severe bladder spasm. Potassium citrate or cranberry juice are both time-honoured remedies, which may be of supportive value but have no evidence for efficacy. When there is significant dysuria or strangury, systemic analgesics are also of value. Secondary infection should always be excluded.

Oropharyngeal mucositis occurs when treating the head and neck region. It is important to maintain a high level of oral hygiene, using regular chlorhexidine mouthwashes and prophylactic anti-candidal preparations with nystatin suspension or clotrimazole gel. Local relief of pain may be achieved using soluble aspirin or benzydamine mouthwashes. If symptoms are severe and nutritional intake is compromised, enteral feeding via a nasogastric fine bore tube or more commonly a percutaneous gastrostomy, may be required. Radical high-dose treatment to the oral cavity, particularly if the salivary glands are included in the treatment volume, can result in troublesome mouth dryness and loss of taste, and predispose to dental caries and osteoradionecrosis of the jaw. Pre-treatment dental assessment and meticulous hygiene using fluoride dental gel during and after treatment is important in these patients. These measures are not required for simple low-dose palliative treatments, such as radiation to a metastasis in the mandible. Oropharyngeal effects are worse in those patients who smoke or imbibe alcohol, and if possible, these should be avoided during treatment.

Pneumonitis may occur, even after palliative treatment to the lungs. Patients develop dry cough and dyspnoea up to four months after treatment and have a radiograph showing patchy shadowing conforming to the geometry of the radiation field (Fig. 12.3.2). A 2–3-week course of systemic steroids and antibiotics for secondary infection is recommended. Symptoms may continue and late radiation fibrosis may occur.

It is always important to anticipate likely acute side effects, explain them to the patient, and encourage the prophylactic use of antiemetics, antidiarrhoeal drugs, and mouthwashes. The patient should also be reassured that these are temporary events which will resolve following completion of radiotherapy.

Combined modality treatment

Combined modality treatment refers to the administration of chemotherapy during a course of radical radiotherapy to enhance the effects. Substantial Level I evidence supports this practice for cancers of the oesophagus (Herskovic et al., 1992), anal canal

Fig. 12.3.2 Interstitial pneumonitis in the right and lower zones on chest radiograph after palliative radiotherapy for carcinoma of the bronchus.

(Ryan et al., 2000), uterine cervix (Thomas, 1999), lung (Komakil et al., 2000) and head and neck (Munro, 1995). Other treatment strategies involve the administration of chemotherapy before (neo-adjuvant) or more commonly after (adjuvant) radiotherapy to control micro-metastases whilst the radiotherapy obtains local control of the more bulky primary site. These approaches are used in the management of breast cancer, bladder cancer, small cell lung cancer, colorectal cancer, and lymphoma.

Radiotherapy and symptom control

Radiotherapy is effective for many cancer-related symptoms, particularly those due to pressure or infiltration by a tumour (Table 12.3.4).

Bone pain

Radiotherapy may be indicated for bone metastases because of bone pain, pathological fracture, or pressure on nerves. It is a highly effective treatment for local pain and achieves durable pain control for the majority of patients. Those with advanced illness can benefit from simple, short treatment schedules, and if pain recurs in those who survive longer, retreatment can be used.

There is extensive evidence supporting the efficacy of radiation for bone pain. Although a fractionated course of treatment delivering 20–30 Gy over 1–2 weeks is preferred by some centres, especially where there is concern over possible fracture or nerve compression, meta-analyses that include more than 3000 patients conclude that single-fraction treatments delivering 8 Gy generally yield comparable results (Fig. 12.3.3) (McQuay et al., 1997; Sze et al., 2003; Wu et al., 2003; Chow et al, 2012). One large randomized trial revealed a response rate of around 80% and pain control maintained out to 12 months (Bone Pain Trial Working Party, 1999) (Fig. 12.3.4). Pain improves progressively for weeks after treatment; about half of patients achieve pain relief within the first 2–4 weeks and others experience adequate relief after 6–8 weeks (Fig. 12.3.4).

Meta-analyses indicate that a higher proportion of patients require retreatment after single-dose treatments than after fractionated treatments. In most trials, about 25% of patients who receive single doses undergo retreatment. This is not a justification for more prolonged treatments, however. The Dutch bone pain trial (van der Linden et al., 2004) confirmed that single-dose

Vaginal bleeding	Primary tumours of vagina, cervix or uterus
	Metastases in vagina
Rectal bleeding	Primary anal or colorectal tumours

radiotherapy is equivalent to multifraction treatment for localized bone pain, even with the requirement for retreatment. The probability of response after re-treatment is around 80%, similar to that after primary treatment, and the effect is not always predicted by the initial response (Huisman et al., 2012). For this reason, re-irradiation should be considered when pain returns after a previous good response and when the initial response is unsatisfactory. The best dose for retreatment is uncertain and is the subject of a recently completed randomized trial comparing single-dose retreatment with multifraction retreatment (Chow et al., 2006).

The treatment techniques for bone metastasis are usually simple. Superficial bones such as the clavicle, ribs, and sacrum

may be treated with a direct field using orthovoltage X-rays or electrons and other sites are treated using a linear accelerator or cobalt beam. Under optimal conditions, the site is localized using a treatment simulator based on clinical examination and radiographic or bone scan evidence of metastatic disease. Increasingly, CT simulation is used to more accurately define the field (Haddad et al., 2004). It is particularly important to document carefully the field margin, since most patients will have multiple sites of metastasis and overlap of fields should be avoided at the time of later treatment. This is especially important in the treatment of spinal metastases. If sequential treatments are required, overlapping fields increase the risk of overdosage to the spinal cord, which may culminate in radiation myelitis and irreversible neurological deterioration developing within 6–9 months from treatment. This is not a concern if patients have a short prognosis, in which case a decision to accept an overlap may be made, with the full knowledge of the patient, if it is perceived that benefit from treatment in the short term outweighs any theoretical hazard of later myelitis.

Patients with multiple sites of disease and pain that is diffuse or multifocal may be considered for wide field radiotherapy or radioisotope therapy. Wide field radiotherapy delivers treatment to an area that may include up to half the body, using doses of 6 Gy to the upper half-body, where the lungs limit higher doses, or 8 Gy to the lower half-body. The response rate is around 80% and pain relief is maintained until death in the majority of patients (Salazar et al., 1986, 2001). There is no advantage to higher doses, although one randomized trial recommended 8 Gy in 2 fractions as the optimum dose (Salazar et al., 2001).

Inevitably, wide field treatment is associated with greater toxicity than local field irradiation. About two-thirds of patients have nausea, vomiting, or diarrhoea, and the majority of patients have a period of bone marrow suppression, which may require blood transfusions but rarely causes clinically relevant neutropenia or thrombocytopenia. Spontaneous recovery is expected, and indeed, sequential treatment of upper and lower half-bodies is possible given a 4–6-week gap for marrow recovery. The most serious consequence of upper hemibody irradiation is the development of radiation pneumonitis, which may be avoided by limiting the dose to 6 Gy through the lungs.

Radioactive isotopes that selectively concentrate at sites of bone metastasis also may be used for diffuse or multifocal bone pain. The ideal isotope delivers radiation by releasing beta particles with a short range of only a few millimetres, thereby concentrating the dose within the immediate area of uptake (Table 12.3.5). Low-energy gamma release is also desirable as this enables imaging of the isotope distribution with a gamma camera. Single injections of strontium (Hoskin, 1994) or samarium (Sartor et al., 2004) are used most often, and samarium, which has no gamma release, requires no restrictions on the patient other than careful disposal of urine. Both these compounds are highly effective, with response rates similar to wide field external beam irradiation and fewer side effects (Hoskin, 1994). Their efficacy has been demonstrated predominantly in prostate cancer, but bone metastases from other primary sites, in particular breast and lung, are also effectively treated. Even metastases from osteosarcoma, which retains an osteblastic response, may concentrate these isotopes and be effectively treated. The treatments are costly, however, and they are relatively underused, particularly in less wealthy health

ecomonies, despite their established efficacy, convenience, and favourable toxicity profile.

Radioisotope treatment can cause transient bone marrow depression, but this is rarely of clinical significance provided patients have a normal blood count at the start of therapy. These compounds are cleared by renal excretion and patients must be continent of urine to prevent contamination, or be prepared to have an indwelling catheter for the duration of radioactive excretion. Renal impairment is a relative contraindication because reduced clearance can prolong radiation exposure and potentially exacerbate bone marrow toxicity.

In contrast to patients with multiple metastases, those with only one or two (oligometastases) are potential candidates for local therapy using a high enough dose to achieve both pain relief and local tumour control. This may be accomplished using stereotactic body radiotherapy, which enables localization of very high-dose radiation in a small area. An example of such a treatment to a solitary metastasis in the pubis is shown in Fig. 12.3.5. The evidence base for such treatments is evolving; good pain relief with local control rates of 60–70% at 1 year have been reported (Lo et al., 2010).

The mechanism by which radiation achieves pain control is not clear. Tumour shrinkage may not be necessary. Although a considerable proportion of malignant cells within a tumour mass are undoubtedly killed after small single doses of radiation, rapid tumour shrinkage is not routinely observed. Pain relief may be seen within 24 hours, particularly after hemibody irradiation and there is no relationship between pain relief and histological types of tumour correlating with variations in radiosensitivity. There also has been no clear dose response effect above 8 Gy. Osteoclast activation may be another important factor, as suggested by the efficacy of bisphosphonate drugs. Following radiotherapy, changes

in biochemical markers of osteoclast activity occur and these may predict response (Hoskin et al., 2000).

The increased understanding of the pathophysiology of metastatic bone pain has led to further developments in treatment. Current research is seeking to evaluate the role of pregabalin with radiotherapy and new agents such as denosumab directed at RANKL (ligand for the receptor activator of nuclear factor kappa B), a pivotal molecule in osteoclast activation are also under evaluation.

Although there is some evidence that radiotherapy can prevent the later development of pain metastases or pain, there is no routine role for prophylactic treatment. Inadvertent treatment of the thoracic spine when a breast is irradiated has been shown to reduce the instance of subsequent bone metastases. Hemibody irradiation and strontium therapy both modestly reduce subsequent episodes of bone pain (Poulter et al., 1992; Porter et al., 1993). There is stronger evidence in favour of bisphosphonate treatment, which is now routinely given for myeloma and high-risk patients with breast cancer (Diel et al., 1998; McCloskey et al., 1998).

The relative roles of radiotherapy and bisphosphonates, and the interaction between them, in the overall management of bone metastases have yet to be adequately defined and are currently an active area of research (Hoskin, 2003). Early results from a recent randomized trial suggest that radiotherapy and ibandronate are equivalent in achieving pain control with some suggestion of a synergistic effect (Hoskin et al., 2011)

Pathological fracture

When surgery is not possible or indicated for pathological fracture, local irradiation remains a valuable tool to achieve local pain relief and enable bone healing. Although there are no data to define the optimal dose, single dose of 8 Gy is adequate when the object of treatment is pain relief alone; about two-thirds of patients achieve pain relief. In practice most patients will receive courses delivering 20–30 Gy in 5–10 fractions over 1–2 weeks. Remineralization is reported in one-third of patients after doses of 40–50 Gy delivered in 4–5 weeks, but anecdotally, also occurs after lower doses of only 20 Gy in 2 weeks.

Radiotherapy may also be indicated postoperatively following internal fixation to prevent further progression of the remaining metastatic tumour and enable healing of the bone around the prosthesis. Although there are few data to support this common practice, a non-randomized study suggests better functional recovery when radiotherapy is given (Townsend et al., 1995). Conventionally, fields covering the entire length of the prosthesis or intramedullary nail are used because of the perceived risk of tumour dissemination through the marrow cavity by the operative procedure. Patients with widespread metastatic disease, limited survival, and adequate pain control gain little benefit from postoperative radiotherapy.

Neurological symptoms and disorders

Spinal cord and cauda equina compression

Spinal cord or cauda equina compression may cause catastrophic loss of limb function and sphincter control (see Chapters 14.1 and 12.5). As tumour compresses neurological tissue in the spinal canal, there is early venous engorgement and oedema followed by mechanical compression that ultimately leads to irreversible damage. About one-quarter of cases occur due to direct encroachment

of the spinal canal by tumour in a vertebral body and the rest are attributable to blood borne extradural or intradural metastases (Fig. 12.3.6) (Pigott et al., 1994). Approximately 70% of cases involve thoracic cord, 20% the lumbosacral region, and 10% the cervical cord.

Early diagnosis and treatment is the major determinant of outcome. Spinal cord or cauda equina compression should be suspected in any patient with sensory or motor findings in the limbs or urinary symptoms, in particular where there is backache or known vertebral metastasis. Prompt visualization of the spinal

Fig. 12.3.6 Magnetic resonance imaging of spinal cord compression demonstrating (A) both extradural and vertebral collapse with adjacent compression and (B) direct infiltration of the canal from bone metastases in the spine.

canal using magnetic resonance imaging is the optimal management, even if recent investigations have shown no evidence of metastatic disease. If magnetic resonance imaging (MRI) is unavailable or contraindicated because of metal implants or a pacemaker, CT imaging should be used. If MRI is negative and the clinical findings are suggestive, a lumbar puncture is needed to exclude meningeal carcinomatosis.

The commonest causes of spinal cord compression are tumours of the breast, lung, or prostate, each of which accounts for about 20% of patients in most series. Most other primary sites have also been associated with spinal canal involvement, with the next two commonest being kidney and lymphoma. If a patient with metastatic disease presents with spinal cord compression, it is usually reasonable to assume that this will be the same disease process unless there are atypical features to suggest a second primary. Patients with spinal cord or cauda equina compression and no history of metastatic disease require a histological diagnosis before treatment. In one series, 48% of patients with spinal cord compression had no previous history of malignant disease (Shaw et al., 1980). In most cases, a CT-guided fine-needle aspirate cytology specimen or needle biopsy will be sufficient (Findlay, 1988).

The initial management of spinal cord or cauda equina compression includes administration of a corticosteroid and local irradiation to the spinal site. The corticosteroid doses used in practice vary greatly but are generally relatively high, for example, dexamethasone 4 mg every 6 hours or higher.

Both radiotherapy and decompressive surgery are effective in the initial management of spinal cord compression. Primary treatment of some tumours, such as lymphoma and small cell lung cancer, includes chemotherapy. One randomized trial that compared radiotherapy with decompressive surgery via an anterior approach followed by radiotherapy showed significant advantage for the group receiving surgery, both for functional status and survival. The population in this trial was selected for those with good performance status, absent metastases elsewhere and a single level of spinal cord compression; patients with these characteristics should be referred for surgery followed by radiotherapy, if possible. Whilst no randomized comparison of the two modalities of treatment with sufficient numbers to provide a true comparison has been undertaken, no advantage of surgery over radiotherapy has been demonstrated in published series where patients have a previously confirmed diagnosis of malignant disease and no evidence of vertebral collapse. The role of postoperative radiotherapy has not been tested but a non-randomized comparison has suggested that better pain relief is seen after radiotherapy or where radiotherapy is given postoperatively (Findlay, 1984).

In patients who have extensive vertebral collapse with intrusion to the spinal canal, radiotherapy is of little value in re-establishing neurological function, and surgery using an anterior approach and spinal stabilization also must be considered. This procedure is far more invasive than radiotherapy and has significant operative morbidity and even mortality, but results in selected patients are superior to either laminectomy or radiotherapy alone, with 62–83% of patients being able to walk and 71% achieving pain relief (Siegal and Siegal, 1985; Moore and Uttley, 1989). Many of these patients, however, are in poor general condition, as shown by a 30% mortality in one series of 26 consecutive patients operated on for pain or neurological deficits. Careful selection of patients for surgical referral is required (Patchell et al., 2005).
When primary radiotherapy is the treatment of choice, the technique in most cases is simple, using a single posterior field to encompass the vertebral level and a suitable margin. With accurate localization using MRI, one vertebral body or 3 cm above and below the area of cord compression is adequate. Problems may arise where there are multiple sites of compression, particularly if anatomically distant. In some patients, more than one radiation field may be required to cover the sites. When there is a large paravertebral mass, more complex planning may be necessary to ensure complete coverage. Two or three angled fields to cover the tumour volume, taking care to avoid sensitive paravertebral structures such as the kidneys, may be needed.

Most patients with good performance status will receive fractionated courses of treatment, delivering 20–30 Gy in 5–10 fractions. Most patients who have lost ambulation for more than 24 hours will not regain it, and in these cases, a single dose of 8–10 Gy often is given for pain relief, without any expectation of neurological recovery. In other selected cases, particularly those with a localized, potentially curable tumour, such as a solitary plasmacytoma, higher doses of up to 40 or 50 Gy over 3–5 weeks may be delivered.

The outcome of radiotherapy depends primarily upon the speed of diagnosis and neurological status at initiation of treatment. When patients begin treatment while ambulatory, more than three-quarters retain the ability to walk; of those who are paraparetic, only 42% become ambulant and 20–25% deteriorate during treatment. More than three-quarters have pain relief, compared with only one-third following laminectomy. Histology may influence outcome, patients with myeloma and lymphoma having a better outcome than those with breast cancer, who in turn respond better than those with lung or kidney tumours. There is some evidence that these patients may benefit from higher-dose radiotherapy (Rades et al., 2011).

Since the outcome of treatment is best when diagnosis is made very early there would be considerable advantages in predicting those patients at risk of spinal cord compression and treating them prophylactically. MRI can detect vertebral metastasis at very early stages when minor encroachment into the spinal canal is clinically asymptomatic and not detectable on plain radiographs. Other predictors for spinal canal compression reported in small cell lung cancer are local back pain associated with positive bone scan in the spine or cerebral metastasis with a positive bone scan; these situations are associated with cord compression in 36% and 25%, respectively (Goldman et al., 1989). Early use of radiotherapy would be likely to have a positive effect on outcomes, and in some centres, there is an aggressive policy of prophylactic irradiation for spinal metastasis on this basis. There is some evidence from the use of bisphosphonates that prophylactic treatment of subclinical bone metastasis can reduce spinal complications and similar observations have been made using early antiandrogen treatment in prostate cancer.

Brain metastasis

Up to 10% of all cancers metastasize to the brain, the most common primary sites being the lung and breast; approximately one-third of these will be solitary deposits (see Chapter 14.1). Disability from brain metastasis is disproportionate to the bulk of the tumour. A very small deposit on the motor cortex can be catastrophic for the patient, whilst a deposit of similar size would have little effect in the lung or liver. Because the spread of malignant cells to the brain is via blood, isolated brain metastases are relatively unusual; the typical patient has widespread metastatic disease. Careful patient assessment and selection of those who may benefit from active treatment is therefore essential, recognizing that for a proportion this will herald the terminal phase of an advanced malignancy for which local treatment will have little benefit.

After confirmation of the diagnosis by CT or MRI, steroids are used to help control raised intracranial pressure and reduce symptoms due to oedema rather than tumour infiltration. There is evidence that high-dose steroids in this setting contribute significantly to morbidity and total doses of 4–8mg dexamethasone daily may be adequate. If the patient does not have known metastatic disease, a histological diagnosis is needed; whilst it is preferable to biopsy a site other than the brain, an intracranial needle biopsy will be needed if a solitary brain lesion is the first manifestation of malignancy.

Further management depends upon the general condition of the patient, underlying primary site, and the distribution of the brain metastases (Fig. 12.3.7). Solitary metastases usually reflect a more favourable prognosis, and in selected patients with no detectable systemic disease, surgical removal gives good local and long-term control. Postoperative radiotherapy is usually recommended on the basis of two randomized trials, which showed a significant reduction in brain recurrence (but no impact on survival because of a high incidence of death from progressive systemic disease); a third larger trial has failed to confirm this advantage for postoperative radiotherapy (Tsao et al., 2012).

Localized high-dose radiotherapy using radiosurgery is an alternative to surgical excision. There has been no formal comparison between the two, but where surgery is limited by the site of metastasis and proximity to critical structures, it may be considered an alternative. Radiosurgery uses either a dedicated multisource cobalt unit (gamma knife) or a stereotactic high-energy X-ray unit to deliver single doses of 15–20 Gy. The role of whole-brain radiotherapy after radiosurgery, analogous to the use of postoperative radiotherapy, remains uncertain, but is recommended in some centres. Recent studies suggest that post-radiosurgery treatment may reduce the likelihood of relapse outside the initial site of treatment, it imparts no survival benefit and may result in impaired neurocognitive functioning (Linskey et al., 2010). Unfortunately, the 1-year survival of patients with solitary brain metastases is 30–50%, despite effective local control with surgery or radiosurgery. Most patients succumb to the effects of distant metastasis and careful selection and screening is required before embarking upon aggressive local therapy of this type.

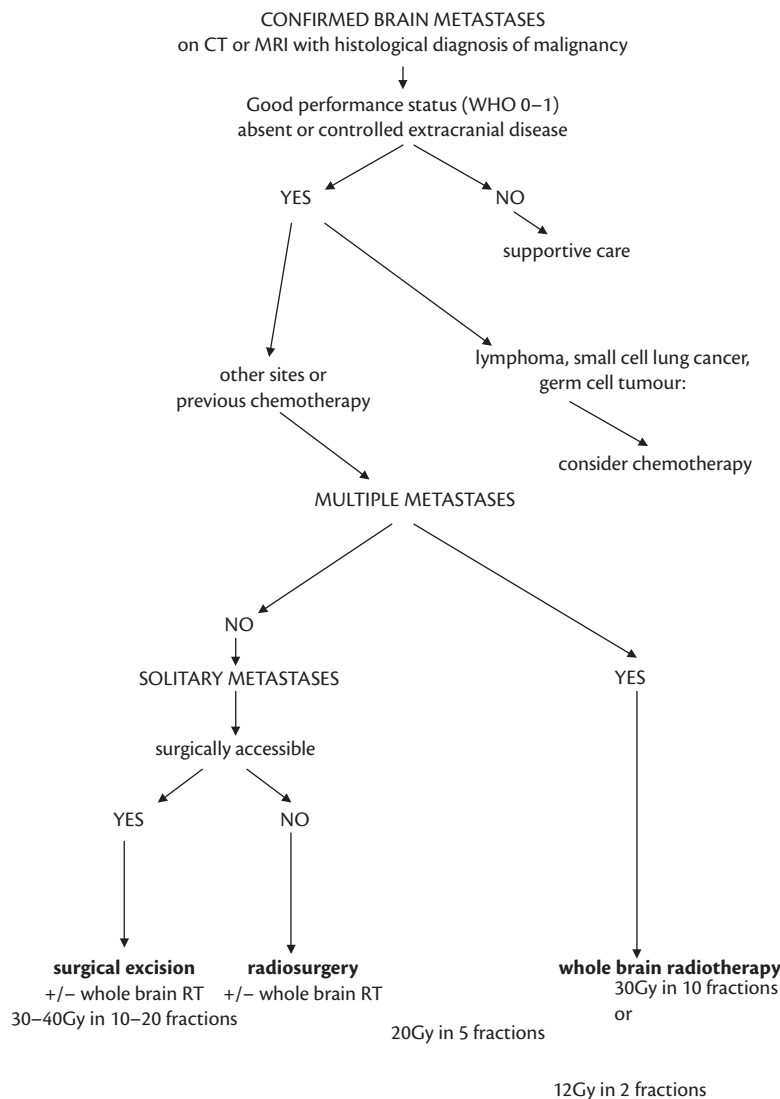
Whole-brain radiotherapy is well established as an effective palliative treatment for multiple cerebral metastases, yielding benefit for headache, motor and sensory loss, and confusion in about 80% of patients; a complete response occurs in 35–55% (Linskey et al., 2010). Median survival after irradiation is less than 6 months, reflecting the fact that brain metastasis often heralds widespread advanced metastatic disease. Twenty per cent of patients who embark upon a course of radiotherapy for brain metastases fail to complete the course, which highlights the need for careful selection in determining which patients may benefit from radiotherapy. Those with multiple metastases outside the central nervous system and those with poor performance status and rapidly progressive disease are most likely to succumb within the period of treatment (Table 12.3.6).


Fig. 12.3.7 Algorithm for the management of brain metastases.

Table 12.3.6 Prognostic factors influencing survival after irradiation of brain metastases

Increased survival	Decreased survival
Brain first site of relapse	Multiple lobes involved
Brain sole site of relapse	> 3 metastases
Long disease-free interval prior to brain relapse	Meningeal disease
Primary site in brain	
Performance status 0/1	
Age < 60 years	

Treatment techniques for multiple brain metastases are simple, using lateral fields from each side (parallel opposed fields) covering the entire intracranial contents. A series of randomized trials have shown no benefit for doses greater than 20–30 Gy in 1–2 weeks (Borgelt et al., 1982) and there is one trial which has shown similar effects after12 Gy in 2 fractions compared to 30 Gy in 10

fractions (Priestman et al., 1996). For patients with advanced disease and only moderate performance status, a simple two fraction schedule can be recommended.

There is usually little acute toxicity from a short palliative course of whole-brain radiotherapy for multiple brain metastases, but an unfortunate and unavoidable effect is complete alopecia. Although hair returns within 2–3 months, some patients are highly distressed by the change, and for some, alopecia is an unacceptable cost of treatment. Mild scalp erythema may also occur, particularly around the external pinnae. Most patients continue steroids through treatment in an effort to prevent transient rises in intracranial pressure. Following completion of cranial irradiation, steroid treatment should be tapered, and if possible, discontinued to minimize long-term side effects. Over the longer term, some patients who receive cranial irradiation experience deterioration in neurocognitive function; this is an important consideration in patients likely to survive for a prolonged period.

About a quarter patients experience persistent or recurrent cerebral metastasis. Re-treatment with radiotherapy following a dose of 20–30 Gy carries a risk of radiation damage to the brain and

there is often reluctance to consider re-irradiation for recurrent disease. Without treatment, however, progressive morbidity and ultimately death from brain metastasis will occur. Neurological sequelae from radiation damage may take many months if not years to manifest and the risks of low dose re-treatment (a further 20–30 Gy in 2–3 weeks) may be worth taking for selected patients who have a good initial response to treatment. Similarly, recurrence at a solitary site can be an indication for stereotactic re-irradiation.

Primary brain tumours

Primary brain tumours usually are treated by surgery, radiotherapy, or both with curative intent. Grade III or IV astrocytomas are extremely malignant and have a prognosis of only a few months if untreated. Palliative radiotherapy for the latter patients may be of value and the best results occur in those aged younger than 60 who have no neurological deficits and present with seizures. In patients with good performance status, high-dose treatment delivering 60 Gy in 30 fractions with adjuvant and concomitant temozolamide, improves median survival from 12.1 months to 14.6 months and 2 year survival from 10.4% to 26.5% compared to radiotherapy alone (Stupp et al., 2005). In those with poor performance status, significant neurological deficits and older age, significant benefit from a high dose treatment schedule is rarely seen and short schedules delivering doses of 20–30 Gy over 1–3 weeks should be considered (Thomas et al., 1994).

Diffuse meningeal carcinomatosis is generally a pre-terminal event, with a median survival of only a few weeks if untreated. It may present with symptoms and signs of multifocal radiculopathy or cranial neuropathy, or with headache or backache. There may be raised intracranial pressure. Common primary sites breast and lung, and central nervous system relapse of leukaemia also typically presents with malignant meningitis. The diagnosis is suspected on MRI and confirmed by cerebrospinal fluid sampling.

Intensive treatment may be indicated where there is a treatable underlying malignancy. In the case of acute leukaemia and lymphoma, sustained remissions may be achieved by the use of intrathecal chemotherapy using methotrexate and cytosine arabinoside, sometimes combined with craniospinal irradiation (radiotherapy to the entire brain and spinal cord) or cranial irradiation alone. Such treatment is no small undertaking and may be associated with significant morbidity due to bone marrow depression, nausea and vomiting, and alopecia. In children, there are also the associated issues of impaired spinal growth and intellectual development after radiotherapy to the spine and brain respectively. Furthermore it is unfortunately the case that despite initial remission, central nervous system relapse of lymphoma or leukaemia is generally associated with a poor overall prognosis,

The outlook for meningeal carcinomatosis from solid tumours is even worse and even intensive therapy with intrathecal chemotherapy and craniospinal irradiation will extend prognosis from a few weeks to a few months, much of which may be taken up with treatment (Wasserstrom et al., 1982). On this basis judicious local irradiation to specific sites causing symptoms, such as the skull base when cranial nerves are involved or the segments of the spinal cord related to nerve root symptoms, delivering a dose of 20 Gy in 5 fractions, offers a more pragmatic approach, potentially palliating symptoms whilst minimizing the morbidity and duration of treatment in a universally fatal condition.

Cranial nerve palsies

Cranial neuropathy may arise from intrinsic metastasis in the brainstem, infiltration of the leptomeninges, compression by extradural deposits, or bone involvement in the skull base. The management of intrinsic metastasis and leptomeningeal metastasis has been discussed above; results of whole-brain irradiation show an overall response rate of 78% and a complete response rate of 42% (Vikram and Chu, 1979). Local irradiation of the skull base when diffuse bone involvement has resulted in cranial nerve compression, yields improvement in 50–78% of patients, which is maintained until death in around 80%. In general, patients with skull base metastasis have a better prognosis (median survival of 10–20 months) than those with intrinsic central nervous system metastases, their (Vikram and Chu, 1979; Hall et al., 1983).

Peripheral nerve symptoms

Tumour compression of nerve roots, nerve plexus, or peripheral nerves can result in motor or sensory loss, or neuropathic pain, in the distribution of the nerve. A large randomized trial that evaluated the efficacy of local radiotherapy in neuropathic pain observed an overall response rate of 57%, with 26% achieving a complete response at three months after treatment (Roos et al., 2005). In keeping with the experience of uncomplicated bone metastases, single doses of 8 Gy were not inferior to more prolonged fractionated doses. Lumbosacral neuropathic pain responded to palliative doses of radiotherapy with complete pain relief within one month in 85–100% of patients (Russi et al., 1993). Pelvic irradiation for pain relief for recurrent colorectal cancer is successful in up to 80% of patients, with no difference detected between a 3-week course of treatment delivering 45 Gy and a single dose of 10 Gy (James et al., 1983). Treatment to apical lung tumours or axillary recurrence of breast cancer causing upper limb pain due to brachial plexus neuropathy is successful in up to 77% of patients using typical doses of 20–30 Gy in 1–2 weeks (Ampil et al., 1985).

Choroidal and orbital metastasis

Metastases to the eye are unusual but may cause distressing proptosis, pain and visual disturbance. Unless treated, there is progressive deterioration and ultimately loss of vision. The most common intraocular site is the choroid and the most common tumour types are breast (> 50%) and lung (30%); about 25% are bilateral. After diagnosis by fundoscopy or slit lamp examination, radiotherapy delivering doses of 30–40 Gy in 2–4 weeks can improve vision in up to 86% of patients (Rudoler et al., 1997; Wiegel et al., 2002). Asymptomatic lesions should also be treated to preserve vision. Local tumour control is reported in 98% of treated patients.

Metastasis at other intra-orbital sites are less common and may arise haematogenously or through direct invasion from other head and neck sites, in particular the nasopharynx, nasal cavity, and sinuses. Palliative irradiation may prevent or relieve local symptoms from pressure and infiltration.

Radiotherapy to the eye and orbit requires meticulous attention to technique, avoiding as far as possible direct irradiation of the cornea, which can result in painful keratitis. Whenever possible, the lens also should be shielded to prevent cataracts, which may be induced after only 5–10 Gy. Radiation cataracts may take many years to evolve and should not be considered a reason for avoiding radiation to the orbit in the context of palliative treatment.

Cerebral lymphoma

The incidence of primary lymphoma of the central nervous system, a rare extranodal non-Hodgkin lymphoma, has increased in recent years due to its association with advanced HIV infection. It may cause headache, fits, cranial nerve palsies, or other focal neurological signs. Initial treatment with a steroid may achieve good symptom palliation and some tumour regression, but the mainstay of modern treatment is chemotherapy, typically using high-dose methotrexate, which results in a median survival of 10–18 months (Laperriere et al., 1997). The role of whole-brain radiotherapy in addition to chemotherapy in radical treatment has been questioned, particularly in the light of late effects on cognitive function in survivors. It is currently under investigation. Whole-brain radiotherapy has a role in primary treatment for older patients unable to tolerate intensive chemotherapy. Doses of 40–50 Gy may be given (Schultz and Bovi, 2010), but late changes in neurocognitive function are common. In advanced cases, those with relapse after chemotherapy, with poor performance status or with a significant co-morbidity, a short treatment delivering a dose of 30 Gy in 10 fractions over 2 weeks will be of value.

Obstructive symptoms

Mediastinal compression and superior vena cava obstruction

The syndrome of superior vena cava obstruction (SVCO) may arise due to occlusion by extrinsic compression, intraluminal thrombosis, or direct invasion of the vessel wall. The majority of cases are due to malignant tumour within the mediastinum but other rare causes which should be excluded include aortic aneurysm, chronic mediastinitis, trauma, or thrombosis following central venous catheterization. Approximately 3% of patients with carcinoma of the bronchus and 8% of those with lymphoma develop SVCO; of those with SVCO, 75% have primary bronchial carcinomas (40% small cell lung cancer) and 15% have lymphoma.

The extent to increased venous pressure above the site of obstruction produces symptoms depends on the efficiency of collateral vessels, particularly the internal mammary vessels, pulmonary veins, and the thoracic and vertebral venous plexuses. Obstruction above the azygos vein produces a lesser effect than obstruction below this level. Impeded venous drainage from the head can cause headaches, somnolence, and dizziness; more rarely convulsions result from cerebral hypertension. Oedema and pressure within the mediastinum may cause dysphagia, dyspnoea, cough, or hoarseness. Examination may reveal fixed engorgement of arm and neck veins with visible dilatation of superficial skin veins, cyanosis, and facial oedema.

Whilst potentially a hazardous condition, emergency treatment rarely is needed, and it is important to have a full and accurate assessment of the underlying disease, together with a histological diagnosis, in order to ensure that correct therapy is instigated. Presentation with SVCO is not a contraindication to radical curative treatment when this is appropriate, for example, mediastinal Hodgkin lymphoma, and it is important not to compromise management by inappropriate emergency treatment. A policy of delayed treatment until definitive tissue diagnosis can be achieved has been evaluated in a large review of 1986 patients presenting with SVCO which found that only one death could be directly attributed to venous obstruction (caused by aspiration of blood after epistaxis) (Ahman, 1984). Although biopsy within a region of raised venous pressure raises concerns about the risk of haemorrhage, in practice bronchoscopy, mediastinoscopy or lymph node biopsy are performed without major complications and should be undertaken unless there is life-threatening large airways obstruction.

Management of SVCO should address both symptoms and the cause of the obstruction. Steroids are usually administered, such as dexamethasone 12–16 mg daily, although there is no good objective data to support this practice. In some cases, prompt symptom relief may be possible with bronchoscopy and stenting, or the insertion of a superior vena cava stent (Lanciego et al., 2001). Chemotherapy is appropriate for some tumour types, in particular small cell lung cancer, Hodgkin's disease, non-Hodgkin's lymphoma, and germ cell tumours. For other tumours, radiotherapy to the mediastinum covering the tumour mass and adjacent lymph nodes areas where appropriate is indicated. If a stent is placed, this is followed by radiotherapy. In the palliative setting, it is usual to deliver doses of 20–30 Gy in 1–2 weeks, but where the primary tumour is localized and radical treatment would otherwise be indicated, a radical course of radiotherapy or chemoradiation should not be denied the patient.

Symptomatic relief following irradiation for SVCO is reported in 50–95% of patients within the first 2 weeks of treatment. Treatment may have little effect upon the obstruction to blood flow in the superior vena cava, which persists in three-quarters of patients. This suggests that the development of collaterals, rather than the physical release of compression from the superior vena cava, is most important in achieving the observed clinical improvement (Ahman, 1984). Long-term survival is determined by the underlying disease, rather than the syndrome itself, with the exception of the relatively rare instance of large airway obstruction or cerebral oedema when urgent treatment is required.

Lung collapse secondary to bronchial obstruction

The most common cause of complete bronchial occlusion leading to collapse of lung is intrinsic carcinoma of the bronchus. Less often, occlusion results from extrinsic compression by mediastinal nodal invasion by carcinoma or lymphoma. When obstruction occurs rapidly, dyspnoea and cough occur, and treatment is aimed at restoring the patency of the bronchus. For intrinsic tumours, this may be best achieved by local treatment, such as cryotherapy or laser therapy via a bronchoscope. For extrinsic tumours appropriate radiotherapy or chemotherapy is indicated. As with SVCO, presentation with bronchial obstruction does not preclude radical treatment in those patients where that would be appropriate. Lymphoma and small cell lung cancer are best treated with primary chemotherapy and localized non-small cell lung cancer may benefit from radical doses of radiotherapy given either as an accelerated schedule such as CHART (continuous hyperfractionated accelerated radiotherapy) or within a chemoradiation programme (Fairchild et al., 2009). For poor performance status patients and those with distant metastasis palliative radiotherapy or chemotherapy is indicated. In large randomized trials, a single dose of 10 Gy is equivalent to a more prolonged schedule in terms of both symptom control and survival, with a reduced risk of acute morbidity (MRC Lung Cancer Working Part, 1991, 1992). There is an intermediate group of good performance status patients with

advanced tumours who may have a small but significant survival advantage from higher-dose radiotherapy. Randomized trials comparing 17 Gy in 2 fractions with either 39 Gy in 13 fractions or 20 Gy in 5 fractions showed a significant survival advantage of around 2 months for the higher dose schedules (Bezjak et al., 2002; Goldstraw et al., 2011). In this setting, radiotherapy may be given before or after palliative chemotherapy, which also may have an important role in symptom control and improving quality of life (Goldstraw et al., 2011).

An alternative method of delivering radiotherapy in the bronchial lumen is endobronchial irradiation. This may be particularly appropriate for patients relapsing after previous external beam irradiation. In this brachytherapy technique, a fine plastic catheter is placed alongside the tumour-bearing region of bronchus (Fig. 12.3.8) and a high dose rate afterloading machine passes a radioactive source, iridium 192, along the catheter to dwell within the area bearing tumour where treatment is required. This technique can be combined with either laser therapy or cryotherapy to restore the lumen where there is complete bronchial obstruction. In a randomized controlled trial comparing endobronchial brachytherapy with external beam radiotherapy (Stout et al., 2000), there was no difference in survival or symptom control scores for cough, haemoptysis, shortness of breath, or hoarseness, but external beam radiotherapy was found to be superior for symptoms of chest pain, anorexia, tiredness and nausea, and brachytherapy was better for dysphagia. The standard dose is 15 Gy at 1 cm and the major advantage of brachytherapy is that it can be given as a single procedure often possible as an outpatient day case.

Dysphagia

Pain and difficulty in swallowing is a common symptom in patients with advanced cancer within the mediastinum. This may be due to intrinsic tumour arising from the wall of the oesophagus, hypopharynx (piriform fossa, post-cricoid region, and posterior pharyngeal wall), and stomach. Alternatively there may be extrinsic compression from mediastinal lymph nodes or tumours in the thymus, thyroid gland, or adjacent bronchus. Postmortem data shows that around 80% of patients presenting with dysphagia have intrinsic tumour within the oesophagus. One study showed multiple levels of obstruction in almost a quarter of these patients (Sykes et al., 1998). Symptoms may be ameliorated with analgesics and anticholingergic drugs to reduce secretions, and nutrition can be maintained by a percutaneous gastrostomy. Where there is widespread metastatic disease in poor performance patients more active treatment may be inappropriate and unsuccessful, but in selected patients with good performance status and limited disease, surgical intervention or if not appropriate laser resection or stenting should be considered.

Given the risk of procedure-related morbidity and mortality, external beam irradiation also may be considered as a means of relieving dysphagia. A typical radiation field is shown in Fig. 12.3.9, and the usual dose is 20–30 Gy in 1–2 weeks. Swallowing is re-established in more than 80% of patients and maintained for a mean duration of 6 months (Wara et al., 1976). The disadvantage of radiotherapy in this setting is the time required to attain relief, which can be several weeks, and the initial period of enhanced dysphagia because of acute oesophagitis. Higher doses of radiotherapy delivering 50 Gy in 5 weeks or more may give a higher and more durable response and should be considered for patients who

(A)

(B)

have good performance status and limited disease (Leslie et al., 1992). If radical treatment is performed, chemoradiation with cisplatin and 5-fluorouracil during the course of radiotherapy has been shown to be superior to radiotherapy alone (Herskovic et al., 2012).

An alternative technique is endo-oesophageal radiotherapy, which is similar to that of endobronchial brachytherapy (Fig. 12.3.8). A high-dose afterloading source can be passed through a fine catheter that fits inside a nasogastric tube, which is passed through the area of oesophageal constriction. The outpatient procedure typically takes only a few minutes. Used alone, sustained improvement in swallowing is reported in 54% of patients (Brewster et al., 1995). This technique has also been

(a)

(b)

used in an attempt to achieve high local doses in combination with external beam radiotherapy for radical treatment. One randomized trial suggests there may be a survival advantage to this approach over the use of stents, with equivalent control of dysphagia (Shenfine et al., 2005). In addition to acute toxicity there may be later side effects, of which oesophageal stricture is the most troublesome; this occurs in less than 5% patients (Shenfine et al., 2005). Late deterioration in swallowing usually is caused by tumour recurrence.

Urinary tract obstruction

Urinary tract obstruction may arise because of obstruction of the renal pelvis, ureter, bladder, or urethra at any point (see Chapter 8.4). The most satisfactory means of re-establishing renal drainage is a procedure to bypass the obstruction using a nephrostomy,

ureteric stents, or transurethral resection of an intrinsic urethral tumour. The role of radiotherapy is restricted to cancer patients for whom a procedure is technically not possible or otherwise inappropriate, and to those who have had a procedure and require treatment of the underlying cause. Common neoplasms include cervix, bladder, or prostate, and recurrent colorectal tumour. It is important to ascertain the primary site, and in the setting of para-aortic lymphadenopathy, obtain histological confirmation given the need to determine chemosensitivity of the lesion. In some instances, for example, lymphoma and germ cell tumour, primary chemotherapy with curative intent will be appropriate.

Primary tumours of the cervix, prostate, or bladder without lymph node or distant metastasis are treated with high radiation doses to achieve tumour shrinkage and re-establish urinary flow with the expectation that a proportion of patients will have long-term disease control or even cure. Cervical cancer may be treated by radical chemoradiation and intrauterine brachytherapy, bladder cancer requires doses 55 Gy in 20 daily fractions or 60–65 Gy in 6–6½ weeks, and prostate cancer may be treated radically with doses of 74–78 Gy in 32–34 fractions. Shorter and lower dose schedules may be chosen in advanced disease. In one series of patients with carcinoma of the prostate presenting with urinary retention, radiotherapy alone was sufficient to restore normal urinary drainage in 84%, with a mean time to catheter removal from completion of radiotherapy of 10 weeks (Wells et al., 1996). In practice, most patients with advanced prostate cancer also are treated with androgen deprivation therapy and similar regression may be achieved with this approach in the short term.

In some instances intraluminal or interstitial radiotherapy may have a role in urinary obstruction. A specific example is suburethral metastasis from endometrial carcinoma. This is a recognized pattern of spread from submucosal vaginal lymphatic invasion to the urethra meatus. Techniques are also available to deliver intraluminal brachytherapy to the urethra for recurrent prostate cancer or bladder base tumours.

Limb oedema

Limb oedema in a patient with advanced cancer may result from venous obstruction, lymphatic obstruction, or both (see Chapter 11.3). This may be compounded by general debility, immobility, and poor nutrition with accompanying hypo-albuminaemia. In a proportion of patients, post-radiation changes may cause lymphatic obstruction; upper limb oedema occurs in more than 30% of patients undergoing both axillary surgery and radiotherapy for breast cancer.

Local radiotherapy may be of value in the treatment of limb oedema when enlarged malignant axillary, inguinal, or pelvic nodes are the cause of obstruction. The best results are obtained with early treatment, when the circulatory obstruction can be reversed. Relatively low doses of 20–30 Gy in 1–2 weeks are used, taking care to preserve wherever possible a channel of unirradiated skin and soft tissue through which lymph drainage can be maintained despite post-radiation changes.

Hydrocephalus

Obstructive hydrocephalus is an uncommon manifestation of cancer within the central nervous system and may result from primary or secondary tumours that obstruct the cerebrospinal fluid at any point in the ventricular system. Typically, it occurs when tumours of either the midbrain or the posterior fossa obstruct the

aqueduct or fourth ventricle; it may also be secondary to malignant meningitis. Patients present with features of raised intracranial pressure together with focal neurological symptoms, depending upon the site of the tumour. Rapid relief of hydrocephalus may be gained by inserting an intraventricular shunt and patients with advanced disease may need no further treatment to achieve temporary symptom control. Where surgery is not feasible or where there are multiple intracerebral lesions, palliative radiotherapy should be given in the same way as discussed for the management of brain metastases in the previous section. Advanced primary central nervous system tumours of the mid brain and posterior fossa are also treated by radiotherapy usually delivering doses of 50–55 Gy given over 6–7 weeks.

Haemorrhage

Haemoptysis

Haemoptysis is a common symptom of bronchial carcinoma, occurring in about 50% of patients at presentation, and may also accompany pulmonary metastasis (see Chapter 8.7). It is distressing for the patient, although rarely of haemodynamic significance unless a major vein or bronchial artery is eroded. Haemoptysis is an indication for local radiotherapy and control rates of up to 80% are reported with palliative doses, using either external beam treatment or endobronchial brachytherapy as discussed above. Randomized trials show that a single dose of 10 Gy external beam is as effective as other more prolonged schedules, with less acute morbidity (MRC Lung Cancer Working Party, 1992).

Haemoptysis is not a contraindication to radical treatment in patients with localized bronchial carcinoma. Screening for this possibility should always occur prior to embarking upon palliative irradiation. Patients with stage I or II non-small cell lung cancer (no involvement of mediastinal lymph nodes) should be considered for high-dose radiotherapy using either accelerated schedules such as CHART or chemoradiation (Fairchild et al., 2009). Some patients with good performance status and stage III disease, (mediastinal node involvement) may also benefit from high-dose chemoradiation. Patients with small cell lung cancer may receive combined chemotherapy, mediastinal radiotherapy, and prophylactic cranial irradiation.

The management of haemoptysis due to pulmonary metastasis is more difficult. Local irradiation is only of value where a specific site of haemorrhage can be identified or where there is only a solitary metastasis. Bronchoscopic confirmation of the origin of bleeding is therefore needed when there are multiple metastases; arbitrary irradiation of the particular area of metastatic disease is not to be recommended, although low-dose whole-lung irradiation delivering a dose of 25 Gy in 20 fractions over 4 weeks has been used in the past for widespread metastasis from radiosensitive tumours such as Ewing's sarcoma or Wilms' tumour. In general, however, chemotherapy or hormone therapy is the preferred treatment in this setting and only when this has failed should palliative irradiation be explored.

There is no proven advantage in terms of survival for treating the asymptomatic patient with inoperable lung cancer. Nonetheless, there is evidence that tumours greater than 10 cm in diameter, whether primary or metastatic, carry a significant risk of haemorrhage and it has been suggested that such lesions should receive prophylactic treatment.

Haematuria

Haematuria may be related to bleeding from primary or metastatic disease at any site along the urinary tract (see Chapter 8.4). Careful localization of the site of bleeding through intravenous urography, CT scanning, or cystoscopy is necessary for treatment planning. In patients with advanced cancer, bleeding is usually caused by a lesion in the bladder, which may be primary or secondary to local infiltration of an advanced rectal or uterine carcinoma, advanced renal cell carcinoma or urethral infiltration by carcinoma of the prostate. Other causes that may be relevant to the cancer patient are infective cystitis, chemical cystitis associated with certain chemotherapy agents such as cyclophosphamide or ifosfamide, bladder telangiectasia as a late change following high-dose radiotherapy to the bladder (or adjacent pelvic organs), and rarely, thrombocytopenia or a blood coagulation defect.

The main role of radiotherapy in this setting is to achieve haemostasis in patients with inoperable or recurrent tumours. When conservative measures, such as bladder irrigation, administration of antifibrinolytic drugs such as tranexamic acid, or cystoscopic diathermy, are unsuccessful, modest doses of irradiation delivered to a small volume encompassing the site of haemorrhage may be successful. A large randomized trial comparing 35 Gy in 10 fractions with 21 Gy given in 3 fractions on alternate days over one week has shown equivalent symptomatic improvement of bladder-related symptoms in patients with advanced bladder cancer invading muscle, with no excess toxicity from the shorter 21 Gy schedule (Duchesne et al., 2000). Haematuria was improved in 50% of patients at completion of treatment and 63% at 3 months after treatment. The same doses and techniques can be used for prostatic cancer causing urethral or bladder base infiltration and haemorrhage. In poor performance status patients, single doses of 8–10 Gy may be equally effective and 17 Gy in 2 fractions has also been reported as a useful schedule in this setting, with a 59% response rate for haematuria (Srinivasan et al., 1994).

As with other sites haematuria may be the presentation of a potentially curable primary bladder or prostatic carcinoma, and full assessment of the patient both in terms of their tumour and general status is important before deciding upon palliative treatment. For advanced tumours of the bladder, radical radiotherapy delivers doses of 55 Gy in 4 weeks or 60–65 Gy in 6–6½ weeks. Radical radiotherapy to the prostate gland delivers doses in excess of 70 Gy in 7 weeks. In selected cases, brachytherapy can be used.

Haematuria due to locally advanced inoperable renal carcinoma may also benefit from local irradiation. The tolerance of the normal kidney to radiation is low and even with modest palliative doses, the kidney will have loss of function. It is therefore important to ensure that renal function from the contralateral kidney is normal before treatment. Doses of 10 Gy as a single dose, 21 Gy in 3 fractions over 1 week, or 20–30 Gy over 1–2 weeks have all been used in this setting; there are few published data on the expected response rate.

Treatment of the bladder or prostate may result in diarrhoea because of the inevitable inclusion of some of the rectum in the treatment volume. In the Medical Research Council randomized trial of palliative radiotherapy in bladder cancer there was a 5% incidence of mild diarrhoea not requiring medication and a 2% incidence of moderate diarrhoea requiring medication for control (Duchesne et al., 2000). Treatment of the kidney may include stomach or small bowel, resulting in nausea, vomiting and

diarrhoea. Careful explanation and reassurance about these side effects, together with ready availability of anti-diarrhoeal agents and antiemetics, is an important part of management.

Uterine and vaginal bleeding

Tumours of the uterus, including endometrial and cervical cancer, and uterine sarcomas, frequently present with abnormal vaginal bleeding. This is rarely excessive but occasionally major haemorrhage is the presenting feature. Haemorrhage may be due to recurrent or locally advanced tumours of the cervix or uterus, local infiltration from advanced cancers of the bladder or rectum, or metastatic mucosal deposits along the vaginal wall typical of the pattern of spread from endometrial cancer. Haemorrhagic mucosal deposits are also a particular feature of vulval or vaginal melanoma.

Radiotherapy is of value in obtaining control of bleeding, using either external beam irradiation or intracavitary brachytherapy as appropriate. When bleeding is the primary presentation of advanced cervical cancer, then radical chemoradiation is often appropriate, delivering external beam treatment to a dose of around 50 Gy in 5 weeks with cisplatin followed by intracavitary brachytherapy to the cervix and para-cervical tissues. Similarly, when locally advanced bladder, rectal or uterine tumours are the cause and previous radiotherapy has not been given, palliative pelvic doses are effective, using a schedule of 21 Gy in 3 fractions or 20–30 Gy over 1–2 weeks. If previous radiotherapy had been given, low doses, for example, single doses of 8 Gy or short courses of up to 20 Gy in 5 fractions, may be considered, although there may be risks of additional late bowel damage associated with this. These decisions must be balanced between the severity of symptoms and the anticipated life expectancy of the patient.

Where bleeding is from small volume disease, such as nodules at the vaginal vault or along the vaginal mucosa, intracavitary brachytherapy may be optimal. Vaginal sources in the form of either ovoids or a vaginal tube can be introduced directly into the vagina and used to carry a radiation source, usually iridium (Fig. 12.3.10) (Hoskin and Coyle, 2011). The use of intracavitary brachytherapy in this way enables a high surface dose to be given to the mucosa but with a rapid fall off in dose away from the source so that critical structures such as bladder and rectum are relatively spared from the radiation dose. It is able to treat only to a depth of 5–10 mm, and for larger tumours, an interstitial implant may be necessary. This requires general anaesthesia and the placement of afterloading radioactive tubes. It enables high dose treatment to be delivered locally within the tumour, even where previous radiotherapy has been given to the pelvis, and may provide highly effective palliation in the difficult situation of progressive tumour in the vulvo-vaginal tissues.

Gastrointestinal haemorrhage

Symptomatic gastrointestinal haemorrhage from the upper or lower gastrointestinal tract may arise from a primary neoplasm of the stomach, large bowel or rectum, or from direct invasion by locally advanced tumour in adjacent structures such as the uterus, bladder, or prostate. Blood borne metastasis to the bowel are rare, but metastatic malignant melanoma is a recognized cause of haemorrhagic deposits within the small bowel wall and Kaposi's sarcoma, seen with HIV infection, may cause a similar problem.
Fig. 12.3.10 X-ray and CT planning films of intravaginal applicator used to treat symptomatic recurrent vaginal tumour showing (A) transaxial and (B) sagittal views. Red line denotes prescription isodose; note low surrounding dose to bowel, bladder, and rectum.

Modest doses of radiotherapy to a site of haemorrhage within the bowel will often achieve effective and durable control of bleeding. In the lower bowel, tumours in the rectum and colon are usually readily identified and localized within a treatment volume. Treatment of the stomach may be more difficult both because it can be a relatively mobile structure and also because the sensitivity of surrounding tissues, in particular liver, small bowel, and kidneys, limits tolerance and the dose that can be delivered safely. Localization of tumours within the small bowel also can be difficult because of its mobility. Radiation to the stomach or small bowel can have considerable associated morbidity with nausea, vomiting, and diarrhoea.

External beam radiotherapy for bleeding from recurrent colorectal cancer has been reported to achieve an overall response rate of 85%, with complete control of bleeding in 63% of patients following a dose of 30–35 Gy in 10 fractions over 2 weeks (Taylor et al., 1987). An alternative approach is again to use intraluminal brachytherapy, similar to the technique used for vaginal bleeding. A tube can be passed into the rectum through which a radioactive source can be placed to deliver a high surface dose to the rectal

mucosa and associated tumour area. This approach has the advantage of being delivered as a single outpatient procedure when high dose rate afterloading brachytherapy is used, the actual technique being little different to a sigmoidoscopic examination. Control of bleeding is achieved in 64% (Corner et al., 2010). It is however limited to accessible tumours in the lower sigmoid colon, rectum, and anal canal.

Chest wall and other skin lesions

Locoregional recurrence remains a significant problem in patients with breast cancer, occurring in 7–10% of those with early disease and up to 40% of those presenting with advanced local disease. Although post-operative irradiation at the time of primary treatment significantly reduces the likelihood of locoregional relapse, some patients develop progressive locoregional tumour on the chest wall which will fungate and bleed. If total mastectomy is possible, this may be the best procedure to surgically clear recurrent tumour on the chest wall. In many cases, however, the tumour will be fixed and inoperable, and associated with multiple satellite nodules across the chest, often involving the contralateral breast or extending laterally across the mid-axillary line on to the back. Chemotherapy may be used, but if no previous radiotherapy had been given and there is no evidence of distant metastasis, high dose local irradiation may be appropriate, delivering doses of up to 60 Gy in 6 weeks. In patients with distant metastasis and a poor prognosis, shorter schedules of 10 Gy in 1 fraction or longer courses of 20–30 Gy in 1–2 weeks may be used. Often it is not possible to encompass the entire extent of clinically detectable disease and in these circumstances those causing greatest symptoms may be targeted.

Recurrence at the site of previous irradiation may still present the option of further radiotherapy to a limited area of symptomatic tumour since the risks of skin necrosis are negligible compared with the effects of progressive fungating tumour within the skin. Superficial X-ray treatment or low energy electrons to fungating or bleeding chest wall nodules is often highly effective and a single dose of 8–10 Gy or a longer course delivering 20–30 Gy over 1–2 weeks is commonly used. More complex techniques using a surface mould in which radioactive sources are placed over the involved area, or interstitial brachytherapy in which large tumour masses are implanted with radioactive needles or afterloading applicator tubes, can also be considered.

Skin nodules may also be a manifestation of primary tumours in other sites. These reflect blood borne metastasis and therefore radical treatment is usually inappropriate but local treatment to symptomatic nodules is of value. Techniques and doses similar to those discussed above for recurrent breast cancer are employed.

Primary skin tumours may also present with locally advanced inoperable disease. Bleeding and fungation are likely to become major problems in the management of these patients and local radiotherapy is of value in their control. In the absence of metastasis, and in the case of basal cell carcinomas which do not metastasize, high radical doses may be considered using appropriate techniques with either electrons of appropriate energy to treat to the depth of the tumour or tangential X-ray beams to cover the tumour volume. Doses of 60 Gy in 6 weeks or equivalent are given to large tumours where this is appropriate in the light of the patient's general performance status. For patients with poor performance status or metastatic disease shorter courses delivering doses of 20–30 Gy in 1–2 weeks may be considered and will be effective in achieving growth delay and stopping haemorrhage. Melanoma characteristically presents with haemorrhagic tumours and may in more advanced cases result in multiple skin nodules. Local radiotherapy delivering higher doses of 30 Gy in 5–6 fractions treating twice weekly is often used with good effect (Overgaard, 1986).

Other local tumour effects

Fungation

Fungation of a superficial tumour mass is a distressing feature of locally advanced cancer (see Chapters 11.1 and 14.4). As noted, it is seen most commonly in chest wall recurrence after breast carcinoma and with metastatic lymph nodes in the neck or groin. Local irradiation is most valuable in the prevention of fungation at a time when the overlying skin is intact. A palliative course of treatment delivering 20–30 Gy in 1–2 weeks will usually delay growth within a tumour mass sufficient to prevent fungation. Higher dose may be appropriate if the local tumour is the sole manifestation of malignancy. The most common scenario of this type is the presence of a cervical lymph node containing squamous carcinoma from the head and neck region or inguinal lymph nodes with squamous carcinoma from the perineal region. Occasionally, large lymph nodes may present without an obvious underlying primary tumour. Radical radiotherapy to malignant nodes from an unknown primary in the neck can achieve long term control in this setting with overall 5-year survival figures of 20–30% in selected series (Fletcher, 1990).

Once fungation has occurred successful treatment is more difficult. Combined with nursing care and administration of analgesics and antibiotics, local irradiation may still be of value in reducing the underlying tumour bulk, arresting surface haemorrhage and drying the surface as the process of healing is allowed to commence. This will make nursing care simpler and relieve the patient from the distress of local haemorrhage.

Kaposi's sarcoma

Kaposi's sarcoma is now most commonly seen as a feature of HIV infection and is the most common AIDS-related malignancy. It may also be seen in sporadic cases when it typically presents in the skin of the lower limbs in European men. Multiple skin lesions are usual but extracutaneous disease is also common affecting the oral cavity and gastrointestinal tract. The characteristic purplish raised plaques may bleed and ulcerate. In contrast to other soft tissue sarcomas, Kaposi's is markedly radiosensitive and small doses of irradiation will result in complete regression of lesions in up to 70% of patients (Munro and Stewart, 1989). There is good evidence that single doses are as effective as more prolonged schedules and superficial irradiation delivering 8 Gy to symptomatic sites is recommended.

Liver metastases

In most instances, the presence of liver metastasis heralds the terminal phases of advanced cancer. Clinical symptoms include anorexia, malaise, and weight loss alongside local pain and discomfort from hepatic enlargement and stretching of the liver capsule. Pain may be acute where there is rapid expansion of the liver or haemorrhage into a metastasis.

A subgroup of patients who have liver oligometastases with only one to three lesions in the setting of a controlled or absent primary

and no other metastatic sites may benefit from radical treatment. Surgical resection is indicated where technically feasible. In inoperable oligometastases, then stereotactic radiotherapy may be used to deliver an ablative dose of radiation. A range of dose fractionation schedules have been reported from single doses of 14–26 Gy to fractionated schedules delivering 30–55 Gy in 3–5 fractions. There is no consensus on the optimal dose schedule but high local control rates from 56% to 100% are reported in cohort studies with little acute or late toxicity (Lo et al., 2010). High-frequency ultrasound has recently introduced a further treatment option for superficial metastases

Local radiotherapy may also be of value in the setting of multiple metastases particularly in those patients with good performance status and normal bilirubin and where the primary site is other than stomach or pancreas (Leibel et al., 1981). If the primary tumour is chemosensitive, this is usually the first line of approach, but for other patients palliative low-dose radiotherapy may provide valuable relief of symptoms. Two prospective randomized trials have demonstrated relief of hepatic pain in 80% of patients, with complete relief in 55% and improvements in nausea, vomiting, fever, and night sweats in 45% (Borgelt et al., 1981; Leibel et al., 1981).

The liver has limited tolerance to radiation. Non-stereotactic hepatic radiotherapy may be associated with side effects, and when doses greater than 30 Gy are given, there is a risk of inducing radiation hepatitis. Toxicity is related not only to dose but also the volume of liver included in the treatment volume. Unless there is diffuse infiltration of the entire organ, uninvolved liver should be excluded from the radiation volume. With doses of 30 Gy delivered in 2–3 weeks, relatively mild self-limiting toxicity is reported with lethargy and nausea being the predominant symptoms.

Splenomegaly

Symptomatic splenomegaly from malignant diseases is usually associated with haematological malignancies, in particular chronic granulocytic leukaemia and certain types of non-Hodgkin's lymphoma. It is also a feature of myelodysplasia. Surgical removal of the spleen is the preferred management, but in advanced disease or in patients with poor performance status this may not be appropriate and local irradiation is an effective means of palliation. Symptoms due to local bulk (causing pain and discomfort) and hypersplenism (causing consumption of red cells and platelets) benefit from treatment. Pain relief is reported in over 90% of patients and durable size reduction in 60% (Paulino and Reddy, 1996). When treatment is for hypersplenism, then caution is required as high doses may precipitate pancytopenia. Single doses of 1 Gy or less delivered at weekly intervals are recommended to a total dose of between 3 and 10 Gy with weekly assessment before each treatment to evaluate the effect on the peripheral blood count and the degree of splenic shrinkage. The spleen containing lymphoma or leukaemia is often extremely sensitive to radiation and whilst standard doses of 20–30 Gy in 10–15 fractions will be needed precautions should be taken against the effects of rapid tumour lysis ensuring the patient is well hydrated and giving allopurinol to prevent hyperuricaemia.

Hypercalcaemia

Hypercalcaemia complicates the clinical course of around 10% of all patients with malignant disease particularly those with common epithelial tumours such as breast, prostate and lung cancer.

Whilst it frequently occurs in patients with widespread metastatic disease, no clear correlation with the extent of bone metastasis is usually demonstrated and most cases arise due to the production of chemical agents promoting osteoclastic reabsorption of bone, in particular parathyroid hormone-related protein. The initial management of a patient with hypercalcaemia secondary to advanced cancer includes rehydration, diuresis, and the introduction of bisphosphonates. However, whilst an initial reduction of serum calcium is usually achieved, rebound hypercalcaemia frequently follows requiring further intensive treatment and often a refractory phase is entered after several episodes. Where a potential source of the chemical agent can be identified such as locally advanced endo-bronchial carcinoma, local irradiation to reduce its production and enable stabilization of blood calcium levels may be of value. Standard palliative doses are usually delivered as described above and whilst anecdotally a valuable treatment in this setting no published data is available for accurate estimates of response.

Paraneoplastic phenomena

The most common paraneoplastic syndromes occur association is with primary carcinoma of the bronchus. These arise in around 2% of patients and include neuropathies, myopathies, myasthenia (the Eaton–Lambert syndrome) and cutaneous manifestations such as acanthosis nigricans, erythema gyratum, or hairy man syndrome. These symptoms reflect secretion of a humeral agent, possibly an auto-antibody. The para-endocrine syndromes are associated with ectopic production of adrenocorticotropic hormone, antidiuretic hormone, human chorionic gonadotrophin, 5-hydroxytryptamine, or thyroid stimulating hormone, as well as those mentioned above in the context of hypercalcaemia. If there is an identifiable local tumour and surgical excision is not possible or appropriate, local irradiation may result in improvement and resolution of the paraneoplastic symptoms as the tumour regresses. In advanced disease, only palliative doses may be appropriate, but in localized disease the presence of a paraneoplastic syndrome should not exclude consideration of radical treatment. As with hypercalcaemia, there is no good data on precise response rates to treatment in this setting.

Conclusion

Local irradiation is a valuable treatment for palliation of local symptoms, with consistently high response rates in the relief and control of bone pain, neurological symptoms, obstructive symptoms, and haemorrhage. Short treatments and simple techniques can minimize disruption and acute morbidity for the patient with advanced cancer whilst enabling control of symptoms.

The role of general surgery in the palliative care of patients with cancer

Brian Badgwell and Robert S. Krouse

Role of the surgeon in palliative care of the cancer patient

Palliation is increasingly becoming recognized as an important component of care of the cancer patient for general surgeons. In fact, studies from tertiary cancer centres have shown that 12.5% of cases were done with a palliative intent while 40% of inpatient surgical consultations met the criteria for palliative evaluation (Krouse et al., 2001; Badgwell et al., 2009). Additionally, in a survey of cancer surgeons, it was estimated that 21% of all surgical procedures for cancer patients are for palliation (McCahill et al., 2002). The diverse surgical indications to improve the quality of life (QOL) in advanced cancer patients include hormonal imbalance, malignant fluid re-accumulation, obstructions, tumour bleeding or other local complications, and pain (Markman, 1995). These may be due to the many various primary or metastatic cancers.

Goals of surgery

Definition of success

The benefits and risks of surgical procedures are always of paramount importance, and are crystallized in the patient with advanced cancer. The benefits of palliative surgery should always focus on QOL, symptom control, and symptom prevention (Markman, 1995). One must also consider that there will frequently be a secondary benefit: survival. This is clearly an important goal of patients and families, even in the setting of incurable disease. Unfortunately, the literature frequently focuses exclusively on survival as an endpoint, leaving surgeons with little information on an intervention's impact on QOL.

A major dilemma for the surgeon caring for a patient with a terminal cancer is measures of success. The surgical literature has been a poor guide for decision-making for this population of patients. Outcome measures related to QOL and symptom distress are not clearly defined and documented. Historically, what little focus there is on palliation in the surgical literature has been remiss in examining appropriate QOL outcomes. In fact, from 1990 to 1996, QOL measurements have been included in only 17% of reports of palliative procedures in the surgical literature and only 12% examined pain (Miner et al., 1999). This is in contrast to the more common outcome measures of physiologic response (69%), survival (64%), and morbidity and mortality (61%). While it is imperative to understand these outcomes, they should not be the primary focus of palliative procedures, as they may not equate with an improvement in QOL. It is possible that palliative surgery would have no effect on general QOL surveys such as the Short Form-36 (SF-36) or Functional Assessment of Cancer Therapy-General (FACT-G) (Ware and Sherbourne 1992; Cella et al., 1993). Future studies will hopefully include targeted measures based upon the indication for surgical intervention and the symptoms that the patients are seeking to improve.

For patients contemplating palliative surgery, the primary decision-making factor has been shown to be the physical impact of uncontrolled symptoms. Secondary factors included the social impact of symptoms and maintenance of hope (Ferrell et al., 2003). Similarly, a study of patients with malignant gastric outlet obstruction requested patients to list and rank factors influencing their choice of palliative intervention (Schmidt et al., 2009). Patients listed physician's recommendation and the desire to eat and drink normally as the most important factors influencing their decision. Such studies may ultimately identify the optimal outcome in palliative surgical assessment (Badgwell et al., 2012).

Pre-emptive surgical palliation

Palliative surgery is most often considered in the setting of an active symptom. Prevention of symptoms in the palliative setting may also be a goal of palliative surgery (Markman, 1995). Many symptoms related to tumours are known to occur, but it is less understood if or when the symptom will actually occur. Therefore, it is not always clear when or if a procedure would be helpful. Appropriate pre-emptive palliative surgery must consider prognostication related to a particular symptom, as well as the lifespan of a patient. For example, in the setting of biliary obstruction where a surgical bypass is attempted, one must also consider a gastric bypass to alleviate the risk of a patient having a gastric outlet obstruction prior to death. Another example may be with nodal dissections in the setting of positive sentinel node mappings, especially if distant disease is noted. A nodal dissection will have little effect on long-term survival, but this procedure may alleviate the risk of nodal recurrence and the suffering this may cause. Therefore, while there is frequently no clear direction for surgeons in these settings, pre-emptive palliative procedures should

be considered in settings where tumour-related morbidity can be anticipated. Although this remains an area of active controversy in research endeavours, invasive procedures to prevent symptoms to improve QOL for patients with incurable illness has been included in the American College of Surgeons Surgical Palliative Care Task Force definition of palliative surgery (Cady et al., 2005). As always, the inherent risks of an operation must be considered, but these are more difficult to assess when the benefits are ultimately unknown.

Surgical risks

With every goal of success must be an understanding of risk. While all treatments contain risk, this is magnified related to a surgical procedure. It is further highlighted with patients who are facing the end of life. There are multiple preoperative considerations to ensure a successful palliative procedure with limited morbidity and mortality. This includes nutritional status. Albumin level is frequently an excellent tool to decide when not to operate. It is mandatory to assess the overall status of patients, including other medical problems and amount and location of primary or metastatic disease. This issue will clearly affect overall risk.

Complications will occur even with the most fastidious care, especially if the patient is debilitated related to the cancer or underlying conditions. Surgical morbidity may include complications unrelated to the surgical site, such as pneumonia, deep venous thrombosis, ileus, and heart failure. With meticulous care, these can often be avoided. Related to the procedure itself, pain is a major issue that occurs in the perioperative setting, and may persist throughout the patient's course. Epidural, patient-controlled analgesia, and local anaesthetic pumps may improve pain control and ultimate outcomes. Related to the surgical site, wound complications must always be considered. For example, it has been noted that lymph node dissections may have high rates of wound problems (47% for axillary node and 71% after inguinal node dissections) (Serpell et al., 2003). Issues such as seromas and infections may be long-term problems that take weeks to months to heal. Lymphatic leaks may necessitate frequent drainage or catheter placement. Patients with advanced cancers may not ever heal their wounds. Postoperative infections and non-healing wounds can also delay or prevent other treatment options. These issues must be discussed in detail prior to an operation. As new innovations are utilized, outcomes will continue to improve for surgical patients.

Acceptance of major disfigurement and lifestyle changes are most pronounced in the immediate postoperative setting. For example, the shock of a permanent stoma may be overwhelming for many patients. While QOL problems related to ostomies may diminish with time (Persson et al., 2005), this may not be possible for the patient facing the end of life.

A poor surgical outcome may be that symptoms worsen after a procedure. In addition, hospital stays may be longer if complications occur. Importantly, an invasive procedure may hasten someone's death, which is the ultimate poor outcome.

Surgical palliative care problems for cancer patients: indications, options, and outcomes

Malignant bowel obstruction (MBO)

Indications of MBO

MBO is the most common indication for palliative surgical consultation (Badgwell et al., 2009) (see also Chapter 14.3). It occurs most frequently with ovarian and colorectal cancers, but occurs with other abdominal and occasionally with non-abdominal malignancies. MBO may be related to tumour, its treatment (e.g. radiation enteritis), or benign aetiologies (e.g. adhesions or internal hernia). One problem in evaluating MBO outcomes in the literature is the myriad of definitions that are utilized. An accepted definition that allows for comparison across studies and hopefully can provide the framework for a clinical trial is the following: (a) clinical evidence of a bowel obstruction via history, physical exam, or radiographic examination, (b) bowel obstruction beyond the ligament of Treitz, (c) intra-abdominal primary cancer with incurable disease, or (d) non-intra-abdominal primary cancer with clear intraperitoneal disease (Anthony et al., 2007). The goals of treatment include relieving nausea and vomiting, allowing oral intake, alleviating pain, and permitting the patient to return to their chosen care setting. Persistent obstructions in the face of conservative therapy (usually nasogastric decompression, hydration, and bowel rest) or evidence of complete obstructions are indications that a surgical procedure should be considered. Surgery should be contemplated for all patients with MBO except those who are actively dying.

Options for MBO

There are a myriad of situations one might encounter in the operating room; typically the approach is unknown until exploring the abdomen. The optimal procedure is that which is the quickest, safest, and most efficacious in alleviating the obstruction. If due to adhesions, adhesiolysis might be the optimal surgical procedure. Bowel resection may lead to the best outcome (Aranha et al., 1981; Legendre et al., 2001), although bypass may be a better option when resection is not possible due to tumour burden or deemed unsafe due to operative risks. In the setting of carcinomatosis, the placement of a gastrostomy tube for intermittent venting might be optimal. An intestinal stoma may be necessary after resection or to adequately bypass the blockage. Laparoscopic procedures may be attempted, although this approach may be difficult due to adhesions, carcinomatosis, or bowel dilatation. Cytoreductive procedures (resection of intraperitoneal tumour) frequently carry a high morbidity and usually are only considered with very low-grade tumours, such as pseudomyxoma peritonei. Many patients are deemed inoperable (6.2–50%) (Feuer et al., 1999). This may be due to poor operative risk or contraindications to surgery. Poor operative risk must be assessed based on co-morbidities (e.g. cardiac and pulmonary function), amount and location of metastatic disease (e.g. overwhelming metastasis to the liver), and current functional status (e.g. Karnofsky < 50%). Potential contraindications for surgery in patients with incurable cancer and MBO include ascites (> 3 L) and particularly ascites that rapidly recurs after drainage, carcinomatosis, multiple obstructions, or a palpable intra-abdominal mass (Ripamonti, 1994).

Endoscopic approaches for MBO

Endoscopic procedures are suited for patients who are poor operative candidates or who decline an open operative intervention. They also may obviate the need for an intestinal stoma. The major approaches include stenting and percutaneous endoscopic gastrostomy (PEG) tube placement. Stenting may include procedures to initially canalize the lumen (e.g. laser or balloon dilatation). PEG tubes are generally well tolerated 'venting' procedures that can alleviate symptoms of intractable vomiting and nausea for upper GI obstructions (Campagnutta and Cannizzaro, 2000). A study from MD Anderson Cancer Center, Texas, United

States, found that percutaneous gastrostomy tubes were utilized for palliation in 23% of small bowel obstructions in patients with advanced malignancy (Badgwell et al., 2011). In combination with other medical techniques, both open and percutaneous gastrostomy offers the possibility of intermittent oral intake.

Outcomes of MBO

Although it is recognized that improvement in QOL after surgery is variable (42–85%) (Feuer et al., 1999; Miner et al., 2002), there is no consistent parameter used to determine this clinical outcome; operations may offer an advantage of an increased survival. Surgical risks must be carefully considered prior to an operation, as morbidity (42%) (Makela et al., 1991) and mortality (5–32%) (Makela et al., 1991; Feuer et al., 1999; Legendre et al., 2001) are common, and the re-obstruction rate is high (10–50%) (Feuer et al., 1999; Miner et al., 2003). Poor prognostic indicators for surgical intervention include ascites, carcinomatosis, palpable intra-abdominal masses, multiple bowel obstructions, prior obstructions, and very advanced disease with poor performance status.

Endoluminal wall stents have a high success rate for relief of symptoms (64–100%) in complete and incomplete colorectal obstructions (Harris et al., 2001), and in over 70% of upper intestinal malignant obstructions including gastric outlet, duodenal, and jejunal obstructions (Soetikno and Carr-Locke 1999). While risks include perforation (0–15%), stent migration (0–40%), or re-occlusion (0–33%), stents can frequently lead to adequate palliation for long periods of time (Harris et al., 2001). Stent occlusion by tumour in-growth is usually amenable to another endoscopic intervention. Complications related to PEGs are rare, even when puncturing other organs (Campagnutta and Cannizzaro, 2000). The presence of significant ascites is a relative contraindication.

Gastric outlet obstruction

Indications of gastric outlet obstruction

There is some controversy as to when to do a surgical procedure for gastric outlet obstruction. Typically, these procedures are considered in the setting of persistent nausea, vomiting, eructation, and early satiety. They also may be considered when there is evidence of duodenal compression on radiographic or endoscopic evaluations. Stents for gastric outlet obstruction are noted to be quite successful (approximately 90%) with rare complications (Kim et al., 2001; Kaw et al., 2003), making an operative approach less common. If the stent fails due to tumour in-growth or migration (around 10%), another stent can often be placed (Kim et al., 2001; Kaw et al., 2003). Unfortunately, few centres have clinicians with the technical ability to accomplish this procedure successfully.

In the setting where a biliary bypass is planned, there is some controversy as to whether to do a pre-emptive gastric bypass (gastrojejunostomy) in the asymptomatic patient. Late gastric obstruction occurs from 9% to 23% (Holbrook et al., 1990; Huguier et al., 1993; Coene et al., 1994), and this must be considered at the time of biliary bypass. If the patient is of good performance status with limited disease (no or minimal metastasis), then a pre-emptive procedure may be indicated.

Options for gastric outlet obstruction

The surgical options for gastric outlet obstruction are a bypass procedure (gastrojejunostomy) or a resection (antrectomy or pancreaticoduodenectomy). There are several technical variations of a gastrojejunostomy, but the results are similar. This can be achieved via open or laparoscopic techniques (Choi, 2002). A distal gastric tumour may also be resected with a palliative intent. Percutaneous gastrostomy is also an option, with some centres reporting use in almost a quarter of their patients with gastric outlet obstruction and advanced malignancy (Miner et al., 2002).

Outcomes of gastric outlet obstruction

If endoscopic expertise is available, stenting is often preferable for gastric obstruction. If endoscopic stenting fails for the gastric outlet blockage or is unavailable, open or laparoscopic bypass is warranted. For those undergoing laparoscopic exploration for resection and found to be unresectable, it is reasonable to discontinue the procedure and then attempt an endoscopic procedure. If the expertise is unavailable, an operative bypass is warranted. If exploration via an open procedure reveals that the patient is unresectable, it is reasonable to bypass the patient.

It has been shown that symptomatic patients (vomiting prior to operation) typically have a poor outcome (approximately 90% did not have relief of symptoms) to gastric bypass. In comparison, if patients were not symptomatic but had evidence of impending obstruction, only about 40% had a poor outcome (Weaver et al., 1987). One consideration as to the reason for this is that symptomatic patients are potentially sicker with a greater tumour burden.

Gastric outlet obstruction has been safely treated with a laparoscopic gastrojejunostomy. In fact, for unresectable gastric cancer this technique has been shown to have less suppression of immune function, less pain, shorter hospital stays, lower postoperative morbidity, and earlier recovery of bowel movements than an open procedure (Choi, 2002).

Antrectomy along with gastrojejunostomy in the setting of unresectable pancreatic cancer has been shown to have excellent results until death in one small series (Lucas et al., 1991). There is limited evidence in the literature to support this procedure in the setting of gastric outlet obstruction, and a simpler bypass may be more reasonable.

Wounds/fistulae

Indications of wounds/fistulae

There are multiple different kinds of wounds related to advanced cancer that require the involvement of a general surgeon and wound problems represent approximately 10% of all palliative surgical consultations (Badgwell et al., 2009). These are often directly related to tumours, but may be due to treatments such as surgical procedures or radiation therapy. Tumour-related wounds can be seen with primary, recurrent, or nodal manifestations of tumours. Primary cancers that frequently lead to wound problems include breast cancer, skin cancers, soft tissue sarcomas, or soft tissue manifestations of other cancers (e.g. lung cancer). Special consideration must be taken related to the primary tumour type. As treatment approaches are frequently multidisciplinary, it is important for the surgeon to include other specialists, including medical and radiation oncologists, in the decision-making. Procedure-related wounds may be due to node dissections, local resections, or simple incisions. Radiation may lead to non-healing ulcers at resection sites. Finally, due to debilitation, patients may have pressure sores which complicate their overall course and lead to suffering. In the debilitated patient, pressure sores are more likely to occur. It is unlikely that there would be an indication for a major procedure for this complication, although minor procedures may be helpful.

Fistulae, like wound problems, may occur in patients who are facing the end of life for various reasons. Fistulae are a heterogeneous group of problems. A fistula is simply a communication of one structure to another, including bowel to bowel, bowel to skin, or pancreas to skin. Fistulae may be a complication of procedures, such as pancreatic fistulae after a resection, or due to other treatments, such as a radiation therapy leading to enterocutaneous fistulae. These problems may be extremely difficult to cure, especially in the setting near death. Indications for surgical options are rare.

Options for wounds/fistulae

Prevention of wounds is of primary importance. For example, resection of a nodal or soft tissue metastasis can simply be excised to avoid the potential wound problems that will ensue if ignored. Another preventative consideration is related to pressure wounds. This entails ensuring patients are not stationary for long periods of time. Once a pressure sore has started, it can be difficult or impossible to heal.

Many wounds, especially related to radiation injury or in the severely malnourished, may not heal. Therefore, this should not be a goal of treatment, but focus should be on control of pain, odour, and mess. Wound care is of primary importance. This may include local debridement as indicated to keep the wound as clean as possible. While surgical options for wounds are limited, operative intervention has been reported in 38% and primarily involves incision and drainage or debridement (Badgwell et al., 2009). Only a minority of patients are able to undergo wide excision and closure of tumours causing wound problems.

One example of a chronic wound problem is chest wall complications of breast tumours. There are many articles in the nursing literature regarding local wound care. Chemotherapy, especially if the patient is chemo-naive, is an option. Radiation therapy, although unlikely to have a great effect with a very large tumour, is possible. Of course, surgical resection is an alternative. The term 'toilet' mastectomy is used in the setting of a fungating incurable breast cancer to remove the tumour with the intent of wound control. It is always important to know the previous treatments to better understand possible success. This will also help to identify the optimal reconstruction alternatives as well as the extent of resection that is possible. The surgical literature is not very helpful in directing the extent of resection, and this must be based on surgeon judgement.

Reconstruction options include primary closure, skin grafts, and an omental flap with skin graft, musculocutaneous flaps or free flaps. The major surgical complications that must be considered include infection, open wounds, and flap loss.

Additional morbid options are possible based on the site of the tumour and medical status of the patient. These may include amputations, limb perfusions, and major head and neck resections. While these options may seem quite radical in the setting of palliation, they may be reasonable solutions based on symptoms and if the patient can withstand a large procedure.

While treatment options for fistulae in the patient with advanced cancer may not significantly differ from those not facing the end of life, there are many issues in this population that necessitate special consideration. As with the non-advanced cancer patient, controlling fistulae is the most important treatment. For cutaneous fistulae, this may be through the utilization of stoma bags, drains, or active wound care. For internal fistulae, such as bowel communicating to bowel or bladder, the specific anatomy of the communication is paramount to decide if a surgical option is reasonable.

Outcomes of wounds/fistulae

There have been many reports concerning local wound care for tumour-related wounds. Most of these are in nursing journals. This component of care is extremely important, and has been shown to have great impact on QOL. For example, controlling odour and seepage has been shown to lead to less isolation, greater comfort, and increased psychosocial well-being (Lund-Nielsen et al., 2004). This straightforward approach to some wounds will lead to the best outcomes for many patients facing the end of life.

Multiple reports have focused on chest wall resections for breast cancer. These were either related to recurrent disease or an initial presentation of a fungating breast tumour. Many different reconstruction techniques have been shown to be efficacious, including myocutaneous or omental flaps. The recurrence rates in this setting may be high. In one small series it was noted to be 73% (Cheung et al., 1997), and 20% to 52% in some of the larger series (Flook et al., 1989; Sweetland et al., 1995; Downey et al., 2000; Henderson et al., 2001). The majority of these recurrences were quite small though, and could be locally excised or observed in patients who already had other major metastatic disease. Local wound morbidity is variable, and most are quite minor, such as local skin necrosis in a skin graft which will not have great impact on the patient's life. Importantly, if there is major local wound morbidity, this could have a profound effect on the patient for the remainder of their life.

Related to amputation, there are multiple small reports that do indicate good to excellent palliation (Paz, 2004). Complications may be over 50%, including flap necrosis, infection, and death. Complication rates will depend on the extent of amputation. In addition to amputation, limb perfusion most commonly utilizing melphalan with or without tumour necrosis factor-alpha (TNF-α) has been advocated in some centres for melanoma or sarcoma recurrences. Complete response rates are 45–72%, usually greater if TNF-α was used (Noorda et al., 2006). Importantly, it has been shown that QOL can be excellent, with reasonable long-term function.

Related to fistulae, there is little evidence specific to the end-of-life patient. Therefore, non-surgical techniques are usually optimal. One can look to the non-palliative literature for guidance, but in patients with limited survival, this is unlikely to be a sufficient guide.

Biliary obstruction

Indications of biliary obstruction

Tumours causing obstruction of the extrahepatic bile duct may also occur all along the biliary tree, most likely at the ampulla of Vatar (see also Chapter 10.4). Blockages must be treated expediently as this will lead to hyperbilirubinaemia which may become symptomatic, leading to pruritus, bleeding diathesis, and liver failure. Surgical involvement today is often in the instances of a failed endoscopic retrograde cholangiography procedure (ERCP) stenting or inoperability at the time of surgical exploration for a presumed resection with a curative intent. There are multiple studies comparing methods, especially stenting versus surgery (Bornman et al., 1986; Shepherd et al., 1988; Andersen et al., 1989; Dowsett et al., 1989;

Smith et al., 1994; Moss et al., 2006; Moss et al., 2007). Endoscopic stenting has been shown to have similar success rates as surgery with less morbidity. However, the risk of recurrent biliary obstruction prior to death is higher in patients undergoing endoscopic stent placement. One approach is to perform endoscopic stent placement in patients considered to have short life spans with limited potential for recurrent obstruction and perform surgical bypass for patients with less aggressive tumours, longer expected life expectancy, and limited access to endoscopic expertise for treatment of recurrent obstruction. Metal stents are reported to have improved patency compared to plastic stents yet there is currently insufficient evidence to make a statement comparing metal stents to surgery. If the bile duct is entered via the ERCP but a stent could not be placed, it may necessitate a relatively urgent surgical procedure due to the potential cholangitis risk. If urgent surgery is not realistic due to patient co-morbidities, overall status, or operating room availability, a transhepatic drain placed by an interventional radiologist is indicated. If a laparoscopic exploration is first undertaken for a potentially resectable mass and metastatic disease is noted, it is reasonable to abort the procedure with the hope that a less morbid endoscopic stenting can be accomplished. Also, if endoscopic stenting fails or is unavailable, open or laparoscopic bypass is warranted. If at open exploration the patient is found to be unresectable, it is reasonable to proceed with a surgical intervention.

Options for biliary obstruction

There are multiple surgical options to bypass the biliary system. They include cholecystojejunostomy, choledochojejunostomy, or choledochoduodenostomy. In addition, the bypass may be performed higher along the duct to the hepatic duct (above the cystic duct). While these procedures may be undertaken with a laparoscope, few surgeons have the technical skills for this procedure (Krouse, 2004). Importantly, in the appropriate operative candidate, a pancreaticoduodenectomy (Whipple procedure) is an option. While the surgeon should not proceed with a Whipple procedure if there are clear signs of metastasis to the liver or other organs or invasion of major vascular structures, many surgeons will complete the procedure if there is limited local nodal disease.

Outcomes of biliary obstruction

The overall morbidity of surgical bypass is almost 20%, and the recurrence rate is 0–15% (Bornman et al., 1986; Shepherd et al., 1988; Andersen et al., 1989; Dowsett et al., 1989; Smith et al., 1994). It has been shown that choledochoduodenostomy has the fewest complications at only 3% (Potts et al., 1990). Of course, the ability to mobilize the duodenum may not be possible in all patients. There have been several reports of laparoscopic biliary bypass of malignant biliary obstructions, mainly via cholecystojejunostomy, although hepaticojejunostomy also might be performed (Gentileschi et al., 2002), though it requires expertise available in only a few centres. Palliative pancreaticoduodenectomies are infrequently performed and likely represent a prohibitive risk for surgery, although there is little data upon which to base such decisions.

Bleeding

Indications of bleeding

Tumour-related bleeding is frequently difficult to treat, especially with patients who may have a coagulopathy related to illness or treatments. Bleeding may be related to superficial tumours such as recurrent breast, head and neck, or sarcomas. Symptoms related to deeper tumours include haemoptysis (e.g. primary or metastatic lung tumours), haematemesis (e.g. gastric cancer), melena or haematochezia (e.g. colorectal tumours), vaginal bleeding (e.g. cervical or endometrial carcinomas), or haematuria (e.g. renal or bladder tumours). Surgical intervention for gastrointestinal bleeding is infrequently required in palliative surgical evaluation (14%) and most often involves bowel resection (Miner et al., 2002). Indications for surgical involvement will be related to location of the tumour and whether another approach is less morbid and has a reasonable chance at success. Non-surgical options include radiation therapy, arterial embolization, endoscopic procedures and bronchoscopic techniques.

Options for bleeding

Obviously, there are multiple reasons for bleeding leading to a very heterogeneous group of patients, and the optimal surgical option will depend mainly on the location and reason for bleeding. For example, if there is superficial tumour bleeding, direct suturing may be possible. It must be considered though, that the bleeding may be diffuse and simple suturing may not be efficacious. Therefore, resection may be indicated. For deeper tumours, such as colon tumours, a resection may more clearly be the best option. Rectal tumours, which necessitate larger, more complex procedures and probably an intestinal stoma, may be better served first with non-surgical attempts (e.g. radiation therapy or interventional radiology embolization). The success of alternative approaches will be based on the availability and expertise at each institution.

Outcomes of bleeding

The outcomes to the treatment of bleeding depend specifically on the treatment approach and the aetiology of the bleeding. Resecting a bleeding tumour will universally stop the bleeding, but there may be added surgical morbidity and mortality than if the operation was performed in the non-emergent setting. Other options to temporize the situation or attempt to alleviate the need for an operation, such as an embolization procedure, may carry a greater risk of recurrence of bleeding but will often be less morbid than a major operation. Of course, this may be quite variable and depends on the tumour location.

Malignant ascites

Indications of malignant ascites

Ascites may be due to overwhelming liver metastasis, cirrhotic liver disease, or carcinomatosis (see also Chapter 10.4). It can be a difficult management problem, and treatment may be determined by the extent of ascites, condition of patient, or aetiology. If ascites is minimal, no therapy is indicated. Treatments will be necessary with larger volumes of ascites, which can lead to discomfort, fullness, or respiratory problems. Surgical options should be considered if diuretics no longer are helping or percutaneous aspirations are becoming painful and frequent. In addition to improving patient comfort, a reasonable indication for surgical interventions is to ease the burden of care. If the patient has very advanced disease, simpler approaches should be initiated. If the patient has a longer lifespan, more invasive techniques may be considered.

Options for malignant ascites

Probably the simplest surgical techniques are the insertion of permanent intraperitoneal drainage catheters. This will allow serial

drainage of fluid by the patient or their caretaker. Catheters can be placed surgically or by the interventional radiology team via computed tomography (Mercadante et al., 1998) or ultrasound guidance (O'Neill et al., 2001). Multiple types of catheters have been used, including a pigtail catheter, peritoneal dialysis catheters (e.g. Tenkoff catheter), pleural cavity catheters (e.g. Pleurx® catheter), fenestrated port-a-catheters, and even a Foley catheter (Richard et al., 2001; Rosenblum et al., 2001; Barnett and Rubins 2002; Iyengar and Herzog 2002; Kuruvillea et al., 2002). The patient and/or caregiver can be trained to drain excess peritoneal fluid when the patient is symptomatic.

Another option for malignant ascites is a peritoneovenous shunt. The two most common are the LeVeen or Denver® shunt. Ascitic fluid travels from the peritoneal cavity into the venous circulation due to higher peritoneal pressures. Surgeons are often apprehensive to perform this procedure due to the historical catastrophic complications, including sepsis, disseminated intravascular coagulation (DIC), heart failure, and pulmonary embolism leading to a rapid death. In addition, patients often die within 1 month of their procedure due to their poor general condition (Smith et al., 1989).

Hyperthermic intraperitoneal chemotherapy (HIPEC), without cytoreduction, is an accepted approach for palliation of malignant ascites with good early data. In addition, this procedure can be performed laparoscopically in an attempt to minimize complications (Valle et al., 2009). A much more invasive surgical technique includes a major debulking of carcinomatosis followed by intraperitoneal hyperthermic chemotherapy. This procedure is only available at specialized institutions but will likely be infrequently performed for palliation in the future based on the results emerging from HIPEC without cytoreduction and laparoscopic HIPEC (Facchiano et al., 2012).

Outcomes of malignant ascites

The success rates for permanent intraperitoneal catheters functioning until death is quite high (90%) (O'Neill et al., 2001; Barnett and Rubins, 2002). There is low procedural morbidity. The major complications are obstruction and infection, and are around 17% (O'Neill et al., 2001; Barnett and Rubins, 2002), although catheter sepsis has been reported to be 35% (Lee et al., 2000). To avoid infection there must be meticulous insertion technique, close patient follow-up, and liberal use of antibiotics (O'Neill et al., 2001). In fact many catheter-related infections can be treated with antibiotics (Kirk et al., 1993). Sometimes the catheters may need to be removed due to infection, occlusion or leakage around the catheter. Leakage has been reported to be alleviated by continuous drainage (Barnett and Rubins, 2002) or a suture around the drain (Lee et al., 2000).

While the incidence of major complications may be less common than previously reported for peritoneovenous shunts, the overall complication rate can be quite high (14–51%) (Smith et al., 1989; Bieligk et al., 2001; Zanon et al., 2002). DIC is the major complication that most frequently will lead to patient death. It has been reported from 5% to 10% of these procedures. Congestive heart failure is another major complication. The more common complication is shunt occlusion. The advantage of the Denver® shunt over the LeVeen shunt is that the Denver® shunt has a pump to help the shunt remain patent (26% Denver® vs 50% LeVeen shunt occlusion rates) (Bieligk et al., 2001). Denver® shunts have been shown to have quite high function of these shunts until death

(96%) (Zanon et al., 2002). The risk of infection is variable (0–18%) (Zanon et al., 2002), and this may lead to shunt removal if not relieved with antibiotics. Importantly, relief of symptoms can be as high as 87.5% (Zanon et al., 2002). Therefore, a peritoneovenous shunt may be an excellent option in properly selected patients.

In the carcinomatosis patient, cytoreduction and intraperitoneal chemotherapy can have dramatic effects on ascites. In one report, 79% of patients did not have recurrence for the remainder of their life (median survival 7.6 months) (Loggie et al., 2000). Surprisingly, their group has also shown that this procedure can lead to an acceptable QOL and return of function status for many patients (McQuellon et al., 2007). Palliative treatment of malignant ascites with cytoreduction and HIPEC may be of historical interest only as the contribution from cytoreduction may be minimal based on reports of laparoscopic HIPEC. Laparoscopic HIPEC without cytoreduction is a less technically demanding procedure with a shorter length of stay and decreased risk of surgical complications. A recent systematic review of 76 patients undergoing palliative laparoscopic HIPEC reported the procedure was considered successful in 72 patients (95%), defined as complete regression of ascites, with no deaths and a morbidity rate of 12% (Bieligk et al., 2001). Laparoscopic HIPEC appears to be safe and highly effective for the treatment of malignant ascites. The morbidity, although low, suggests this procedure is best utilized in settings of ascites refractory to less aggressive treatments (Cavazzoni et al., 2013). The improvement in ascites and lack of a need for catheters or follow-up procedures is encouraging but it should be noted that none of the studies of palliative laparoscopic HIPEC have included symptom assessment or QOL outcomes measures.

Splenomegaly

Indications of splenomegaly

Splenectomy due to splenomegaly may be on an urgent/emergent basis due to injury, or in an elective setting related to symptomatic splenic hypertrophy. Splenomegaly may have profound symptoms due to a mass effect, most commonly on the stomach leading to early satiety. Large spleens may also compress other structures, such as the kidney. In addition, splenomegaly may lead to an increased chance of injury, with consideration of a prophylactic splenectomy to avoid such a complication. Related to splenic trauma, in the non-palliative setting it is common to try to preserve the spleen and avoid an operation. In the context of a patient facing the end of life, splenic preservation is less of a priority and may be more dangerous. Therefore, urgent splenectomy is usually indicated in this setting, provided the patient is an operative candidate. For symptomatic splenomegaly, the choice of treatment is usually related to the anticipated survival of the patient and the estimated operative risks. If the patient is felt to have a survival of at least 3–6 months, an operation is usually the best alternative as the recurrence rate related to radiation for haematological disorders is quite high (Weinmann et al., 2001). If survival is predicted to be low, it is reasonable to attempt radiation therapy.

Options for splenomegaly

Splenectomy can frequently be accomplished via laparoscopy. Laparoscopically, splenic tissue is removed via morcellation. This is acceptable as margin of resection is not of significance in this setting. Some feel that laparoscopic splenectomy is the procedure of choice for elective spleen removal (Rosen et al., 2002). Massive splenomegaly may make a laparoscopic procedure difficult or

impossible. Open splenectomy may carry a higher morbidity and mortality, especially in this sick population. In the setting of splenic trauma, a laparoscopic approach may not be reasonable.

Outcomes of splenomegaly

Laparoscopic splenectomy has been reported to carry a complication rate of 13%, and a mortality of 1%, with decreased hospitalization and pain (Brodsky et al., 2002). These rates are likely to be higher in the setting of advanced cancer. Use of a hand port (the introduction of a surgeon's hand into the peritoneal cavity to assist the procedure) may greatly facilitate the operation, and is advocated by some surgeons especially for significantly enlarged spleens (Hellman et al., 2000; Targarona et al., 2001; Ailawadi et al., 2002; Rosen et al. 2002). While port-site splenosis has been documented (Kumar and Borzi, 2001), this is unlikely to be an issue for patients facing the end of life. Only a surgeon skilled in the procedure should undertake laparoscopic splenectomy in a patient with massive splenomegaly (Terrosu et al., 2002; Targarona et al., 2000). No matter how a spleen is removed, obstructive symptoms such as early satiety should ultimately be resolved. There is little data on palliative splenectomy in advanced cancer patients upon which to base treatment decisions. The majority of reports focus on splenectomy in patients with myelofibrosis with myeloid metaplasia. In a study from the Mayo Clinic, Minnesota, United States, 76% of patients experienced a palliative benefit, although morbidity was 28% with a 7% mortality rate (Mesa et al., 2006). Until better evidence-based guidelines are available, surgeons will continue to rely on their best estimation of operative risks, which are considerable, in relation to the anticipated symptom improvement in the background of life expectancy.

Hormonal control of hepatic metastases of neuroendocrine tumours

Indications of hormonally active tumours

The surgical goals of treating hormonally active tumours (i.e. metastatic gastrointestinal carcinoid, insulinoma, gastrinoma, VIPoma) are to limit or minimize the endocrine symptoms or to lessen the medications patients are currently taking. Nonfunctional endocrine tumours may lead to fatigue or pain, and it may be reasonable to attempt an intervention to relieve these symptoms. When surgery is not an option or felt to be too high risk in a patient that is not achieving acceptable palliation with biotherapy, transarterial embolization (alone or with chemotherapy) is a good palliative treatment modality.

Options for hormonally active tumours

Invasive options for symptomatic endocrine tumours are based on location of the tumour, type of tumour, and alternative treatment options. For pancreatic neuroendocrine tumours, aggressive surgical treatment of the primary tumour is usually indicated (Schurr et al., 2007). For metastatic gastrinoma, total gastrectomy may also be indicated, although newer medications may alleviate the necessity for such a drastic procedure. While somatostatin analogues frequently modulate symptoms in the setting of liver metastases, it may be short-lived and necessitate increasing doses. The major invasive options for liver metastasis include surgical debulking or ablative techniques. Surgical debulking may necessitate a major hepatectomy or segmental ('wedge') resections. The major ablative technique currently utilized is radiofrequency ablation (RFA), which is associated with low morbidity and mortality (Erce and Parks, 2003). RFA also allows options to perform open, laparoscopic or radiologist-guided procedures. Finally, it has even been suggested that liver or multivisceral transplantation is a therapeutic option for metastatic neuroendocrine tumours (Olausson et al., 2007).

Outcomes of hormonally active tumours

In addition to minimizing treatment-related complications and shortening hospital stays, ablative techniques can also offer improved QOL in the treatment of pain and tumour hormone output. Anecdotal accounts and small series have shown RFA to be useful in treating metastatic endocrine tumours, but the long-term outcomes are not yet known. Laparoscopic RFA has been shown to achieve symptomatic improvement in patients with secreting neuroendocrine tumours (Siperstein et al., 1997; Berber et al., 2002). This technique does not require an advanced skill set, but does have a learning curve to efficiently complete procedures. The laparoscopic approach should be considered for patients with symptomatic neuroendocrine liver metastases, although the procedure may be difficult to accomplish in the setting of extensive adhesions.

While ablation of metastatic neuroendocrine tumours is an option for some patients with bulky disease, radical resection with or without ablation must still be an alternative for these patients. As there is a more defined long-term history with radical resection of metastatic hepatic tumours, it should remain the first choice of care in the appropriately selected patient. The surgery must accomplish a significant reduction of tumour bulk to have a symptomatic response, although this number is difficult to quantify (Gronbech et al., 1992). Nevertheless, cytoreductive surgery for selected patients with carcinoid tumours does seem to accomplish a symptomatic advantage related to relief/prevention of obstructions or relief of the carcinoid syndrome (Chamberlain et al., 2000; Gulec et al., 2002). Resection and ablative techniques, when followed by a somatostatin analogue, can lead to extremely high rates of long-term symptom-free survival (Chung et al., 2001).

There are limited reports of liver or multivisceral transplantation in the setting of metastatic neuroendocrine tumours. A recent report has shown a 5-year survival of 90% (N = 15) (Olausson et al., 2007). The QOL benefit is unclear. While this may be a consideration, the experience is quite small and therefore should be attempted with trepidation.

Future directions

Technology

As technology improves for the surgical treatment of tumours for cure, this will also have impact on palliative care. For example, the use of RFA techniques, chemoembolization, and radioactive TheraSphere® for primary hepatomas and metastatic colorectal cancers also has a role for the less common endocrine metastases. Many other technologies, including minimally invasive techniques can effectively treat complications related to tumours or their care with less morbidity.

Education

While education of the surgeon has been lacking, its importance is being increasingly recognized, which will lead to improved patient

care. The reasons for a lack of focus on end-of-life care in surgical residency programmes are multifaceted, and are based in the culture of surgeons and the clinical dilemmas they face. First, many surgeons may not feel comfortable or competent with end-of-life issues. This is in part due to the 'cut to cure' mentality that has been passed on through the generations. Medical students over the years have been drawn to surgery because they want to 'fix' the problem. In the setting of the cancer patient with advanced disease, where cure is not an option, then QOL must be the focus as the problem to be 'fixed'.

While all medical specialties have been remiss in the teaching of palliative care, general surgery has been especially deficient. Surgical textbooks are inferior to all others in ensuring that end-of-life topics are addressed. One investigation revealed that 71.8% of all end-of-life topics were not included in the leading surgery textbooks (Rabow et al., 2000). Furthermore, in a survey by the Society of Surgical Oncology, 48% of respondents said they had had no palliative care training while in medical school (McCahill et al., 2002), and 30% of the respondents had had no training in these issues during their residency or fellowship training. Almost 80% reported 10 hours or less of such instruction during all of their training. This confirms a previous report that surgical training is deficient in adequately educating residents in end-of-life care (Rappaport et al., 1991). Of greatest concern, however, is the lack of postgraduate CME in end-of-life care, as 23.6% of surgeons with a special interest or focus in cancer said that they have had no continuing education in palliative care.

The American College of Surgeons has recognized the need for increased palliative surgical education and has created an education tool to assist residents and surgeons in improving palliative care for surgical patients and their families (American College of Surgeons 2009). In addition, the American College of Surgeons created the Surgical Palliative Care Task Force, now the Committee on Surgical Palliative Care, as part of their Division of Education to meet the Promoting Excellence in End-of-Life Care National Program Office priorities by gathering data and developing tools to help surgeons become more effective in palliative care.

Research

There is currently a paucity of prospective palliative studies in the surgical literature (Miner et al., 1999). This is for many reasons, including ethical considerations in surgical palliative care studies (Krouse et al., 2003). Issues such as vulnerability of patients or the clinician as the researcher are not exclusive to palliative research, but they certainly are highlighted in the advanced cancer setting. There are matters unique to palliative research itself, such as the lack of clarity of the risk-benefit relationship. Another concern is with randomization, which can be quite difficult, especially if there is a placebo arm. A placebo arm is likely impossible in a palliative surgery trial. Finally, there are issues unique to surgical palliative research in that surgery is obviously quite invasive. In addition, once a procedure is completed it is difficult or impossible to reverse, unlike a chemotherapy trial where the medication can be stopped.

In addition to ethics, there are other barriers to surgical research on those with advanced cancer. These include surgeon and procedure variability, patient and family agreement to participate in a trial, the consent process (especially if there are mental status changes or no family member available), inaccessibility of patients

based on referring practitioner bias or patients being in hospice care, and the high attrition rate associated with palliative surgical interventions. This has proved difficult in outcomes assessment for prospective observational studies comparing operative to non-operative management. In a recent prospective observational study of patients undergoing palliative surgical consultation, 40% of the patients died prior to completion of the study at 3 months (Badgwell et al., 2013).

Research in the advanced cancer patient is important to pursue to improve patient care related to treatment alternatives, but also to improve the care by the surgical team. In assessing QOL in extremity sarcoma trials, it was observed that the very act of trying to determine what QOL means to people seemed to have had a humanizing effect on the investigative team (Sugarbaker et al., 1982). Therefore, additional importance placed on palliative care through research could lead to greater importance of QOL issues for surgeons.

Importantly, as standard methods of research may not be applicable or possible in the palliative surgery setting, researchers must consider alternative methodologies to examine optimal care questions. This likely will mean utilizing comparative effectiveness techniques to include alternative outcome measures (rather than survival, mortality, and morbidity), as well as novel statistical manoeuvres to assess surgical treatment benefit. In addition, surgical questions beyond the outcomes of an actual operation should be examined, such as costs, communication issues, and symptom prevention.

Conclusions

Palliative procedures are an important component of the practice for general surgeons who care for cancer patients. It is imperative to understand the surgical and non-surgical options afforded each patient. If a surgical procedure is considered, the patient, family, and treating teams must have a firm understanding of realistic goals of success which focus on QOL. In addition, the chances of attaining those goals must be understood. Finally, the risks of the procedure, including worsening of symptoms and death must be clearly described. As long as these criteria are met, surgical procedures may be undertaken in the setting of terminal cancer. In addition, surgeons should maintain follow-up with the patient whether they operate or not. If an alternative approach is attempted, there may be evolution of disease and surgical intervention may be subsequently indicated. Importantly, the surgeon should continue to follow their patient if at all possible, even if no surgical procedure is undertaken, especially if a relationship has been established. Care of patients by a surgeon includes much more than the operations they perform.

Orthopaedic surgery in the palliation of cancer

John H. Healey and David McKeown

Introduction to orthopaedic surgery in the palliation of cancer

Orthopaedic surgery is a powerful tool in the palliation of pain and disability in cancer patients who develop metastasis to bone, with the capacity to maintain quality of life and, occasionally, extend life. Even in late-stage disease, orthopaedic surgery plays an important role in cancer care and may be the definitive method to relieve pain and maintain patient independence, as well as assist in terminal care. In order to guide the complex decision-making in the care of these patients, the clinician must employ a broad understanding of metastatic bone disease and a specific understanding of appropriate surgical techniques. This chapter provides the context in which to evaluate patients with metastatic bone disease and offers management guidelines for common disease patterns.

Bone metastases are a significant source of morbidity and mortality among cancer patients. Annually, approximately half of patients who die from cancer have metastatic disease (American Cancer Society, 2006). Progression of primary carcinoma to bone is most commonly associated with breast, prostate, lung, kidney, and thyroid cancers (Coleman, 2001). Metastasis to bone occurs during the course of disease in 75–85% of patients with advanced prostate or breast cancer, in as many as 40% of patients with lung cancer, and in about 25% of those with renal cancer (Coleman, 1997). Improvements in treatment during the past few decades have prolonged the survival of patients with advanced disease. The long-term survival of patients with metastatic bone disease varies according to the type of primary lesion, with a median survival of 40 months for prostate cancer, 24 months for breast cancer, 48 months for thyroid cancer, and less than 6 months for lung cancer (Rubens and Coleman, 1995). In certain situations, surgical intervention can provide better or more prompt pain relief than available medical interventions; thus, providing pain relief to patients with metastatic disease is a common role of the orthopaedic surgeon in palliative cancer care.

Patient presentation

In addition to pathological fractures and bone pain, metastatic bone disease can lead to hypercalcaemia, spinal instability, and spinal cord compression. Knowledge of these potentially life-threatening complications is essential for all clinicians caring for patients with metastatic bone disease. Although a patient can present with any of these processes, the most common presenting sign or symptom of metastatic bone disease is pain.

Bone pain from cancer invasion can result from the mechanical instability that occurs at sites of osteoclastic bone destruction, triggered by the release of cytokines and growth factors by tumour cells. Bone pain can also result from tumour cell stimulation of primary sensory afferent nerve fibres (Goblirsch et al., 2005). Sensory afferent fibres are abundant within the periosteum and the medullary canal of bones, in close proximity to blood vessels within the haversian canals. Neurochemical studies of protein production within the spinal cord and afferent nerve fibres have shown that cancer-induced bone pain differs from neuropathic and inflammatory type pain (Honore et al., 2000). Mechanical and structural stability also play a substantial role in bone pain. The same microenvironment that contributes to nerve sensitization has a major impact on structural stability. The pH of the tumour microenvironment is known to be acidic, and osteoclasts resorb bone in a locally acidic environment (Healey, 2007). Thus, the acidity of the tumour microenvironment ultimately promotes significant bone resorption, though the degree varies in different primary cancers. Pain will occur when the structure has been affected to such a degree that microfractures propagate or the nerve supply within the periosteum is activated (Weilbaecher et al., 2011; Yoneda et al., 2011).

Bone metastases most frequently arise within the axial skeleton. Metastases to the appendicular skeleton occur most commonly in the femur and humerus (Harrington, 1997), with less frequent incidence of metastases in more distal regions. Pain in the axial skeleton may be diffuse and poorly localized, while in the appendicular skeleton, it is often more discrete. In both situations, abnormal stimulation of afferent nerve fibres can cause night pain or pain at rest, for which anti-inflammatory agents provide insufficient relief. If bone pain worsens with functional activities or weight bearing, there may be a mechanical component, as functional pain frequently indicates a bone at risk for fracture.

The clinician must identify and distinguish between localized pain within the axial or appendicular skeleton and radicular pain that radiates most commonly from the spine. Patients with radicular pain arising from metastases near the spinal nerve root will often complain of shooting pain into their legs or arms and may report symptoms of spinal stenosis or spinal canal compromise, characterized by improvement in pain with bending forward. On examination, reproduction of the patient's symptoms will occur with a straight leg raise test for the lower extremities or a positive

Spurling's test for symptoms in the upper extremities. Deep tendon reflexes and pathological reflexes must be carefully examined to rule out myelopathic symptoms as well.

Evaluation of a patient with a bone lesion

For symptomatic bone lesions from metastatic disease, patients will typically present with (a) known widely disseminated metastatic disease, (b) a known primary and a new bone lesion, or (c) an unknown primary and a bone lesion. Each scenario must be addressed differently.

In patients known to have widely disseminated metastatic disease, biopsy of a bone lesion is unnecessary. It is more important to identify the location of the pain, the type of pain, and the severity of bone involvement. In a patient with a known primary who was otherwise disease free but who now presents with a new bone lesion, imaging studies to identify other possible bone and/or visceral metastases must be undertaken and should include the initial primary site; the chest, abdomen, and pelvis; and the rest of the skeleton. In this situation, a biopsy of the most easily accessible metastatic site should be performed to confirm disease recurrence.

In patients who present with an unknown primary and a bone lesion, the other sites of involvement must be identified. Computed tomography (CT) of the chest, abdomen, and pelvis should be used to evaluate the visceral system for a primary site of involvement and/or additional metastases. A bone scan should also be performed to identify any other skeletal metastases.

Imaging of patients with metastatic bone disease

Plain radiographs

Initial evaluation of a patient with bone pain should be performed via plain radiography, with at least two views of the area of interest. Plain X-rays are especially useful in evaluating the overall structural integrity of the bone, identifying patients who can benefit from surgery, and for planning surgical interventions or areas of radiation treatment. However, plain radiography is an insensitive method for metastasis detection, as a minimum lesion diameter of 1 cm and bone mineral loss of at least 50% are required (Salvo et al., 2009). In home care and hospice environments, however, plain X-rays are a practical, cost-effective method for the initial evaluation of new pain or functional loss.

The patterns of bone destruction visible on plain radiographs may help guide treatment, and are often characterized as moth-eaten, permeative, or geographic. A moth-eaten appearance often occurs with multiple myeloma and indicates a slightly more aggressive process. A permeative pattern is seen with the most aggressive bone destruction, while a geographic pattern may indicate a slow-growing tumour process.

Bone scintigraphy

Bone scintigraphy can be extremely useful in detecting other bone lesions throughout the skeleton. It utilizes a technetium-labelled diphosphonate, which is incorporated into the hydroxyapatite mineral matrix of bone. Hence, bone scintigraphy will detect the disease progression only when new bone formation is occurring. For instance, lesions from multiple myeloma will often be cold on bone scan, despite bone destruction, due to the lack of new bone

deposition. Similarly, highly aggressive lesions that do not involve new bone deposition, such as lung carcinoma or melanoma metastases, will not be detected by bone scintigraphy. Although scintigraphy detects bone disease with a sensitivity of approximately 72–75% (Eustace et al., 1997; Hahn et al., 2011), it lacks specificity and does not provide information about structural integrity.

Computed tomography

CT is very useful for evaluating the structural integrity of bone and is helpful in preoperative planning, particularly for pelvis and spine lesions. It can also detect occult fractures in the setting of a metastatic lesion, which can be difficult to see on magnetic resonance imaging (MRI) because of marrow oedema caused by the tumour itself. It is more useful than plain radiographs because it better delineates bone involvement of a lesion and can reveal soft tissue extension.

Magnetic resonance imaging

MRI, which provides excellent contrast between normal bone marrow and tumour-involved marrow space, is a valuable tool for studying the anatomic characteristics of a metastatic lesion to bone. However, it lacks the ability to provide detailed information about the structural integrity of the bone. Therefore, it is best used in conjunction with plain films and/or CT scan. MRI of the entire spine with sagittal images is now the most efficient way to conduct an overall evaluation of the patient. It helps to avoid missing a critical remote lesion that is producing neurogenic or referred pain.

Positron emission tomography

Positron emission tomography (PET) scan is a nuclear study that utilizes ^{18}F radioactive-labelled fluorodeoxyglucose, a glucose analogue, as a tracer element. Cells with high metabolic activity, such as tumour cells, demonstrate higher tracer uptake and visually are easily distinguished from cells with normal or low metabolic activity.

PET imaging likely has diagnostic potential in the setting of metastatic bone disease, but investigations of its utility are ongoing. Like MRI and bone scintigraphy, PET does not provide information on the structural integrity of the bone and must be used in conjunction with plain radiography or CT imaging.

Therapeutic considerations in patients with metastatic bone disease

When treating metastatic bone disease, the goal is to increase the quality of the patient's remaining life, through increasing mobility, improving function, and decreasing tumour burden and pain. Often, throughout this process, multiple treatment modalities, such as systemic bisphosphonate treatment, local and global radiation therapy, hormonal therapy, and chemotherapy, must be appropriately coordinated.

Bone pain can result from local environment changes, caused by the tumour itself, that cause abnormal stimulation of afferent nerve fibres, or it can be associated with the mechanical weakening of bone. Therefore, surgical interventions can reduce pain either by mechanical stabilization of a metastatic site or by decreasing the tumour burden at a given site. The ultimate goal of almost all orthopaedic interventions in patients with metastatic disease is immediate weight bearing as tolerated, which facilitates the quickest return to normal function.

The vast majority of surgical interventions in patients with metastatic bone lesions are for the treatment of impending or existing pathological fractures. In rare instances, patients with impending or existing pathological fractures are too sick to undergo surgery or their life expectancies are too short to benefit from surgical intervention. In these patients, casting or splinting the areas of involvement may provide mechanical pain relief but will usually not provide improved function. The cast or splint should be well padded and free of any areas of increased pressure to prevent skin breakdown and ulceration. Casts should be avoided for limbs with lymphoedema, as they can cause tissue damage or compartment syndrome.

In almost all other instances, impending and existing pathological fractures should be surgically stabilized, ideally prior to actual fracture. Surgical intervention is more easily performed in this setting and the patient will experience less pain. Because pathological fractures have a poor healing rate, surgical fixation is essential for providing long-term stability to the area (Fig. 12.5.1).

It is important to note that not all fractures sustained by patients with advanced cancer are pathological tumour-related fractures. Elderly cancer patients and patients who have received androgen deprivation therapy for prostate cancer can develop osteoporotic fractures. In one population-based study, patients with prostate cancer who were treated with luteinizing hormone-releasing hormone agonists had a 19% incidence of non-pathological fractures and only a 6% incidence of pathological fracture (Krupski et al., 2004).

Classification and characterization of impending pathological fractures

Much research in orthopaedics has been devoted to identifying factors that accurately predict the likelihood of a pathological fracture developing from a metastatic lesion. Metastatic lesions that are at low risk for pathological fracture are often best treated with non-surgical systemic interventions and radiation therapy.
Fig. 12.5.1 Examples of metastatic bone lesions and surgical fixation techniques. (A) A patient with metastatic prostate cancer who developed multiple osteoblastic lesions of the pelvis and proximal femur. (B) Metastatic renal carcinoma of the right scapula, with involvement of the glenoid and entire scapula; (C) a titanium scapular replacement was used to reconstruct the area after resection of the native scapula. (D–E) A hemiarthroplasty was performed on this 40-year-old female with metastatic breast cancer to the proximal femur. A cemented long-stem component was used; note that only one side of the joint was replaced with a large head that articulates with the native acetabulum. (F) A patient with metastatic breast cancer involving the proximal femur and acetabulum was treated with a total hip arthroplasty, including a Harrington reconstruction of the acetabulum. The large pins and surrounding cement provide support for the cup component of the arthroplasty.

Patients with lesions not at risk for fractures treated in this manner have less morbidity and equal or better pain control. It is essential in the treatment of patients with metastases to distinguish these two groups of patients.

In 1989, Mirels published the first scoring system for predicting the likelihood of pathological fracture in patients with metastatic lesions (Mirels, 1989). He then analysed 78 metastatic lesions in 38 patients with various malignancies. All lesions were evaluated prior to irradiation. All patients were followed for 6 months. Patients with a score of 7 had a fracture probability of only 4%. Those with a score of 6 or less experienced no fractures during his study period. A score of 8 was associated with a fracture probability of 15%, with a false positive rate of 6%, and patients with a score of 9 had a 33% probability of fracture and a 0% false positive rate. He concluded that all patients with scores of 9 or higher should undergo prophylactic stabilization of the involved bone, while all patients with scores of 7 or less can be treated with irradiation and subsequent monitoring. For those with a score of 8, he advised further imaging studies to better characterize the lesion's extent in order to determine possible benefits of prophylactic surgery.

Unfortunately, Mirels' rating system does not include several factors that are considered important for assessing pathological fracture risk. At Memorial Sloan Kettering Cancer Center, New York City, surgery is performed in any patient with endosteal cortical destruction greater than 50%, with functional pain after radiotherapy, or with cortical defects larger than 2.5 cm or the diameter of the bone.

Bone biology and biomechanics

The overall strength and structural properties of bone are determined by the shape and distribution of cortical and cancellous bone. Cortical bone has a greater density than cancellous bone and a higher resistance to deformation and failure under given stresses. Therefore, the greater the amount of cortical bone present, the lower is the likelihood of fracture.

Bone is comprised of an organic matrix (40% total content of bone) and an inorganic matrix (60%). The organic matrix is made of collagen (90%), matrix proteins (10%), and proteoglycans (< 1%). The inorganic matrix is composed largely of calcium hydroxyapatite. Collagen in bone provides most of the tensile strength, while the calcium hydroxyapatite provides most of the compressive strength. Tumour-induced osteolysis occurs when cytokines from tumour cells stimulate osteoclast activity. The osteoclasts reabsorb the organic and inorganic components of bone and release free calcium from the calcium hydroxyapatite into the circulation. Lytic lesions trigger greater removal of both the mineral and organic components of bone, leading to greater losses in strength and stiffness. Blastic lesions, however, do not disturb the mineral content of bone and only act to disrupt the normal trabecular framework of the cancellous bone, resulting in a lower likelihood of fracture. Chemotherapy and radiation therapy also contribute to a reduction in bone strength by impairing both osteoblast and osteoclast function and compromising bone repair mechanisms (Hopewell, 2003).

Bone fracture from metastatic disease can occur through one of two processes. First, smaller osteolytic defects in the cortex can lead to stress risers, which are areas of bone where stresses are concentrated around a small hole. A 62% reduction in a bone's bending strength has been associated with a lesion diameter to bone diameter ratio of only 0.2 (McBroom et al., 1988). With smaller lesions, torsional strength is reduced more than compressive or bending strength. Torsional loads to bone occur most frequently during normal daily activities that involve turning or pivoting from a standing position. Activity such as getting up from a chair to transfer can also lead to high torsional loads. The other mechanism of bone fracture results from an open section defect that forms when a larger metastatic lesion creates a hole in the bone larger than the bone's diameter.

The location of a skeletal metastatic lesion greatly influences the likelihood of fracture. The upper extremities are generally subjected to lower stress loads than the lower extremities; therefore, lower-extremity lesions are much more likely to fracture. The proximal femur is also a majority metaphyseal area where cortical bone is thin and cancellous bone comprises the bulk of the structural integrity of the bone. Hence, the proximal femur is the most common site of pathological fracture in the appendicular skeleton.

Metastatic lesions affect not only the strength of bone, but also its healing capacity. Other factors that influence bone healing in patients with metastatic disease are radiation exposure to the area, use of systemic chemotherapy, type of surgical fixation, and histology of the lesion. In a classic study by Gainor and Buchert, bone healing in the setting of pathological fractures was examined in 129 pathological fractures. The overall fracture healing rate was 35% for all cancer types and correlated positively with longer patient survival. Multiple myeloma had the highest healing rate (67%), followed by renal cancer (44%) and breast cancer (37%) (Gainor and Buchert, 1983). Lung cancer patients with pathological fractures had the poorest healing rate; all patients died before healing had occurred. The treatment of internal fixation combined with radiotherapy resulted in the highest union rate in this study (Gainor and Buchert, 1983). Other factors that can influence bone healing in the setting of pathological fracture are nutritional status, use of hormone therapy, and pre-existing osteoporosis.

The surgical procedure chosen should provide stabilization that will last the patient's lifetime; therefore, proper assessment of life expectancy is necessary to make the best decision (Box 12.5.1). However, prediction of survival is fraught with uncertainty, because there are no reliable objective standards. Factors including staging studies, laboratory factors, patient performance status, and experienced clinical judgement account for only half of the variance of life expectancy (Honore et al., 2000). Recent work suggests that the patient's self-assessment may contribute to the accuracy of prediction, and that Bayesian analysis shows the best predictive value across different cultures (Forsberg, 2012).

Box 12.5.1   Factors predicting life expectancy

- Multiple bone involvement
- Parenchymal organ involvement
- Low absolute neutrophil count
- Hypoalbuminaemia
- Anaemia
- Hypercalcaemia.

Types of orthopaedic surgical interventions

Tumour excision

Reducing the tumour burden is an important part of orthopaedic treatment of metastatic lesions and can be accomplished through either intralesional or extralesional excision. Intralesional excision, which is the more common treatment choice, provides significant pain reduction and is associated with fewer fixation failures and a lower risk of tumour progression at the involved site.

Marginal or wide excision has been advocated for certain tumours. Marginal excision removes the bulk of the tumour by excising it just at the border where normal and abnormal tissue meet. Microscopic disease often remains, but the tumour burden is greatly reduced. Marginal excision is often performed in conjunction with arthroplasty.

Wide excision of a metastatic lesion may occasionally be indicated, particularly for patients with a long projected period of survival, such as those with renal, thyroid, or breast cancer. Complete resection of an isolated tumour can reduce the risk of local recurrence to the area and, consequently, the need for further surgery. Such a treatment strategy can improve long-term pain control in these patients (Althausen et al., 1997).

Prosthetic joint replacement (arthroplasty)

Joint arthroplasty, which is performed most frequently in the knee, hip, shoulder, and elbows, involves resection of either one side (hemiarthroplasty) or both sides (total arthroplasty) of the joint surface with prosthetic replacement of the resected joint components. In fractures that involve the epiphyseal surface of joints, healing is exceedingly poor. In such cases, the best treatment is resection of the lesion and prosthetic replacement of the joint; this strategy provides the best long-term outcome. If both sides of the joint are involved, then total joint replacement should be considered. After resection and curettage of the lesion, the prosthetic components are cemented into the remaining bone. The stem of the prosthetic component should always bypass any distal lesions by at least twice the diameter of the involved bone to prevent later periprosthetic fracture. Cement is almost always used in the setting of malignancy because the bone ingrowth required for achieving stability with a non-cemented component will typically not occur.

Plate fixation

Plate fixation provides load-bearing stability to a fracture site by supporting the weight transmitted through the bone until union of the fracture occurs. The disadvantage of this type of stabilization is that the repeated weight-bearing stresses affecting the plate can lead to screw and plate breakage. If tumour progression occurs at the site of the plate, then the screws used to stabilize the plate may also dislodge from the bone in a loss of fixation. Plates are useful devices in places where bone healing is expected to occur in a relatively short period of time; however, this rarely occurs in pathological fractures. Plates are best used in bones that cannot accommodate intramedullary devices, as in severely sclerotic medullary cavities, or to augment another type of fixation.

Intramedullary fixation

In intramedullary fixation, a rod or nail is placed down the centre of the medullary cavity of the bone. Intramedullary devices are load-sharing devices, partially bearing the weight transmitted through the bone. Because the device is in the centre of the bone, where most forces are directed, the device is subjected to less bending force than plate fixation, making fracture much less likely in the setting of slower bone healing and allowing for more immediate weight bearing. Intramedullary devices are particularly useful in diaphyseal fractures, as they are fixed proximally and distally with interlocking screws to help create torsional control at the fracture site. The implanted device can also be augmented with cement to provide additional torsional stability and prevent failure in the setting of disease progression. Any metastatic lesion should be curetted prior to insertion of the intramedullary device to help prevent seeding the rest of the bone with tumour cells.

Bone cement

Bone cement is a very useful adjuvant stabilizer of a fracture site. In a well-delineated lesion, the cement can fill the defect that remains after excision and curettage of the lesion. Bone cement has very strong compressive force resistance and can be used in conjunction with any of the above-mentioned devices to improve the torsional and compressive strength of the fixation. The barium contrast used in the cement also facilitates plain-radiograph monitoring of disease progression or recurrence at the site of cement placement. An additional benefit is the emission of large quantities of heat as the cement solidifies in the bone, destroying tumour cells and further reducing tumour burden.

In 1976, Harrington and colleagues reported on 323 patients treated with cement augmentation of conventional intramedullary fracture fixation techniques (Harrington et al., 1976). They reported 94% return to function and 85% satisfactory pain relief in their patient population.

Amputation

Amputation has a very limited role in the treatment of patients with metastatic disease. The current indications include a limb that cannot be reconstructed due to extensive disease involvement or in situations where complications of the disease leave no other options. These complications include fungating masses, recurrent infections that cannot be controlled with antibiotics, and intractable pain in a limb that has failed treatment by other conventional methods. The most common malignancies to metastasize to the hands and feet are lung, renal, and oesophageal (Healey et al., 1986). An amputation can often provide lasting pain relief for the patient with good functional outcomes.

Anatomic considerations

The type of fixation used to stabilize a fracture site or site of metastasis is dependent on the site of bone involvement. These anatomic considerations are important in choosing the correct type of stabilization in a patient.

Epiphyseal fractures

Epiphyseal fractures, which occur at the ends of long bones near or involving the articular surface, have a very poor healing rate and are not easily stabilized in the setting of malignancy. They are best treated with cemented arthroplasty, which provides a stable, pain-free joint and allows the patient to tolerate immediate weight bearing.

Metaphyseal fractures

Metaphyseal fractures create quite a dilemma in orthopaedic oncology. They frequently occur at sites where intramedullary fixation is difficult, due to insufficient bone on the joint side of the fracture to provide adequate torsional or translational stability. Therefore, the options that remain are usually plate fixation or arthroplasty. As mentioned previously, plate fixation has a high failure rate (22%) when used alone (Wedin et al., 2012). Plates are better suited for patients with radiosensitive tumours that will heal after surgery with radiation treatment, by providing support to the limb during fracture healing. Plates are also suitable for patients with longer life expectancies who can tolerate partial or non-weight bearing for a period of time, while the fracture heals. Rarely can full weight bearing be allowed on a bone that is stabilized with only a plate and screws. Cement augmentation can improve stability when plate fixation is the chosen form of treatment.

Diaphyseal fractures

Diaphyseal lesions are usually well treated with intramedullary nails. In most situations the site of malignant involvement should be opened for complete curettage of the tumour, which will reduce tumour burden and prevent its further dissemination. Once curetted, the site can be filled with bone cement after nail insertion to provide further compressive strength to the area.

In bones that have both diaphyseal and epiphyseal or metaphyseal involvement, arthroplasty for the periarticular involvement should be performed and a cemented long-stem device should be used. The cemented long-stem component of the joint prosthetic device will provide stability to a diaphyseal lesion similar to the intramedullary nail.

Upper extremity

Upper-extremity metastases comprise approximately 20% of all bone metastases. Although the upper extremities are typically subjected to less weight bearing, in many instances, the patient must use the upper extremities for weight bearing during transfers and for using walkers or other mobility aids if necessary. Treatment goals for pathological lesions of the upper extremity are (a) to enable use of the limb in carrying out these basic activities of daily living and (b) to relieve pain.

Pathological fractures of the humerus occur more frequently in torsion than as a result of compressive loads. Obtaining torsional stability is an essential goal in treating humeral fractures. Fractures that involve the periarticular surfaces of the humerus can usually be treated with cemented arthroplasty. In the proximal humerus, if there is tumour in the greater and/or lesser tuberosities of the proximal humerus, then maintenance of rotator cuff attachments and function may be impossible. If the greater and lesser tuberosities cannot be spared, attempts to reattach the rotator cuff using synthetic material like mesh or polyethylene terephthalate (Dacron®) can be performed with variable success. Patients without rotator cuff function will still have a relatively pain-free arm and will retain enough use of the elbow and hand to carry out most activities of daily living, but they will likely be unable to perform activities requiring over-the-head arm movements.

Elbow replacement for distal humeral metastases can provide pain relief and adequate function. For diaphyseal lesions of the humerus, cemented intramedullary devices have the greatest success. In one series of 59 patients treated for pathological fractures of the humerus with either cemented intramedullary nailing or prosthetic replacement, all patients had good pain relief, but patients treated with intramedullary fixation augmented with cement had the best functional outcomes (Bickels et al., 2005).

Most lesions of the scapula and clavicle can be treated with radiation therapy, although irradiation of the lung and other vital organs may be a concern with higher doses. For lesions that are unresponsive to radiation therapy, resection and/or reconstruction may be required. The clavicle is an expendable bone and frequently can be resected without serious functional sequelae. Metal scapula replacements can be used when resection of the entire scapula, including the glenoid, is necessary for tumour control. Smaller portions of the scapula can be resected without prosthetic reconstruction.

Lower extremity

The femur is the third most common site of skeletal metastases. Fractures of the femur account for two-thirds of all pathological long-bone fractures. The proximal femur accounts for 90% of all pathological femur fractures (Sim, 1992). Forces within the proximal femur can be as high as 8 N with certain activities, which may explain why fractures to this region are so frequent (Jacofsky and Haidukewych, 2004). Any reconstruction to this area also must be able to support significant loads.

Metastatic lesions of the proximal femur involving the femoral neck should be treated with arthroplasty. The advantages of hemiarthroplasty over total joint arthroplasty are a shorter operative time, less blood loss, and less risk of postoperative dislocation. However, total hip replacement should be considered when there is evidence of disease within the acetabulum. Peritrochanteric lesions can be treated with arthroplasty as well. Treatment of pathological peritrochanteric fractures with intramedullary nails that include cephalomedullary screws can sometimes provide further stability proximally in the neck region, but the long-term results of these constructs in this setting are still unknown; hence, the standard of care remains joint replacement (Steensma, 2012).

Lesions below the lesser trochanter should be treated like femoral shaft fractures with intramedullary nail stabilization. Lesions very distal in the femur near the knee joint should be treated with cemented total knee arthroplasty or, if well contained and not involving the epiphyseal region, can be treated with curettage, cement, and plate fixation.

Tibial lesions comprise about 4.5% of skeletal metastases (Kelly et al., 2003). In a retrospective study of 25 patients with impending and pathological fractures in the tibia, 23 were proximal or diaphyseal and two were distal lesions. Well-contained metaphyseal lesions not involving the epiphysis were treated with curettage, cement, and plate fixation, while diaphyseal lesions were treated with intramedullary nailing and cement augmentation. Two patients with aggressive metaphyseal lesions extending into the epiphysis underwent endoprosthetic replacement. All patients experienced good pain relief and there was only a 4% failure rate in this series of patients (Kelly et al., 2003).

Pelvis and acetabulum

Metastatic disease to the pelvis and acetabulum are frequent causes of pain and mechanical instability in patients with cancer.

Conventional total hip arthroplasty can fail when there is inadequate bone stock on the acetabular side to support the metal and polyethylene cup component of the implant. The bone stock must be evaluated via CT scan of the pelvis and acetabulum to determine the appropriate treatment option. Only in situations where there is limited disease and intact superior, medial, and anterior and posterior cortices can a conventional total hip arthroplasty, with cementing of the cup component, be performed. When bone is deficient, acetabular reconstruction usually requires protection with a protrusio ring and transferring force transfer past the deficient bone with pins and cement constructs (Marco, 2000).

The most difficult scenarios involve patients with complete destruction of the acetabulum with significant disease involvement of the medial wall, superior dome, and anterior and posterior columns. For such patients, the acetabulum either needs to be completely resected and replaced or supplemental fixation around the acetabulum must be provided. The saddle prosthesis, which was originally created for large acetabular defects following failed conventional total hip arthroplasty, has been used in the setting of pelvic reconstructions for metastatic disease as well as after resection of primary bone tumours of the pelvis. Successful implantation requires a portion of retained ilium as the weight-bearing component of the reconstruction. Although there has been some success in patients with metastatic disease, its use has been fraught with complications. Any concern about disease progression into the ilium precludes use of this device, since a minimum of 2 cm of adequate bone within the ilium located close to the sacroiliac joint is required for stability of this construct. Even with adequate bone remaining, limb shortening, device dislocation, infection, and periprosthetic fracture are frequent complications (Aljassir et al., 2005). This type of reconstruction should be reserved for select patients with intermediate life expectancies.

When solid iliac bone remains, pins or screws can be secured into it and the defect filled with cement and a large anti-protrusio cup to relieve mechanical pain and prevent acetabular cup migration.

Minimally invasive and adjuvant treatment options

Kyphoplasty and vertebroplasty

Vertebroplasty and kyphoplasty are both techniques used to treat painful compression fractures in the spine due to osteoporosis or malignancy. Both vertebroplasty and kyphoplasty are minimally invasive techniques performed through percutaneous instrumentation. Both techniques involve the injection of bone cement posteriorly through the spinal pedicles into the vertebral body. The cement stabilizes the fractured vertebral body, preventing further collapse and reducing mechanical pain created at the site of fracture.

In kyphoplasty, a balloon is first inserted through the pedicle into the vertebral body and then inflated. This re-expands the collapsed vertebra and creates an open space for the injection of cement into the vertebral body. One advantage of kyphoplasty is that some of the height of the vertebral body is restored, improving spinal biomechanics and preventing collapse of other weakened adjacent vertebra. Another advantage is a lowered risk of cement extrusion into the spinal canal, because the space created by the balloon allows for lower-pressure cement injection (Masala et al., 2003). Both techniques provide significant pain relief in patients

with metastatic spinal disease and pain non-responsive to other treatments (Masala et al., 2003).

These techniques should only be considered in patients who have no evidence of cord compromise from tumour involvement and who, aside from pain, have an otherwise normal neurological exam. These techniques are minimally invasive, but are not without risks, including cement migration into the spinal canal, fat embolization, and abnormal cardiovascular response to the cement monomer.

Cryotherapy

In cryosurgery, liquid nitrogen is used to achieve a fast freeze followed by slow thaw, resulting in intracellular protein denaturation, water crystallization, cell membrane destabilization, and, ultimately, cell death. Cryotherapy can be used as the primary treatment for a lesion or as an adjuvant to other surgical techniques.

Newer percutaneous techniques now exist in which a probe is used to introduce liquid nitrogen or an argon beam into the area of involvement (Simon and Dupuy 2005), and have been used in areas of soft-tissue metastases with good success. The technique is less useful in bone metastases, due to the difficulty of probe insertion into bone, and it cannot be used to treat larger lesions, because the probes can only cover a small area of involvement. With percutaneous techniques, bone cement cannot be used to stabilize the area, making them even less desirable in areas where fracture is a concern.

Radiofrequency ablation

Radiofrequency (RF) ablation makes use of alternating electrical current with the same frequency range as radio waves (460–480 kHz) (Simon and Dupuy, 2005). A small electrode, placed near or directly into the target tissue, emits a current that produces ion vibration within the tissue, leading to increased local temperatures and thermal necrosis of the tissue.

The size of the lesion influences the efficacy of RF ablation. Tumours larger than 5 cm can be adequately treated with this technique (Simon and Dupuy, 2005) and it is a good alternative to surgical stabilization for isolated small painful lesions in the extremity. Similarly, lesions within the flat bones of the pelvis and remaining axial skeleton may respond well to this treatment and not require further surgical intervention.

The most common complications associated with RF ablation include skin necrosis, unplanned tissue damage, and fracture at the site of involvement (Simon and Dupuy, 2005). In areas where impending pathological fracture is a concern, surgical intervention is required and RF ablation is not appropriate.

Embolization

Embolization is used to reduce blood flow to vascular tumours. The technique is usually performed by the interventional radiologist and involves the injection of small particles or stainless steel coils into vascular pedicles feeding into tumours, ultimately resulting in diminished blood flow to the lesion and local tissue necrosis. Hypervascular tumours are most responsive to this technique. Renal and thyroid carcinomas are the two most common hypervascular tumours that metastasize to bone, and both haemorrhage significantly when surgically disrupted. Embolization can be used as primary treatment of lesions in areas at low risk of

fracture or can be performed 24–72 hours prior to further surgical stabilization and tumour excision. Several studies have shown a significant reduction in intraoperative blood loss and transfusion requirement with use of preoperative embolization (Roscoe et al., 1989; Chatziioannou et al., 2000; Pazionis et al., 2014).

Conclusion

Orthopaedic surgical intervention can be quite successful in reducing pain and improving function in patients with metastatic bone disease, particularly when combined with other treatment modalities. All patients who undergo surgery for treatment of bone metastases should be considered for postoperative radiation therapy as well as systemic treatment with bisphosphonates, hormone therapy, and/or chemotherapy whenever appropriate (Hillner et al., 2000; Saad et al., 2006). This requires the integration of all modalities of oncologic care and coordination of all teams caring for the patient.

The physician's goal when treating patients with metastatic bone disease is to cure some, help most, and provide comfort for all. Proper fracture care is a fundamental element in achieving this goal.

Interventional radiology in the palliation of cancer

Tarun Sabharwal, Nicos I. Fotiadis, and Andy Adam

Introduction to interventional radiology in the palliation of cancer

Over the past four decades, a variety of invasive diagnostic and therapeutic procedures have been developed by radiologists. The term 'interventional radiology' most appropriately refers to therapeutic procedures performed under imaging guidance (Adam, 1998). The emergence of this specialty has been made possible by enormous technological advances in relation to catheter and instrument design and manufacture, imaging systems, and radiological expertise. Interventional radiological procedures have virtually replaced several more invasive and hazardous surgical alternatives. Other interventional techniques offer completely new therapeutic options. Some diagnostic radiological procedures are frequently followed by therapeutic manoeuvres. For example, percutaneous antegrade pyelography, performed to delineate the site and nature of renal obstruction, is usually followed immediately by the placement of a nephrostomy drainage catheter. Purely diagnostic procedures, such as percutaneous biopsy, will not be discussed in any detail, as they are largely inappropriate for the patient with a known neoplastic process receiving palliative care.

All interventional procedures carry some risk, which is related to the underlying condition, the nature of the procedure, and the experience of the radiologist. Therefore, it is important in patients with advanced malignant disease receiving palliative care to contemplate only those procedures that will alleviate symptoms, and in which the potential benefits outweigh the risks (Bogda, 2003).

Interventional radiology can make a significant contribution to the palliation of patients with irresectable malignant tumours, as many of the procedures can relieve symptoms without the need for general anaesthesia, a prolonged stay in hospital, or the discomfort associated with recovery from a surgical operation. The vast majority of procedures are performed using local anaesthesia and mild sedation. The emphasis in this chapter is on the indications, contraindications, and likely outcomes, rather than on detailed technical descriptions.

Therapeutic interventional radiological procedures

A summary of procedures that may be useful in patients undergoing palliative care is shown in Table 12.6.1.

Percutaneous puncture and drainage procedures

Utilizing fluoroscopy, ultrasound, computed tomography (CT), or magnetic resonance imaging (MRI) guidance it is possible to image and drain obstructed renal and biliary systems, cysts, abscesses, and effusions.

Renal tract

Antegrade pyelography and percutaneous nephrostomy are used in the management of a variety of situations, including malignant obstruction of the urinary tract, haemorrhagic cystitis secondary to chemotherapy (where it is desirable to divert the urine to 'rest' the bladder), and in patients with recto-vaginal or recto-vesical fistula caused by pelvic malignancy. Diversion of urinary flow may assist in healing of the fistulas, ease nursing problems, and allow patients to become 'dry'.

The pelvicalyceal system is initially punctured under ultrasound guidance with a fine-gauge needle through which radiographic contrast medium is instilled to demonstrate the anatomy and determine the level of obstruction. Urine can be aspirated for microbiological and cytological examinations. Percutaneous nephrostomy entails the insertion into the collecting system of a pigtail configuration catheter with multiple, large side-holes. If drainage is to be of short duration, an external bag may be satisfactory; however, if long-term drainage is required and if it is possible to cross the area of obstruction, an internal stent is preferred (Pingound, 1980), as it allows the patient to be free of 'bags'. It is noteworthy that, in most cases, it is possible to manipulate a catheter across an area of apparently complete obstruction. Although a contrast study may indicate total obstruction, a hydrophilic guidewire can usually be advanced through the 'obstruction', as it finds the (very narrow) lumen and follows it. The balloon catheter can then be advanced over the guidewire to dilate the stricture and restore patency before a stent is inserted.

In patients with pelvic malignancy and fistulas to the perineum it may prove necessary to combine nephrostomy with ureteric embolization using steel coils or segments of gelatine sponge to prevent any urine reaching the skin of the perineum. A catheter can be manipulated into the ureter and embolic materials, such as steel coils and sterile sponge, can be injected to occlude the ureter (Gaylord and Johnsrude, 1989).

Table 12.6.1 Interventional radiological procedures

Procedure	Examples of indications
Drainage	Malignant obstruction of renal and biliary tract, pleural effusions, and ascites
Stenting	Malignant gastrointestinal, biliary, ureteric and airway obstruction, superior or inferior vena caval obstruction, etc.
Feeding	Venous access—Hickman lines peripherally-inserted central catheter (PICC) lines
	Percutaneous gastrostomy
Extraction	Retrieval or re-siting of venous lines
Infusion	Regional, selective infusion of chemotherapeutic agents
Embolization	Hormone-producing metastases, primary hepatocellular carcinoma, skeletal metastases, etc.
Neurolysis	Coeliac axis block in pancreatic cancer
Vertebroplasty	Vertebral metastasis, multiple myeloma, and osteoporosis
Tumour ablation	Liver, renal, lung, bony, and soft tissue tumours

Biliary tract

Patients with obstructive jaundice due to irresectable malignant biliary strictures can be palliated by the insertion of an endoprosthesis (stent) (Fig. 12.6.1). Stents may be inserted endoscopically for lesions affecting the low common bile duct or percutaneously in patients with lesions at the hilum of the liver or when endoscopic retrograde cholangiopancreatography (ERCP) fails to relieve the obstruction. In most cases unilateral drainage is usually sufficient for relieving jaundice and pruritus. The procedure is usually carried out under fluoroscopic and ultrasound guidance. Self-expandable metallic stents are now widely available and generally preferable to the conventional plastic endoprosthesis. Such stents can be inserted using a small introducing catheter (5–7 French diameter) and yet they achieve a large internal diameter (10 mm) when released across the obstructing lesion.

The large calibre of these devices ensures that the rate of occlusion is lower than that of a plastic endoprosthesis. The overall failure rate of plastic stents is in the region of 30–40%, whereas that of metallic stents is 10–15%. The frequency of cholangitis is approximately 30% in patients with plastic stents and approximately 10% in patients with metallic endoprostheses (Morgan and Adam, 2001). Occluded plastic stents can be replaced using a variety of endoscopic or percutaneous techniques. Occluded metallic endoprostheses cannot be removed but their patency can be restored by the introduction of a second device inserted coaxially within the first. Unless life expectancy is very short, it is well worth considering restoring the patency of an occluded stent, as this can greatly improve the patient's quality of life (Davids et al., 1992).

Malignant pleural effusions

Malignant pleural effusions (MPEs) can produce significant respiratory symptoms and diminished quality of life in patients with terminal malignancies. A patient who presents with a MPE should first have a diagnostic and therapeutic thoracocentesis. This can be done under ultrasound guidance. It is important to assess for symptom improvement and the ability of the lung to re-expand. The fluid will re-accumulate in almost all patients, at which time local treatment is needed. This typically consists of tube thoracostomy, usually followed by instillation of a sclerosing agent (doxycycline, bleomycin, or talc) to chemically induce pleurodesis (Patz et al., 1996). A tunnelled pleural catheter, the Denver Pleurx® catheter (Denver Biomaterials, Inc., Golden, CO) is also available for those patients who are ineligible or fail sclerotherapy. This is a 66-cm long 15.5 French soft silicone catheter with a polyester cuff to promote fibrosis to the subcutaneous tissue and multiple side-holes to enhance drainage. A valve in its hub is opened only when a dilator is passed through it. This prevents inadvertent entry of air or leakage of fluid. The drainage system consists of a vacuum bottle with a pre-connected tube that has a dilator at its

Fig. 12.6.1 Percutaneous biliary drainage. (A) Percutaneous cholangiogram showing stricture of the central bile ducts and proximal common bile duct due to cholangiocarcinoma (Klatskin tumour), and dilated intrahepatic ducts. (B) Biliary drainage with two metallic endoprosthesis.

end to pass into the hub of the catheter. Drainage will typically take no longer than 15 minutes and should be performed at least every other day. In the outpatient setting, this can be done by a visiting nurse, family members, or the patient (Pollak et al., 2001).

Malignant ascites

The accumulation of large volume ascites is a common occurrence for patients with intraperitoneal spread of tumour. These patients have a very poor prognosis, with anticipated mean survival ranging from 1 to 4 months. Patients often experience symptoms of abdominal pressure, shortness of breath, nausea, early satiety, and limited mobility because of the mass effect of the fluid. Management of symptoms is palliative and methods used include percutaneous drainage, diuretics, shunt placement, and intraperitoneal drug therapy. Paracentesis is not only the most common treatment method used by physicians, but also the most effective at relieving symptoms (Becker et al., 2006). Unfortunately, management of recurrent ascites with paracentesis requires frequent trips to the hospital and has greater risk of complications associated with multiple needle passes into the abdomen. There is an increasing number of published reports which show that a 15.5 French tunnelled draining catheter, the Pleurx® Catheter, provides effective palliation with a complication rate similar to that for large volume paracentesis, while obviating the need for frequent trips to the hospital for repeated percutaneous drainage (Tapping et al., 2012).

Dilatation/stenting techniques

These techniques are employed for the treatment of a variety of malignant strictures and occlusions in many systems, including the gastrointestinal tract, the respiratory system, and the renal and biliary tract.

Gastrointestinal tract

Oesophagus

The aim of palliation in patients with inoperable oesophageal cancer is to relieve dysphagia with minimal morbidity and mortality, and thus improve quality of life. The use of a self-expanding metal stent (SEMS) is a well-established modality for palliation of dysphagia in such patients (Sabharwal et al., 2004). Placement of the stent can be achieved under fluoroscopic (Fig. 12.6.2) or endoscopic guidance, or both. The procedure is relatively straightforward with negligible mortality and low morbidity. Advantages of radiological placement of oesophageal stents include (Sabharwal, 2005):

- accurate positioning under X-ray guidance
- ability to traverse even tight stenoses or occlusions
- ability to use small-calibre catheters and wires which minimizes the risk of perforation and bleeding.

New advances in oesophageal stent technology include smaller introductory devices, more flexible stents, retrievable stents which can be used as a bridge to surgery, biodegradable stents, and devices with an anti-reflux valve which are used for stenting across the gastro-oesophageal junction (Katsanos et al., 2010).

Covered metallic stents are also very useful in the management of malignant oesophageal fistulas. Unlike fistulas associated with benign diseases, which may heal with conservative therapy, fistulas associated with malignant lesions do not heal spontaneously. Without definitive treatment, most patients succumb to malnutrition and thoracic sepsis within weeks. Radiological insertion of a covered metallic stent can result in immediate sealing of the fistula and the patient can drink fluids a few hours after the procedure, resuming a normal diet on the following day (Morgan et al., 1997).

Gastroduodenal and colorectal

SEMSs are playing an increasingly important role in the treatment of gastroduodenal obstruction and acute colonic obstruction (Katsanos et al., 2011). Patients with these conditions are often elderly and frail with dehydration and electrolyte imbalance. Self-expanding stents offer a non-surgical therapeutic alternative that rapidly relieves the obstruction and improves their clinical condition, with a high success rate and low morbidity (Fig. 12.6.3). This may be a temporizing measure allowing stabilization of the patient prior to definitive surgery, or alternatively, patients who
Fig. 12.6.2 Oesophageal stenting.
Fig. 12.6.3 Concurrent percutaneous biliary (Wallstent®) and gastroduodenal (enteral) stent in patient with inoperable pancreatic cancer.

are not surgical candidates, the stent may provide adequate palliation (Sebastian et al., 2004).

Tracheobronchial

Malignant airways obstruction can cause considerable distress to patients. When surgical resection is not possible, SEMSs can provide good palliation. This procedure is best carried out under general anaesthesia, as a combined effort between an interventional radiologist and a bronchoscopist. Bronchoscopic visualization is used to determine the position of the stricture, the limits of which are marked with a radio-opaque marker. The stricture is then dilated under fluoroscopic guidance. Following dilatation, a SEMS is released across the stricture, again under fluoroscopic guidance. This can result in significant symptomatic improvement and prevent collapse and/or infection and abscess formation beyond an obstructing lesion (Tan et al., 1996). Placement of plastic-covered metallic stents in the trachea is an effective method of managing tracheo-oesophageal fistulae unsuitable for treatment with covered oesophageal stents (Morgan et al., 1997).

Venous obstruction

The superior vena cava syndrome often presents as a very distressing pre-terminal event in patients with thoracic malignancy. It is most commonly related to mediastinal neoplasia, particularly primary and secondary lung tumours and lymphoma. The obstruction, which can be partial or complete, can be caused by caval compression and/or invasion by tumour and is frequently complicated by venous thrombosis.

Superior venocavography delineates the site and extent of the obstruction. If extensive thrombosis is present, selective intravenous thrombolysis with a catheter placed within the thrombus is undertaken under local anaesthesia. Percutaneous transfemoral dilatation of the narrowed superior vena cava is followed by the insertion of a self-expandable metallic endoprosthesis. Flow is restored immediately, providing excellent and immediate palliation of symptoms

(Lanciego et al., 2009). This procedure can be performed prior to, in conjunction with, or after therapy, including radiotherapy or chemotherapy. It can also be performed in conjunction with airway stenting (Fig. 12.6.4). Malignant involvement of the inferior vena cava can be managed in a similar fashion. All patients with malignant superior or inferior vena caval obstruction should be considered for this relatively straightforward and usually successful procedure, which can readily improve their quality of life.

Percutaneous insertion of an *inferior vena cava filter* is indicated in patients with recurrent pulmonary embolism refractory to or unsuitable for treatment with anticoagulation therapy and in those patients with free-floating thrombus in the inferior vena cava (Hammond et al., 2009).

Feeding techniques

Venous access

Central venous access may be essential in some patients with terminal disease for feeding and the delivery of medication, palliative chemotherapy or analgesia. A variety of long-term venous access systems (e.g. tunnelled central venous catheters, peripherally inserted central catheters (PICCs), and venous ports), have been developed for insertion under fluoroscopic and ultrasound guidance. The procedure is now usually performed in the radiology department under local anaesthesia and strict asepsis (Adam, 1995). The main advantage over the surgical venous cut-down technique is that performing the procedure under fluoroscopic guidance ensures that the tip of the catheter is always in the correct position and virtually eliminates the need for repositioning the catheter at a later date. The procedure is rapid, well tolerated by the patient, and associated with high success and low complication rates. In our experience, it is virtually always possible to gain venous access using interventional radiological methods. The rate of occurrence of pneumothorax when using a subclavian approach is approximately 1%. This complication is very rare when access is gained via the internal jugular vein. The long-term complications of occlusion and infection of the catheter are not significantly different from those observed when a surgical method of venous access is used (Adam, 1995).

Percutaneous gastrostomy

Nutritional support may be required in patients with end-stage disease. This sometimes raises difficult questions, particularly in relation to parenteral nutrition. Enteric feeding is generally a simpler option and can be accomplished by the insertion of gastrostomy tubes. The insertion of a feeding gastrostomy tube either under fluoroscopic (Fig. 12.6.5) or endoscopic guidance and local anaesthesia can significantly improve the patient's well-being and ease of management, often avoiding the need for uncomfortable psychologically distressing nasogastric tubes and intravenous lines. A gastrostomy tube can be readily managed in the home environment by the patient's family and carers as well as by nursing staff (Lowe et al., 2012).

Gastro-jejunostomy tubes are preferable when there is gastric outlet obstruction or in cases of gastro-oesophageal reflux.

Extraction techniques

Developments in intravenous feeding therapy and monitoring techniques have led to a vast increase in the number of indwelling venous
Fig. 12.6.4 Tracheal and superior vena cava (SVC) stenting. (A) Computed tomography shows a Pancoast tumour occluding the SVC and compromising the trachea. (D) Completion venogram shows patency of the SVC stent and also the widely opened tracheal stent.

Fig. 12.6.5 Radiologically inserted gastrostomy (RIG).

cannulas and catheters. Unfortunately, these occasionally break or become disconnected and a part or all of the catheter is 'lost' within the venous system. It is important to retrieve these intravascular foreign bodies as they not only perforate vascular structures and cause dysrhythmias but also act as a seat of infection, particularly in immunosuppressed patients. Surgical retrieval of catheter fragments is hazardous (and sometimes impractical), necessitating a thoracotomy. It is almost invariably possible to retrieve these catheter fragments, which usually lodge within the right side of the heart or the pulmonary arteries, percutaneously under fluoroscopic guidance. Detailed descriptions of all the retrieval techniques available are beyond the scope of this chapter but any interventional radiologist offering a comprehensive vascular service is well advised to become acquainted with the various methods and have the necessary equipment available (Wolf et al., 2008).

The ability to snare or 'catch' the end of a catheter can also be of value when the tip of an indwelling central venous catheter has become displaced into the jugular vein. It is usually possible to

'pull' such a catheter back into a correct position using a percutaneous vascular approach under local anaesthesia.

Infusion techniques

The ability of the radiologist accurately to site a catheter into virtually any blood vessel within the body has brought into play the concepts of regional infusion of chemotherapeutic agents, monoclonal antibodies and isotopes. The principle underlying these techniques is that a high dose of the therapeutic agent is delivered to the tumour(s) with minimal side effects. Recent advances include the addition of embolic materials (see embolization section, below) and the microencapsulation of cytotoxic agents to achieve gradual and sustained release. Lipiodol® has been used for many years in combination with cytotoxic drugs for the treatment of certain hepatic tumours; it is retained in tumour vessels and also acts as a contrast agent, thus allowing monitoring of tumour response to treatment using CT imaging.

These techniques have been used with varying degrees of success to treat primary and metastatic liver tumours, bone neoplasms, cerebral neoplasms, sarcomas, melanomas, and pelvic neoplasms (Lewandowski et al., 2011).

Vascular embolization

The deliberate occlusion of arteries and/or veins by the injection of embolic agents through selectively placed catheters, is one of the major therapeutic applications of interventional radiology in the patient with neoplastic disease. This technique has been employed in the management of severe and disabling symptoms from a very wide variety of tumours throughout the body. Embolization, which usually involves a percutaneous technique with local anaesthesia, offers an attractive alternative to surgery under general anaesthesia and, in some situations, is the only therapeutic option available. A wide variety of embolic agents are available. The broad categories of substances used include particulate emboli (sterile sponge, polyvinyl alcohol, and the newer clear acrylic microspheres), mechanical emboli (balloons, steel coils), and liquids (n-butyl cyanoacrylate (glue), absolute alcohol, Lipiodol®). The appropriate agent or combination of agents depends on the lesion to be treated and its site (with particular reference to adjacent vulnerable vascular structures).

Embolization can be used definitively to stop internal bleeding and pre-operatively to assist effective, safe surgery, but in many cases it is used palliatively to alleviate distressing symptoms (Fig. 12.6.6).

Palliative embolization

Embolization can be used to control pain, haemorrhage, and hormone production as well as to reduce tumour bulk. The technique may be used as the primary mode of treatment in inoperable malignancy and embolization of metastatic deposits has, in some situations, been shown to extend survival times in advanced disease (Lovet and Bruix, 2003). Tumours in all sites have been treated in this fashion (liver, kidney, bone, lung, soft tissues, nervous system, and gastrointestinal tract). Hormone secreting neoplasms such as metastatic neuroendocrine tumours show the greatest therapeutic response to arterial embolization. Appropriate pharmacological blockade is necessary during the embolization to avoid the effects of a dramatic outpouring of hormone as the tumour is deprived of its blood supply. The beneficial effects of embolization may become apparent within a matter of hours. In embolization procedures it

(A)

(B)
Fig. 12.6.6 Hepatic embolization for metastatic carcinoid tumour. (A) The arterial parenchymal phase shows hepatic enlargement and reveals multiple tumour deposits. (B) Post-embolization arteriogram shows that the arterial supply has been obliterated. The patient's symptoms (flushing and diarrhoea) were dramatically alleviated by this procedure.

is important that adequate premedication is given prior to the procedure, including broad-spectrum antibiotics. In many situations, for example, liver and bone, it is necessary to continue antibiotics for 10 days after the procedure to prevent sepsis developing in the devascularized tissue.

A major advance in tumour embolization has been the development of transcatheter arterial chemoembolization (TACE). In this technique embolic materials are mixed with chemotherapeutic drugs; the emboli cause ischaemia of the tumour cells and by increasing the transit time through the tumour vascular bed, the contact time between the cytotoxic agent and the neoplastic cells is prolonged, resulting in a greater therapeutic effect.). At present TACE is considered to be the mainstay of treatment for unresectable hepatocellular carcinoma (HCC). It provides significantly prolonged survival in selected patients with preserved liver function and adequate performance status (Lover and Bruix, 2003). Prolonged survival can be achieved in selected patients with a combination of local ablative techniques (percutaneous ethanol injection (PEI), radiofrequency ablation (RFA)) and TACE (Marelli et al., 2006). TACE also has been used as a bridge for orthotopic liver transplantation.

Drug-eluting beads, polyvinyl alcohol-based microspheres that can be loaded with various types of chemotherapeutic agents, have more recently been developed in effort to improve the pharmacokinetic profile of the chemotherapeutic agents administered during TACE (Varela et al., 2007). Such a system loaded with doxorubicin has shown promising results in patients with unresectable HCC with an advantageous pharmacokinetic profile, reduced adverse effects, and improved tumour response as shown by imaging when compared with conventional TACE (Lammer et al., 2010).

After embolization of large tumour masses, patients may experience some discomfort and pain and they may have a fever for a few days accompanied by a feeling of malaise and an elevated white cell count. This combination of signs and symptoms has been called the *post-embolization syndrome*, and is an indicator of the presence of necrotic tissue. Sustained pyrexia should alert the clinician to the possibility of abscess formation and blood cultures plus regional ultrasound should or CT be performed.

Neurolysis

Alcohol injection is useful in the palliation of intractable pain which occasionally accompanies retroperitoneal malignancy. Pain associated with pancreatic and gastric cancer can be severely debilitating with significant impairment in quality of life. Frequently, this chronic abdominal pain does not respond adequately to conventional analgesics including opioids. Coeliac plexus neurolysis and coeliac plexus block are aimed at either selectively destroying the coeliac plexus or temporarily blocking visceral afferent nociceptors to alleviate chronic pain. Both techniques require injection of the chosen agent at the coeliac axis. Agents most commonly used include alcohol for neurolysis and bupivacaine and triamcinolone for temporary block. The procedure is performed percutaneously either under CT or fluoroscopic guidance. Between 70% and 85% of patients experience pain relief lasting from 1 month up to 1 year post procedure (Kambadakone et al., 2011). Complications include transient diarrhoea, orthostasis, and transient increase in pain but the incidence of these is low. Major complications occur in less than 1% of patients and include retroperitoneal bleeding, abscess formation, and transient or permanent paraplegia (Kambadakone et al., 2011).

Bone strengthening techniques

Percutaneous vertebroplasty, kyphoplasty and osteoplasty

Percutaneous vertebroplasty is a therapeutic, image-guided procedure that involves injection of polymethylmethacrylate (bone cement) into a partially collapsed vertebral body, in an effort to relieve pain and provide stability (Gangi et al., 1994). This procedure is being used for patients with intractable debilitating pain due to vertebral compression fractures that is refractory to conventional therapies such as analgesic use, bed rest, and bracing. Neoplastic causes of vertebral compression fractures include bone metastases, multiple myeloma, lymphoma and aggressive haemangiomas. Up to 80% of patients with pain unresponsive to conventional medical treatment experience a significant degree of pain relief (Gangi et al., 2006).

Percutaneous vertebroplasty is performed under conscious sedation or general anaesthesia, and may be carried out as an outpatient procedure or may require a short hospital stay. CT and/or fluoroscopic guidance is used. The patient lies in the prone position, and then a large-bore (10–15 gauge) needle is placed into the vertebral body, through a transpedicular route for the lumbar spine or a intercostovertebral route for the thoracic spine. Access to cervical lesions is via an anterolateral approach. Once positioned in the vertebral body acrylic bone cement, usually methyl methacrylate, mixed with contrast medium, is then injected into the affected vertebra. This material is viscous to minimize leakage into adjacent structures or blood vessels. The whole procedure usually takes 1–2 hours. Non-steroidal anti-inflammatory drugs can be used for 2–4 days after vertebroplasty to minimize the inflammatory reaction to the acrylic compound. Pain relief is expected within 24 hours of the procedure. Complication rates are lower than 2% for osteoporotic indications and lower than 10% for malignant indications and include temporary or permanent neurologic deficit, infection, bleeding from puncture site, and allergic reaction (Gangi et al., 2006).

Kyphoplasty is a refinement of the vertebroplasty procedure. In addition to the reduction of fracture-related pain, some or all of the height is restored to the compressed vertebral body. Normalizing the height of the fractured vertebra reduces the focally exaggerated curvature of the spine (i.e. kyphosis). This effect, in turn, results in an aesthetic improvement, improved posture, and a reduced risk of fracture of the adjacent vertebra as a result of abnormal load bearing. The restoration of a more normal appearing configuration of the vertebral body and improvement in the load-bearing physics is accomplished with the intravertebral inflation of one or two high-pressure balloon tamps prior to the infusion of methylmethacrylate (Sabharwal et al., 2006).

Osteoplasty involves the injection of bone cement into a painful lytic pelvic lesion in patients who are unable to tolerate surgery and conventional treatments (radiotherapy, opioids) fail (Fig. 12.6.7). It achieves immediate bone strengthening, reduces the risk of pathological fracture, and improves mobility and pain control (Sabharwal, 2006). Contraindications include local infection and uncorrected coagulopathy. The major complication encountered when treating acetabular lesions is intra-articular injection. The risk is minimized by continuous monitoring of the bone-filling procedure with fluoroscopic guidance.

Percutaneous tumour ablation

Ablation refers to local (rather than systemic) methods that destroy the tumour without removing it. These techniques are usually reserved for patients with recurrent malignancy in areas of previous radiation therapy, localized metastatic disease, and primary neoplasms in patients who are poor surgical candidates. They are not always considered curative but can produce survival rates equal to surgery in people with small tumours. Percutaneous techniques of local tumour ablation may be categorized into three major groups: injection (ethanol, acetic acid, hot saline), heating (RFA, electrocautery, interstitial laser therapy, microwave coagulation therapy, high-intensity focused ultrasound), and freezing (cryotherapy). Advantages of the ablative therapies compared to surgical resection include reduced morbidity and mortality, low cost, and the ability to perform procedures on an outpatient basis (Ahmed et al., 2011). All these techniques induce cell death by coagulative necrosis.
Fig. 12.6.7 Symptomatic metastatic left acetabular deposit that was injected with cement for consolidation and pain relief. (A) Insertion of the needle under CT guidance into the lesion. (B) Injection of cement under fluoroscopic guidance. (C) CT confirming good fill with no leaks.

Percutaneous liver tumour ablation

The liver is the organ with the greatest number of patients eligible for treatment with percutaneous tumour ablation given the large number of patients with primary or secondary hepatic malignancies and the low number eligible for surgical resection. Multiple minimally invasive techniques have been developed including PEI, interstitial laser photocoagulation (ILP), microwave, cryotherapy, focused ultrasound, and RFA. Thermal ablation is the most widely used techniques both for HCC and hepatic metastasis (Gillams, 2008).

Thermal ablation

Lesional heating techniques such as RFA and ILP affect tumour necrosis by hyperthermia. RF electrodes or laser fibres are inserted into the tumour under ultrasound, CT, or MRI guidance.

ILP produces thermal coagulation by conversion of absorbed light energy into heat (Nikfarjam and Christophi, 2003). In RFA, alternating current induces ionic agitation, which results in frictional heat production within the tissues. The size and shape of the necrotic lesion produced by RF has been shown to be a function of the probe gauge, length of the exposed tip, temperature along the exposed electrode, and duration of therapy. Strategies aiming at increasing the volume of tissue coagulation include the use of multi-probe electrodes and saline enhancement (Ahmed et al., 2011). Cooling the electrode with saline during the ablation prevents charring of the liver and reduces the impedance of the tissues adjacent to the electrode. In turn, this permits dissemination of heat further out into the tumour and increases the area of coagulation. The procedure is tolerated well and causes either no or only slight and transient abnormalities of liver function tests. Serious complications are rare and consist mainly of intraperitoneal haemorrhage and liver abscess formation.

The follow-up of patients after all forms of percutaneous tumour ablation includes a combination of imaging, tumour marker assay, and selected use of fine-needle aspiration biopsy. It is useful to follow serial levels of alpha-fetoprotein or carcino-embryonic antigen, in the case of HCC or metastatic disease, respectively, only when the serum levels of these markers are elevated prior to the initiation of therapy. The immediate goal of imaging is to assess whether complete necrosis has been achieved. Ultrasound does not usually provide useful information, as the echogenicity of fibrosis and neoplastic tissue overlap. Contrast enhanced-MRI and contrast enhanced-CT are capable of demonstrating remaining viable tumour requiring treatment. However, in difficult cases, positron emission tomography/CT scanning may provide additional information (Thulkar et al., 2012).

Several clinical series using different methods of RFA have been reported. The results appear to be promising, showing a 35% 5-year survival rate and 70% complete ablation rate for selected patients with colorectal metastasis (Gillams and Lees, 2009) and a 43%, 5-year survival rate for patients with HCC (Yan et al., 2008). RF thermal ablation is a quick, relatively safe, and highly effective technique for bulky primary and secondary malignant hepatic tumours. Also, it holds great promise as a technique for local tumour eradication. However, it is difficult to create an adequate tumour-free margin around larger (> 5 cm) tumours and failure to do so results in incomplete ablations and tumour recurrence.

RF thermal ablation has many potential advantages over existing therapies. It is far more effective for debulking tumours than is radiation therapy or systemic chemotherapy. Unlike surgical resection, it is minimally invasive and can be repeated as necessary to treat new tumours. It has far fewer complications than chemoembolization and could be used in conjunction with other systemic and local treatments.

Radiofrequency ablation of renal and adrenal masses

In patients with renal or adrenal tumours, recurrent malignancy in areas of prior radiation treatment, localized metastatic disease and primary neoplasms in patients who are poor surgical candidates RFA may be a suitable treatment option. Renal cell carcinomas are often incidental findings in older patients in which the standard of care has been total or partial nephrectomy. The growth pattern in many renal cell carcinomas can be slow and the risk of metastasis variable. VHL and hereditary RCC may also be successfully treated with RFA, which preserves kidney function (Gervais et al., 2005).

Patient selection should include those with known contraindications to partial or complete nephrectomy due to co-morbid conditions or advanced age, and small tumour burden. Centrally located masses may be harder to treat and the complication rate may be higher. This is likely related to the higher blood flow in

(A)

(B)

(C)
Fig. 12.6.8 RFA of a pancreatic secondary tumour. Patient had inoperable disease with metastatic melanoma and suffered with symptoms of severe abdominal pain and bowel obstruction. (A) CT scan of abdomen demonstrating large tumour in the head of the pancreas thought to be responsible for current symptoms. (B) Triple-cooled RF probe that was used for percutaneous RFA therapy. (C) Follow-up CT scan (1 week later) showed a low attenuation area within the tumour mass that represents necrosis; the pancreatic tumour lesion is smaller and there was now less mass effect. Patient's symptoms were significantly alleviated.

the renal hilum that prevents complete thermocoagulation due to a heat sink effect. Complications in the kidney include haemorrhage, urinoma, abscess, paraesthesias, transient haematuria, and pain. Ureteral stricture may occur with a tumour touching the ureter. RFA has also been found to be effective for the control of persistent haematuria in patients with kidney tumours (Neeman et al., 2005).

Treatment options for primary and metastatic adrenal tumours are limited. For adrenocortical carcinoma, chemotherapy and radiation therapy play a limited role. However, repeat surgical resection may prolong survival. Extrapolation from these data suggests that local adrenal tumour destruction with RFA may improve survival in selected patients. Phaeochromocytoma, aldosteronoma, and metastases to the adrenal may also be treated with RFA, with the appropriate endocrine evaluation and blockade for phaeochromocytoma (Wood et al., 2003).

Radiofrequency ablation of lung tumours

First reported in 2000 (Dupuy et al., 2000), RFA for primary and metastatic lung tumours is now gaining momentum. Results are encouraging particularly when palliation for pain or mass lesion is needed. Pneumothorax rates appear to be in the range of 10–20%, with other complications less common, such as bleeding, fistula, haemoptysis, subcutaneous emphysema, effusions, fever, infection, and pain (Kashima et al., 2011).

The surrounding air in adjacent normal lung parenchyma may provide insulation for the thermal lesion, making cooking easier or faster than in the well-vascularized liver.

Radiofrequency ablation of painful metastases

Early reports show promise for RFA of painful soft tissue tumours that are resistant to conventional radiation and pharmacological therapies. RFA has been found to be effective for short-term local control of painful soft tissue tumours and of bone metastases in multiple locations, decreasing or obviating the need for opioids (Dupuy et al., 2010). Other examples of the role of RFA in palliative care include the relief of distressing symptoms of bowel obstruction, abdominal distension, and pain from a large pancreatic mass (Fig. 12.6.8).

Better methods of imaging guidance and more sophisticated equipment are likely to increase the importance of percutaneous tumour ablation in the future.

Conclusions

This chapter was not intended to be an exhaustive list of every procedure that can be performed but to give an overall impression of the vast range of interventional techniques available. The patient undergoing palliative care should not be subjected to any unnecessary procedures or instrumentation. However, there are many readily performed, well-tolerated, and safe interventional procedures which can significantly alleviate distressing symptoms, improve the quality of remaining life, and ease the nursing burden. Further detailed information can be obtained from the many reviews, journals, and books on the subject, some of which are included in the reference list.

SECTION 13

Cancer pain syndromes

13.1

Cancer pain syndromes: overview

Nathan I. Cherny

Acute pain syndromes

Cancer-related acute pain syndromes are most commonly due to diagnostic or therapeutic interventions (Stull et al., 1996; Jain and Chatterjee, 2010) and they generally pose little diagnostic difficulty. Although some tumour-related pains have an acute onset (such as pain from a pathological fracture), most of these will persist unless effective treatment for the underlying lesion is provided.

Acute pain associated with diagnostic and therapeutic interventions

Many investigations and treatments are associated with predictable, transient pain. For those patients with a pre-existing pain syndrome, otherwise innocuous manipulations can also precipitate incident pain.

Acute pain associated with diagnostic interventions
Lumbar puncture headache

Lumbar puncture (LP) headache is the best characterized acute pain syndrome associated with a diagnostic intervention. This syndrome is characterized by the delayed development of a positional headache, which is precipitated or markedly exacerbated by upright posture. Less commonly dural puncture may also cause back pain, arm pain, thoracic pain, and bowel and bladder dysfunction (Schabel et al., 2000; Ho et al., 2005). The pain is believed to be related to reduction in cerebrospinal fluid volume, due to ongoing leakage through the defect in the dural sheath, and compensatory expansion of the pain-sensitive intracerebral veins (Levine and Rapalino, 2001). The incidence of headache is related to the calibre of the LP needle (0–2% with 27–29-gauge, 0.5–7% with 25–26-gauge, 5–8% with 22-gauge, 10–15% with 20-gauge, and 20–30% with 18-gauge needles) (Bonica, 1953; McConaha et al., 1996; Lambert et al., 1997).

The risk of LP headache can be reduced by several strategies: when using a regular bevelled needle, longitudinal insertion of the needle bevel, which induces less trauma to the longitudinal elastic fibres in the dura, may reduce the incidence of headache (Kempen and Mocek, 1997).

Non-traumatic, conical tipped needles with a lateral opening are associated with a substantially lesser risk of post-LP headaches than regular cannulae (Prager et al., 1996; Corbey et al., 1997; Lambert et al., 1997; Vallejo et al., 2000; Toyka et al., 2002). The evidence that recumbency after LP reduces the incidence

of this syndrome is controversial (Gonzalez, 2000; Ebinger et al., 2004).

LP headache, which usually develops hours to several days after the procedure, is typically described as a dull occipital discomfort that may radiate to the frontal region or to the shoulders. Pain is commonly associated with nausea and dizziness. The duration of the headache is usually 1–7 days (Lybecker et al., 1995; Vilming and Kloster, 1998), and routine management relies on rest, hydration, and analgesics (Evans, 1998). Persistent headache may necessitate application of an epidural blood patch (Evans, 1998). Although a controlled study suggested that prophylactic administration of a blood patch may reduce this complication (Martin et al., 1994), the incidence and severity of the syndrome do not warrant this routinely. Severe headache has also been reported to respond to treatment with intravenous or oral caffeine (Morewood, 1993).

Transthoracic needle biopsy

Transthoracic fine-needle aspiration of intrathoracic mass is generally a non-noxious procedure. Severe pain has, however been associated with this procedure when the underlying diagnosis was a neurogenic tumour (Jones et al., 1993).

Transrectal prostatic biopsy

Transrectal ultrasound-guided prostate biopsy is an essential procedure in the diagnosis and management of prostate cancer. In a prospective study, 16% of the patients reported pain of moderate or greater severity and 19% would not agree to undergo the procedure again without anaesthesia (Irani et al., 1997). Subsequent studies have demonstrated low rate of severe pain (Sheikh et al., 2005). When present, pain may persist up to 4 weeks after the biopsy (Naughton et al., 2000). Periprostatic lidocaine infiltration (Jones et al., 2003; Stravodimos et al., 2007; Gurbuz et al., 2010), intrarectal introduction of lidocaine cream 2% (Kandirali et al., 2009; Skriapas et al., 2009; Issa et al., 2000), and unilateral pudendal nerve block (Adsan et al., 2004; Bhomi et al., 2007) may reduce the pain associated with this procedure.

Mammography pain

Breast compression associated with mammography can cause moderate, and rarely severe, pain (Leaney and Martin, 1992; Aro et al., 1996). The duration of the pain is generally short (Sapir et al., 2003). Unless patients are adequately counselled and treated, occasional patients will refuse repeat mammograms because of pain (Leaney and Martin, 1992). Pain may be reduced by using a lesser level of compression (Chida et al., 2009). In a systematic

review the only intervention to significantly reduce the pain was of patient-controlled compression (Miller et al., 2002).

Acute pain associated with therapeutic interventions
Postoperative pain

Acute postoperative pain is universal unless adequately treated. Unfortunately, undertreatment is endemic despite the availability of adequate analgesic and anaesthetic techniques (Anonymous, 2008b; Sommer et al., 2008; Wu and Raja, 2011). Guidelines for management have been reviewed (NHS Quality Improvement Scotland, 2004; Savoia et al., 2010; Wu and Raja, 2011). Postoperative pain that exceeds the normal duration or severity should prompt a careful evaluation for the possibility of infection or other complications.

Radiofrequency tumour ablation

Radiofrequency tumour ablation is commonly used in the management of liver metastases. It is also increasingly used in other settings including adrenal metastases and renal tumours as well as in lung, bone, breast, and bone tumours. Percutaneous ablation of liver tumours may be associated with severe right upper quadrant abdominal pain or pain radiating to the right shoulder (Zagoria et al., 2002; Buscarini and Buscarini, 2004) in 5–10% of patients. Pain has also been reported after radiofrequency ablation of renal lesions (Baker et al., 2007) and it is presumably possible with the use of this approach in other sites.

Cryosurgery

Cryotherapy is commonly applied in the management of skin, cervical, and prostatic tumours. Topical cryotherapy typically causes a local painful reaction that decreases in severity over 2–7 days (Wang et al., 2001; Thai et al., 2004). Cryosurgery of the cervix in the treatment of intraepithelial neoplasm commonly produces an acute cramping pain syndrome. The severity of the pain is related to the duration of the freeze period and it is not diminished by the administration of prophylactic non-steroidal anti-inflammatory drugs (NSAIDs) (Harper, 1994). Cryotherapy for prostate cancer may uncommonly result in persistent pain (Ismail et al., 2007) which may sometimes be related to abscess formation (Wu and Jones, 2010).

Other interventions

Invasive interventions other than surgery are commonly used in cancer therapy and may also result in predictable acute pain syndromes. Examples include the pains associated with tumour embolization techniques (Yu et al., 2008; Aliberti et al., 2011) radio-embolization of liver tumours (Sato et al., 2008), and chemical pleurodesis (Antunes et al., 2003; Shaw and Agarwal, 2004).

Acute pain associated with analgesic techniques
Local anaesthetic infiltration pain

Intradermal and subcutaneous infiltration of lidocaine produces a transient burning sensation before the onset of analgesia. This can be modified with the use of buffered solutions (Hanna et al., 2009) or by warming of the solution (Hogan et al., 2011). Slowing rate of injection does not diminish injection pain (Scarfone et al., 1998).

Opioid injection pain

Intramuscular (IM) and subcutaneous (SC) injections are painful. When repetitive dosing is required, the IM route of administration is not recommended (NHS Quality Improvement Scotland, 2004; Savoia et al., 2010; Wu and Raja, 2011). The pain associated with SC injection is influenced by the volume injected and the chemical characteristics of the injectant.

Opioid headache

Rarely, patients develop a reproducible generalized headache after opioid administration. Although its cause is not known, speculation suggests that it may be caused by opioid-induced histamine release.

Spinal opioid hyperalgesia syndrome

Intrathecal and epidural injection of high opioid doses is occasionally complicated by pain (typically perineal, buttock, or leg), hyperalgesia, and associated manifestations including segmental myoclonus, piloerection, and priapism. This is an uncommon phenomenon that remits after discontinuation of the infusion (De Conno et al., 1991; Cartwright et al., 1993).

Spinal injection pain

Back, pelvic, or leg pain may be precipitated by epidural injection or infusion. The incidence of this problem has been estimated at approximately 20% (Naumann et al., 1999; Willis and Doleys, 1999). It is speculated that it may be caused by the compression of an adjacent nerve root by the injected fluid (De Castro et al., 1991; Buchser and Chedel, 1992). Similar problems have been described with intrathecal injections associated with pericatheter fibrosis (Gaertner et al., 2003)

Acute pain associated with anticancer therapies
Acute pain associated with chemotherapy infusion techniques
Intravenous infusion pain

Pain at the site of cytotoxic infusion is a common problem. Four pain syndromes related to intravenous infusion of chemotherapeutic agents are recognized: venous spasm, chemical phlebitis, vesicant extravasation, and anthracycline-associated flare. Venous spasm causes pain that is not associated with inflammation or phlebitis, and which may be modified by application of a warm compress or reduction of the rate of infusion. Chemical phlebitis can be caused by cytotoxic medications including amsacrine, dacarbazine, carmustine (Hundrieser, 1988; Mrozek-Orlowski et al., 1991), vinorelbine (Rittenberg et al., 1995; de Lemos, 2005; Porzio et al., 2008), as well as the infusion of potassium chloride and hyperosmolar solutions (Pucino et al., 1988). The pain and linear erythema associated with chemical phlebitis must be distinguished from the more serious complication of a vesicant cytotoxic extravasation (Bertelli, 1995; Boyle and Engelking, 1995; Langer, 2010). Vesicant extravasation may produce intense pain followed by desquamation and ulceration (Sauerland et al., 2006; Wickham et al., 2006). Finally, a brief venous flare reaction is often associated with intravenous administration of the anthracycline, doxorubicin. The flare is typically associated with local urticaria and occasional patients report pain or stinging (Vogelzang, 1979; Curran et al., 1990).

Hepatic artery infusion pain

Cytotoxic infusions into the hepatic artery (for patients with hepatic metastases) are often associated with the development of a diffuse abdominal pain (Kemeny, 1991; Barnett and Malafa, 2001). Continuous infusions can lead to persistent pain. In some patients, the pain is due to the development of gastric ulceration

or erosions (Shike et al., 1986), or cholangitis (Batts, 1998). If the latter complications do not occur, the pain usually resolves with discontinuation of the infusion. A dose relationship is suggested by the observation that some patients will comfortably tolerate reinitiating of the infusion at a lower dose (Kemeny, 1992).

Intraperitoneal chemotherapy pain

A transient mild abdominal pain, associated with sensations of fullness or bloating is reported by approximately 25% of patients after intraperitoneal chemotherapy (Almadrones and Yerys, 1990; Jaaback and Johnson, 2006; American College of Obstetricians and Gynecologists, 2008a). A further 25% of patients reports moderate or severe pain necessitating opioid analgesia or discontinuation of therapy (Almadrones and Yerys, 1990). Moderate or severe pain is usually caused by chemical serositis or infection (Jaaback and Johnson, 2006). Chemical serositis is a common complication of intraperitoneal of the anthracycline agents mitoxantrone and doxorubicin and with taxol, but it is relatively infrequent with 5-flurouracil (5-FU) or cis-platinum. Pain may indicate suboptimal drug distribution within the abdominal cavity. Some patients experience discomfort related to sensing abdominal distention, or from intercostal nerve irritation (Topuz et al., 2000). Abdominal pain associated with fever and leucocytosis in blood and peritoneal fluid is suggestive of infectious peritonitis.

Intravesical chemo- or immunotherapy

Intravesical bacillus Calmette–Guérin (BCG) therapy for transitional cell carcinoma of the urinary bladder usually causes a transient bladder irritability syndrome characterized by frequency and/or micturition pain (Palou et al., 2001; Shelley et al., 2003, 2004). Similarly, intravesical doxorubicin (Matsumura et al., 1992), mitomycin C (Shelley et al., 2004), and thiotepa (Choe et al., 1995) can also cause a painful chemical cystitis. Rarely, intravesical BCG treatment may trigger a painful polyarthritis sometimes associated will a full blown Reiter's syndrome (Pardalidis et al., 2002; Okamoto et al., 2010) or localized regional or systemic infections with abscess formation (Alvarez-Mugica et al., 2009; Harving et al., 2009).

Acute pain associated with chemotherapy toxicity
Mucositis

Severe mucositis is an almost invariable consequence of the myeloablative chemotherapy and radiotherapy that precedes bone marrow transplantation, but it is less common with standard intensity therapy (Peterson and Lalla, 2010). The cytotoxic agents most commonly associated with mucositis are cytarabine, doxorubicin, etoposide, 5-FU, and methotrexate. Pretreatment oral pathology and poor dental hygiene increase the risk of chemotherapy-induced mucositis. Younger patients have a relatively greater risk of chemotherapy-induced stomatitis, perhaps related to a higher epithelial mitotic rate. Damaged mucosal surfaces may become superinfected with microorganisms, such as *Candida albicans* and herpes simplex (Peterson and Lalla, 2010). The latter complication is most likely in neutropenic patients, who are also predisposed to systemic sepsis arising from local invasion by aerobic and anaerobic oral flora.

Corticosteroid-induced perineal discomfort

A transient burning sensation in the perineum is described by some patients following rapid infusion of large doses (20–100 mg) of dexamethasone (Perron et al., 2003). Clinical severity is variable and may be severe (Neff et al., 2002). Experience suggests that this syndrome is prevented by slow infusion.

Steroid withdrawal pseudorheumatism

The withdrawal of corticosteroids may produce a pain syndrome which manifests as diffuse myalgias, arthralgias, and tenderness of muscles and joints. These symptoms occur with rapid or slow withdrawal and may occur in patients taking these drugs for long or short periods of time. Treatment consists of reinstituting the steroids at a higher dose and withdrawing them more slowly (Rotstein and Good, 1957, Weissman et al., 1991).

Painful peripheral neuropathy

Chemotherapy-induced painful peripheral neuropathy, which is usually associated with vinca alkaloids, cis-platinum, oxaliplatin, and paclitaxel can have an acute course. The vinca alkaloids (particularly vincristine) are also associated with other, presumably neuropathic, acute pain syndromes, including pain in the jaw, legs, arms, or abdomen that may last from hours to days (Sandler et al., 1969; Rosenthal and Kaufman, 1974; Legha, 1986; McCarthy and Skillings, 1992). Vincristine-induced orofacial pain in the distribution of the trigeminal and glossopharyngeal nerves occurs in approximately 50% of patients at the onset of vincristine treatment (Rose, 1967; McCarthy and Skillings, 1992). The pain, which is severe in about half of those affected, generally begins 2–3 days after vincristine administration and lasts for 1–3 days. It is usually self-limiting and if recurrence occurs, it is usually mild (McCarthy and Skillings, 1992). Vinorelbine is associated with mild paraesthesias in about 20% of patients and severe neuropathy is rare (Scalone et al., 2004). The neuropathy associated with paclitaxel neuropathy is dose related and is generally subacute in onset with resolution after the completion of therapy (Loprinzi et al., 2011); however, in a proportion of cases it can be severe and persistent (Argyriou et al., 2006a). Most patients treated with oxaliplatin experience symptoms of acute neurotoxicity including paraesthesias and dysaesthesias of the hands, feet, and perioral region and muscle cramps (Argyriou et al., 2013).

Headache

Intrathecal methotrexate in the treatment of leukaemia or leptomeningeal metastases produces an acute meningitic syndrome in 5–50% of patients (Weiss et al., 1974). Headache is the prominent symptom and may be associated with vomiting, nuchal rigidity, fever, irritability, and lethargy. Rarely, it may present as a polyradiculopathy (Pascual et al., 2008). Symptoms usually begin hours after intrathecal treatment and persist for several days. Patients at increased risk for the development of this syndrome include those who have received multiple intrathecal injections and those patients undergoing treatment for proven leptomeningeal metastases (Weiss et al., 1974). The syndrome tends not to recur with subsequent injections.

Systemic administration of L-asparaginase for the treatment of acute lymphoblastic leukaemia may cause a thrombosis of cerebral veins or dural sinuses in 1–2% of patients (Eloraby, 2009; Wani et al., 2010). Headache is the most common initial symptom, and seizures, hemiparesis, delirium, vomiting, or cranial nerve palsies may also occur. The diagnosis is established by magnetic resonance imaging (MRI) scan (Kieslich et al., 2003).

Trans-retinoic acid therapy, which may be used in the treatment of acute promyelocytic leukaemia (APML), can cause a transient

severe headache (Visani et al., 1996; Avvisati and Tallman, 2003). The mechanism may be related to pseudotumour cerebri induced by hypervitaminosis A.

Diffuse bone pain

Trans-retinoic acid therapy in patients with APML often produces a syndrome of diffuse bone pain (Avvisati and Tallman, 2003; Pilatrino et al., 2005). The pain is generalized, of variable intensity, and closely associated with a transient neutrophilia. The latter observation suggests that the pain may be due to marrow expansion.

Taxol-induced arthralgia and myalgia

Administration of paclitaxel generates a syndrome of diffuse arthralgias and myalgia in 10–20% of patients (Garrison et al., 2003; Loprinzi et al., 2007, 2011). They are related to individual doses; associations with the cumulative dose and infusion duration are less clear. Diffuse pain in joints and muscle generally appear 1–2 days after the infusion and lasted for a median of 4–5 days. Pain is commonly located in the back, hips, shoulders, thighs, legs, and feet. The pain is often exacerbated by weight bearing, walking, or tactile contact. Steroids may reduce tendency to myalgia and arthralgias (Markman et al., 1999).

5-flurouracil-induced anginal chest pain

Patients receiving 5-FU may develop ischaemic chest pain (Tsibiribi et al., 2006; Saif et al., 2009). Although the overall risk is generally considered low (1–2%), this is debated and there is some evidence suggesting risk as high as 20% (Saif et al., 2009). Overall the risk is higher with patients receiving continuous infusion than those receiving bolus therapy and patients with pre-existing ischaemic heart disease (Labianca et al., 1982). It is widely speculated that coronary vasospasm may be the underlying mechanism (Wacker et al., 2003; Shoemaker et al., 2004; Saif et al., 2009). Similar ischaemic cardiotoxicity has been reported in patients receiving the 5-FU prodrug capecitabine (Cardinale et al., 2006; Sestito et al., 2006; Monsuez et al., 2010).

Palmar–plantar erythrodysaesthesia syndrome

(Also called acral erythema, hand–foot syndrome, toxic erythema of the palms and soles, and Burgdof's syndrome.) This is a painful rash seen in association with continuously infused 5-FU, capecitabine (Gressett et al., 2006), and liposomal doxorubicin (Alberts and Garcia, 1997). It has also been reported with paclitaxel (Vukelja et al., 1993), the tyrosine kinase inhibitors sorafenib and sunitinib (Lipworth et al., 2009), and the mTOR inhibitor everolimus (Balagula et al., 2010). It is characterized by the development of a tingling or burning sensation in the palms and soles followed by the development of an erythematous rash. The pathogenesis is unknown. Management often requires the discontinuation of therapy and symptoms may be more manageable at lower doses of therapy. Symptomatic measures are often required (Bellmunt et al., 1988) and treatment with pyridoxine has been reported to induce resolution of the lesions (Fabian et al., 1990).

Post-chemotherapy gynaecomastia

Painful gynaecomastia can occur as a delayed complication of chemotherapy. Testis cancer is the most common underlying disorder (Aki et al., 1996; Uygur and Ozen, 2003), but it has been reported after therapy for other cancers as well (Glass and Berenberg, 1979; Trump et al., 1982). Gynaecomastia typically develops after a latency of 2–9 months and resolves spontaneously within a few months. Persistent gynaecomastia is occasionally observed (Trump et al., 1982).

Chemotherapy-induced acute digital ischaemia

Raynaud's phenomenon or transient ischaemia of the toes is a common complication of bleomycin, vinblastine, and cisplatin (PVB) treatment for testicular cancer (Aass et al., 1990). Rarely, irreversible digital ischaemia leading to gangrene has been reported after bleomycin (Elomaa et al., 1984). Capecitabine and vincristine have been implicated in case reports (Gottschling et al., 2004; Coward et al., 2005).

Chemotherapy-induced tumour pain

Pain at the site of tumour is reported to occur in some patients (7%) after treatment with vinorelbine. Typically, pain begins within a few minutes of the vinorelbine infusion, is moderate to severe in intensity and requires analgesic therapy. Premedication with ketorolac may prevent recurrence in some cases (Colleoni et al., 1995; Kornek et al., 1996; De Marco et al., 1999).

Acute pain associated with hormonal therapy

Luteinizing hormone-releasing factor tumour flare in prostate cancer

Initiation of luteinizing hormone-releasing factor (LHRF) hormonal therapy for prostate cancer produces a transient symptom flare in 5–25% of patients (Chrisp and Goa, 1991; Chrisp and Sorkin, 1991). The flare is presumably caused by an initial stimulation of luteinizing hormone release before suppression is achieved. The syndrome typically presents as an exacerbation of bone pain or urinary retention; spinal cord compression and sudden death have been reported (Thompson et al., 1990). Symptom flare is usually observed within the first week of therapy, and lasts 1–3 weeks in the absence of androgen antagonist therapy. Co-administration of an androgen antagonist during the initiation of LHRF agonist therapy can prevent this phenomenon (Labrie et al., 1987).

Hormone-induced pain flare in breast cancer

Any hormonal therapy for metastatic breast cancer can be complicated by a sudden onset of diffuse musculoskeletal pain commencing within hours to weeks of the initiation of therapy (Plotkin et al., 1978). Other manifestations of this syndrome include erythema around cutaneous metastases, changes in liver function studies, and hypercalcaemia. This may be associated with increased metabolic activity at tumour sites that can be detected on positron emission tomography (PET) scan (Mortimer et al., 2001). The underlying mechanism is not understood and the flare reaction is often predictive of later tumour response to the hormonal therapy.

Aromatase inhibitor-induced arthralgias

Aromatase inhibitor medications used in the hormonal therapy of breast cancer may cause a multifocal arthralgia syndrome in 10–20% of patients (Chlebowski, 2009). This most commonly manifests as early morning stiffness and hand/wrist pain. Pain intensity is variable and in some patients it interferes in daily activities. Occasionally it justifies discontinuation of treatment due to severe symptoms (Chlebowski, 2009). The possible mechanisms are unclear but an association with the development of osteoporosis has been noted (Muslimani et al., 2009). Treatment options for arthralgia (primarily NSAIDs) are often inadequate, and areas of active research include high-dose vitamin D and new targeted therapies to inhibit bone loss.

Acute pain associated with immunotherapy
Interferon-induced acute pain

Virtually all patients treated with interferon experience an acute syndrome consisting of fever, chills, myalgias, arthralgias, and headache (Quesada et al., 1986). The syndrome usually begins shortly after initial dosing and frequently improves with continued administration of the drug (Quesada et al., 1986). Doses of 1–9 million units of alpha-interferon are usually tolerated, but doses greater than or equal to 18 million units usually produce moderate to severe toxicity (Quesada et al., 1986). Acetaminophen pre-treatment is often useful in ameliorating these symptoms.

Acute pain associated with bisphosphonates
Bisphosphonate-induced bone pain

Bisphosphonates are widely used in the care of patients with bony metastases. Infusion of bisphosphonates is commonly associated with the development of multifocal bone pain and/or myalgia. Typically, pain occurs within 24 hours of infusion and may last up to 3 days. Pain intensity is variable and may be severe. The condition is self-limiting but may require analgesic therapy (Coukell and Markham, 1998; Lipton, 2007).

Acute pain associated with growth factors

Granulocyte-macrophage colony-stimulating factor (GM-CSF) and granulocyte colony-stimulating factor (G-CSF) commonly produce mild to moderate bone pain and constitutional symptoms such as fever, headache, and myalgias during the period of administration (Vial and Descotes, 1995; Veldhuis et al., 1995). In studies of G-CSF in dose-dense chemotherapy the prevalence of pain is 20–30% (Paciucci et al., 2002; Venturini et al., 2005) and similar prevalence is seen with pegylated G-CSF (Hill et al., 2006). Pain intensity is variable and may be severe. Co administration of dexamethasone may reduce the prevalence and severity of bone pain (Heuft et al., 2004).

Subcutaneous administration of recombinant human erythropoietin (r-HuEPO) alpha is associated with pain at the injection site in about 40% of cases (Frenken et al., 1991). Subcutaneous injection of r-HuEPO alpha is more painful than r-HuEPO beta (Morris et al., 1994). Alpha erythropoietin injection pain can be reduced by dilution of the vehicle with benzyl alcohol saline, reduction of the volume of the vehicle to 1.0–0.1 mL (Frenken et al., 1994) or addition of lidocaine (Alon et al., 1994).

Acute pain associated with radiotherapy

Incident pains can be precipitated by transport and positioning of the patient for radiotherapy. Other pains can be caused by acute radiation toxicity, which is most commonly associated with inflammation and ulceration of skin or mucous membranes within the radiation port. The syndrome produced is dependent upon the involved field: head and neck irradiation can cause a stomatitis or pharyngitis (Rider, 1990), treatment of the chest and oesophagus can cause an esophagitis (Vanagunas et al., 1990), and pelvic therapy can cause a proctitis, cystitis-urethritis, vaginal ulceration, or radiation dermatitis.

Oropharyngeal mucositis

Radiotherapy-induced mucositis is invariable with doses above 1000 cGy, and ulceration is common at doses above 4000 cGy. Although the severity of the associated pain is variable, it is often severe enough to interfere with oral alimentation. Painful mucositis can persist for several weeks after the completion of the treatment (Scully et al., 2003, 2004).

Acute radiation enteritis and proctocolitis

Acute radiation enteritis occurs in as many as 50% of patients receiving abdominal or pelvic radiotherapy. Involvement of the small intestine can present with cramping abdominal pain associated with nausea and diarrhoea (Andreyev et al., 2005). Pelvic radiotherapy can cause a painful proctocolitis, with tenesmoid pain associated with diarrhoea, mucous discharge, and bleeding (Babb, 1996; Andreyev et al., 2005). These complications typically resolve shortly after completion of therapy, but may have a slow resolution over 2–6 months (Nussbaum et al., 1993; Babb, 1996; Andreyev et al., 2005). Acute enteritis predicts for an increased risk of late-onset radiation enteritis (see following paragraphs).

Early-onset brachial plexopathy

A transient brachial plexopathy has been described in breast cancer patients immediately following radiotherapy to the chest wall and adjacent nodal areas (Salner et al., 1981; Pierce et al., 1992) and after mantle radiotherapy for Hodgkin's disease (Churn et al., 2000). In retrospective studies, the incidence of this phenomenon has been variably estimated as 1.4–20% (Salner et al., 1981; Pierce et al., 1992); clinical experience suggests that lower estimates are more accurate. The median latency to the development of symptoms was 4.5 months (3–14 months) in one survey (Salner et al., 1981). Paraesthesias are the most common presenting symptom, and pain and weakness occur less frequently. The syndrome is self-limiting and is not predictive of the subsequent development of delayed onset, progressive plexopathy.

Subacute radiation myelopathy

Subacute radiation myelopathy is an uncommon phenomenon that may occur following radiotherapy of extraspinal tumours (Ang and Stephens, 1994; Schultheiss, 1994). It is most frequently observed involving the cervical cord after radiation treatment of head and neck cancers and Hodgkin's disease. In the latter case, patients develop painful, shock-like pains in the neck that are precipitated by neck flexion (Lhermitte's sign); these pains may radiate down the spine and into one or more extremities. The syndrome usually begins weeks to months after the completion of radiotherapy, and typically resolves over a period of 3–6 months (Ang and Stephens, 1994)

Radiotherapy-induced pain flare

Palliative radiotherapy of bone metastases causes a temporary increase in bone pain in 30–40% of patients immediately after radiotherapy (Loblaw et al., 2007; Hird et al., 2009a). This is better treated with prophylactic medication rather than management with breakthrough pain medications. A single 8 mg dose of dexamethasone before radiotherapy has been effective in reducing the severity and prevalence of pain (Hird et al., 2009c).

The radiopharmaceuticals strontium-89, rhenium-186 hydroxyethylidene diphosphonate, and samarium-153 are systemically administered beta-emitting calcium analogues that are taken up by bone in areas of osteoblastic activity and which may help relieve pain caused by blastic bony metastases (McEwan, 1997). A 'flare' response, characterized by transient worsening of pain 1–2 days after administration, occurs in 15–20% of patients (Robinson et al., 1995). This flare usually resolves after 3–5 days and most effected patients subsequently develop a good analgesic response (Robinson et al., 1995).

Acute pain associated with infection

Acute herpetic neuralgia

A significantly increased incidence of acute herpetic neuralgia occurs among cancer patients, especially those with haematological or lymphoproliferative malignancies and those receiving immunosuppressive therapies (Portenoy et al., 1986; Rusthoven et al., 1988; Insinga et al., 2005). The pain, which may be continuous or lancinating, usually resolves within 2 months (Galer and Portenoy, 1991). Pain persisting beyond this interval is referred to as post-herpetic neuralgia (PHN) (see 'Post-herpetic neuralgia' section). Patients with active tumour are more likely to have a disseminated infection (Rusthoven et al., 1988). In those predisposed by chemotherapy, the infection usually develops less than 1 month after the completion of treatment. The dermatomal location of the infection is often associated with the site of the malignancy (Rusthoven et al., 1988). The infection also occurs twice as frequently in previously irradiated dermatomes as non-radiated areas (Dunst et al., 2000).

Acute pain associated with vascular events

Acute thrombosis pain

Thrombosis is the most frequent complication and the second cause of death in patients with overt malignant disease (Ashrani and Heit, 2009; Rana and Levine, 2009). Thrombotic episodes may precede the diagnosis of cancer by months or years and represent a potential marker for occult malignancy (Prandoni and Piccioli, 2006). Postoperative deep vein thrombosis is more frequent in patients operated for malignant diseases than for other disorders, and both chemotherapy and hormone therapy are associated with an increased thrombotic risk (Ashrani and Heit, 2009; Rana and Levine, 2009).

Possible prothrombic factors in cancer include the capacity of tumour cells and their products to interact with platelets, clotting and fibrinolytic systems, endothelial cells, and tumour-associated macrophages. Cytokine release, acute phase reaction, and neovascularization may contribute to *in vivo* clotting activation (Sood, 2009). Data from a very large cohort of 66 329 cancer patients demonstrated that bone, ovary, brain, and pancreas cancers are associated with the highest incidence thrombosis and that distant metastases, chemotherapy and hormonal therapy all led to a 1.5–2.5 times increased risk (Blom et al., 2006).

Lower-extremity deep venous thrombosis

Pain and swelling are the commonest presenting features of lower extremity deep vein thrombosis (Criado and Burnham, 1997; Qaseem et al., 2007). The pain is variable in severity and it is often mild. It is commonly described as a dull cramp, or diffuse heaviness. The pain most commonly affects the calf but may involve the sole of the foot, the heel, the thigh, the groin, or pelvis. Pain usually increases on standing and walking. On examination, suggestive features include swelling, warmth, dilatation of superficial veins, tenderness along venous tracts, and pain induced by stretching (Criado and Burnham, 1997).

Rarely, patients may develop tissue ischaemia or frank gangrene, even without arterial or capillary occlusion; this syndrome is called phlegmasia cerulea dolens. It is most commonly seen in patients with underlying neoplasm (Hirschmann, 1987; Lorimer et al., 1994) and it is also seen proximal to inferior vena cava

filters (Cookson and Caldwell, 2012; Kiefer and Colletti, 2013). Clinically it is characterized by severe pain, extensive oedema, and cyanosis of the legs. Gangrene can occur unless the venous obstruction is relieved. Intravenous thrombolytic therapy (Tardy et al., 2006) may be more effective than traditional treatments with anticoagulation and thrombectomy (Perkins et al., 1996). Until recently, the mortality rate for ischaemic venous thrombosis was about 30–40%, the cause of death usually being the underlying disease or pulmonary emboli (Vysetti et al., 2009)

Upper-extremity deep venous thrombosis

The three major clinical features of upper-extremity venous thrombosis are oedema, dilated collateral circulation, and pain (Flinterman et al., 2008). Approximately two-thirds of patients have arm pain. Among patients with cancer the most common causes are central venous catheterization and extrinsic compression by tumour (Flinterman et al., 2008). Although much less common, phlegmasia of the upper limb has been reported (Bedri et al., 2009; Petritsch et al., 2012). Although thrombosis secondary to intrinsic damage usually responds well to anticoagulation alone and rarely causes persistent symptoms, when extrinsic obstruction is the cause, persistent arm swelling and pain are commonplace (Flinterman et al., 2008).

Superior vena cava obstruction

Superior vena cava (SVC) obstruction is most commonly caused by extrinsic compression by enlarged mediastinal lymph nodes (Rice et al., 2006; Wilson et al., 2007; Wan and Bezjak, 2009). In contemporary series, lung cancer and lymphomas are the most commonly associated conditions. Increasingly, thrombosis of the SVC is caused by intravascular devices (Morales et al., 1997; Rice et al., 2006) particularly with left-sided ports and when the catheter tip lies in the upper part of the vena (Puel et al., 1993). Patient usually present with facial swelling and dilated neck and chest wall veins. Chest pain, headache, and mastalgia are less common presentations.

Acute mesenteric vein thrombosis

Acute mesenteric vein thrombosis is most commonly associated with hypercoagulability states. Rarely, it has been associated with extrinsic venous compression by malignant lymphadenopathy (Traill and Nolan, 1997), extension of venous thrombosis (Vigo et al., 1980), as a result of iatrogenic hypercoagulable state (Sahdev et al., 1985) or as an adverse effect of pancreatic resection (Zyromski and Howard, 2008).

Superficial thrombophlebitis

Superficial thrombophlebitis is more common among patients with cancer and may be a presenting symptom of cancer (Mouton et al., 2009; van Doormaal et al., 2010). It presents with the development of a palpable tender cord in the course of a superficial vein; often associated with erythema of the overlying skin. Duplex ultrasound should be considered to rule out occult deep venous thrombosis, particularly when the greater or lesser saphenous veins are involved (Blumenberg et al., 1998).

Trousseau's syndrome or migratory thrombophlebitis is a rare condition characterized by a recurrent and migratory pattern and involvement of superficial veins, frequently in unusual sites such as the arm or chest (Varki, 2007).

Chronic pain syndromes

Most chronic cancer-related pains are caused directly by the tumour. Data from the largest prospective survey of cancer pain syndromes revealed that almost one-quarter of the patients experienced two or more pains. Over 90% of the patients had one or more tumour related pains and 21% had one or more pains caused by cancer therapies. Somatic pains (71%) were more common than neuropathic (39%) or visceral pains (34%) (Caraceni and Portenoy, 1999). Bone pain and compression of neural structures are the two most common causes.

Bone pain

Bone metastases are the most common cause of chronic pain in cancer patients. Cancers of the lung, breast, and prostate most often metastasize to bone, but any tumour type may be complicated by painful bony lesions. Although bone pain is usually associated with direct tumour invasion of bony structures, more than 25% of patients with bony metastases are pain free (Wagner, 1984), and patients with multiple bony metastases typically report pain in only a few sites.

Differential diagnosis

Bone pain due to metastatic tumour needs to be differentiated from less common causes. Non-neoplastic causes in this population include osteoporotic fractures (including those associated with multiple myeloma), focal osteonecrosis, which may be idiopathic or related to chemotherapy, corticosteroids, or radiotherapy (see following paragraphs) and osteomalacia (Gray et al., 1992; Shane et al., 1997). Rarely, a paraneoplastic osteomalacia, which is associated with elevated levels of fibroblast growth factor 23, can mimic multiple metastases (Woznowski et al., 2008; Zadik and Nitzan, 2012).

Multifocal or generalized bone pain

Bone pain may be focal, multifocal, or generalized. Multifocal bone pains are most commonly experienced by patients with multiple bony metastases. A generalized pain syndrome is occasionally produced by replacement of bone marrow (Jonsson et al., 1990; Wong et al., 1993; Hesselmann et al., 2002; Lin et al., 2002; Hussain and Chui, 2006). This bone marrow replacement syndrome has been observed in haematogenous malignancies and, less commonly, in solid tumours (Cohen et al., 1982; Wong et al., 1993; Hussain and Chui, 2006) and brain tumours (Didelot et al., 2006; Cordiano et al., 2011). This syndrome can occur in the absence of abnormalities on bone scintigraphy or radiography, increasing the difficulty of diagnosis. It is best demonstrated on MRI scanning (Ollivier et al., 2006) or using PET scanning techniques (Evangelista et al., 2012).

Vertebral syndromes

The vertebrae are the most common sites of bony metastases. More than two-thirds of vertebral metastases are located in the thoracic spine; lumbosacral and cervical metastases account for approximately 20% and 10%, respectively. Multiple level involvement is common, occurring in greater than 85% of patients (Constans et al., 1983).

The early recognition of pain syndromes due to tumour invasion of vertebral bodies is essential, since pain usually precedes compression of adjacent neural structures and prompt treatment of the lesion may prevent the subsequent development of neurologic deficits. Several factors often confound accurate diagnosis; referral of pain is common, and the associated symptoms and signs can mimic a variety of other disorders, both malignant (e.g. paraspinal masses) and non-malignant.

Atlantoaxial destruction and odontoid fracture

Nuchal or occipital pain is the typical presentation of destruction of the atlas or fracture of the odontoid process. Pain often radiates over the posterior aspect of the skull to the vertex and is exacerbated by movement of the neck, particularly flexion (Bilsky et al., 2002; Lakemeier et al., 2009). Pathological fracture may result in secondary subluxation with compression of the spinal cord at the cervicomedullary junction. This complication is usually insidious and may begin with symptoms or signs in one or more extremity. Typically, there is early involvement of the upper extremities and the occasional appearance of so-called 'pseudo-levels' suggestive of more caudal spinal lesions; these deficits can slowly progress to involve sensory, motor, and autonomic function (Sundaresan et al., 1981).

C7–T1 syndrome

Invasion of the C7 or T1 vertebra can result in pain referred to the interscapular region. These lesions may be missed if radiographic evaluation is mistakenly targeted to the painful area caudal to the site of damage. Additionally, visualization of the appropriate region on routine radiographs may be inadequate due to obscuration by overlying bone and mediastinal shadows. Patients with interscapular pain should therefore undergo radiography of both the cervical and the thoracic spine.

T12–L1 (thoracolumbar junction) syndrome

A T12 or L1 vertebral lesion can refer pain to the ipsilateral iliac crest or the sacroiliac joint. Imaging procedures directed at pelvic bones can miss the source of the pain.

Sacral syndrome

Severe focal pain radiating to buttocks, perineum, or posterior thighs may accompany destruction of the sacrum (Nader et al., 2004). The pain is often exacerbated by sitting or lying and is relieved by standing or walking (Payer, 2003). Tumour can spread laterally to involve muscles that rotate the hip (e.g. the pyriformis muscle). This may produce severe incident pain induced by motion of the hip, or a malignant 'pyriformis syndrome', characterized by buttock or posterior leg pain that is exacerbated by internal rotation of the hip. Local extension of the tumour mass may also involve the sacral plexus (see following paragraphs).

Back pain and epidural compression

Epidural compression of the spinal cord or cauda equina is a common neurologic complication of cancer. In a large retrospective series, 0.23% of cancer patients had epidural compression at the presentation of their disease and 2.5% of patients dying of cancer had at least one admission for cord compression in the 5 years preceding death (Loblaw et al., 2012). Breast, lung, and prostate cancers each account for 20–25% of events (Loblaw et al., 2012). Most epidural compression is caused by posterior extension of vertebral body metastasis to the epidural space. Occasionally, epidural compression is caused by tumour extension from the posterior arch of the vertebra or infiltration of a paravertebral tumour through the intervertebral foramen.

Untreated, epidural compression leads inevitably to neurological damage. Effective treatment can potentially prevent these complications. The most important determinate of the efficacy of treatment is the degree of neurological impairment at the time therapy is initiated. Seventy-five per cent of patients who begin treatment while ambulatory remain so; the efficacy of treatment declines to 30–50% for those who begin treatment while markedly paretic, and is 10–20% for those who are plegic (Prasad and Schiff, 2005). Despite this, delays in diagnosis are commonplace (Loblaw et al., 2005; Abrahm et al., 2008).

Back pain is the initial symptom in almost all patients with epidural compression (Posner, 1987; Dugas et al., 2011), and in 10% it is the only symptom at the time of diagnosis (Greenberg et al., 1980). Since pain usually precedes neurologic signs by a prolonged period, it should be viewed as a potential indicator of epidural compression, which can lead to treatment at a time that a favourable response is most likely. Back pain, however, is a non-specific symptom that can result from bony or paraspinal metastases without epidural encroachment, from retroperitoneal or leptomeningeal tumour, epidural lipomatosis due to steroid administration (Stranjalis et al., 1992) or from a large variety of other benign conditions. Since it is not feasible to pursue an extensive evaluation in every cancer patient who develops back pain, the complaint should impel an evaluation that determines the likelihood of epidural compression and thereby selects patients appropriate for definitive imaging of the epidural space. The selection process is based on symptoms and signs and the results of simple imaging techniques.

Suggestive clinical features

Some pain characteristics are particularly suggestive of epidural extension (Helweg-Larsen and Sorensen, 1994). Rapid progression of back pain in a crescendo pattern is an ominous occurrence (Rosenthal et al., 1992). Radicular pain, which can be constant or lancinating has similar implications (Helweg-Larsen and Sorensen, 1994). It is usually unilateral in the cervical and lumbosacral regions and bilateral in the thorax, where it is often experienced as a tight, belt-like band across the chest or abdomen (Helweg-Larsen and Sorensen, 1994). The likelihood of epidural compression is also greater when back or radicular pain is exacerbated by recumbency, cough, sneeze, or strain (Ruff and Lanska, 1989). Other types of referred pain are also suggestive, including Lhermitte's sign (Ventafridda et al., 1991) and central pain from spinal cord compression, which usually is perceived some distance below the site of the compression and is typically a poorly localized, non-dermatomal dysaesthesia (Posner, 1987).

Weakness, sensory loss, autonomic dysfunction, and reflex abnormalities usually occur after a period of progressive pain (Helweg-Larsen and Sorensen, 1994). Weakness may begin segmentally if related to nerve root damage or in a multisegmental or pyramidal distribution if the cauda equina or spinal cord, respectively, is injured. The rate of progression of weakness is variable; in the absence of treatment, following the onset of weakness one-third of patients will develop paralysis within 7 days (Barron et al., 1959). Without effective treatment, sensory abnormalities, which may also begin segmentally, may ultimately evolve to a sensory level, with complete loss of all sensory modalities below the site of injury. The upper level of sensory findings may correspond to the location of the epidural tumour or be below it by many segments (Helweg-Larsen and Sorensen, 1994). Ataxia without pain is the initial presentation of epidural compression in 1% of patients; this finding is presumably due to early involvement of the spinocerebellar tracts (Gilbert et al., 1978).

Bladder and bowel dysfunction generally occur late, except in patients with a conus medullaris lesion who may present with acute urinary retention and constipation without preceding motor or sensory symptoms (Helweg-Larsen and Sorensen, 1994).

Other features that may be evident on examination of patients with epidural compression include scoliosis, asymmetrical wasting of paravertebral musculature, and a gibbus (palpable step in the spinous processes). Spinal tenderness to percussion, which may be severe, often accompanies the pain.

Imaging modalities

Definitive imaging of the epidural space confirms the existence of epidural compression (and thereby indicates the necessity and urgency of treatment), defines the appropriate radiation portals, and determines the extent of epidural encroachment (which influences prognosis and may alter the therapeutic approach). The options for definitive imaging include MRI, myelography, and computed tomography (CT) myelography or spiral CT without myelographic contrast.

MRI is non-invasive and offers accurate imaging of the vertebrae, intraspinal, and paravertebral structures. When available it is generally the preferred mode of evaluation (Loblaw et al., 2005). Whenever possible, total spine imaging should be performed since multiple level involvement is common and other sites may be clinically occult. In a study of 65 patients with cord compression, 32 (49%) showed multiple level involvement and of these, 28 (66%) were clinically occult (Heldmann et al., 1997). MRI has multiple advantages: metastases can be distinguished from other pathological processes involving the axial skeleton, epidural and intradural space, and spinal cord. This is particularly true for bacterial abscesses, leptomeningeal carcinomatosis, intradural extramedullary or, rarely, intramedullary metastases or primary tumours and infectious or inflammatory myelitis.

MRI is relatively contraindicated in patients with severe claustrophobia and certain metallic implants, and is absolutely contraindicated for patients with cardiac pacemakers or aneurysm clips. Several other groups who may not be suitable for MRI include very obese patients and those with severe kyphosis or scoliosis.

CT: similar to MRI, CT scanning is non-invasive, and it provides excellent visualization of the vertebrae, vertebral structural integrity, paravertebral soft tissues, and of the vertebral foraminae. The improved resolution observed with contemporary spiral techniques facilitate very clear imaging of the spinal canal contents. CT scanning of regions identified by either plain radiography or bone scan usually provides excellent visualization of cortical integrity, the intervertebral foraminae, and canal contents and correlation studies with MRI findings demonstrated very high sensitivity and specificity (Crocker et al., 2011). Bone and soft tissue windows are used in a complementary manner; bone windows allow evaluation of bony integrity and, in particular, of cortical breach, and soft-tissue windows are used to evaluate the contents of the spinal canal. Using this approach one can reserve more expensive and less readily available MRI imaging for equivocal cases, when leptomeningeal metastases are suspected, or when total spinal imaging is required.

With the improved resolution of standard CT techniques, post-myelographic CT is a technique that is now rarely used. Besides immediate patient discomfort, myelography is often complicated by post-procedure side effects that include back pain, headache, vomiting, seizures, and adverse neurobehavioral reactions. The risk of adverse effects is related to the gauge and type of needle used (Wilkinson and Sellar, 1991), the contrast medium (Killebrew et al., 1983), and the anatomy of the epidural compression.

Pain syndromes of the bony pelvis and hip

The pelvis and hip are common sites of metastatic involvement. Lesions may involve any of the three anatomic regions of the pelvis (ischiopubic, iliosacral, or periacetabular), the hip joint itself, or the proximal femur (Papagelopoulos et al., 2007). The weight-bearing function of these structures, essential for normal ambulation, contributes to the propensity of disease at these sites to cause incident pain with walking and weight bearing.

Hip joint syndrome

Tumour involvement of the acetabulum or head of femur typically produces localized hip pain that is aggravated by weight bearing and movement of the hip (Singh et al., 2006). The pain may radiate to the knee or medial thigh, and occasionally, pain is limited to these structures (Sim, 1992). Medial extension of an acetabular tumour can involve the lumbosacral plexus as it traverses the pelvic sidewall. Evaluation of this region is best accomplished with CT or MRI, both of which can demonstrate the extent of bony destruction and adjacent soft tissue involvement more sensitively than other imaging techniques (Vijayanathan et al., 2009), PET/CT approaches assist by identifying disease activity (Vijayanathan et al., 2009). Important differential diagnoses include avascular necrosis, radicular pain (usually L1) or, occasionally, occult infections.

Acrometastases

Acrometastases, metastases in the hands and feet are rare and often misdiagnosed or overlooked. In the feet, the larger bones containing the higher amounts of red marrow, such as the os calcis, or talus are usually involved (Kouvaris et al., 2005; Bahk et al., 2006). Symptoms may be vague and can mimic other conditions, such as osteomyelitis, gouty rheumatoid arthritis, Reiter's syndrome, Paget's disease, osteochondral lesions, and ligamentous sprains.

Arthritides

Hypertrophic pulmonary osteoarthropathy

Hypertrophic pulmonary osteoarthropathy (HPOA) is a paraneoplastic syndrome that incorporates clubbing of the fingers, periostitis of long bones, and occasionally a rheumatoid-like polyarthritis (Martinez-Lavin, 1997). Periostitis and arthritis can produce pain, tenderness, and swelling in the knees, wrists, and ankles. The onset of symptoms is usually subacute, and it may precede the discovery of the underlying neoplasm by several months. It is most commonly associated with non-small cell lung cancer; however, even in that setting it is uncommon (Ito et al., 2010). Rarely, it may be associated with benign mesothelioma, pulmonary metastases from other sites, smooth muscle tumours of the oesophagus, breast cancer, and metastatic nasopharyngeal cancer.

HPOA is diagnosed on the basis of physical findings, radiological appearance, and radionuclide bone scan (Greenfield et al., 1967; Sharma, 1995; Martinez-Lavin, 1997). Effective anti-tumour therapy is sometimes associated with symptom regression (Hung et al., 2000; Kishi et al., 2002; Ito et al., 2010), bisphosphonate therapy may help relieve symptoms (Suzuma et al., 2001; Amital et al., 2004), and there are case reports of resolution after vagotomy (Treasure, 2006; Ooi et al., 2007)

Other polyarthritides

Rarely, rheumatoid arthritis, systemic lupus erythematosus, and an asymmetrical polyarthritis may occur as paraneoplastic phenomena that resolve with effective treatment of the underlying disease (Racanelli et al., 2008). A syndrome of palmar plantar fasciitis and polyarthritis characterized by palmar and digital with polyarticular painful capsular contractions, has been associated with ovarian (Shiel et al., 1985; Giannakopoulos et al., 2005), breast (Saxman and Seitz, 1997), and gastric (Enomoto et al., 2000) cancers.

Muscle pain

Muscle cramps

Persistent muscle cramps in cancer patients are usually caused by an identifiable neural, muscular, or biochemical abnormality (Siegal, 1991). In one series of 50 patients, 22 had peripheral neuropathy, 17 had root or plexus pathology (including six with leptomeningeal metastases), two had polymyositis and one had hypomagnesaemia. In this series, muscle cramps were the presenting symptom of recognizable and previously unsuspected neurologic dysfunction in 27 of 42 (64%) of the identified causes (Steiner and Siegal, 1989). Cramps have been reported as an adverse effect of imatinib (Breccia et al., 2005), goserelin (Ernst et al., 2004), and vincristine (Haim et al., 1994).

Skeletal muscle tumours

Soft tissue sarcomas arising from fat, fibrous tissue, or skeletal muscle are the most common tumours involving the skeletal muscles. Skeletal muscle is one of the most unusual sites of metastasis from any malignancy. They occur disproportionally at sites of prior muscle trauma (Magee and Rosenthal, 2002). Lesions are usually painless but they may present with persistent ache.

Headache and facial pain

Headache in the cancer patient results from traction, inflammation, or infiltration of pain-sensitive structures in the head or neck. Early evaluation with appropriate imaging techniques may identify the lesion and allow prompt treatment, which may reduce pain and prevent the development of neurological deficits (Vecht et al., 1992).

Intracerebral tumour

The prevalence of headache in patients with brain metastases or primary brain tumours is 60–90% (Chidel et al., 2000; El Kamar and Posner, 2004; Kirby and Purdy, 2007) and headache is often the first presenting symptom of patients with brain tumours or metastases (Argyriou et al., 2006b; Wilne et al., 2006; Kirby and Purdy, 2007) and is often associated with dizziness (Hird et al., 2009b). Among 183 patients with new-onset chronic headache, as an isolated symptom, investigation revealed underlying tumour

in 15 cases (Vazquez-Barquero et al., 1994). The headache is presumably produced by traction on pain-sensitive vascular and dural tissues. Patients with multiple metastases and those with posterior fossa metastases are more likely to report this symptom (Kirby and Purdy, 2007). The pain may be focal, overlying the site of the lesion, or generalized. Headache has lateralizing value, especially in patients with supratentorial lesions (Suwanwela et al., 1994; Argyriou et al., 2006b; Kirby and Purdy, 2007). Posterior fossa lesions often cause a bi-frontal headache. The quality of the headache is usually throbbing or steady, and the intensity is usually mild to moderate (Suwanwela et al., 1994; Argyriou et al., 2006b).

Among children, headache is the most common presenting symptom of brain tumours (Wilne et al., 2006) The clinical features predictive of underlying tumour include sleep-related headache, headache in the absence of a family history of migraine, vomiting, absence of visual symptoms, headache of less than 6 months' duration, confusion, and abnormal neurologic examination findings (Medina et al., 1997; Wilne et al., 2006). The headache is often worse in the morning and is exacerbated by stooping, sudden head movement, or Valsalva manoeuvres (cough, sneeze or strain) (Suwanwela et al., 1994).

Leptomeningeal metastases

Leptomeningeal metastases, which are characterized by diffuse or multifocal involvement of the subarachnoid space by metastatic tumour occur in 1–8% in patients with systemic cancer (Grossman and Krabak, 1999; Taillibert et al., 2005). Non-Hodgkin's lymphoma and acute lymphocytic leukaemia both demonstrate predilection for meningeal metastases (Nolan and Abrey, 2005); the incidence is lower for solid tumours alone (Bruno and Raizer, 2005). Of solid tumours, adenocarcinomas of the breast and small cell lung cancer predominate (Bruno and Raizer, 2005).

Leptomeningeal metastases present with focal or multifocal neurological symptoms or signs that may involve any level of the neuraxis (Wasserstrom et al., 1982; Grossman and Krabak, 1999; van Oostenbrugge and Twijnstra, 1999; Yamanaka et al., 2011). The most common presenting symptoms are headache, cranial nerve palsies (Yamanaka et al., 2011), and radicular pain in the low back and buttocks (van Oostenbrugge and Twijnstra, 1999). More than one-third of patients presents with evidence of cranial nerve damage, including double vision, hearing loss, facial numbness, and decreased vision (Wasserstrom et al., 1982; van Oostenbrugge and Twijnstra, 1999; Yamanaka et al., 2011). Less common features include seizures, papilloedema, hemiparesis, ataxic gait, and confusion (Balm and Hammack, 1996).

The headache is variable and may be associated with changes in mental status (e.g. lethargy, confusion, or loss of memory), nausea, vomiting, tinnitus, or nuchal rigidity. Pains that resemble cluster headache (DeAngelis and Payne, 1987) or glossopharyngeal neuralgia with syncope (Sozzi et al., 1987) have also been reported.

Increasingly, gadolinium-enhanced MRI imaging of the neuraxis is the investigation of choice when leptomeningeal metastases are suspected. Compared to CSF cytology examination, MRI probably is more sensitive but it is less specific as false positive cytologies are rare (Straathof et al., 1999). When headache is the presenting feature, gadolinium-enhanced MRI examination of the brain, is the initial imaging investigation, especially if signs of cranial nerve involvement are present (Collie et al., 1999; Straathof et al., 1999). If this is non-diagnostic and if the pain

distribution indicates spinal involvement, sensitivity is enhanced by performing an examination of the whole spine. There is evidence that gadolinium-enhanced spinal MRI may be positive in almost 50% of patients without clinical findings related to the spinal region and in 60% of patients with negative cerebrospinal fluid (CSF) cytology (Gomori et al., 1998). Additionally, findings of contrast enhancement of the basilar cisterns, parenchymal metastases, hydrocephalus without a mass lesion, or spinal subarachnoid masses or enhancement may all have therapeutic implications (Grossman and Krabak, 1999).

The diagnosis of leptomeningeal metastases may be confirmed through analysis of the CSF. The CSF may reveal elevated pressure, elevated protein, depressed glucose, and/or lymphocytic pleocytosis. Ninety per cent of patients ultimately show positive cytology, but multiple evaluations may be required. After a single LP, the false-negative rate may be as high as 55%; this falls to only 10% after three LPs (Olson et al., 1974; Wasserstrom et al., 1982; Kaplan et al., 1990). Despite these measures, CSF cytology is persistently negative in as many as 20% of patients with clinically or radiographically unequivocal leptomeningeal involvement presumably because the malignant cells adhere to the leptomeninges rather than float in the CSF. The sensitivity and specificity of CSF cytology may be enhanced by the use of fluorescence *in situ* hybridization (FISH) (van Oostenbrugge et al., 1998, 2000) or immunocytochemical techniques (Thomas et al., 2000). Tumour markers, such as lactic dehydrogenase (LDH) isoenzymes (Wasserstrom et al., 1982), carcinoembryonic antigen (Liu et al., 2009), beta-2-microglobulin (Twijnstra et al., 1987), and tissue polypeptide antigen (Soletormos and Bach, 2001) may help to delineate the diagnosis. Flow cytometry for detection of abnormal DNA content may be a useful adjunct to cytological examination (Schinstine et al., 2006).

Untreated leptomeningeal metastases cause progressive neurologic dysfunction at multiple sites, followed by death in 4–6 weeks. Current treatment strategies, which includes radiation therapy to the area of symptomatic involvement, corticosteroids, and intraventricular or intrathecal chemotherapy or systemic chemotherapy, are of limited efficacy and in general patient outlook remains poor (Clarke et al., 2010).

Base of skull metastases

Base of skull metastases are associated with well-described clinical syndromes (Greenberg et al., 1981; Laigle-Donadey et al., 2005), which are named according to the site of metastatic involvement: orbital, parasellar, middle fossa, jugular foramen, occipital condyle, clivus, and sphenoid sinus (Fig. 13.1.1). Cancers of the breast, lung, and prostate are most commonly associated with this complication (Greenberg et al., 1981; Hawley et al., 1999; Laigle-Donadey et al., 2005), but any tumour type that metastasizes to bone may be responsible. When base of skull metastases are suspected, axial imaging with CT (including bone window settings) is the usual initial procedure (Greenberg et al., 1981; Laigle-Donadey et al., 2005). MRI is more sensitive for assessing soft tissue extension, and CSF analysis may be needed to exclude leptomeningeal metastases.

Orbital syndrome

Orbital metastases usually present with progressive pain in the retro-orbital and supraorbital area of the affected eye (Ben Simon et al., 2006; Ahmad and Esmaeli, 2007). Blurred vision and
Fig. 13.1.1 Axial CT scan of a 54-year-old man with tumour arising in paranasal sinuses (arrow 1) with extension to the orbit (arrow 2) and nasopharynx (arrow 3).

diplopia may be associated complaints. Signs may include proptosis, chemosis of the involved eye, external ophthalmoparesis, ipsilateral papilloedema, and decreased sensation in the ophthalmic division of the trigeminal nerve.

Parasellar syndrome

The parasellar syndrome typically presents as unilateral supraorbital and frontal headache, which may be associated with diplopia (Yi et al., 2000). There may be ophthalmoparesis (Besada et al., 2007) or papilloedema, and formal visual field testing may demonstrate hemianopsia or quadrantinopsia.

Middle cranial fossa syndrome

The middle cranial fossa syndrome presents with facial numbness, paraesthesias, or pain, which is usually referred to the cheek or jaw (in the distribution of second or third divisions of the trigeminal nerve) (Lossos and Siegal, 1992). The pain is typically described as a dull continual ache, but may also be paroxysmal or lancinating. On examination, patients may have hypaesthesia in the trigeminal nerve distribution and signs of weakness in the ipsilateral muscles of mastication. Occasional patients have other neurological signs, such as abducens palsy (Greenberg et al., 1981; Bullitt et al., 1986).

Jugular foramen syndrome

The jugular foramen syndrome usually presents with hoarseness or dysphagia. Pain is usually referred to the ipsilateral ear or mastoid region and may occasionally present as glossopharyngeal neuralgia, with or without syncope (Greenberg et al., 1981; Laigle-Donadey et al., 2005). Pain may also be referred to the ipsilateral neck or shoulder. Neurologic signs include ipsilateral Horner's syndrome, and paresis of the palate, vocal cord, sternocleidomastoid, or trapezius. Ipsilateral paresis of the tongue may also occur if the tumour extends to the region of the hypoglossal canal.

Occipital condyle syndrome

The occipital condyle syndrome presents with unilateral occipital pain that is worsened with neck flexion (Loevner and Yousem, 1997; Moris et al., 1998; Martinez Salamanca et al., 2006). The patient may complain of neck stiffness. Pain intensity is variable, but can be severe. Examination may reveal a head tilt, limited movement of the neck, and tenderness to palpation over the occipitonuchal junction. Neurological findings may include ipsilateral

hypoglossal nerve paralysis and sternocleidomastoid weakness (Capobianco et al., 2002).

Clivus syndrome

The clivus syndrome is characterized by vertex headache, which is often exacerbated by neck flexion. Lower cranial nerve (Vl–XII) dysfunction may develop (Ulubas et al., 2005; Malloy, 2007) and may become bilateral (Fink et al., 1987).

Sphenoid sinus syndrome

A sphenoid sinus metastasis often presents with bi-frontal and or retro-orbital pain, which may radiate to the temporal regions (Lawson and Reino, 1997). There may be associated features of nasal congestion and diplopia (Mickel and Zimmerman, 1990). Physical examination is often unremarkable, although unilateral or bilateral sixth nerve paresis can be present.

Painful cranial neuralgias

As noted, specific cranial neuralgias can occur from metastases in the base of skull or leptomeninges. They are most commonly observed in patients with prostate and lung cancer (Gupta et al., 1990; McDermott et al., 2004). Invasion of the soft tissues of the head or neck, or involvement of sinuses can also eventuate in such lesions. Each of these syndromes has a characteristic presentation. Early diagnosis may allow effective treatment of the underlying lesion before progressive neurologic injury occurs.

Glossopharyngeal neuralgia

Glossopharyngeal neuralgia has been reported in patients with leptomeningeal metastases (Sozzi et al., 1987), the jugular foramen syndrome (Greenberg et al., 1981), or head and neck malignancies (Metheetrairut and Brown, 1993; Pfendler, 1997; Ribeiro et al., 2007). This syndrome presents as severe pain in the throat or neck, which may radiate to the ear or mastoid region. Pain may be induced by swallowing. In some patients, pain is associated with sudden orthostasis and syncope (Weinstein et al., 1986; Metheetrairut and Brown, 1993; Ribeiro et al., 2007).

Trigeminal neuralgia

Trigeminal pains may be continual, paroxysmal, or lancinating. Pain that mimics classical trigeminal neuralgia can be induced by tumours in the middle or posterior fossa (Bullitt et al., 1986; Cheng et al., 1993; Barker et al., 1996; Hirota et al., 1998; Benoliel et al., 2007) or leptomeningeal metastases (DeAngelis and Payne, 1987). Sometimes, pain may be caused by perineural spread without evidence of a discrete mass (Boerman et al., 1999). Continual pain in a trigeminal distribution may be an early sign of acoustic neuroma (Payten, 1972). All cancer patients who develop trigeminal neuralgia should be evaluated for the existence of an underlying neoplasm.

Orthostatic headache with cervical spine metastases

Headache triggered by upright posture has been described in patients with metastases of the upper cervical spine with compression of the C2 or C3 nerve roots (Kim et al., 2008).

Ear and eye pain syndromes
Otalgia

Otalgia is the sensation of pain in the ear, while referred otalgia is pain felt in the ear but originating from a non-otologic source (Siddiq and Samra, 2008). The rich sensory innervation of the ear derives from four cranial nerves and two cervical nerves which

also supply other areas in the head, neck, thorax, and abdomen. Pain referred to the ear may originate in areas far removed from the ear itself. Otalgia may be caused by acoustic neuroma (Morrison and Sterkers, 1996) and metastases to the temporal bone or infratemporal fossa (Hill and Kohut, 1976; Shapshay et al., 1976; Leonetti et al., 1998). Referred otalgia is reported among patients with tumours involving the oropharynx or hypopharynx (Scarbrough et al., 2003).

Eye pain

Blurring of vision and eye pain are the two most common symptoms of choroidal metastases (De Potter, 1998). More commonly, chronic eye pain is related to metastases to the bony orbit (Shih et al., 2007), intraorbital structures such as the rectus muscles (Weiss et al., 1984; Friedman et al., 1990), the optic nerve (Laitt et al., 1996), or the cavernus sinus (Rodriguez et al., 2007). Physical examination should include evaluation of visual fields, oculomotor function, fundi, and a careful evaluation for evidence of exophthalmos.

Oral cancer pain

Studies in patents with newly diagnosed oral cancer commonly reported significant levels of spontaneous pain and functional restriction with either talking or eating restriction associated with the pain (Lam and Schmidt, 2011).

Uncommon causes of headache and facial pain

Headache and facial pain in cancer patients may have many other causes. Unilateral facial pain can be the initial symptom of an ipsilateral lung tumour (Sarlani et al., 2003; Evans, 2007; Navarro et al., 2010). Presumably, this referred pain is mediated by vagal afferents. Facial squamous cell carcinoma of the skin may present with facial pain due to extensive perineural invasion (Schroeder et al., 1998). Patients with Hodgkin's disease may have transient episodes of neurological dysfunction that has been likened to migraine (Dulli et al., 1987). In some cases this may be a reversible posterior leucoencephalopathy syndrome (RPLS) which is characterized by headache, conscious disturbance, seizure, and cortical visual loss with neuroimaging finding of oedema in the posterior regions of the brain (Miyazaki et al., 2004).

Headache may occur with cerebral infarction or haemorrhage, which may be due to non-bacterial thrombotic endocarditis or disseminated intravascular coagulation. Headache is also the usual presentation of sagittal sinus occlusion, which may be due to tumour infiltration, hypercoagulable state or treatment with L-asparaginase therapy (Sigsbee et al., 1979). Headache due to pseudotumour cerebri has also been reported to be the presentation of SVC obstruction in a patient with lung cancer (Portenoy et al., 1983). Tumours of the sinonasal tract may present with deep facial or nasal pain (Marshall and Mahanna, 1997).

Neuropathic pains involving the peripheral nervous system

Neuropathic pains involving the peripheral nervous system are common. The syndromes include painful radiculopathy, plexopathy, mononeuropathy, or peripheral neuropathy.

Painful radiculopathy

Radiculopathy or polyradiculopathy may be caused by any process that compresses, distorts or inflames nerve roots. Painful radiculopathy is an important presentation of epidural tumour and leptomeningeal metastases (see earlier paragraphs).

Post-herpetic neuralgia

The precise clinical definition of PHN has been a matter of dispute. There is agreement that acute herpetic neuralgia refers to pain preceding or accompanying the eruption of rash that persists up to 30 days from its onset. Some authorities refer to all persistent pain as PHN, others describe a subacute herpetic neuralgia that persists beyond healing of the rash but which resolves within 4 months of onset, reserving the term PHN to pain persisting beyond 4 months from the initial onset of the rash (Dworkin and Portenoy, 1996). One study suggests that PHN is two to three times more frequent in the cancer population than the general population (Rusthoven et al., 1988).

Cervical plexopathy

Among cancer patients cervical plexus injury is frequently due to tumour infiltration or treatment (including surgery or radiotherapy) to neoplasms in this region (Jaeckle, 1991). Tumour invasion or compression of the cervical plexus can be caused by direct extension of a primary head and neck malignancy or neoplastic (metastatic or lymphomatous) involvement of the cervical lymph nodes (Jaeckle, 1991). Pain may be experienced in the preauricular (greater auricular nerve) or postauricular (lesser and greater occipital nerves) regions, or the anterior neck (transverse cutaneous and supraclavicular nerves). Pain may refer to the lateral aspect of the face or head, or to the ipsilateral shoulder. The overlap in the pain referral patterns from the face and neck may relate to the close anatomic relationship between the central connections of cervical afferents and the afferents carried in cranial nerves V, VII, IX and X in the upper cervical spinal cord.

Associated features can include ipsilateral Horner's syndrome or hemidiaphragmatic paralysis. The diagnosis must be distinguished from epidural compression of the cervical spinal cord and leptomeningeal metastases. MRI or CT imaging of the neck and cervical spine is usually required to evaluate the aetiology of the pain.

Brachial plexopathy

The two most common causes of brachial plexopathy in cancer patients are tumour infiltration and radiation injury. Less common causes of painful brachial plexopathy include trauma during surgery or anaesthesia, radiation-induced second neoplasms, acute brachial plexus ischaemia, and paraneoplastic brachial neuritis.

Malignant brachial plexopathy

Plexus infiltration by tumour is the most prevalent cause of brachial plexopathy. Malignant brachial plexopathy is most common in patients with lymphoma, lung cancer, or breast cancer. The invading tumour usually arises from adjacent axillary, cervical, and supraclavicular lymph nodes (lymphoma and breast cancer), or from the lung (superior sulcus tumours or so-called Pancoast tumours) (Kori et al., 1981; Kori, 1995; Jaeckle, 2004). Pain is nearly universal, occurring in 85% of patients, and often precedes neurologic signs or symptoms by months (Kori, 1995). Lower plexus involvement (C7, C8, T1 distribution) is typical, and is reflected in the pain distribution, which usually involves the elbow, medial forearm and fourth and fifth fingers. Pain may sometimes localize

Fig. 13.1.2 Coronal CT reconstruction of a patient with bilateral brachial plexopathy. Arrow A: bulky metastases arising from ribs compressing inferior right plexus. Arrow B: tumour infiltrates deposited on left plexus.

to the posterior arm or elbow. Severe aching is usually reported, but patients may also experience constant or lancinating dysaesthesias along the ulnar aspect of the forearm or hand.

Tumour infiltration of the upper plexus (C5–C6 distribution) is less common. This lesion is characterized by pain in the shoulder girdle, lateral arm, and hand. Seventy-five per cent of patients presenting with upper plexopathy subsequently develop a panplexopathy, and 25% of patients present with panplexopathy (Kori et al., 1981).

Cross-sectional imaging is essential in all patients with symptoms or signs compatible with plexopathy (Fig. 13.1.2). Although comparative data on the sensitivity and specificity of MRI to CT in evaluating lesions of the brachial plexus is not available, MRI is widely thought to be the best choice for evaluating the anatomy and pathology of the brachial plexus (van Es et al., 2010). Limited experience has been reported for PET-CT imaging (Luthra et al., 2006).

Electrodiagnostic studies may be helpful in patients with suspected plexopathy, particularly when neurological examination and imaging studies are normal (Ferrante and Wilbourn, 2002). Although not specific for tumour, abnormalities on electromyography (EMG) or somatosensory-evoked potentials may establish the diagnosis of plexopathy, and thereby confirm the need for additional evaluation.

Patients with malignant brachial plexopathy are at high risk for epidural extension of the tumour (Portenoy et al., 1989; Jaeckle, 1991). Epidural encroachment can occur as the neoplasm grows medially and invades vertebrae or tracks along nerve roots through the intervertebral foramina. In the latter case, there may be no evidence of bony erosion on imaging studies. The development of Horner's syndrome, evidence of panplexopathy, or finding of paraspinal tumour or vertebral damage on CT or MRI are highly associated with epidural extension and should lead to definitive imaging of the epidural tumour (Portenoy et al., 1989; Jaeckle, 1991).

Radiation-induced brachial plexopathy

Two distinct syndromes of radiation-induced brachial plexopathy have been described: (1) early-onset transient plexopathy (see earlier paragraphs) and (2) delayed-onset progressive plexopathy. Delayed-onset progressive plexopathy can occur 6 months to 20 years after a course of radiotherapy that included the plexus in the radiation portal. In contrast to tumour infiltration, pain is a relatively uncommon presenting symptom (18%), and when present, is usually less severe (Kori et al., 1981). After surpraclavicular node radiotherapy there is a progressively increasing incidence over time which rises to 56% after 20 years (Bajrovic et al., 2004). Weakness and sensory changes predominate in the distribution of the upper plexus (C5, C6 distribution) (Mondrup et al., 1990; Olsen et al., 1990; Vecht, 1990; Schierle and Winograd, 2004; Jaeckle, 2010). Radiation changes in the skin and lymphoedema are commonly associated.

The typical appearance of radiation fibrosis of the plexus on CT studies is a diffuse infiltration and loss of tissue planes without a mass lesion (Cascino et al., 1983). There is often associated lymphoedema in the arm, evident on CT, and occasionally, radiation necrosis of the clavicle or rib or humeral head occurs at the adjacent level (Schulte et al., 1989). Tumour infiltration of the plexus cannot be differentiated from radiation fibrosis by CT studies when diffuse infiltration is noted. On MRI the most common findings observed with radiation fibrosis are thickening and diffuse enhancement of the brachial plexus without a focal mass and/or soft-tissue changes with low signal intensity on both T1- and T2-weighted images (Wittenberg and Adkins, 2000).

Electrodiagnostic studies in patients with radiation fibrosis typically include widespread infraclavicular demyelinating conduction blocks on motor nerve conduction studies, and myokymic discharges and fasciculation potentials on needle electrode examination (Ferrante, 2004, 2012). Widespread myokymia is strongly suggestive of radiation-induced plexopathy (Flaggman and Kelly, 1980; Albers et al., 1981; Lederman and Wilbourn, 1984; Harper et al., 1989; Roth et al., 1988). Although a careful history, combined with neurologic findings and the results of tomographic and electrodiagnostic studies can strongly suggest the diagnosis of radiation-induced injury, repeated assessments over time may be needed to confirm the diagnosis. Rare patients require surgical exploration of the plexus to exclude neoplasm and establish the aetiology.

The natural history of brachial plexus fibrosis is variable. Motor dysfunction may be incomplete, or may progress to a severe paresis (Killer and Hess, 1990; Olsen et al., 1990; Olsen et al., 1993). In a long-term follow-up study of 71 patients radiated to 57 Gy, 11 of the 12 surviving patients had severe arm paralysis (Johansson et al., 2000). Even with advanced radiation fibrosis, severe pain is relatively uncommon and its presence should prompt evaluation of the patient for recurrent tumour (Kori et al., 1981).

Uncommon causes of brachial plexopathy

Malignant peripheral nerve tumour or a second primary tumour in a previously irradiated site can account for pain recurring late in the patient's course (Binder et al., 2004). Pain has been reported to occur as a result of brachial plexus entrapment in a lymphoedematous shoulder (Vecht, 1990), and as a consequence of acute ischaemia many years after axillary radiotherapy (Gerard et al., 1989). An idiopathic brachial plexopathy has also been described in patients

with Hodgkin's disease (Lachance et al., 1991). Paraneoplastic brachial plexopathy associated with anti-amphiphysin antibodies has been described (Coppens et al., 2006).

Lumbosacral plexopathy

In the cancer population, lumbosacral plexopathy is usually caused by neoplastic infiltration or compression. Radiation-induced plexopathy also occurs, and occasional patients develop the lesion as a result of surgical trauma, infarction, cytotoxic damage, infection in the pelvis or psoas muscle, abdominal aneurysm, or idiopathic lumbosacral neuritis. Polyradiculopathy from leptomeningeal metastases or epidural metastases can mimic lumbosacral plexopathy.

Malignant lumbosacral plexopathy

The primary tumours most frequently associated with malignant lumbosacral plexopathy include colorectal, cervical, breast, sarcoma, and lymphoma (Jaeckle et al., 1985). Most tumours involve the plexus by direct extension from intrapelvic neoplasm; metastases account for only one-quarter of cases. Rarely, plexopathy can arise by perineural spread from a prostate cancer along prostatic nerves into the lumbosacral plexus (Ladha et al., 2006).

Pain is, typically, the first symptom and it is experienced by almost all patients at some point, and it is the only symptom in almost 20% of patients. The quality is aching, pressure-like, or stabbing; dysaesthesias are relatively uncommon. Most patients develop numbness, paraesthesias, or weakness weeks to months after the pain begins. Common signs include leg weakness that involves multiple myotomes, sensory loss that crosses dermatomes, reflex asymmetry, focal tenderness, leg oedema, and positive direct or reverse straight-leg raising signs.

A lower plexopathy is most common accounts for just over 50% of patients with malignant lumbosacral plexopathy (Jaeckle et al., 1985). It is usually caused by direct extension from a pelvic tumour, most frequently rectal cancer, gynaecological tumours, or pelvic sarcoma. Pain may be localized in the buttocks and perineum, or referred to the posterolateral thigh and leg. Associated symptoms and signs conform to an L4–S1 distribution. Examination may reveal weakness or sensory changes in the L5 and S1 dermatomes and a depressed ankle jerk. Other findings include leg oedema, bladder or bowel dysfunction, sacral or sciatic notch tenderness, and a positive straight-leg raising test. A pelvic mass may be palpable.

An upper plexopathy occurs in almost one-third of patients with lumbosacral plexopathy (Jaeckle et al., 1985). Pain may be experienced in the back, lower abdomen, flank or iliac crest, or the anterolateral thigh. Examination may reveal sensory, motor, and reflex changes in a L1–4 distribution.

A subgroup of these patients present with a syndrome characterized by pain and paraesthesias limited to the lower abdomen or inguinal region, variable sensory loss, and no motor findings. CT scan may show tumour adjacent to the L1 vertebra (the L1 syndrome) (Jaeckle et al., 1985) or along the pelvic sidewall, where it presumably damages the ilioinguinal, iliohypogastric, or genitofemoral nerves.

Another subgroup has neoplastic involvement of the psoas muscle and presents with a syndrome characterized by upper lumbosacral plexopathy, painful flexion of the ipsilateral hip, and positive psoas muscle stretch test; this has been termed the malignant psoas syndrome (Stevens and Gonet, 1990; Agar et al., 2004). Similarly,

pain in the distribution of the femoral nerve has been observed in the setting of recurrent retroperitoneal sarcoma (Zografos and Karakousis, 1994) and tumour in the iliac crest can compress the lateral cutaneous nerve of the thigh producing a pain that mimics meralgia paraesthetica (Tharion and Bhattacharji, 1997).

Sacral plexopathy may occur from direct extension of a sacral lesion or a presacral mass (Payer, 2003). This may present with predominant involvement of the lumbosacral trunk, characterized by numbness over the dorsal medial foot and sole and weakness of knee flexion, ankle dorsiflexion, and inversion. Other patients demonstrate particular involvement of the coccygeal plexus, with prominent sphincter dysfunction and perineal sensory loss. The latter syndrome occurs with low pelvic tumours, such as those arising from the rectum or prostate.

A panplexopathy with involvement in a L1–S3 distribution occurs in almost one-fifth of patients with lumbosacral plexopathy (Jaeckle et al., 1985). Local pain may occur in the lower abdomen, back, buttocks, or perineum. Referred pain can be experienced anywhere in distribution of the plexus. Leg oedema is extremely common. Neurological deficits may be confluent or patchy within the L1–S3 distribution and a positive straight leg raising test is usually present.

Cross-sectional imaging, with either CT or MRI, is the preferred diagnostic procedure to evaluate lumbosacral plexopathy (Fig. 13.1.3). Scanning should be done from the level of the L1 vertebral body, through the sciatic notch. Limited data suggests superior sensitivity MRI over CT imaging. Definitive imaging of the epidural space adjacent to the plexus should be considered in the patient who has features indicative of a relatively high risk of epidural extension including bilateral symptoms or signs, unexplained incontinence, or a prominent paraspinal mass.

Radiation-induced lumbosacral plexopathy

Radiation fibrosis of the lumbosacral plexus is a rare complication that may occur from 1 to over 30 years following radiation treatment. The use of intracavitary radium implants for carcinoma of the cervix may be an additional risk factor (Stryker et al., 1990; Gonzalez-Caballero et al., 2000). Radiation-induced plexopathy typically presents with progressive weakness and leg swelling; pain is not usually a prominent feature (Thomas et al., 1985; Stryker et al., 1990). Weakness typically begins distally in the L5–S1 segments and is slowly progressive. The symptoms and signs may be bilateral (Thomas et al., 1985). If CT scanning demonstrates a lesion, it is usually a non-specific diffuse infiltration of the tissues. Electromyography may show myokymic discharges (Thomas et al., 1985).

Uncommon causes of lumbosacral plexopathy

Lumbosacral plexopathy may occur following intra-arterial cis-platinum infusion (see following paragraphs) and embolization techniques. This syndrome been observed following attempted embolization of a bleeding rectal lesion. Raised intrapelvic pressure due to a collection (Lin et al., 2009) or even a massively distended bladder or rectum may sometimes cause a plexus compression syndrome with radicular pain. Benign conditions that may produce similar findings include haemorrhage or abscess in the iliopsoas muscle (Chad and Bradley, 1987), abdominal aortic aneurysms, diabetic radiculoplexopathy, vasculitis, and an idiopathic lumbosacral plexitis analogous to acute brachial neuritis (Chad and Bradley, 1987).

Fig. 13.1.3 Axial CT scan image of a 29-year-old male with known renal cell cancer and pain radiating into his left buttock. CT demonstrated a soft tissue lesion in the foramen of S2 (arrowed).

Painful mononeuropathy

Tumour-related mononeuropathy

Tumour-related mononeuropathy usually results from compression or infiltration of a nerve from tumour arising in an adjacent bony structure. The most common example of this phenomenon is intercostal nerve injury in a patient with rib metastases. Other examples include the cranial neuralgias previously described, sciatica associated with tumour invasion of the sciatic notch, and common peroneal nerve palsy associated with primary bone tumours of the proximal fibula and lateral cutaneous nerve of the thigh neuralgia associated with iliac crest tumours.

Other causes of mononeuropathy

Cancer patients also develop mononeuropathies from many other causes. Post-surgical syndromes are well described (see following paragraphs) and radiation injury of a peripheral nerve occurs occasionally. Rarely, cancer patients develop nerve entrapment syndromes (such as carpal tunnel syndrome) related to oedema or direct compression by tumour (Desta et al., 1994).

Painful peripheral neuropathies

Painful peripheral neuropathies have multiple causes, including nutritional deficiencies, other metabolic derangements (e.g. diabetes and renal dysfunction), neurotoxic effects of chemotherapy, and, rarely, paraneoplastic syndromes.

Paraneoplastic painful peripheral neuropathy

Paraneoplastic painful peripheral neuropathy can be related to injury to the dorsal root ganglion (also known as subacute sensory neuronopathy or ganglionopathy) or injury to peripheral nerves (Grisold and Drlicek, 1999; Oki et al., 2007). These syndromes may be the initial manifestation of an underlying malignancy. Except for the neuropathy associated with myeloma (Kissel and Mendell, 1996; Rotta and Bradley, 1997), their course is usually independent of the primary tumour (Dalmau and Posner, 1997; Grisold and Drlicek, 1999).

Subacute sensory neuronopathy is characterized by pain (usually dysaesthetic), paraesthesias, sensory loss in the extremities, and severe sensory ataxia (Brady, 1996). Although it is usually associated with small cell carcinoma of the lung (van Oosterhout et al., 1996), other tumour types, including breast cancer (Peterson

et al., 1994), Hodgkin's disease (Plante-Bordeneuve et al., 1994), and other solid tumours are rarely associated. The pain usually develops before the tumour is evident and its course is typically independent.

Coexisting autonomic, cerebellar, or cerebral abnormalities are common (Brady, 1996). An antineuronal IgG antibody ('anti-Hu'), which recognizes a low-molecular-weight protein present in most small cell lung carcinomas, has been associated with the condition (Dalmau and Posner, 1997). A number of other paraneoplastic antibodies have been identified these include anti-CV2 (Antoine et al., 2001) and anti-Ri (Fasolino et al., 2004).

A sensorimotor peripheral neuropathy, which may be painful, has been observed in association with diverse neoplasms, particularly Hodgkin's disease and paraproteinaemias (Kelly and Karcher, 2005). Clinically evident peripheral neuropathy occurs in approximately 15% of patients with multiple myeloma, and electrophysiological evidence of this lesion can be found in 40% (Kissel and Mendell, 1996). The pathophysiology of the neuropathy is unknown.

Pain syndromes of the viscera and miscellaneous tumour-related syndromes

Pain may be caused by pathology involving the luminal organs of the gastrointestinal or genitourinary tracts, the parenchymal organs, the peritoneum, or the retroperitoneal soft tissues. Obstruction of hollow viscus, including intestine, biliary tract, and ureter, produces visceral nociceptive syndromes that are well described in the surgical literature (Silen, 1983). Pain arising from retroperitoneal and pelvic lesions may involve mixed nociceptive and neuropathic mechanisms if both somatic structures and nerves are involved.

Hepatic distention syndrome

Pain sensitive structures in the region of the liver include the liver capsule, blood vessels, and biliary tract. Nociceptive afferents that innervate these structures travel via the coeliac plexus, the phrenic nerve, and the lower right intercostal nerves. Extensive intrahepatic metastases, or gross hepatomegaly associated with cholestasis, may produce discomfort in the right subcostal region, and less commonly in the right mid-back or flank (Harris et al., 2003) (Fig. 13.1. 4). Referred pain may be experienced in the right neck or shoulder, or in the region of the right scapula (Mulholland et al., 1990).

Occasional patients who experience chronic pain due to hepatic distension develop an acute intercurrent subcostal pain that may be exacerbated by respiration. Physical examination may demonstrate a palpable or audible rub. These findings suggest the development of an overlying peritonitis, which can develop in response to some acute event, such as a haemorrhage into a metastasis (La Fianza et al., 1999).

Midline retroperitoneal syndrome

Retroperitoneal pathology involving the upper abdomen may produce pain by injury to deep somatic structures of the posterior abdominal wall, distortion of pain sensitive connective tissue, vascular and ductal structures, local inflammation, and direct infiltration of the coeliac plexus. The most common causes are pancreatic cancer (Kelsen et al., 1995; Grahm and Andren-Sandberg, 1997; Kelsen et al., 1997) and retroperitoneal lymphadenopathy

Fig. 13.1.4 CT scan of a 53-year-old woman with right upper quadrant abdominal pain caused by multiple liver metastases.

(Krane and Perrone, 1981; Neer et al., 1981; Sponseller, 1996), particularly coeliac lymphadenopathy (Schonenberg et al., 1991).

In some instances of pancreatic cancer, obstruction of the main pancreatic duct with subsequent ductal hypertension generates pain which can be relieved by stenting of the pancreatic duct (Tham et al., 2000).

The pain is experienced in the epigastrium, in the low thoracic region of the back, or in both locations. It is often diffuse and poorly localized. It is usually dull and boring in character, exacerbated with recumbency, and improved by sitting. The lesion can usually be demonstrated by CT, MRI, or ultrasound scanning of the upper abdomen (Fig. 13.1.5).

Intestinal obstruction

(Also see Chapter 14.3.)

Abdominal pain is an almost invariable manifestation of intestinal obstruction, which may occur in patients with abdominal or pelvic cancers (Ripamonti et al., 2008; Dolan, 2011). The factors

Fig. 13.1.5 Axial CT scan of a 72-year-old man with epigastric and back pain caused by cancer in the head of the pancreas (arrowed).

that contribute to this pain include smooth muscle contractions, mesenteric tension, and mural ischaemia. Obstructive symptoms may be due primarily to the tumour, or more likely, to a combination of mechanical obstruction and other processes, such as autonomic neuropathy and ileus from metabolic derangements or drugs. Both continuous and colicky pains occur which may be referred to the dermatomes represented by the spinal segments supplying the affected viscera. Vomiting, anorexia, and constipation are important associated symptoms.

Peritoneal carcinomatosis

Peritoneal carcinomatosis occurs most often by transcoelomic spread of abdominal or pelvic tumour; excepting breast cancer, haematogenous spread of an extra-abdominal neoplasm in this pattern is rare. Carcinomatosis can cause peritoneal inflammation, mesenteric tethering, malignant adhesions, and ascites, all of which can cause pain. Pain and abdominal distension are the most common presenting symptoms. Adhesions can also cause obstruction of hollow viscus, with intermittent colicky pain (Averbach and Sugarbaker, 1995). CT scanning may demonstrate evidence of ascites, omental infiltration, and peritoneal nodules.

Malignant perineal pain

Tumours of the colon or rectum, female reproductive tract, and distal genitourinary system are most commonly responsible for perineal pain (Stillman, 1990; Boas et al., 1993; Hagen, 1993; Miaskowski, 1996; Rigor, 2000). Severe perineal pain following resection of pelvic tumours often precede evidence of detectable disease and should be viewed as a potential harbinger of progressive or recurrent cancer (Stillman, 1990; Boas et al., 1993; Rigor, 2000). There is evidence to suggest that this phenomenon is caused by microscopic perineural invasion by recurrent disease (Seefeld and Bargen, 1943). The pain, which is typically described as constant and aching, is often aggravated by sitting or standing, and may be associated with tenesmus or bladder spasms (Stillman, 1990).

Tumour invasion of the musculature of the deep pelvis can also result in a syndrome that appears similar to the so-called tension myalgia of the pelvic floor (Sinaki et al., 1977). The pain is typically described as a constant ache or heaviness that exacerbates with upright posture. When due to tumour, the pain may be concurrent with other types of perineal pain. Digital examination of the pelvic floor may reveal local tenderness or palpable tumour.

Adrenal pain syndrome

Large adrenal metastases, common in lung cancer, may produce unilateral flank pain, and less commonly, abdominal pain. Pain is of variable severity, and it can be severe (Berger M.S. et al., 1995). Adrenal metastases can be complicated by haemorrhage which may cause severe abdominal pain (Karanikiotis et al., 2004) (Fig. 13.1.6).

Ureteric obstruction

Ureteric obstruction is most frequently caused by tumour compression or infiltration within the true pelvis (Harrington et al., 1995; Russo, 2000). Less commonly, obstruction can be more proximal, associated with retroperitoneal lymphadenopathy, an isolated retroperitoneal metastasis, mural metastases, or intraluminal metastases. Cancers of the cervix, ovary, prostate, and rectum are most commonly associated with this complication. Pain

Fig. 13.1.6 Axial CT scan image of a 62-year-old male with small cell lung cancer and pain radiating into his right loin. CT demonstrated bilateral adrenal metastases. The right lesion is much larger than that on the left.

may or may not accompany ureteric obstruction. When present, it is typically a dull chronic discomfort in the flank, with radiation into the inguinal region or genitalia (Little et al., 2003). If pain does not occur, ureteric obstruction may be discovered when hydronephrosis is discerned on abdominal imaging procedures or renal failure develops. Ureteric obstruction can be complicated by pyelonephritis or pyonephrosis, which often present with features of sepsis, loin pain, and dysuria. Diagnosis of ureteric obstruction can usually be confirmed by the demonstration of hydronephrosis on renal sonography. The level of obstruction can be identified by pyelography, and CT scanning techniques will usually demonstrate the cause (Russo, 2000).

Ovarian cancer pain

Moderate to severe chronic abdominopelvic pain is the most common symptom of ovarian cancer; it is reported by almost two-thirds of patients in the 2 weeks prior to the onset or recurrence of the disease (Portenoy et al., 1994). Pain is experienced in the low back or abdomen (Goff et al., 2004; Webb et al., 2004). In patients who have been previously treated it is an important symptom of potential recurrence (Portenoy et al., 1994).

Lung cancer pain

Even in the absence of involvement of the chest wall or parietal pleura, lung tumours can produce a visceral pain syndrome. In a large case series of lung cancer patients, pain was unilateral in 80% of the cases and bilateral in 20%. Among patients with hilar tumours the pain was reported to the sternum or the scapula. Upper and lower lobe tumours referred to the shoulder and to the lower chest respectively (Marino et al., 1986; Marangoni et al., 1993). As previously mentioned, early lung cancers can generate ipsilateral facial pain (Sarlani et al., 2003). It is postulated that this pain syndrome is generated via vagal afferent neurons.

Other uncommon visceral pain syndromes

Sudden onset severe abdominal or loin pain may be caused by non-traumatic rupture of a visceral tumour. This has been most frequently reported with hepatocellular cancer (Miyamoto et al., 1991) but also with other liver metastases (Marini et al., 2002). Kidney rupture due to a renal metastasis from an adenocarcinoma

of the colon (Wolff et al., 1994), splenic rupture in acute leukaemia (Rajagopal et al., 2002), rupture of adrenocortical cancers (Stamoulis et al., 2004) and metastasis-induced perforated appendicitis (Ende et al., 1995) have been reported. Torsion of pedunculated visceral tumours can produce a cramping abdominal pain.

Paraneoplastic nociceptive pain syndromes

Tumour-related gynaecomastia

Tumours that secrete chorionic gonadotrophin (HCG), including malignant and benign tumours of the testis (Daniels and Layer, 2003; Duparc et al., 2003; Foppiani et al., 2005) and rarely cancers from other sites (Wurzel et al., 1987; Nishiyama et al., 1992; Forst et al., 1995; Liu et al., 1999), may be associated with chronic breast tenderness or gynaecomastia. Approximately 10% of patients with testis cancer have gynaecomastia or breast tenderness at presentation and the likelihood of gynaecomastia is greater with increasing HCG level (Tseng et al., 1985). Breast pain can be the first presentation of an occult tumour (Haas et al., 1989; Mellor and McCutchan, 1989; Cantwell et al., 1991).

Paraneoplastic pemphigus

Paraneoplastic pemphigus is a rare mucocutaneous disorder associated with non-Hodgkin's lymphoma and chronic lymphocytic leukaemia. The condition is characterized by widespread shallow ulcers with haemorrhagic crusting of the lips, conjunctival bullae and, uncommonly, pulmonary lesions. Characteristically, histopathology reveals intraepithelial and subepithelial clefting and immunoprecipitation studies reveal autoantibodies directed against desmoplakins and desmogleins (Camisa et al., 1992; Allen and Camisa, 2000).

Paraneoplastic Reynaud's syndrome

Paraneoplastic is a rare manifestation of solid tumours. It has been reported with lung cancer, ovarian cancer, testicular cancer, and melanoma (Wilmalaratna and Sachdev, 1987; Borenstein et al., 1990; DeCross and Sahasrabudhe, 1992).

Chronic pain syndromes associated with cancer therapy

Most treatment-related pains are caused by tissue-damaging procedures. These pains are acute, predictable and self-limited. Chronic treatment-related pain syndromes are associated with either a persistent nociceptive complication of an invasive treatment (such as a postsurgical abscess), or more commonly, neural injury. In some cases, these syndromes occur long after the therapy is completed, resulting in a difficult differential diagnosis between recurrent disease and a complication of therapy.

Post-chemotherapy pain syndromes
Toxic peripheral neuropathy

Chemotherapy-induced peripheral neuropathy is a common problem, which is typically manifested by painful paraesthesias in the hands and/or feet, and signs consistent with an axonopathy, including 'stocking-glove' sensory loss, weakness, hyporeflexia, and autonomic dysfunction (Ocean and Vahdat, 2004). The pain is usually characterized by continuous burning or lancinating pains, either of which may be increased by contact (Windebank and Grisold, 2008; Kautio et al., 2011). The drugs most commonly associated with a peripheral neuropathy are the vinca alkaloids

(especially vincristine), cis-platinum, oxaliplatin, and paclitaxel. Procarbazine, carboplatin, ixabepilone, misonidazole and hexamethylmelamine are less common causes. Data from several studies indicates that the risk of neuropathy associated with cis-platinum and oxaliplatin can be diminished by amifostine (Spencer and Goa, 1995; Penz et al., 2001), glutathione (Cascinu et al., 1995, 2002), and calcium and magnesium infusion at the time of treatment (Gamelin et al., 2004). Conflicting data exists regarding the potential efficacy of prophylactic vitamin E in reducing paclitaxel neuriopathy (Argyriou et al., 2006a; Kottschade et al., 2011).

Avascular (aseptic) necrosis of femoral or humeral head

Avascular necrosis (AVN) of the femoral or humeral head may occur either spontaneously or as a complication of intermittent or continuous corticosteroid therapy (Cook et al., 2001; Virik et al., 2001) or high-dose chemotherapy with bone marrow transplantation (Fink et al., 1998). Osteonecrosis may be unilateral or bilateral. Involvement of the femoral head is most common and typically causes pain in the hip, thigh, or knee. Involvement of the humeral head usually presents as pain in the shoulder, upper arm, or elbow. Pain is exacerbated by movement and relieved by rest. There may be local tenderness over the joint, but this is not universal. Pain usually precedes radiological changes by weeks to months; bone scintigraphy and MRI are sensitive and complementary diagnostic procedures For the detection of radiographically occult AVN, radionuclide bone scanning and MRI are both sensitive methods but, MRI is preferred because it has greater sensitivity and a greater specificity than bone scanning (DeSmet et al., 2000). Early treatment consists of analgesics, decrease or discontinuation of steroids, and sometimes surgery. With progressive bone destruction, joint replacement may be necessary.

Plexopathy

Lumbosacral or brachial plexopathy may follow cis-platinum infusion into the iliac artery (Castellanos et al., 1987) or axillary artery (Kahn et al., 1989), respectively. Affected patients develop pain, weakness, and paraesthesias within 48 hours of the infusion. The mechanism for this syndrome is thought to be due to small-vessel damage and infarction of the plexus or nerve. The prognosis for neurologic recovery is not known.

Raynaud's phenomenon

Among patients with germ cell tumours treated with cisplatin, vinblastine, and bleomycin, persistent Raynaud's phenomenon is observed in 20–30% (Berger C.C. et al., 1995). This effect has also been observed in patients with carcinoma of the head and neck treated with a combination of cisplatin, vincristine, and bleomycin (Kukla et al., 1982). Pathophysiological studies have demonstrated that a hyper-reactivity in the central sympathetic nervous system results in a reduced function of the smooth muscle cells in the terminal arterioles (Hansen et al., 1990).

Chronic pain associated with hormonal therapy
Gynaecomastia with hormonal therapy for prostate cancer

Chronic gynaecomastia and breast tenderness are common complications of antiandrogen therapies for prostate cancer (McLeod and Iversen, 2000). The incidence of this syndrome varies among drugs; it is frequently associated with diethylstilbestrol and bicalutamide, is less common with flutamide and cyproterone and is uncommon among patients receiving luteinizing hormone-releasing hormone agonist therapy. Gynaecomastia in the elderly must be distinguished from primary breast cancer or a secondary cancer in the breast (Olsson et al., 1984; Ramamurthy and Cooper, 1991).

Aromatase inhibitor pain syndromes

Aromatase inhibitor therapy in the treatment of hormones responsive breast cancer is often by musculoskeletal pain and stiffness. Common manifestations include hand osteoarthritis, tendonitis, trigger finger, and carpal tunnel syndrome. In one series of 51 patients, arthralgia and/or bone pain was reported in 61% of patients. Pain was severe in 30%, continuous in 41%, central in 50%, peripheral in 79%, and resulted in discontinuation of the drug in 20% of patients (Presant et al., 2007). The mechanism is not known (Moxley, 2010). Additionally other pain syndromes including Raynaud's syndrome (Bertolini et al., 2011) and carpal tunnel syndrome have also been observed (Nishihori et al., 2008).

Chronic pain associated with bisphosphonate therapy
Osteonecrosis of the jaw

Osteonecrosis of the jaw is described as an intraoral complication after administration of intravenous nitrogen-containing bisphosphonates. It is an uncommon complication whose incidence rate has climbed in recent years (Migliorati et al., 2010). It is defined as an unexpected development of necrotic bone in the oral cavity, and is commonly associated with administration of the bisphosphonates pamidronate and zoledronate. Clinical features include local pain, soft-tissue swelling, and/or loose teeth. Symptoms can mimic routine dental problems such as decay or periodontal disease (Migliorati et al., 2010; Yamashita et al., 2010). Osteonecrosis of the jaw is also often correlated with previous dental procedures, such as tooth extractions, during bisphosphonate therapy. Symptoms can mimic routine dental problems such as decay or periodontal disease (Migliorati et al., 2010). To reduce this risk clinical dental examination and a panoramic jaw radiograph should be performed before patients begin bisphosphonate therapy; dental treatment and other oral procedures should be completed before initiating bisphosphonate therapy and patients should be informed and instructed on the importance of maintaining good oral hygiene and having regular dental assessment (Migliorati et al., 2010).

Chronic diffuse pain

In June 2008, the US Food and Drug Administration issued a special warning regarding the possibility of severe and sometimes incapacitating bone, joint, and/or muscle (musculoskeletal) pain in patients taking bisphosphonates. The severe musculoskeletal pain may occur within days, months, or years after starting a bisphosphonate. Some patients have reported complete relief of symptoms after discontinuing the bisphosphonate, whereas others have reported slow or incomplete resolution. The risk factors for and incidence of severe musculoskeletal pain associated with bisphosphonates are unknown (Lenzer, 2008).

Chronic post-surgical pain syndromes

Surgical incision at virtually any location may result in chronic pain. Although persistent pain is occasionally encountered after nephrectomy, sternotomy, craniotomy, inguinal dissection, and other procedures, these pain syndromes are not well described in the cancer population. In contrast, several syndromes are now clearly recognized as sequelae of specific surgical procedures. The

predominant underlying pain mechanism in these syndromes is neuropathic, resulting from injury to peripheral nerves or plexus.

Breast surgery pain syndromes

Chronic neuropathic pain of variable severity is a common sequela of surgery for breast cancer. Although chronic pain has been reported to occur after almost any surgical procedure on the breast from lumpectomy to radical mastectomy, it is most common after procedures involving axillary dissection (Vecht et al., 1989; Vecht, 1990; Hladiuk et al., 1992; Maunsell et al., 1993), occurring in 25–70% of patients (Keramopoulos et al., 1993; Maunsell et al., 1993; Tasmuth et al., 1995, 1996; Carpenter et al., 1998; Warmuth et al., 1998; Kakuda et al., 1999; Smith et al., 1999; Kuehn et al., 2000; Taylor, 2004; Vilholm et al., 2008).

The risk for, and severity of, pain is correlated positively with the number of lymph nodes removed (Hack et al., 1999; Johansson et al., 2000; Hack et al., 2010), presence of tumour in the upper outer quadrant of the breast (Vilholm et al., 2008) and is inversely correlated with age (Warmuth et al., 1998; Hack et al., 1999; Smith et al., 1999, Vilholm et al., 2008; Hack et al., 2010). There is conflicting data as to whether preservation of the intercostobrachial nerve during axillary lymph node dissection can reduce the incidence of this phenomenon (Temple and Ketcham, 1985; Salmon et al., 1998; Freeman et al., 2003; Torresan et al., 2003; Taylor, 2004; Ivanovic et al., 2007).

The incidence is reduced, but not avoided, when axillary dissection is avoided either by sentinel node excision without full dissection (Schulze et al., 2006; Baron et al., 2007; Langer et al., 2007; Lucci et al., 2007; Hack et al., 2010) or when nodes are irradiated without dissection (Albrecht et al., 2002).

The pain is usually characterized as a constricting and burning discomfort localized to the medial arm, axilla, and anterior chest wall (Wood, 1978; Granek et al., 1983; Vecht et al., 1989; Paredes et al., 1990; van Dam et al., 1993). Pain may begin immediately or as late as many months following surgery. The natural history of this condition appears to be variable, and both subacute and chronic courses are possible (International Association for the Study of Pain: Subcommittee on taxonomy, 1986, Ernst et al., 2002). The onset of pain later than 18 months following surgery is unusual, warranting careful evaluation to exclude recurrent disease. On examination, there is often an area of numbness within the region of the pain (van Dam et al., 1993; Schell, 2006; Baron et al., 2007; Ivanovic et al., 2007). Chronicity of pain is related to the intensity of the immediate postoperative pain (Stevens et al., 1995; Tasmuth et al., 1996), postoperative complications, and subsequent treatment with chemotherapy and radiotherapy (Tasmuth et al., 1995).

It is most commonly associated with neuropraxia of the intercostobrachial nerve during the process of axillary lymph node dissection (Vecht et al., 1989; Bratschi and Haller, 1990; van Dam et al., 1993). There is marked anatomic variation in the size and distribution of the intercostobrachial nerve, and this may account for some of the variability in the distribution of pain observed in patients with this condition (Assa, 1974).

This syndrome must be differentiated from post-mastectomy phantom breast pain (Rothemund et al., 2004), neuroma pain (Jung et al., 2003), post-mastectomy frozen shoulder (Johansen et al., 2000; Deutsch and Flickinger, 2001), axillary web syndrome (Moskovitz et al., 2001), and breast cellulitis (Hughes et al., 1997). In some cases of pain after breast surgery, a trigger point can be palpated in the axilla or chest wall.

Post-radical neck dissection pain

Chronic neck and shoulder pain after radical neck dissection is common (Dijkstra et al., 2001; Whale et al., 2001; Laverick et al., 2004; Donatelli-Lassig et al., 2008). Shoulder pain is most often caused by damage to the spinal accessory nerve (CN XI) (van Wilgen et al., 2003; Laverick et al., 2004). In other cases it can result from musculoskeletal imbalance in the shoulder girdle following surgical removal of neck muscles (Talmi et al., 2000). Similar to the droopy shoulder syndrome (Swift and Nichols, 1984), this syndrome can be complicated by development of a thoracic outlet syndrome or suprascapular nerve entrapment, with selective weakness and wasting of the supraspinatus and infraspinatus muscles (Brown et al., 1988).

Escalating pain in patients who have undergone radical neck dissection may signify recurrent tumour or soft tissue infection. These lesions may be difficult to diagnose in tissues damaged by radiation and surgery. Repeated CT or MRI scanning may be needed to exclude tumour recurrence. Empiric treatment with antibiotics should be considered (Bruera and MacDonald, 1986; Coyle and Portenoy, 1991; Reinbolt et al., 2005).

Post-thoracotomy pain

There are several patterns of post-thoracotomy pain:

Prolonged post-thoracotomy pain: this is the most common pattern. Pain has been reported most profound around the scar, and 82–90% of pain patients relate their pain directly to the surgical site (Wildgaard et al., 2009). The pain is primarily described as aching, tender, with numbness and to a lesser degree burning (Wildgaard et al., 2009). It is usually caused by trauma and compression to the intercoastal nerves, fractured and compressed ribs, inflammation of the chest muscles, atrophy of chest muscles, or scar tissue rubbing (Hopkins and Rosenzweig, 2012). Neuropathic component to the pain, related to intercostal nerve damage is very common (Guastella et al., 2011). Although it usually resolves after within 2 months after surgery, it may persist for up to 10 years (Grosen et al., 2013).

Increasing pain: a second group (16%) experienced pain that persisted following the thoracotomy, then increased in intensity during the follow-up period. Local recurrence of disease and infection were the most common causes of the increasing pain.

Recurrent pain: chest wall pain that recurs following resolution of the postoperative pain is often due to recurrent neoplasm. In one series, the development of recurrent or increasing post-thoracotomy pain was due to recurrent or persistent tumour in greater than 95% of patients (Kanner, 1982) . This finding was corroborated in a study which evaluated the records of 238 consecutive patients who underwent thoracotomy which identified recurrent pain 20 patients, all were found to have tumour regrowth (Keller et al., 1994).

Patients with recurrent or increasing post-thoracotomy pain should be carefully evaluated, preferably with a chest CT scan or MRI. Chest radiographs are insufficient to evaluate recurrent chest disease. In some patients, post-thoracotomy pain appears to be caused by a taut muscular band within the scapular region. In such cases, pain may be amenable to trigger point injection of local anaesthetic (Hamada et al., 2000).

Postoperative frozen shoulder

Patients with post-thoracotomy or post-mastectomy pain are at risk for the development of a frozen shoulder (Maunsell et al.,

1993). This lesion may become an independent focus of pain, particularly if complicated by reflex sympathetic dystrophy. Adequate postoperative analgesia and active mobilization of the joint soon after surgery are necessary to prevent these problems.

Phantom pain syndromes

Phantom limb pain is perceived to arise from an amputated limb, as if the limb were still contiguous with the body. Phantom pain is experienced by 60–80% of patients following limb amputation but is only severe or persistent in 5–10% of cases (Ehde et al., 2000; Nikolajsen and Jensen, 2000; Flor, 2002; Burgoyne et al., 2012). The incidence of phantom pain is significantly higher in patients with a long duration of pre-amputation pain and those with pain on the day before amputation (Weinstein, 1994; Nikolajsen et al., 1997b; Burgoyne et al., 2012). Patients who had pain prior to the amputation may experience phantom pain that replicates the earlier one (Katz and Melzack, 1990).

Phantom pain is more prevalent after tumour related than traumatic amputations, and postoperative chemotherapy is an additional risk factor (Smith and Thompson, 1995; Flor, 2002). The pain may be continuous or paroxysmal and is often associated with bothersome paraesthesias. The phantom limb may assume painful and unusual postures and may gradually telescope and approach the stump. Phantom pain may initially magnify and then slowly fade over time. There is growing evidence that preoperative or postoperative neural blockade reduces the incidence of phantom limb pain during the first year after amputation (Pavy and Doyle, 1996; Enneking and Morey, 1997; Katz, 1997; Nikolajsen et al., 1997a; Karanikolas et al., 2011).

Some patients have spontaneous partial remission of the pain. The recurrence of pain after such a remission, or the late onset of pain in a previously painless phantom limb, suggests the appearance of a more proximal lesion, including recurrent neoplasm (Chang et al., 1997).

Phantom pain syndromes have also been described after other surgical procedures. Phantom breast pain after mastectomy, which occurs in 15–30% of patients (Kroner et al., 1989; Kwekkeboom, 1996; Tasmuth et al., 1996; Rothemund et al., 2004, Bjorkman et al., 2008; Steegers et al., 2008), also appears to be related to the presence of preoperative pain (Kroner et al., 1989). The pain tends to start in the region of the nipple and then spread to the entire breast. The character of the pain is variable and may be lancinating, continuous or intermittent (Kroner et al., 1989; Rothemund et al., 2004). A phantom rectum pain syndrome occurs in approximately 15% of patients who undergo abdominoperineal resection of the rectum (Ovesen et al., 1991; Boas et al., 1993). Phantom rectal pain may develop either in the early postoperative period or after a latency of months to years. Late-onset pain is almost always associated with tumour recurrence (Boas et al., 1993, Ovesen et al., 1991). Rare cases of phantom bladder pain after cystectomy and phantom eye pain after enucleation have also been reported.

Stump pain

Stump pain occurs at the site of the surgical scar several months to years following amputation (Davis, 1993). It is usually the result of neuroma development at a site of nerve transection. This pain is characterized by burning or lancinating dysaesthesias, which are often exacerbated by movement or pressure and blocked by an injection of a local anaesthetic. Pain that is associated by signs of local inflammation may indicate abscess formation.

Postsurgical pelvic floor myalgia

Surgical trauma to the pelvic floor can cause a residual pelvic floor myalgia, which like the neoplastic syndrome described previously, mimics so-called tension myalgia (Sinaki et al., 1977). The risk of disease recurrence associated with this condition is not known, and its natural history has not been defined. In patients who have undergone anorectal resection, this condition must be differentiated from the phantom anus syndrome (see 'Burning perineum syndrome').

Chronic post-radiation pain syndromes

Chronic pain complicating radiation therapy tends to occur late in the course of a patient's illness. These syndromes must always be differentiated from recurrent tumour.

Radiation-induced brachial and lumbosacral plexopathies

Radiation-induced brachial and lumbosacral plexopathies were described previously in this chapter.

Chronic radiation myelopathy

Chronic radiation myelopathy is an uncommon late complication of spinal cord irradiation (Macbeth et al., 1996). The latency is highly variable but is most commonly 12–14 months. The most common presentation is a partial transverse myelopathy at the cervicothoracic level, sometimes in a Brown-Séquard pattern (Schultheiss and Stephens, 1992). Sensory symptoms, including pain, typically precede the development of progressive motor and autonomic dysfunction (Schultheiss and Stephens, 1992). The pain is characterized as a burning dysaesthesia localized to the area of spinal cord damage or below. Imaging studies, particularly MRI, are important to exclude an epidural metastases and demonstrate the nature and extent of intrinsic cord pathology, which may include atrophy, swelling, or syrinx. On MRI the signs of radiation myelitis include high-intensity signals on T2-weighted images or gadolinium enhancement of T1-weighted images (Alfonso et al., 1997). The course of chronic radiation myelopathy is characterized by steady progression over months, followed by a subsequent phase of slow progression or stabilization.

Chronic radiation enteritis and proctitis

Chronic enteritis and proctocolitis occur as a delayed complication in 2–10% of patients who undergo abdominal or pelvic radiation therapy (Yeoh and Horowitz, 1987; Nussbaum et al., 1993). The rectum and rectosigmoid are more commonly involved than the small bowel, a pattern that may relate to the retroperitoneal fixation of the former structures. The latency is variable (3 months–30 years) (Yeoh and Horowitz, 1987; Nussbaum et al., 1993; Tagkalidis and Tjandra, 2001). Chronic radiation injury to the rectum can present as proctitis (with bloody diarrhoea, tenesmus, and cramping pain), obstruction due to stricture formation, or fistulae to the bladder or vagina. Small bowel radiation damage typically causes colicky abdominal pain, which can be associated with chronic nausea or malabsorption. Barium studies may demonstrate a narrow tubular bowel segment resembling Crohn's disease or ischaemic colitis. Endoscopy and biopsy may be necessary to distinguish suspicious lesions from recurrent cancer (Chi et al., 2005).

Radiation cystitis

Radiation therapy used in the treatment of tumours of the pelvic organs (prostate, bladder, colon/rectum, uterus, ovary, and vagina/

vulva) may produce a chronic radiation cystitis (Pavlidakey and MacLennan, 2009). The late sequelae of radiation injury to the bladder can range from minor temporary irritative voiding symptoms and asymptomatic haematuria to more severe complications such as gross haematuria, contracted non-functional bladder, persistent incontinence, and fistula formation. The clinical presentation can include frequency, urgency, dysuria, haematuria, incontinence, hydronephrosis, pneumaturia, and faecaluria.

Lymphoedema pain

One-third of patients with lymphoedema as a complication of breast cancer or its treatment, experience pain and tightness in the arm (Newman et al., 1996; Hamner and Fleming, 2007) and pain is a major part of the morbidity among affected patients (McWayne and Heiney, 2005). In some patients, pain is caused by a secondary rotator cuff tendonitis caused by internal derangement of tendon fibres caused by impingement, functional overload, and intrinsic tendinopathy. Conservative treatment with NSAIDs and physiotherapy is a safe and effective treatment (Herrera and Stubblefield, 2004). Some patients develop nerve entrapment syndromes of the carpal tunnel syndrome or brachial plexus (Ganel et al., 1979; Vecht, 1990). Severe or increasing pain in a lymphoedematous arm is strongly suggestive of tumour invasion of the brachial plexus (Kori et al., 1981; Kori, 1995).

Burning perineum syndrome

Persistent perineal discomfort is an uncommon delayed complication of pelvic radiotherapy. After a latency of 6–18 months, burning pain can develop in the perianal region; the pain may extend anteriorly to involve the vagina or scrotum (Minsky and Cohen, 1988; Mannaerts et al., 2002). In patients who have had abdominoperineal resection, phantom anus pain and recurrent tumour are major differential diagnoses.

Post-prostate brachytherapy pelvic pain

Brachytherapy patients with prostate cancer may produce a chronic radiation-related pelvic pain syndrome that is exacerbated by urination or perineal pressure. Data suggests that it may be partly related to higher central prostatic radiation doses (Wallner et al., 2004).

Osteoradionecrosis

Osteoradionecrosis is another late complication of radiotherapy. Bone necrosis, which occurs as a result of endarteritis obliterans, may produce focal pain. Overlying tissue breakdown can occur spontaneously or as a result of trauma, such as dental extraction or denture trauma (Epstein et al., 1987, 1997). Delayed development of a painful ulcer must be differentiated from tumour recurrence.

Conclusion

Adequate assessment is a necessary precondition for effective pain management. In the cancer population, assessment must recognize the dynamic relationship between the symptom, the illness, and larger concerns related to quality of life. Syndrome identification and inferences about pain pathophysiology are useful elements that may simplify this complex undertaking.

Cancer-induced bone pain

Lesley A. Colvin and Marie T. Fallon

Introduction to cancer-induced bone pain

Bone is the third most common site of metastatic disease, after liver and lung, with approximately 75% of these patients suffering from related pain (Ibrahim et al., 2013). Cancer-induced bone pain (CIBP) is a major clinical problem, with limited options for predictable, rapid, and effective treatment for some of the elements without unacceptable adverse effects. When treating the different components of CIBP, background pain may respond reasonably well to opioids, whereas both spontaneous and movement-evoked pain may be much more problematic. Our understanding of how current therapy acts is based mainly on studies in non-cancer pain syndromes, which are likely to be quite different, not only in clinical presentation, but also in terms of pathophysiology. It can be difficult to study the specific neurobiological changes associated with CIBP, although development of laboratory models of isolated bone metastases has allowed more specific study of pain mechanisms in this syndrome. Most of the previous models involved systemic disease, making it difficult to determine the specific changes associated with CIBP. In order to evaluate our current therapies properly and direct the development of new therapies logically, it is important to understand the underlying mechanisms of CIBP (Portenoy, 2011).

Animal models

The laboratory models of CIBP, developed within the past 10–15 years, involve focal inoculation of tumour cells into the intramedullary cavity of a single bone in rodents. This results in the growth of an isolated bone metastasis, without any of the systemic effects associated with widespread tumour, as was seen in previous models. These models allow measurement of behavioural signs of pain behaviour as well as study of pathophysiological changes and appear to correlate well with the clinical syndrome.

A range of sites such as humerus, femur, and calcaneus have been used, with tumour cell lines varying from osteosarcoma to breast, prostate, and melanoma (Schwei et al., 1999; Medhurst et al., 2002; Wacnik et al., 2003; Seong et al., 2004; Zhang et al., 2005). The underlying changes in nociceptive pathways are unique and quite distinct from those seen in other pain states, such as neuropathic or inflammatory pain (Honore et al., 2000). There is also some evidence that tumour type may have subtle changes on nociceptive processing in CIBP, with evidence that cortical destruction is not necessary for CIBP to develop (Sabino et al., 2003; Luger et al., 2005). It is clear that there are complex interactions between tumour, the tumour environment, nociceptive processing, and other factors (e.g. genetic) that will define precisely the nature of CIBP and response to treatment in any one individual (Mantyh et al., 2002).

Pain processing

In order to understand the pathophysiology of CIBP, it is useful to consider the neurobiology of nociception prior to the occurrence of tissue injury. Much of our understanding of this is based on basic science research, although brain imaging techniques are providing exciting evidence of alterations in many areas of the brain. This confirms earlier laboratory work with direct clinical evidence of how pain perception is processed at a cortical level. The International Association for the Study of Pain (IASP) definition of pain as 'an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage' is useful in reminding us that pain is more than nociception and involves a balance between sensory, cognitive, and affective components (Merskey, 1986). The traditional concept of sensory input being processed in the brain, with little interaction between spinal and cortical response is incomplete, as increasing evidence from brain imaging studies indicates significant potential for bi-directional modulation between sensory input and cortical activity (Ploghaus et al., 1999; Longe et al., 2001; Tracey et al., 2002).

It was not until the 1960s that nociceptors were first identified and the gate control theory of pain was introduced by Melzack and Wall (1965). This theory emphasized the importance of spinal modulation, with continuous interaction between small- and large-diameter afferents, local spinal neurons, and descending systems from the brain.

A basic outline of the nociceptive system is shown in Fig. 13.2.1, showing the neuraxis (the peripheral and central nervous system) involved in sensory processing and giving a framework for understanding the changes occurring in CIBP. Importantly, this is a dynamic system, with the potential for significant alterations at all levels within the system dependent on sensory input, tumour effects, and treatment.

Peripheral processing

Painful stimuli, whether mechanical, thermal, or chemical, may activate nociceptors (non-specialized free nerve endings) on particular sensory neurons (or primary afferent fibres). Sensory neurons vary in function, size, and conduction velocity, as outlined in Table 13.2.1, with generation of action potentials in C and A-delta fibres in response to noxious stimuli (Besson and Chaouch, 1987).

Nociceptive pathway
Fig. 13.2.1 Nociceptive pathway: peripheral noxious stimuli activate nociceptors, generate action potentials in C and A delta fibres, that may result in neuronal activity within the brain and pain perception. Descending systems from the brain modulate this process, as do local interneurons within the spinal cord. NRM, nucleus raphe magnus; PAG, periaqueductal grey matter.

Table 13.2.1 Classification of sensory neurons

Fibre type	Diameter (μm)	Conduction velocity (m/s)	Sensory modality
A-beta: large, myelinated	6–15	30–100	Light touch, proprioception
A-delta: small, myelinated	2–6	12–30	Noxious and innocuous sensory
C: unmyelinated	0.5–2	0.5–2.0	Pain, temperature; also post-ganglionic autonomic

The sensory fibres ascend towards the spinal cord in mixed nerves. Close to the spinal cord, the sensory fibres split into the dorsal root and enter the spinal cord. The cell bodies of all sensory fibres are situated close to the spinal cord, in the dorsal root ganglia. This is where the cell nucleus lies and where neurotransmitters essential for synaptic transmission are synthesized, before peripheral and central transport to axon terminals (Willis and Coggeshall, 1991).

Peripheral receptors and ion channels

A range of receptors has been identified on the peripheral terminations of sensory neurons. These are important in transduction of noxious mechanical, thermal, and chemical stimuli, with the potential for modulating pain processing providing potential sites of action for analgesics. These include mechanically gated ion channels, which have a role in mechanical transduction, and the transient receptor potential (TRP) family of ion channels, involved in noxious heat and cold processing. For example, the vanilloid receptor (TRPV1) is activated by noxious heat stimuli. Some receptors may also detect alterations in pH (acid-sensing ion channels) and may be more active when there has been tissue injury (Burnstock and Wood, 1996; Price et al., 2001; Welsh et al., 2002; Bandell et al., 2004; Wang and Woolf, 2005; Wemmie et al., 2006; Cortright et al., 2007; Fleetwood-Walker et al., 2007; Sluka et al., 2007). Sodium channels are essential in transmission of neuronal action potentials, with a number of subtypes that may

alter in CIBP (Liu et al., 2011; Dib-Hajj et al., 2013). In addition, there are several types of receptor detecting noxious chemical stimuli such as prostaglandins, endothelins (ETs), nerve growth factor (NGF), and bradykinin, as may be found in response to tissue injury (Kidd and Urban, 2001; Marceau and Regoli, 2004; Urch, 2004; Voilley, 2004). Peripheral opioid receptors are also found and may have a role in certain pain states, including CIBP (Janson and Stein, 2003; Menendez et al., 2003).

Central processing

Spinal cord

After entering the dorsal horn, the majority of C fibres and A-delta fibres synapse, in a somatotopic manner, in laminae I and II of the superficial dorsal horn (the substantia gelatinosa), with some A-delta fibres terminating in lamina V (Handwerker et al., 1975; Cervero and Iggo, 1980; Swetl and Woolf, 1985; Woold and Fitzgerald, 1986). The sensory fibres synapse with second-order projection neurons that ascend to the brain in specific tracts. These second-order neurons vary in their response, with, for example, nociceptive specific (NS) neurons, responding only to noxious stimuli, and wide dynamic range (WDR) neurons, responding to innocuous and noxious stimuli. Complex modulation of second-order activity occurs both via intrinsic spinal mechanisms and descending systems (Willis and Coggeshall, 1991; Coghill et al., 1993; Biella and Sotgui, 1995; Stamford, 1995). At a local

level within the spinal cord, there are a range of inhibitory mechanisms at a spinal level which may be augmented by descending inhibitory pathways from the brain (Fig. 13.2.1), acting to reduce nociceptive transmission (Besson and Chaouch, 1987; Antal et al., 1996; Dickenson, 2002).

Within the spinal cord, the main neurotransmitter involved in fast synaptic transmission in the spinal cord is glutamate, acting at a range of ionotropic (ion channels) and metabotropic (G-protein coupled) receptors. Normally, the alpha-amino-3-hydroxyl-5-methyl-4- isoxazole propionic acid (AMPA) receptor is involved in nociceptive transmission. The main inhibitory neurotransmitters, predominantly found in local interneurons and descending projection neurons, are glycine and gamma-aminobutyric acid (GABA) (Antal et al., 1996; Todd, 1996; Wiensenfeld-Hallin et al., 1997; Baba et al., 2003). Neuropeptides, such as substance P, are also released in response to noxious stimulation, with some endogenous opioid peptides acting to reduce onward transmission of noxious input (Allen et al., 1997; Duggan et al., 1998; Costigan and Woolf, 2002).

Spinal connections and supraspinal pathways

Ascending spinal tracts

After synapsing in the dorsal horn, second-order spinal neurons mainly cross to the opposite side of the spinal cord and ascend in the spinothalamic tracts to thalamic nuclei, conveying predominantly noxious information (Giesler et al., 1994; Todd, 2002). There are also spinomesencephalic tracts, originating from cells in laminae I, V, and VI to the mesencephalic tegmentum region, which includes the periaqueductal grey area (PAG) (Menetrey et al., 1982).

Descending systems

The concept of descending inhibitory pathways, or 'descending noxious inhibitory control' first originated from Melzack and Wall's gate control theory of pain (Wall, 1967; Morgan, 1994). There are several areas within the brainstem that the descending pathways originate from, including the medullary nucleus raphe magnus (NRM) and rostral ventromedial medulla (RVM). The NRM contains endogenous opioids and has been shown to have an anti-nociceptive effect, with a major descending serotonergic input to the dorsal horn (Basbaum and Fields, 1984; McGaraughty and Heinricher, 2002; Polgar et al., 2002). In the midbrain, the PAG is also involved in opioid-mediated analgesia and the locus coeruleus (LC) in modulating nociceptive transmission, via its actions on the parafascicular neurons (PF) of the thalamus (Gray and Dostrovsky, 1983; Mokha et al., 1985; Men et al., 1996; Zhang et al., 1997; Sonohata et al., 2004).

There is accumulating evidence for the existence of both anti- and pro-nociceptive pathways from the RVM, via a mechanism that may involve the N-methyl-D-aspartate (NMDA) receptor (Suzuki et al., 2004).

If there is persistent noxious input, such as may occur in CIBP, this may increase activity of this system contributing to increased spinal excitability. There is also some evidence of an indirect connection of the RVM with the anterior cingulate cortex, normally associated with the affective–motivational aspects of pain perception. Thus alterations in the balance of inhibition and facilitation from the brainstem, which may itself be modulated by higher centres, can alter inherent excitability at the level of the spinal cord (for review, see Porreca et al., 2002).

Cortical processing

Multiple areas of the brain are activated in response to pain, reflecting the complex nature of pain perception. In the clinical setting, the use of brain imaging techniques, such as functional magnetic resonance imaging (fMRI), is expanding and providing insights into our understanding of pain perception. Cortical responses to nociceptive stimuli can be demonstrated (the most consistently activated areas include the insular and the anterior cingulate regions) as well as the considerable top-down regulation of the context on peripheral nociceptive stimuli (Berman et al., 1998; Davis, 2000; Peyron et al., 2000; Bingel et al., 2011; Lee and Tracey, 2013). It is clear that there are many complex bi-directional interactions between the brain and the spinal cord in pain processing (Tracey et al., 2002; Eccleston and Crombez, 2005).

Mechanisms of cancer-induced bone pain

Peripheral factors

Evidence from the animal models of CIBP demonstrates wide-ranging alterations in the peripheral environment around the site of the bony metastasis and subsequent sensory processing. The relationship between the site of bone metastasis, the sensory nerves, and the surrounding microenvironment plays a key role in CIBP.

The complex interaction between the tumour itself and the development of CIBP may be modulated by tumour type, site, and degree of bony destruction (Dore-Savard et al., 2013). CIBP may occur prior to evidence of bony destruction, with clear signs of pain behaviours found in animal models (Luger et al., 2005). Other factors, both local and central, must play a role in the generation of pain in CIBP. The type of tumour clearly influences the likelihood of bony metastases occurring, although the relationship to CIBP has not been described (Halvorson et al., 2006; Alarmo et al., 2008).

Local changes in sensory neurons

Direct pressure and compression of surrounding structures, including the sensory nerves innervating the bone and periosteum, will occur with tumour growth. Both myelinated and unmyelinated primary afferent neurons innervating the marrow and mineralized bone may be injured and sensitized in CIBP (Peters et al., 2005). Although not examined in CIBP, a rodent bone fracture model found that the periosteum is densely innervated by a meshwork of calcitonin gene-related peptide (CGRP) containing fibres. This subgroup of C fibres is thought to be involved in nociceptive transmission and could thus contribute to the marked movement-related pain that is such a challenging component of CIBP (Martin et al., 2007). It has also been shown that purinergic receptors (P2X3) on these fibres are upregulated in CIBP and may contribute to peripheral sensitization, although the role of purines in CIBP may be less important than in some other chronic pain states, such as inflammation (Gilchrist et al., 2005; Hansen et al., 2012).

The capsaicin receptor, TRPV1, is increased on sensory neurons close to the tumour site and also within the dorsal root ganglia, preferentially in CGRP-containing neurons. TRPV1 antagonists reduce pain behaviour in CIBP models (Men et al., 1996; Ghilardi et al., 2005; Niiyama et al., 2007; Gui et al., 2013).

Ion channel changes in sensory neurons occur in CIBP: There is a decrease in some types of K^+ channels (KCNQ2 and -3) in small-diameter neurons, associated with the development of CIBP and neuronal excitability (Zheng et al., 2013). Sodium channel subtypes also change and may be associated with generation of spontaneous ectopic discharges in CIBP, similar to that seen in neuropathic pain (where they are thought to be linked with the generation of spontaneous pain) (Schafers et al., 2008; Ke et al., 2012; Qiu et al., 2012).

Inflammation

In the area of bony metastases, a range of pro-hyperalgesic mediators, commonly associated with inflammation, is released from the tumour and associated immune system cells, including macrophages, neutrophils, and T cells. This includes prostaglandins, ETs, bradykinin, tumour necrosis factor (TNF) alpha and a number of growth factors, such as transforming growth factor beta (TGF-β) all of which are likely to contribute to CIBP (Wagner and Myers, 1996; Woolf et al., 1996; DeLeo et al., 1997; Cain et al., 2001; Sabino et al., 2002). These will not only sensitize peripheral nociceptors to subsequent stimuli, but also have a direct action on specific receptors on the primary sensory neurons in the area. For example, TGF-β may promote proliferation of prostate cancer cells, activate osteoclasts, and has been implicated in the development of bone metastases (Buijs et al., 2007; Sato et al., 2008). Interleukin 1(IL-1) beta has been shown to be upregulated in a rodent model: electroacupuncture decreased this increase in IL-1 beta as well as reducing pain behaviours (Zhang et al., 2007). Bradykinin antagonist may have a therapeutic role and non-steroidal anti-inflammatory drugs (NSAIDs) may also modulate CIBP. Of the growth factors, there is some evidence that nerve growth factor (NGF) has a particular role in CIBP, with a potential therapeutic option in the form of an anti-NGF antibody (Halvorson et al., 2005; Sevcik et al., 2005; Jimenez-Andrade et al., 2007). Pre-treatment with anti-NGF was found to reduce pain behaviours and reduce sensory sprouting and neuroma formation (Jimenez-Andrade et al., 2011).

Factors secreted by the tumour may include not only cytokines and other pro-inflammatory mediators, but also substances such as formaldehyde, with resultant increases in pain (Coluzzi et al., 2011; Liu et al., 2013).

CIBP, at least peripherally, seems to display a combination of neuropathic pain, either due to direct tumour compression or ischaemia, plus peripheral sensitization as is found in inflammatory pain, with release of cytokines and other mediators.

Bone microenvironment

Other factors specific to the bone, its response to tumour implantation, and the effect of the microenvironment must also be considered (Marguiles et al., 2006). Within the tumour there may be low oxygen levels, an acidic pH, and high extracellular calcium concentrations (Kingsley et al., 2007). When tumour cells spread to bone, the balance of bone turnover is disrupted, with an increase in bone resorption, formation of abnormal bone matrix and disruption of the precise balance between osteoclast and osteoblast activity, such that normal regulatory mechanisms are lost (Boyle et al., 2008; Peyruchaud et al., 2013).

An increase in osteoclasts and their activity results in increased degradation of bone matrix, by secretion of acid and lytic enzymes. Bone resorption is increased correspondingly. The RANK (receptor
Fig. 13.2.2 Schematic diagram of bone and tumour cell interaction. The balance between OPG and RANKL is disrupted with a relative reduction in OPG and thus an increase in osteoclast activation and hypertrophy resulting in increased bone resorption. Oc, osteoclast.

for activator of nuclear factor kappa B) signalling pathway plays a key role in this process. The TNF-related cytokine, RANK ligand (RANKL), expressed on osteoblasts, and colony stimulating factor (CSF)-1 combine to stimulate production of activated osteoclasts. This process is normally controlled via a negative feedback loop, involving osteoprotegerin (OPG), a secreted soluble receptor that is also a member of the TNF family. OPG acts by sequestering RANKL, preventing osteoclast activation and reducing bone resorption (Boyle et al., 2008). This feedback loop is disrupted in CIBP, with a marked osteoblastic inflammatory response, increased secretion of a range of cytokines increasing osteoclast activity, and an increased ratio of RANKL to OPG (Nagae et al., 2007; Kinder et al., 2008) (Fig. 13.2.2).

Agents that interfere with osteolysis may therefore improve therapy of CIBP. This includes not only currently available agents such as bisphosphonates, but also novel agents that would alter the balance of bone metabolism to reduce CIBP. These include OPG-type drugs, anti-NGF, and other agents that interfere with intracellular pathways in osteoclasts (Medhurst et al., 2001; Walker et al., 2002; Clohisy and Mantyh, 2004; Roudier et al., 2006; Jimenez-Andrade et al., 2007; Tsubaki et al., 2007).

Central factors

While it is clear that peripheral changes, due to tumour effects on the bone, drive or at least initiate central responses, it is not understood at all how much the central changes contribute to the degree of severity of the pain syndrome. It is known from other chronic pain states that changes in spinal pain processing, with central sensitization, and wind up, play a major role in the development of chronic pain (Woolf, 2007).

What has been found in animal models of CIBP is that the central changes are quite different from either inflammatory or neuropathic pain (Honore and Mantyh, 2000).

Glial cells

A particular feature that has been noted is an increase in glial cells, with a marked astrocytosis in the spinal cord on the side of the lesion. Interventions to reduce glial activation have been shown to correlate with reductions in pain behaviour and reduced spinal cord cytokines (Wang et al., 2011). Increases in extracellular signal regulated kinase occurs in both astrocytes and microglia and is associated with allodynia, while the microglial inhibitor, minocycline, reduces brain-derived neurotrophic factor levels and CIBP behaviour (Zhang et al., 2005; Wang et al., 2012a, 2012b).

The central neuroinflammation that seems to occur in CIBP may be mediated via the Toll-like receptor-4, which has also been implicated in central neuroinflammatory effects of opioids (Watkins et al., 2005; Mao-Ying et al., 2012). An increase in T-cell death-associated gene 8 (TDAG8) protein expression was found in CIBP, with knockdown of TDAG8 reducing spinal protein kinase A activity and reducing CIBP (Hang et al., 2012).

Current standard clinical treatment for bone pain, local radiotherapy, will reduce glial activity in the spinal cord, as well as reversing some of the abnormal neurochemistry (Vet et al., 2006). There is increasing interest in the interaction between the immune system and sensory neurons in the generation of chronic pain syndromes and it seems likely that this may be particularly relevant to CIBP (Scholz and Woolf, 2007).

Glutamate and neuronal responsiveness

Metabotropic glutamate receptors are found on glial cells within the spinal cord and may contribute to pain behaviour, in addition to more well-defined glutamate receptors, such as the NMDA receptor (Saito et al., 2006).

The likely involvement of glutamate, one of the main excitatory neurotransmitters in the spinal cord, has been confirmed by the efficacy of gabapentin in CIBP models, with a presynaptic effect on glutamate release (Donovan-Rodriguez et al., 2005).

Gabapentin has also been found to reduce activity of a particular type of dorsal horn neuron—the WDR neuron. WDR neurons appear to alter in CIBP, with increased responsiveness to mechanical and thermal stimuli in addition to ongoing spontaneous activity (Urch et al., 2003; Donovan-Rodriguez et al., 2005; Khasabov et al., 2007). An alteration in descending pathways from the brainstem to the spinal cord has also been found, with an increase in activity of pro-nociceptive pathways, as can occur in other chronic pain states (Porreca et al., 2002; Donovan-Rodriguez et al., 2006).

Opioids

Clinically, opioids may control some elements of CIBP well, but have significant limitations in controlling aspects of breakthrough pain, which is common in CIBP. There may be a neurobiological basis for this, with alterations in the endogenous opioid systems found in animal models of CIBP.

Mu opioid receptors (MOR) have been found to decrease in specific subpopulations of primary afferent neurons in the dorsal root ganglia. These neurons were predominantly CGRP or TRPV1-containing neurons, known to be involved in CIBP. This reduction in MOR expression seemed to correlate to a reduced analgesic response to intrathecal morphine and was not seen in an inflammatory model (Yamamoto et al., 2008). The dose–response curve for morphine is shifted to the right, with greater doses

needed to reduce pain behaviour compared to inflammatory pain, suggesting fundamental differences in the underlying mechanisms (Luger et al., 2002). Prolonged morphine treatment may increase pain behaviour, associated with an increase in CGRP neurons in the dorsal root ganglia and increased osteoclast activity (King et al., 2007). Conversely, another group found that chronic systemic morphine had greater efficacy than acutely administered morphine (Urch et al., 2005). There is also evidence that binding to MORs may be attenuated in CIBP, with a variable effect between opioids resulting in differential analgesic effects, where oxycodone binding was minimally attenuated and its analgesic effect was more than morphine (Nakamura et al., 2013).

Other opioid receptors may also be important, with evidence for an analgesic effect of kappa agonists (Kim et al., 2011). The pro-nociceptive opioid peptide, dynorphin, increases markedly in the dorsal horn of the spinal cord (Honore et al., 2000). This may contribute to an increase in the activity of descending facilitatory systems from the brain (Vanderah et al., 2001; Porreca et al., 2002).

Summary of pre-clinical aspects of CIBP

The advent of locally restricted bone metastases models has allowed us to begin defining the underlying mechanisms related to CIBP, separate from the systemic effects of widespread tumour. There are complex interactions between local factors at the site of tumour metastasis to bone, with inflammatory and neuropathic processes, contributing to the response that is elicited within the central nervous system. The spinal cord changes occurring in CIBP appear to be unique and distinct from other chronic pain states. Improved understanding of all these processes should aid development of novel targeted therapies that may improve our clinical armamentarium for managing this challenging clinical problem.

Clinical features

Introduction to clinical features

Pain as a result of metastatic spread to bone is a significant clinical problem for patients, their carers, and health-care professionals (Fallon and McConnell, 2007). Bone pain can have a significant impact on physical, psychological, and social functioning (and so overall quality of life) (Rusteon et al., 2005). CIBP can be difficult to manage and treatment may require the use of multiple types of interventions (Clare et al., 2005). The optimum use of the World Health Organization (WHO) analgesic ladder is critical for successful management of CIBP. This, of course, means using the ladder as outlined in Chapter 9.4 but remembering that the ladder was never intended for use in isolation of other methods of cancer pain relief. CIPB provides a classical paradigm for the WHO analgesic ladder, sitting within a wider context of other pain-relieving techniques (Fig. 13.2.3).

Epidemiology

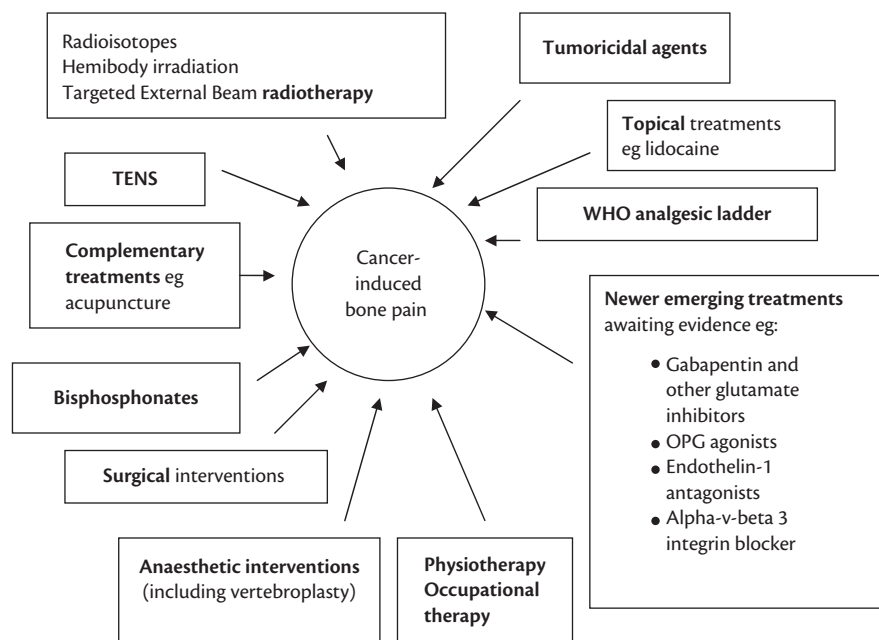
Bone is the most common source of pain in patients with malignant disease with studies suggesting that approximately 28% of hospice inpatients, 34% of patients in a cancer pain clinic, and 45% of advanced cancer patients followed up at home, are affected by pain from bone metastases (Twycross and Fairfield, 1982; Banning et al., 1991a; Portenoy and Lesage, 1999; Loeser, 2000). Studies also suggest that lesions in bone account for 30–35% of


Fig. 13.2.3 CIBP requires a multimodality approach individualized for each patient.

all cancer pains in patients with advanced disease (Twycross and Fairfield, 1982; Grond et al., 1996). Some patients will experience multiple sites of pain due to bone metastases.

However, not everyone will have pain as a result of bone metastases. For example, one-third of patients with metastatic breast disease affecting the skeleton, do not complain of pain (Front et al., 1979). The mechanisms which mediate the onset of pain in some metastases but not others in the same patient are poorly understood, however the local tumour and its immediate environment must play an important role.

Clinical characteristics

Descriptors of cancer-related bone pain are varied, but it is generally accepted that there is a triad of background pain, spontaneous pain at rest, and movement-related pain. Movement-related pain is a form of incident pain and along with spontaneous pain at rest are types of breakthrough pain (Mercadante and Arcuri, 1998; Urch, 2004).

Breakthrough pain is referred to as 'transitory exacerbation of pain experienced by the patient who has relatively stable and adequately controlled baseline pain' (Portenoy et al., 2004). Spontaneous pain refers to episodes of breakthrough pain that occur unexpectedly at rest. In contrast, movement-related pain (also known as incident pain or 'precipitated pain') refers to episodes of breakthrough pain that are related to specific events
Fig. 13.2.4 Clinical characteristics of CIBP.

(Davies, 2006). Movement-related pain is the more common form of incident pain in patients with CIBP, however other types of incident pain, such as pain on coughing or breathing, associated with rib or sternal metastases, are common (Fig. 13.2.4).

Background pain

Temporal pattern of pain

Background pain can be intermittent initially, but rapidly progresses to become constant in nature. Once established it is usually unrelenting.

Site of pain

In a study where 41% of participants had pain due to neoplastic damage to bones and joints, 13% had vertebral (including sacral) pain, 7.1% had pelvic pain, 6.8% had pain in the chest wall from rib lesion(s), 3.9% had pain in the long bones, and 10.2% had generalized bone pain from multiple bone metastases (Caraceni and Portenoy, 1999). The skeleton was affected in slightly different patterns depending on the primary site of the tumour (Table 13.2.2).

Radiation of pain

Usually the pain is localized to a specific area (and frequently there is point tenderness over the affected area of bone). In other cases, pain may be referred (Mercadante, 1997). For example, a metastatic deposit in the hip may result in pain in the knee area; a lesion in the T12/L1 site may cause pain felt in the iliac crest or sacro-iliac joint (either unilaterally or bilaterally); a cervical spine metastasis may have pain referred to the occipital region or the skull vertex (Loeser, 2000).

Another feature which is recognized in CIBP is the phenomenon of a 'migratory pattern of pain', where pain might appear in one area of the body at a given time, then move to a completely different part of the body with total resolution of the pain at the original site (Pollen and Schmidt, 1979).

Table 13.2.2 Prevalence of different pain syndromes in patients with different tumours

Cancer diagnosis	Pain syndrome					
	Skull	Vertebral	Pelvis and long bones	Generalized bone pain	Chest wall	Pathological fracture
All tumours	5.2	13.0	10.5	11.4	6.8	5.0
Breast	2.1	20.9	12.5	25.3	9.7	8.3
Lower GI tract	1.9	10.6	17.4	0	0.9	1.9
Upper GI tract	1.9	4.8	0.9	0.9	0	0
Head & neck	21.6	4.5	6.3	5.4	0.9	0.9
Leukaemia/lymphoma	0	4.7	11.9	14.2	0	0
Lung	4.6	18.0	8.8	10.4	20.7	7.7
Prostate	1.5	21.5	26.1	40.0	4.6	3.0
Uterus	0	4.2	4.2	0	2.8	0

Quality (character) of pain

Background pain is often described as a dull ache (Colleau, 2002). However, the descriptions of the pain were variable in a study of patients with bone pain from metastatic prostate cancer (Pollen and Schmidt, 1979). Recent work has suggested that it may be more commonly associated with terms like 'sharp', 'throbbing', and 'tingling' (Laird et al., 2011).

Intensity (severity) of pain

The intensity of bone pain is independent of tumour type, location, number and size of metastases, gender, and age of patient (Oster et al., 1978).

In a study of patients with bone pain from metastatic prostate cancer, 60% had 'severe' pain, 30% had 'moderate' pain, and the rest described their pain as being 'mild (Pollen and Schmidt, 1979). Bone pain usually increases in intensity over time (Mercadante, 1997).

A study of hospitalized patients with advanced cancer demonstrated that, while 49% of patients with bone metastases reported severe pain, only 31% of patients without bone involvement reported a similar level of pain (Brescia et al., 1999). This concurs with the clinical impression that CIBP often presents a therapeutic challenge.

Exacerbating factors of pain

As discussed above, exacerbation of pain is often related to specific events ('incident pain'). Incident pain can be further divided into (a) volitional pain—precipitated by a voluntary act (e.g. walking) and (b) non-volitional—precipitated by an involuntary act (e.g. coughing) (Davies, 2006). However, for practical purposes, it is the individual patient's history which is key as there clearly exists an overlap between these categories. We suggest always using explicit terms to describe the different categories of CIBP outlined in Fig. 13.2.4.

Relieving factors of pain

A variety of different non-pharmacological, pharmacological, oncological, and other types of interventions have been used to treat bone pain. These interventions are discussed below and outlined in Fig. 13.2.3.

Other features of pain

As bone pain due to cancer becomes more established, mechanical allodynia can develop, resulting in pain from a stimulus or activity which was normally not painful, for example, moving in bed (Clohisy and Mantyh, 2003). Recent studies also suggest that cancer-related bone pain can result in paraesthesia (altered sensation), dynamic allodynia (perception of pain in response to light brushing of the skin), static allodynia (perception of pain in response to pressure), or thermal hyperalgesia (pain at normal, low, and high temperature thresholds) (Medhurst et al., 2002; Menendez et al., 2003a). Interestingly, normalization of thermal hyperalgesia and hypoalgesia have been shown to be associated with successful pain relief from palliative radiotherapy and improved function (Scott et al., 2012; Sande et al., 2013).

Breakthrough pain: epidemiology

An IASP survey found that breakthrough pain was present according to clinicians in 65% of patients with cancer-related pain (Caraceni and Portenoy, 1999; Caraceni et al., 2004). However, breakthrough pain was more likely to be reported in English-speaking countries, which may reflect factors more to do with the definition, than the recognition, of the phenomenon.

Bone pain is a major source of breakthrough pain and has been reported as the predominant source of incident pain (Caraceni et al., 2004). In the aforementioned survey, breakthrough pain was significantly associated with certain pain syndromes, including those due to vertebral lesions and lesions in the pelvis, long bones, or joints. Thus, of the patients with vertebral pain syndrome, 85% had breakthrough pain. Similarly, of the patients with pelvis and long bone lesions, 78% had breakthrough pain.

The clinical features of breakthrough pain vary from individual to individual (Portenoy et al., 2004). Nevertheless, breakthrough pain is often reported to be frequent in occurrence, acute in onset, short in duration, and moderate to severe in intensity (Portenoy and Hagen, 1990; Portenoy et al., 1999; Zeppetella et al., 2000). Zeppetella et al. reported a mean number of four episodes per day (range 0–14 episodes per day) among hospice inpatients with pain (Zeppetella, 2000). Portenoy et al. found the median interval

between onset and peak of pain to be 3 minutes, with a range of 1 second to 30 minutes (Portenoy et al., 1999). In addition, Portenoy and Hagen reported a median duration of 30 minutes (range 1–240 minutes) amongst hospital inpatients with pain (Portenoy and Hagen, 1990). The clinical features of breakthrough pain often mirror the clinical features of the background pain; however, they may differ.

The clinical features of breakthrough pain may also vary within an individual. For example, patients may experience both spontaneous pain and incident pain. In the study by Portenoy et al. almost two-thirds of patients could identify a precipitant for their pain, such as weight-bearing and/or movement (Portenoy et al., 1999). However, nearly half of patients also stated that their pain could be unpredictable at times.

Patients with breakthrough pain have more intense background pain that those without breakthrough pain (Portenoy et al., 1999; Caraceni et al., 2004). Moreover, the study by Portenoy et al. confirms that patients with breakthrough pain have greater functional impairment (as measured on the interference scale of the Brief Pain Inventory) when compared to patients without such pain (Portenoy et al., 1999). In addition, patients with breakthrough pain have significantly increased levels of depression and anxiety (as measured by the Beck Depression Inventory and the Beck Anxiety Inventory) when compared with patients without such pain.

While the tonic background pain is usually controlled with opioid analgesia, the other two components, spontaneous or movement related (including incident pain which is not movement related), are problematic because:

1. There is a mismatch between temporal onset of pain in relation to temporal onset of analgesia from opioids.

2. Resolution of pain in relation to duration of opioid analgesia again has a mismatch. While immediate (normal) release morphine may have analgesic effects for up to 4 hours, spontaneous and movement-related pain can resolve in less than 30 minutes in 50% of patients, rendering the patient more susceptible to opioid side effects

3. There is evidence of poor opioid responsiveness of some aspects of the underlying neurophysiology of the spontaneous and movement-related pain components (Martin et al., 2007; Yamamoto et al., 2008; Laird et al., 2011). This may mean that some patients may fail to achieve adequate analgesia with even the 'ideal' formulation of opioid.

The combination of the above factors indicates that opioid side effects, especially sedation, are more likely to dominate over analgesia. In any pain syndrome where there are sudden, short-lived, peaks of pain, over and above a stable background pain, the opioid side effects are more likely to be problematic. In particular, such patients may become opioid toxic.

Opioid toxicity

Opioid toxicity is a spectrum which at one extreme may involve sleepiness, poor concentration, and vivid dreams while at the other end of the spectrum may involve hallucinations, confusion, agitation, and even a paradoxical increase in pain known also as hyperalgesia. A survey of inpatients in a regional cancer centre showed 50% of patients to have some symptoms of opioid toxicity,

most of which were not identified by staff (Isherwood et al., 2012). Significant opioid toxicity is associated with a 50% mortality and it is known clinically, that in those patients who recover, the distress experienced was profound. It is therefore very important to avoid opioid toxicity and to develop treatments which minimize this risk.

Current management of CIBP

Currently, NSAIDs and palliative radiotherapy form the key strategies which complement simple or opioid analgesia in CIBP relief. The evidence base for these strategies, along with emerging newer strategies is discussed below; however, a major problem with the evidence base is the lack of information on which components of CIBP are helped by which treatments. Many studies of bone pain treatment have used single-item scales such as a visual analogue scale to assess pain, which may give an inadequate assessment of the true clinical significance of treatments, with some interest in developing more comprehensive standardized assessments for clinical trials (Caissie et al., 2012; Matza et al., 2012; Zeng et al., 2012a, 2012b).

The standard approach to the management of CIBP is a combination of analgesia and radiotherapy. While it is accepted that radiotherapy is the gold standard treatment for pain relief in CIBP, there are a significant number of patients who fail to receive adequate analgesia. A systematic review showed external beam radiotherapy, whether single or multiple fractions, produced 50% pain relief in 41% of patients and complete pain relief at 1 month in 24% of patients (McQuay et al., 2000). However, many patients are too frail to attend for palliative radiotherapy or it is too late to reasonably expect pain relief before death.

We know that current therapeutic regimens leave up to 45% of patients with inadequate and under-managed pain control (de Wit et al., 2001; Meuser et al., 2001).

For such reasons, an improved understanding of the pathophysiological mechanisms underlying, in particular, spontaneous pain at rest and movement-related pain, are important. The development of effective pharmacological interventions to act as adjuvants or synergists to palliative radiotherapy to improve the degree of pain relief, in addition to providing analgesia to those too unwell to benefit from palliative radiotherapy, is an important area of research.

Opioid-based therapy does remain the basis for most analgesia in CIBP and in theory there are two aspects to the optimization of opioid analgesia. Firstly, to establish the best opioid for an individual, based on the pharmacogenomic principle of interindividual variation in balance between analgesia and side effects and secondly, to assess the optimal pharmacokinetic:pharmacodynamic profile from the opioids available (Quigley, 2004). There is more weight given to the first aspect in relation to chronic background pain, however more weight is given to the second in relation to spontaneous pain at rest and movement-related pain. For example, a patient may use a long-acting opioid preparation, such as morphine, for background pain and a fast-acting fentanyl preparation for breakthrough pain.

A subgroup of patients experience uncontrolled CIBP only after considerable and predictable movement, such as a long walk. This group is often satisfied to use a standard opioid such as immediate (normal)-release morphine, 30 minutes in advance of such activity.

Conversely, in those patients whose pain, or the exacerbating factor, is unpredictable and of fast onset, unacceptable side effects are likely to occur with standard opioids. In such cases a faster, short-acting opioid is more appropriate. Most of the evidence for opioids with faster onset of analgesia and faster peak plasma analgesic levels is limited to fentanyl (Zeppetella and Ribeiro, 2006).

Non-steroidal anti-inflammatory drugs

The use of NSAIDs in CIBP has been questioned due to the lack of robust, clinical evidence (Fucella et al., 1975; Stambaugh et al., 1988; Sunshine and Olson, 1988; Staquet, 1989; Estape et al., 1990; Minotti et al., 1998). The COX2 (an inducible isoform of cyclooxygenase (COX) enzyme involved in prostaglandin synthesis) specific inhibitors may in theory be of greater therapeutic potential due to their anti-tumour/antiangiogenesis properties (Shengetal, 1997; Sumitani et al., 2001). In an animal model of CIBP acute treatment with a highly selective COX2 inhibitor attenuated both background and movement-related pain, whilst chronic treatment additionally reduced tumour burden and osteoclast destruction (Sabino et al., 2002). Clearly the use and availability of COX2 inhibitors has fluctuated since they were first available because of concerns with some drugs within this class. A systematic review of randomized controlled clinical trials of NSAIDs for cancer pain was published in 2004 (McNicol et al., 2004; Zeppetella, 2007). It included 42 trials involving 3084 patients. The review concluded that NSAIDs were effective for the short-term treatment of cancer pain and that there was no clear evidence to support a superior efficacy or safety of one NSAID over another. It included 14 trials involving patients with bone metastases, although the authors were unable to conclude from the data presented whether NSAIDs have a specific role in CIBP.

The results of this systematic review were in keeping with the results of an earlier systematic review of the literature on NSAIDs for cancer pain and a concurrent evidence-based review of the literature on the generic treatment of cancer pain (Eisenberg et al., 1994; Carr et al., 2004). It should be noted that many of the trials included in these reviews are single-dose studies and few of the trials evaluate the efficacy or safety of NSAIDs beyond a few days of treatment.

In summary, therefore, despite good pre-clinical evidence, there is a lack of clinical evidence for a specific role for NSAIDs in the management of CIBP. Despite this, some clinicians continue to regard NSAIDs as an important part of CIBP management unless contraindications exist.

Breakthrough pain

Here we are referring to all types of breakthrough pain, other than that caused by inadequate around-the-clock analgesia to control background pain or 'end-of-dose' failure. It is a heterogeneous phenomenon, although it is typically of fast onset and short duration as previously discussed.

Despite implementation of guidelines, patients continue to have inadequate pain control and often express a variety of problems secondary to this. Breakthrough pain associated with CIBP can be particularly difficult to control (Banning et al., 1991b).

Three principles have been proposed for the management of general breakthrough pain, not specifically related to bone metastases (Portenoy, 1997):

1. Implementation of primary therapies for the underlying aetiology of the pain

2. Optimizing around-the-clock analgesia

3. Specific pharmacological or non-pharmacological interventions for the breakthrough pain.

It is generally agreed that one of the main problems with breakthrough pain due to bone metastases is that multiple breakthrough doses of opioid to control pain on movement and/or spontaneous pain at rest, usually leave the patient with frank, unacceptable opioid side effects, especially sedation, or with frank opioid toxicity. However, it has been suggested that increasing around-the-clock medication may prevent or limit breakthrough pain associated with CIBP (Mercadante et al., 2004a). Twenty-five patients admitted to a palliative care unit with movement-related breakthrough pain were titrated with intravenous morphine to background pain relief. The morphine dose was then increased further until patients began to experience unacceptable side effects at which point the increase was either stopped, or the morphine dose reduced. Patients remained as inpatients for an average of 5 days, and the breakthrough pain intensity on a 0–10 scale fell from an average of 9.2 before titration to 4.6 at the time of discharge. Most patients tolerated the higher dose of morphine. Translation of these findings to other settings may be limited by the fact that inpatients are often less mobile and there may be particular characteristics in this group which are not representative of CIBP patients in general.

The commonest method of managing breakthrough pain continues to be the use of so-called rescue medication ('breakthrough medication'). Ideally, rescue medication should have an onset/duration of action appropriate for the pain, should have a potency of effect appropriate for the pain and be easily administered. Rescue medication should be offered soon after the pain has started in cases of unpredictable pain, and before the pain has started in cases of predictable pain.

Opioids are commonly used as rescue medication. Morphine, hydromorphone, and oxycodone are the most common oral opioids used, and a fixed proportion of the daily dose is usually advised (e.g. the 4-hourly dose equivalent or 10–20% of the total daily dose) (Hanks et al., 2001). One study formally addressed the use of a fixed dose of rescue medication (Mercadante et al., 2004b): 48 patients using oral morphine for background cancer pain, and admitted to a palliative care unit, were treated with intravenous morphine, equivalent to one-fifth of the around-the-clock dose, for management of their breakthrough pain. A total of 172 episodes of pain were assessed and most patients had a 33% reduction in their pain within 18 minutes. Although most patients had somatic cancer pain, there was no specific reference to CIBP.

Non-opioids such as NSAIDs could have a role in the management of breakthrough pain as their mode of action suggests that they could be efficacious. However, with an onset of action of approximately 30 minutes, a relatively long duration of action, and dose-limiting adverse effects, they are not ideally suited to the management of breakthrough pain. There are no studies to suggest that they are effective in this clinical scenario.

A systematic review on the use of opioids for breakthrough pain identified four studies, each concerned with the application of oral transmucosal fentanyl citrate (OTFC) (Zeppetella and Ribeiro, 2006). These studies confirmed the efficacy of this delivery system for the management of breakthrough pain (Farrar et al., 1988; Christie et al., 1998; Portenoy et al., 1999; Coluzzi et al.,

2001). However, all of the studies failed to demonstrate a relationship between the effective dose of OTFC and the effective dose of around-the-clock medication and, as a result, the optimum dose of OTFC is determined by titration. This differs from usual practice of prescribing one-sixth of the 24-hour opioid dose as a breakthrough dose. It is, however, hardly surprising that when an opioid dose is carefully titrated for breakthrough pain in the context of a clinical trial, that the individual effective doses vary between patients and rarely work out as one-sixth of the 24-hour opioid dose. Although one of these OTFC studies did describe the number of patients with CIBP (Christie et al., 1998), none of the studies distinguished between CIBP and non-CIBP in their analyses which perhaps leaves a question over the favourable efficacy of OTFC or other fentanyl equivalents over standard opioids for breakthrough pain in CIBP.

Bisphosphonates for bone pain

Over the years, a number of different bisphosphonates have been developed, with the newer agents exhibiting increased potency as compared to the original agents (Wong, 2007). There are an increasing number of studies on bisphosphonates in the management/prevention of CIBP and other skeletal-related events (SRE), including pathological fracture, spinal cord compression, and hypercalcaemia (Krempien et al., 2005; Stewart, 2005).

Structure of bisphosphonates

With side-chain modifications from a simple methyl group (CH_3) to progressively longer alkyl chains, successive generations of bisphosphonates have been developed, each with increasing potency to inhibit osteoclast-mediated bone resorption.

Bisphosphonates have a number of actions, which account for their anti-resorptive properties (Santini et al., 2003; Green, 2004). They inhibit dissolution of hydroxyapatite crystals, have an effect on osteoclasts and osteoblasts, and also can have an effect on the underlying tumour. Different bisphosphonates have a different range of activities.

Bisphosphonates can inhibit the differentiation of stem cells to osteoclasts, affect the structure and function of osteoclasts, and cause apoptosis of osteoclasts (Santini et al., 2003). The latter actions rely on the bisphosphonate being taken up into the osteoclast by a process of endocytosis. Bisphosphonates also affect the interaction between osteoclasts and osteoblasts via the OPG RANK and RANKL axis. The normal RANK–RANKL balance is described in the basic science section of this chapter.

In addition, bisphosphonates can inhibit the growth of tumour cells, stimulate the immune system (against the tumour), and cause apoptosis of tumour cells (Santini et al., 2003). The inhibition of growth is achieved by a reduction in the adhesion of tumour cells to bone, a reduction in the secretion of tumour growth factors into the bone (secondary to a reduction in bone resorption), and an inhibition of tumour angiogenesis.

Bisphosphonates delay the development of skeletal events, particularly in patients with breast cancer, multiple myeloma, and prostate cancer (Bloomfield, 1998; Michaelson and Smith, 2005). A positive effect of delaying skeletal events is clearly a reduction in pain (e.g. pathological fracture).

However, bisphosphonates can also improve pain secondary to established bone lesions: many patients only respond after months of treatment, whilst other patients respond soon after treatment is initiated. The mechanism by which bisphosphonates cause

long-term pain relief is likely to be due to their effect on bone resorption (and healing of the bone lesions) (Sevcik et al., 2004). The mechanism by which bisphosphonates cause short-term pain relief is unclear, but is likely to be related to their effect on tumour growth factors and other nociceptive agents.

A Cochrane systematic review addressing the (acute) analgesic effect of bisphosphonates was first published by Wong and Wiffen (2002). The data were subsequently updated to create a Health Technology Report for the Canadian Coordinating Center of Health Technology Assessment (Wong et al., 2004). The data were further updated by Wong.

Fifty-six trials fulfilled the selection criteria for the most recent analysis. The data support the fact that bisphosphonates provide moderate relief of pain within 12 weeks of therapy. The odds ratio (OR) for the best response within 12 weeks was 1.87 (95% confidence interval (CI) 1.23–2.86). The time-course of the effect was not immediate. While there was a trend towards pain relief at weeks 4 and 8, this only became statistically significant at week 12.

A more recent systematic review and meta-analysis found a reduction in SREs and improved pain control when bisphosphonates were added to another oncological treatment such as chemotherapy or radiotherapy (RR 1.18; 95% CI 1.0–1.4) (Lopez-Olivo et al., 2012)

It is not possible to say from the studies available if there is a different analgesic effect with different primary tumour sites.

Results for different bisphosphonates

Five randomized trials provided direct comparisons between different bisphosphonates. All of them compared pamidronate against a different bisphosphonate: three compared it with clodronate (Zhang et al., 1997; Diel et al., 1999; Jagdev et al., 2001) and two against zoledronate (Berensen et al., 2001; Rosen et al., 2001). Based on the limited data available, pamidronate appears to be a better choice than clodronate with a greater response rate and a greater magnitude of pain relief. Further studies are necessary to elucidate the relative merits of pamidronate and the more potent bisphosphonates, such as ibandronate and zoledronate (Cameron et al., 2006).

Clinical data tolerability

Bisphosphonate side effects commonly described include flu-like syndromes and injection site reactions. Randomized trials with standard doses did not identify excessive gastrointestinal toxicities, although concern has been raised about this (Lanza, 2002).

Renal toxicity is another important area. Rapid infusions may result in renal toxicity, especially in patients with renal compromise. Pamidronate infusions (90 mg) are typically delivered over a period of 2 hours, while zoledronate infusions (2 mg) are typically delivered over 15 minutes. Ibandronate does not appear to possess the same renal toxicity concerns and can be used in patients with varying degrees of renal impairment (Jackson, 2005; von Moos, 2005). Adverse ocular events including uveitis, scleritis, and conjunctivitis have been reported with amino-bisphosphonate use, particularly pamidronate use (Leung et al., 2005).

Bisphosphonate-associated osteonecrosis of the mandibular and maxillary bone has been described (Migliorati et al., 2005). The pathophysiology of this condition is unknown, but the risk factors include dental extraction, local trauma, local infection, and systemic chemotherapy. The condition has been reported with pamidronate and zoledronate and usually appears after many

months of treatment. Appropriate prophylactic dental assessment and management, along with antibiotic therapy if indicated, are keystone to minimizing occurrence of this complication.

Summary of clinical use of bisphosphonates in CIBP

Bisphosphonates delay the development of skeletal events, particularly in patients with breast cancer, multiple myeloma, and prostate cancer. A positive effect of delaying these skeletal events is an overall reduction in pain secondary to bone resorption and its complications (e.g. pathological fracture). In addition, bisphosphonates also provide relief of bone pain, although the magnitude of the effect is modest in the short term and can take up to 12 weeks to work. Currently there are numerous small studies which suggest a potential role for bisphosphonates in acute CIBP relief; however, the studies are very heterogeneous and all use different outcome measurements. Further work is underway to evaluate the utility of the potent bisphosphonates such as ibandronate in achieving acute pain relief (Ibrahim et al., 2013). A double-blind, randomized controlled trial of single-dose ibandronate versus palliative radiotherapy for management of CIBP has been completed by Peter Hoskin and his team and is soon to report.

Radiotherapy

External beam radiotherapy is by far the most commonly used radiation modality in the management of bone pain: the most common type of treatment is local field radiotherapy (van As and Huddart, 2007) (see Chapter 12.3). Wide field radiotherapy and radioisotopes are used in treating disseminated bone metastases.

In 2000, the Cochrane group published on the use of radiotherapy for painful bone metastases. The review included data from 20 randomized controlled trials; 15 other studies were excluded for various methodological reasons. The trials were not sufficiently alike to allow pooling of data and therefore no meta-analysis was performed. Nevertheless, the authors concluded that radiotherapy provides effective analgesia for bone metastases. Over 40% of patients could expect at least 50% pain relief at 1 month and 20% could expect complete relief (McQuay et al., 2000). There was no discernible difference between fractionation schedules, or between different doses using the same schedule.

The Bone Pain Trial Working Group led a study to compare treatment with an 8 Gy single fraction and a multiple fraction regimen of either 20 Gy in five fractions or 30 Gy in 10 fractions (98% of patients in the multiple fraction arm received 20 Gy in five fractions and only 2% of patients received 30 Gy in 10 fractions) (Anonymous, 1999).

There was no difference between the arms in the time to first improvement in pain, time to complete pain relief, or time to increase in pain at any time over the 12-month follow-up period. There was also no difference in the acute toxicity of a single fraction of 8 Gy and the multiple-fraction regimens. Although retreatment was more common in the single-fraction arm, this was felt possibly to be due to clinicians being more likely to re-treat after a single-fraction than after a multiple-fraction regimen (Anonymous, 1999). In general, the equal efficacy, patient convenience, and lower cost should make a single 8 Gy fraction the standard treatment for palliation of pain from bone metastases. A review of studies of the efficacy of reirradiation for CIBP found variable study quality, but around 58% of patients did derive some additional analgesic benefit (Huisman et al., 2012).

Wide field radiotherapy

Wide field radiotherapy can be done in several ways, including radiation to the entire upper half of the body, radiation to the entire lower half of the body, radiation to the mid-section (from the lower chest to the upper thighs), and sequential hemi-body radiation in which half the body is irradiated in one session and the other half of the body is irradiated in a later session (4–6 weeks later). The latter procedure allows enough time for the bone marrow from the un-irradiated half of the body to re-populate the marrow cavity in the irradiated half of the body (van As and Huddart, 2007).

A number of radioisotopes have been used in the treatment of bone metastases (e.g. phosphorus-32, strontium-89, samarium-153, rhenium-186). In a systematic review and meta-analysis of radiopharmaceuticals in the treatment of CIBP (mainly from prostate or breast) approximately 70% of patients had some analgesic benefit with toxicity occurring in up to 15% of those treated (D'angelo et al., 2012). There is continued interest in this form of therapy with newer agents being developed (Yuan et al., 2013). Despite evidence, they are not widely used currently and while there are a number of potential reasons for low use of radioisotopes, cost may be an issue in many countries.

Chemotherapy

Chemotherapy can also be of considerable value in the management of metastatic bone pain where a tumour is chemosensitive. Examples would include myeloma, both small cell and non-small cell lung cancer, and breast cancer, where the natural history of these tumours is for widespread dissemination including bone as a common site of metastasis (Table 13.2.3).

Hormone therapy

Hormone therapy is also of value in hormone-sensitive tumours and both breast cancer and prostate cancer commonly spread to bone; in the latter this is the most common site and pattern of metastasis. Quite dramatic responses can be achieved within a few days of starting anti-androgen therapy in prostate cancer.

Response in metastatic breast cancer is generally slower and additional measures for pain relief are usually required in the first few weeks of starting hormone therapy. Hormone therapy, as with any other treatment which may induce acute new activity in bone, may be associated with a transient flare-up of pain which needs to be managed with appropriate manipulation of analgesia (Fig. 13.2.5).

Physiotherapy and occupational therapy

Many of the techniques in maximizing pain control through a multidisciplinary team approach discussed in Chapter 4.15 are integral to the adequate care of patients with CIBP. Life can be made infinitely easier for the patient who has difficulty mobilizing and problems in such areas as toileting and bathing, by the introduction of specific mobilizing techniques along with appropriate individualized aides.

Interventional analgesia

Vertebral cementoplasty

Instability of vertebrae due to metastatic disease can cause significant pain. Vertebral collapse causes pain per se, but structural change may also risk nerve root compression (Farquhar-Smith,

Table 13.2.3 Chemosensitivity of primary tumours commonly metastasizing to bone

Primary site	Sensitivity[a]
Myeloma	High
Bronchus	High
Breast	High
Rectum	Mid
Oesophagus	Mid/low
Prostate	Low
Thyroid	Low
Kidney	Low

[a] High = > 50% response rate; mid = 25–50% response rate; low = < 25% response rate.
Fig. 13.2.5 Management of metastatic bone pain.

2007). Percutaneous vertebral cementoplasty (also known as percutaneous vertebroplasty) under radiological control has been used to reduce pain and treat vertebral body collapse (Gangi et al., 1996). Access to this technique depends on local expertise.

The analgesic mechanism of this technique is not explained solely by treating collapse, since as little as 2 mL of methylmethacrylate cement can achieve good pain relief (Gangi et al., 2003). Stabilization of microfractures, and subsequent reduction in mechanical forces through the bone, have been postulated as analgesic mechanisms (Legroux-Gerot et al., 2004). Analgesia could also be secondary to cytotoxic and thermal destruction of tumour cells, and interference with tumour blood supply.

A study of patients with intractable pain from vertebral myeloma found that 97% of patients had at least a 'moderate' reduction in pain following percutaneous vertebral cementoplasty (Cortet et al., 1997). The improvement in pain of 36/37 patients in this study was unrelated to the proportion of vertebral filling, reiterating the importance of tumour destruction rather than anatomical correction (Cotton et al., 1996).

Complications

Cement leak is a potential problem, which can encroach upon the epidural space, risking root or cord compression, and also chemothermal damage (Gangi et al., 2003). Cement embolism may also occur if there is evidence of a venous leak. In a case series of 868 percutaneous cementoplasty procedures for malignant and non-malignant vertebral body collapse, epidural leak was only observed in 15 cases (three had neuropathic pain) and asymptomatic pulmonary embolism in two cases (Gangi et al., 2003).

It is interesting that injection of methylmethacrylate is not restricted to the vertebrae and has been reported to be successful in the management of bone pain involving the pelvic bones (Cotton et al., 1995, 1996).

Lesioning of isolated metastases

There is some interest in targeted lesioning of isolated painful bony metastases using either radiofrequency (RF), or cryoablation. A small multicentre study of computed tomography-guided RF ablation did find some evidence of efficacy and this may have potential for single lesions (Guenette et al., 2013). Another multicentre study, again with relatively small numbers (I = 69) of cryoablation with follow-up to 6 months found sustained pain relief, although there was one episode of osteomyelitis (Callstrom et al., 2013).

Spinal analgesia

Generally, where patients suffer uncontrolled CIBP despite optimal pharmacological and non-pharmacological management, then either epidural or intrathecal analgesia should be considered. This is discussed in more detail in Chapter 9.4; however, it involves infusion of small amounts of opioid combined with local anaesthetic, sometimes in combination with clonidine.

Local anaesthetic is particularly useful for movement and other incident-related pains.

It is important that patients who have a pathological fracture but who are too unwell and close to death to consider internal fixation, are assessed urgently for an epidural or intrathecal line. Such patients often suffer extreme pain on even slight movement and their end-of-life care can be improved by interventional analgesia.

Orthopaedic interventions

Surgery for pathological fracture

The aim of fixing pathological fractures is different from that of traumatic (non-pathological) fractures (Al-Hakim et al., 2007) (see Chapter 12.5). Bone healing in these situations is impaired and often the fragments do not unite together. It is, therefore, a priority that the operation involves a method of fracture fixation that can allow immediate return to normal function.

Surgery for impending fracture

Some malignant bone lesions cause symptoms in the absence of a fracture; such lesions are at risk of fracturing at some point in the future (although many do not fracture and the symptoms settle with conservative measures). In general, metastases in long bones progress to fractures in 25% of cases (although this rises to approximately 60% in the proximal femur).

The criteria for operating on impending fractures vary. A widely used method is Mirels' scoring system (Table 13.2.4). This uses

Table 13.2.4 Mirels' scoring system for impending pathological fracture (Mirels, 1989)

Variable	Score		
	1	2	3
Site	Upper limb	Lower limb	Peritrochanteric
Pain	Mild	Moderate	Functional
Lesion	Blastic	Mixed	Lytic
Size[a]	< 1/3	1/3 to 2/3	> 2/3

[a] Maximum destruction of cortex in any view as seen on plain X-ray.

Reproduced with permission from Mirels H., Metastatic Disease in Long Bones A Proposed Scoring System for Diagnosing Impending Pathologic Fractures, *Current Orthopaedic Practice*, Volume 249, pp.256–264, Copyright © 1989 Lippincott-Raven Publishers.

four factors related to the likelihood of a malignant bone lesion fracturing. These include:

◆ the site of the lesion

◆ the amount of pain caused by the lesion

◆ whether the lesion is blastic, lytic, or a combination

◆ the size and involvement of the lesion (defined as the maximum amount of cortex destroyed).

A score of 1–3 is given for each variable, so that the lowest total score is 4 and the highest total score is twelve. A score of 7 or lower indicates that surgery is not needed, whereas a score of 9 or more indicates that surgery is warranted; a score of 8 means that the decision has to be taken in the context of the patient and his/her disease.

However, patients with severe pain every time they weight-bear, in spite of appropriate analgesics, radiotherapy, and other appropriate measures, may benefit from surgery, no matter what their calculated score.

There is mixed evidence to support the case that the outcome for surgical management of impending pathological fractures is better than that for actual fractures. Ward et al. reported a significant difference in favour of patients with impending fractures in terms of perioperative blood loss, shorter hospital stay, greater likelihood of discharge home instead of temporary step-down facilities, and higher rates of unassisted ambulation (Ward et al., 2003). In contrast, Dijkstra et al. reported no significant difference in outcomes such as pain relief, physical function, complications, and survival (Dijkstra et al., 1994). The decision about surgical intervention has to be highly individualized while taking into account the accepted, but limited, evidence base.

New approaches under evaluation

Glutamate inhibitors and NMDA antagonists

On the basis that CIBP has neuropathic and inflammatory components and clinical and laboratory evidence of central wind-up, it is not surprising that inhibitors of glutamate release have been considered and investigated. It is known that in animal studies, gabapentin reverses dorsal horn changes associated with CIBP resulting in relief of spontaneous and movement-related pain

(Donovan-Rodriguez et al., 2005). The specific role of pregabalin as adjuvant drug therapy in CIBP is under evaluation in a double-blind randomized, placebo-controlled study on a background of standardized best supportive care (Delaney et al., 2008). This is a good example of translational research in palliative medicine and follows on from Dickenson's group's preclinical work (Donovan-Rodriguez et al., 2005).

Inhibitors of the NMDA glutamate receptor complex may also be of interest, especially if NMDA subtype inhibitors are developed. At present the non-specific NMDA antagonist, ketamine, is used in some difficult to manage cases.

Osteoprotegerin

OPG is a promising target, which may act through reduction of osteoclast function to diminish tumour-induced bone destruction. Indeed early clinical work with OPG is interesting and may hold future promise (Gramoun et al., 2007). A single subcutaneous dose of AMGN-0007 (a recombinant construct of OPG) suppressed bone resorption as indicated by a rapid, sustained and profound decrease of urinary N-terminal telopeptide of collagen (NTX)/creatinine in multiple myeloma and breast carcinoma patients. Changes were comparable to those with pamidronate.

Denosumab

Denosumab is a human monoclonal antibody that binds to and inhibits RANKL (see Fig. 13.2.2), thus reducing osteoclastic activity. There have been a number of clinical trials of denosumab in osteoporosis and also in malignant disease. In a phase III study comparing denosumab to zoledronate in patients with advanced cancer, there was a reduced need for radiotherapy, in addition to less worsening of pain and a lower opioid requirement (Vadhan-Raj et al., 2012; Cleeland et al., 2013).

Endothelin-1 antagonists

Androgen refractory prostate cancer continues to evade effective treatment. The potent vasoconstrictor ET-1 is produced by prostate cancer and appears to have a role in prostate cancer progression and morbidity. Based on preclinical and clinical trial data, the ET axis is emerging as potentially important in this response (Body et al., 2003). Drugs targeting the endothelin axis, such as the potent ET_A receptor antagonists atrasentan, have been studied in large clinical trials and appear to have an impact on disease progression and morbidity. The role of the ET axis in prostate cancer deserves further investigation in the laboratory and clinic. Laboratory studies of ET_A in CIBP have demonstrated analgesic effects on both background and movement-evoked pain (Peters et al., 2005).

Monoclonal antibodies for nerve growth factor

NGF is a neurotrophin that regulates the structure and function of neurons. A humanized monoclonal antibody against NGF has been developed by two different pharmaceutical companies.

Tanezumab has been used in hip osteoarthritis studies with superior pain relief and improvement in physical function compared to placebo (Brown et al., 2013). Phase II studies have been completed in CIBP and the results are awaited. This may be a completely novel and opioid-sparing way of managing CIBP, however trial results are awaited.

Future concepts

Alphavbeta3 (αvβ3) integrin blocker

The integrin αvβ3 mediates cell-matrix interactions (Nelson 2003). Vitaxin®, a humanized monoclonal antibody that blocks human and rabbit αvβ3 integrins, is in clinical trials for metastatic melanoma and prostate cancer. Vitaxin® decreases bone resorption by impairing osteoclast attachment, without affecting osteoclast multinucleation. Data also show that the inhibitory effects of Vitaxin® on osteoclasts can be modulated by factors known to alter the conformation of αvβ3. The effects of Vitaxin® on reducing osteoclast activity may have future clinical utility in the management of CIBP.

Summary

CIBP remains a clinical challenge if we aim to achieve pain relief without unacceptable opioid side effects. An accurate assessment followed by an individualized management plan is key. A multimodality approach is required. Standard analgesic approaches using the WHO guidelines along with palliative radiotherapy as appropriate form the basis of management; however, every patient should be assessed with all modalities in mind. Clearly the patient's general physical condition, primary tumour diagnosis, extent of bone disease, previous treatments, and treatment response, along with specific features such as the likelihood of pathological fracture, are among the factors which will influence management decisions.

It is encouraging that we are emerging into an era where, largely due to an improved pre-clinical understanding of CIBP along with new drug development, we are likely to see the emergence of an improved evidence-based armamentarium for this challenging and frequent clinical problem.

Management issues in neuropathic pain

Nanna Brix Finnerup and Troels Staehelin Jensen

Introduction to management issues in neuropathic pain

Neuropathic pain is a heterogeneous group of chronic pain conditions arising from a lesion or disease of the peripheral or central somatosensory nervous system (Jensen et al., 2011). The responsible lesion may be of any type and occur at any location along the sensory transmission pathways. Neuropathic pain is commonly divided into peripheral and central neuropathic pain, and further classified according to anatomical site and disease (Table 13.3.1).

Neuropathic pain may be challenging therapeutically and have a substantial impact on quality of life, sleep, and mood. Treatment often is difficult and may involve interventions distinct from those typically used for nociceptive pains. Given these challenges, awareness of the various neuropathic pain syndromes and an understanding of issues related to assessment and treatment may lead to better recognition and improved outcomes.

Clinical characteristics

Neuropathic pain may develop immediately after a nerve injury or disease or occur as a late effect, often after several months. The pain is likely to be chronic and is characterized by spontaneous and evoked types of pain perceived in areas of sensory abnormality, either hyposensitivity and/or hypersensitivity. In certain cases, neuropathic pain may develop as an acute pain, for example, cold-evoked pain after treatment with the chemotherapeutic drug, oxaliplatin.

Spontaneous pain may be ongoing, with a constant or fluctuating pain intensity, or dominated by pain paroxysms of short duration with pain-free intervals or a less intense background pain. Other sensations, such as paraesthesia (abnormal sensation that is not painful or unpleasant) and dysaesthesia (unpleasant abnormal sensation) may be present spontaneously or occur only when evoked by a stimulus (Merskey and Bogduk, 1994). Allodynia is a type of evoked pain that is elicited by a non-noxious stimulation. Dynamic mechanical allodynia or touch-evoked allodynia is the most common form, but allodynia to cold or warm may also be present. Hyperalgesia, which describes an increased response to a stimulus that is normally painful, also is often present but usually not described as a symptom by the patient.

Table 13.3.1 Classification of neuropathic pain

Peripheral	Central
Mono- and polyneuropathy	
diabetes	Multiple sclerosis
alcohol	
HIV	
chemotherapy	
other	
Plexopathy	Neoplasms
Radiculopathy	Spinal cord injury
Nerve injury:	
postsurgical	Syringomyelia
post-traumatic	
Amputation:	
phantom limb pain	Myelopathy
stump pain	
Root avulsion	Stroke
Post-herpetic neuralgia	
Trigeminal neuralgia	
Neoplasms	

Definition and diagnosis of neuropathic pain

Neuropathic pain is defined as pain caused by a lesion or disease of the somatosensory system (Jensen et al., 2011). To diagnose neuropathic pain, an effort must be made to demonstrate a nervous system lesion, a relevant onset of pain related to this, and a location of pain in areas of sensory disturbance that are neuroanatomically compatible with the lesion (Treede et al., 2008). The diagnosis cannot rely on single pain descriptors and is not always easy to confirm in the absence of clear diagnostic criteria. The diagnosis may be particularly challenging when sensory loss is masked by areas of hypersensitivity, and when neuropathic and nociceptive components to the pain occur together. The latter is often the case in cancer patients, where nociceptive muscle, bone, visceral pain, etc. is often mixed with neuropathic pain, making the clinical picture difficult to elucidate (Vadalouca et al., 2012).

A medical history, including a detailed pain history and a careful medical and neurological examination, is essential (Haanpaa et al., 2011). The neurological examination is essential for the diagnosis of neuropathic pain and should include a careful sensory examination evaluating decreased or increased responses to touch, vibration, pinprick, and thermal stimuli, as well as a mapping of the distribution of the sensory dysfunction. At times, additional diagnostic testing, such as scanning with computed tomography or magnetic resonance imaging, electromyography and nerve conduction velocity testing, or nerve biopsy may be indicated. Electromyography and nerve conduction velocity testing only assess large-fibre function and may be supplemented with quantitative sensory testing using thermal testing to identify a small fibre neuropathy.

Tools have been developed for identifying patients with neuropathic pain based on clusters of symptoms and signs: the Leeds Assessment of Neuropathic Symptoms and Signs (LANNS scale) (Bennett 2001), the ten-item questionnaire DN4 (Bouhassira et al., 2005), the Neuropathic Pain Questionnaire (NPQ) (Krause and Backonja 2003), painDETECT (Freynhagen et al., 2006), and the ID-Pain (Portenoy 2006). While these questionnaires, which include descriptors like burning pain, painful cold, electric shocks, pins and needles, tingling, numbness, and itching, are useful for epidemiological research, the diagnosis of neuropathic pain cannot be confirmed on the basis of these tools alone, but should always be accompanied by a clinical examination (Haanpaa et al., 2011).

Neuropathic pain syndromes

Neuropathic pain may occur in many advanced progressive diseases. Any disease affecting the nervous system, including cancer, HIV/AIDS, stroke, herpes zoster, diabetic polyneuropathy, chemotherapy-induced neuropathy, and multiple sclerosis may cause neuropathic pain. Description of all neuropathic pain syndromes is beyond the scope of this chapter and only some with special reference to palliative care will be mentioned here.

Neuropathic pain syndromes have become an increasing problem in cancer patients, affecting up to 40% of patients (Caraceni and Portenoy, 1999; Forman, 2004). In a recent systematic review including 22 studies and 13 683 patients with active cancer and pain, 19% (95% confidence interval (CI) 9.4–28.4%) had neuropathic pain, and a liberal estimate of 39.1% (95% CI 28.9–49.5%) was calculated when patients with mixed pain were included (Bennett et al., 2012). This study also suggested that a greater proportion of neuropathic pain in cancer patients is caused by cancer treatment or comorbid disease compared with all cancer pain. Neuropathic pain conditions may persist independently of the cancer and affect the quality of life in disease-free cancer survivors. In those with active disease, painful mononeuropathy or plexopathy often is caused by direct infiltration of peripheral nerves by the cancer. Neuropathic pain is also a frequent complication of treatment of cancer including cancer surgery (Kehlet et al., 2006; Nikolajsen and Jensen, 2006; Gartner et al., 2009; Hoimyr et al., 2011; Wildgaard et al., 2011) and radio therapy. Polyneuropathy may occur in association with malnutrition or paraneoplastic syndromes, which may affect as many as 5% of patients (Forman, 2004). Probably of more importance is painful peripheral polyneuropathy as a complication of treatment with specific types of chemotherapy (Forman, 2004). Chemotherapy-induced neuropathy usually is a dose-dependent, cumulative side effect with the 'glove-and-stocking' distribution. Symptoms include sensory loss, paraesthesia, dysaesthesia, and pain sometimes accompanied with muscle weakness. Oxaliplatin-induced neuropathy is characteristic as it has an acute phase characterized with cold allodynia and pricking dysaesthesia affecting hands and feet but also characteristic pharyngolaryngeal dysaesthesia with sensations of shortness of breath or swallowing difficulties induced by cold drinks (Leonard et al., 2005; Binder et al., 2007; Attal et al., 2009).

Distal sensory, predominantly axonal, polyneuropathy is the most common form of neuropathy associated with HIV and occurs in about one-third of patients (Evans et al., 2011). Immunological dysfunction secondary to the HIV infection itself and toxicity caused by nucleoside antiretroviral agents are thought to be the two most important mechanisms (Evans et al., 2011).

Central pain develops in about 8% of stroke patients, 25% of patients with multiple sclerosis, and 40–50% of patients with spinal cord injury; brain and spinal cord tumours, and other diseases affecting the central nervous system, are other, less common, causes of central pain (Klit et al., 2009; Wasner 2010).

Herpes zoster is due to reactivation of varicella zoster infection and occurs most often in later life and in immunocompromised patients, such as those with HIV infection. The most common and disabling complication is post-herpetic neuralgia, which is characterized by steady burning and paroxysmal, lancinating pain in the affected dermatome, often associated with allodynia.

Pharmacological treatment of neuropathic pain

Treating neuropathic pain remains a great challenge. The drugs that are used commonly for these disorders have limited response rates, and typically responders experience only partial reduction in pain at tolerable doses. Neuropathic pain treatment is often symptomatic, but in some cases, for example, in the use of corticosteroids for the treatment of compression of spinal cord or peripheral nerve, the underlying cause of neuropathic pain can be treated. Today, more than 170 randomized controlled trials (RCTs) support decision-making and provide a basis for evidence-based treatment algorithms (Finnerup et al., 2010). Few comparative drug trials exist, however, and the most rational approach to comparing treatments involves calculation of the number needed to treat (NNT) and the number needed to harm (NNH) from clinical trials data. NNT is calculated as the number of patients needed to treat with a certain drug to obtain one patient with a defined degree of pain reduction (usually 50%) and is calculated as the reciprocal of the absolute risk reduction. NNH is likewise calculated as the reciprocal of the absolute difference in risk, with risk defined as side effects or dropouts. In the following, only double-blind RCTs will be considered.

Anticonvulsants

Anticonvulsant drugs are used primarily for the treatment of epilepsy. They have several pharmacological actions that can interfere with processes involved in neuronal hyperexcitability, either by decreasing excitatory or increasing inhibitory transmission, thereby exerting a net neuronal depressant effect. These effects may underlie the analgesic effects that some of these drugs exert in neuropathic pain states.

Gabapentin and pregabalin

Gabapentin and pregabalin are structurally related compounds. Their analgesic effect in neuropathic pain is thought to be mediated through antagonism of the $\alpha_2\delta$ subunit of voltage-dependent calcium channels at presynaptic sites (Sills 2006).

The effects of gabapentin and pregabalin are well established in post-herpetic neuralgia, painful diabetic neuropathy, and spinal cord injury pain (Finnerup et al., 2010), and also in neuropathic cancer pain (Mishra et al., 2012). Both drugs seem equally effective, with NNTs ranging from 4.2 to 6.4. The pain relief is rapid, within the first or second week, and often accompanied by improvements in sleep and quality of life measures. The effects of gabapentin in HIV neuropathy and peripheral nerve injury are inconclusive (Phillips et al., 2010).

Both gabapentin and pregabalin are generally well tolerated. Neither drug has any known drug–drug interactions. Somnolence and dizziness are the most common side effects and peripheral oedema, weight gain, nausea, vertigo, asthenia, dry mouth, and ataxia may occur. Side effects may resolve over time or improve with dose reduction. Gabapentin is usually administered three times daily. Dosing is initiated slowly, for example, starting with 300 mg the first day and increased by 300 mg every 1–7 days. The final daily dose is between 1800 and 3600 mg, but side effects may limit dose escalation. Pregabalin may be initiated with 75 or 150 mg daily and increased every 3–7 days by 150 mg, up to 600 mg in two divided doses. Both gabapentin and pregabalin undergo renal excretion and renal impairment requires dosage adjustment. Pregabalin has anxiolytic effects in patients with generalized anxiety disorders (Frampton and Foster, 2006) and may therefore be the first drug choice in patients with anxiety. It is still unknown whether patients failing to respond to one of these drugs will benefit from the other.

Other anticonvulsants

The main action of carbamazepine, and its analogue oxcarbazepine, is blocking of sodium channels. Carbamazepine and oxcarbazepine are first-line drugs for trigeminal neuralgia (Zakrzewska and McMillan, 2011). Newer trials comparing oxcarbazepine to carbamazepine have reported comparable analgesic effects, but fewer side effects during oxcarbazepine treatment. Additional studies have not confirmed clinically significant effects on other neuropathic pain conditions (Finnerup et al., 2010).

Carbamazepine treatment is associated with cognitive side effects, drowsiness, dizziness, ataxia, diplopia, and, in elderly patients, confusion (Rogvi-Hansen and Gram, 1995). Other side effects include rash, nausea, weight gain, and hyponatraemia. Slow titration is needed to minimize side effects. In rare cases, severe blood dyscrasia may be seen and a full blood count should be obtained prior to treatment and continuously throughout treatment. Carbamazepine has several drug interactions and is contraindicated in patients with atrioventricular block and hepatic insufficiency. Oxcarbazepine is generally better tolerated but side effects include drowsiness, ataxia, diplopia, dizziness, headache, hyponatraemia, rash, and nausea. Carbamazepine is usually initiated with 300 mg/day and increased by 100 mg every other day to a maximum dosage of 1500–2000 mg/day. The starting dose of oxcarbazepine may be 600 mg/day, increased by 150–300 mg every other day to 1500–3000 mg/day.

Lamotrigine and valproate have limited roles in the treatment of neuropathic pain as results from RCTs are conflicting (Finnerup et al., 2010).

Antidepressants

Antidepressants have a well-established beneficial effect on various neuropathic pain states. Antidepressants used in neuropathic pain treatment include tricyclic antidepressants (TCAs) (e.g. amitriptyline and imipramine) and the selective serotonin noradrenaline reuptake inhibitors (SNRIs) (duloxetine and venlafaxine). The analgesic effects of the selective serotonin reuptake inhibitors (SSRIs) are less certain (Sindrup et al., 2005). Antidepressants relieve pain in non-depressed patients, and it is well established that their pain-relieving effects are independent of their antidepressant effects. However, because of this dual effect, antidepressants may be the first drug of choice in patients with a coexisting depression.

Tricyclic antidepressants

Several randomized controlled trials have documented the effect of TCAs in different neuropathic pain conditions with NNT values ranging from 2.1 to 2.8 (Finnerup et al., 2010) and are also suggested effective in neuropathic cancer pain (Mishra et al., 2012). As the majority of TCA trials are small cross-over trials with results that are not based on the intention-to-treat population and with low placebo responses, the NNT values cannot be directly compared with those from gabapentin, pregabalin, and duloxetine trials. In HIV-related neuropathy, amitriptyline failed to relieve neuropathic pain in two randomized trials (Phillips et al., 2010). Nortriptyline up to 100 mg/day was evaluated in the treatment of cis-diamminedichloroplatinum (CDDP)-induced dysaesthesia in a randomized trial (Hammack et al., 2002). Nortriptyline only provided modest relief of dysaesthesia and pain.

Anticholinergic side effects are common during TCA therapy and include dry mouth, constipation, urinary retention, sweating, and blurred vision. The risk of somnolence and confusion may be present when initiating treatment, and the risk is increased in elderly patients and others predisposed to such side effects, including patients treated with concomitant centrally acting drugs. Orthostatic hypotension and gait disturbances are concerns, especially in the elderly. Combination with class IC antiarrhythmics or SSRIs that are metabolized by cytochrome P450 2D6 may cause toxic serum levels of TCAs. TCAs are contraindicated in patients with epilepsy.

The most serious side effect of TCAs is cardiotoxicity. TCAs are contraindicated in patients with heart failure and cardiac conduction blocks, and an electrocardiogram is needed before initiating treatment. A recent large retrospective cohort study found that TCAs in doses of 100 mg or more daily were associated with increased relative risk of sudden cardiac death, which suggests that such doses should be used cautiously, particularly in patients with an elevated baseline risk of sudden death (Ray et al., 2004). The secondary amines (desipramine and nortriptyline) may be better tolerated than tertiary amines (imipramine, amitriptyline, and clomipramine), with imipramine causing fewer sedating side effects than amitriptyline (McQuay et al., 1996).

Initiation of TCA treatment is best done slowly, starting with 25 mg daily (10 mg in the elderly) and slowly increasing (25 mg every 3–7 days) up to 50–150 mg daily. There is a large pharmacokinetic

variability in the metabolic pathways of TCAs due to a genetic polymorphism of the enzymes that metabolize these drugs. Some patients may therefore attain high plasma drug concentrations at normal doses, while others may have subtherapeutic concentrations at such doses, and monitoring of serum drug concentrations may be helpful in guiding treatment.

Selective serotonin noradrenaline reuptake inhibitors

Recent randomized trials have documented the effect of venlafaxine and duloxetine in painful diabetic polyneuropathy and chemotherapy-induced painful peripheral neuropathy (Finnerup et al., 2010; Smith et al., 2013). The combined NNT from these five trials of SNRIs in painful polyneuropathy was 5.0 (3.9–6.8). The effect of duloxetine was present from week 1, and the most effective dose, associated with fewest side effects, was 60 mg once daily. Only one randomized trial has studied bupropion in neuropathic pain (Semenchuk and Davis 2000). Results were positive. This drug is less sedating than other antidepressants and therefore tolerated better in patients with fatigue or sedation.

The SNRIs are generally well tolerated, and side effects tend to decrease with continued treatment (Stahl et al., 2005). The most common side effect is nausea. Other side effects include somnolence, dizziness, constipation, anorexia, and hyperhidrosis. Sexual dysfunction with decreased libido, ejaculation failure, and erectile dysfunction related to serotonergic actions has been reported for the SNRIs, as well as for the SSRIs (Stahl et al., 2005). Regular monitoring of blood pressure is recommended during venlafaxine treatment due to risk of elevated blood pressure. Duloxetine should not be used in patients with hepatic dysfunction, and venlafaxine dose should be decreased in patients with renal or hepatic insufficiency. Duloxetine can be started at 30 mg once daily and increased to 60 mg once daily after one week, and venlafaxine should be initiated with 37.5 mg and increased by 75 mg weekly up to 150–225 mg daily.

Topical lidocaine

Randomized trials have shown positive effects of a lidocaine patch 5% in post-herpetic neuralgia and mixed peripheral focal neuropathy with allodynia (Meier et al., 2003; Rowbotham et al., 1996).

Side effects from the lidocaine patch are mild, usually skin irritation. Lack of systemic side effects is favourable, particularly in the treatment of the elderly and in patients prone to side effects. It also may be useful as add-on therapy due to the lack of interference with systemic treatment. Although there is minimal absorption, it should not be used in patients taking oral class I antiarrhythmic drugs. A maximum of three to four patches should be applied for 12 hours per day.

Opioids in neuropathic pain

Neuropathic pain responds to opioids with an effect size similar to antidepressants and gabapentin/pregabalin with no proven difference between various opioids (oxycodone, morphine, methadone, levorphanol, and tramadol) (Raja et al., 2002; Arbaiza and Vidal 2007; Finnerup et al., 2010). The combined NNT in peripheral neuropathic pain range from 2.6 to 5.1. In a recent evidence-based guideline for the use of opioid analgesics in the treatment of cancer pain, there was a weak recommendation that patients receiving step II opioids who do not achieve adequate analgesia and have side effects that are severe or unmanageable, might benefit from switching to an alternative opioid, although there are no RCTs to support this (Quigley 2004; Caraceni et al., 2012). In chronic non-cancer pain, opioids are not first-line analgesics and long-term therapy is generally considered only after other reasonable therapies have failed to provide adequate pain relief (Kalso et al., 2003).

Other pharmacological agents

N-methyl-D-aspartate receptor (NMDA) antagonists

NMDA antagonists given as intravenous infusions have been shown to relieve varied types of neuropathic pain, but the effects of oral NMDA antagonists, such as dextromethorphan, riluzole and memantine, have been less convincing because of low response rates and unfavourable therapeutic indices (Finnerup et al., 2010). In cancer patients on morphine therapy, IV ketamine improved analgesia, but the study also pointed out the need to take central adverse effects into account (Mercadante et al., 2000). A recent RCT could not, however, confirm the efficacy of ketamine for opioid refractory cancer pain, although it did suggest that some patients could be 'good responders' (Salas et al., 2012).

Cannabinoids

Cannabinoids have recently been studied in a few RCTs with positive outcomes (Lynch and Campbell, 2011). Cannabinoids were generally well tolerated with gradually increasing doses. Side effects include dizziness, drowsiness, impaired psychomotor function, and dry mouth, especially during the run-in period, and other psychoactive effects like dysphoria (Rice, 2008). Cannabinoid use is associated with concerns about abuse and addiction as well as legal and regulatory issues. Cannabinoids have antiemetic effects and improve appetite, and may therefore be considered for treating neuropathic pain in patients with AIDS-related wasting disease or in the palliative care of patients with nausea and decreased appetite (Hall et al., 2005).

Capsaicin

Capsaicin is thought to act by depleting substance P from primary afferent nociceptors. Recently, studies have found at least a 12-week modest pain reduction following application of a single high-concentration capsaicin patch on painful polyneuropathy and post-herpetic neuralgia (Finnerup et al., 2010; Wallace and Pappagallo 2011). The effect size is rather small and the application of capsaicin is painful and requires prior application of a local anaesthetic, but the treatment has long-term effect and no or only limited systemic exposure and systemic side effects, suggesting that it may be a safe treatment option. A cutaneous patch of capsaicin 8%, has been given marketing authorization in Europe with the indication: 'treatment of peripheral neuropathic pain in non-diabetic adults' and US Food and Drug Administration approval for post-herpetic neuralgia (Wallace and Pappagallo, 2011).

Botulinum toxin type A

Botulinum toxin has been found to have antihyperalgesic effects and thus may be of potential value in treating chronic pain conditions. Botulinum toxin type A injected intradermally in the painful area has been shown to relieve painful neuropathy (Ranoux et al., 2008; Yuan et al., 2009). Besides pain upon application, the treatment had no further local or systemic side effects. Future studies are needed to determine if the long-term effect is consistent.

Combination therapy

If treatment with a single drug is only partly effective, other drugs may be added. In patients with painful diabetic neuropathy or post-herpetic neuralgia, high quality studies have documented greater pain relief and less pain interference with the combination of gabapentinoids and TCAs or opioids, than the single drugs alone (Gilron et al., 2005, 2009; Achar et al., 2010). Also in patients with cancer related neuropathic pain, gabapentin (400 mg) in combination with imipramine (20 mg) as add-on therapy caused a greater pain reduction than in patients in the monotherapy groups (Arai et al., 2010).

In the late stages of cancer, three-quarters of patients have pain, and will usually be treated with opioids when decisions regarding adding other analgesics are made (Lussier et al., 2004), but if patients do not have nociceptive pain, initiation with an antidepressant or gabapentinoid is advised. In cancer patients treated with opioids for nociceptive cancer pain, adding an additional analgesic for neuropathic pain may also allow for reduction of opioid dose. In mixed cancer patients with neuropathic pain partially controlled with opioids, amitriptyline had no pain-relieving effect and was associated with adverse effects (Mercadante et al., 2002). The treatment period was, however, short (1 week) and the dose was relatively low (up to 50 mg daily). In another RCT in cancer patients with neuropathic pain already treated with opioids, gabapentin improved analgesia (Caraceni et al., 2004). In a systematic review including also open-label studies, the addition of an antiepileptic or antidepressant to existing opioid analgesia was shown to result in modest improvement in pain, but also to cause significantly more adverse events (Bennett, 2011). It was suggested that better outcomes might be achieved if opioid doses are reduced initially when first-line drugs for neuropathic pain is commenced and both drugs are then titrated according to response.

While some combinations reduce side effects, others may cause intolerable side effects. Sedation, dizziness, nausea, and other side effects needs to be monitored carefully and it is important to be aware of specific side effects, for example, the serotonergic syndrome that may occur when combining, for example, tramadol with serotonin reuptake inhibitors.

Because of possible additive side effects, risk of medication overuse, and noncompliance, it is generally preferable to minimize polypharmacy (Gilron and Max 2005). Therefore, when combination therapy is needed, sequential add-on therapy is recommended in patients who show a partial response to the first or both drugs given alone and a rational approach is to use drugs with complementary modes of actions. During the course of pain treatment, the level and character of the pain, and side effects should be monitored and dose adjustments should be made. Despite common clinical practice and rationale for combination therapy, we still lack important information on combination therapy including which drugs to combine, optimal dosing and dose titration methods, combinations that include non-pharmacological treatment, responder analysis, long-term effects and side effects, adherence to therapy, and cost-effectiveness.

Pre-emptive treatment

Chronic postoperative pain may be limited when minimally invasive techniques are used, presumably with less risk of damaging major nerves (Kehlet et al., 2006). Although pre-emptive or preventive analgesia may be able to accomplish the same result, studies that have evaluated the use of aggressive or multimodal analgesia in the perioperative period have yielded contradictory results regarding the effect on chronic pain (Kehlet et al., 2006).

Few studies in non-surgical neuropathic pain have evaluated the effect of early treatment in preventing or reducing pain. A study that compared low-dose amitriptyline 25 mg daily with placebo during the initial 90 days after eruption of herpes zoster, found that the active drug reduced pain prevalence at 6 months by more than 50% (Bowsher, 1997). In the prevention of chemotherapy-induced neuropathy, venlafaxine reduced the number of patients experiencing acute neurologic toxicity following oxaliplatin treatment (Durand et al., 2012). These studies were small and results need to be replicated in larger prospective trials. In another study, amitriptyline with a target dose of 100 mg daily for the duration of the chemotherapy did not prevent neuropathy (Kautio et al., 2009). However, in this study, neuropathic symptoms were mild and outcomes were not limited to pain but included also loss of sensory and motor function, which are probably less likely to be prevented by amitriptyline. Neuroprotective agents may, combined with chemotherapy regimens, protect peripheral nerves from chemotherapeutic injury with preserved control of malignancy (Forman, 2004). Such agents, for example, vitamin E or sulphur-containing thiol drugs, are under investigation as neuroprotective agents preventing chronic neuropathy caused by chemotherapy or antiviral AIDS treatment.

Non-pharmacological treatment

When chronic pain is severe or associated with a high level of disability, concurrent treatment with multiple modalities via a multidisciplinary approach may be preferred. There is increasing evidence for the effect of cognitive behavioural therapy in chronic pain (Morley et al., 1999; Turk and Flor, 2006). Cognitive behavioural therapy includes a variety of approaches, including cognitive reconstructuring and coping strategies, problem solving, relaxation training, attention–diversion techniques, assertiveness training, and modification in activity and exposure to feared activities.

Physiotherapy may be indicated in some patients with neuropathic pain to alleviate complications related to immobility or to other effects of the neurological disease. Nociceptive pain contributing to overall pain intensity and disability may be reduced by techniques that may include correcting poor posture, dystonia and contractures, passive mobilization, stretching and massage, and active exercise. The evidence for the use of different non-pharmacological management strategies, for example, massage, acupuncture, fitness and mind–body techniques, to enhance pain management of neuropathic pain associated with cancer has been summarized (Cassileth and Keefe, 2010). Other non-pharmacological treatments such as sympathetic blockade, spinal cord and motor cortex stimulation, and neurosurgery may be considered in severe refractory pain, but depend on many factors such as pain type, and life expectancy.

General treatment principles

A broad approach to the treatment of chronic neuropathic pain is essential. Patients may be elderly; may have concurrent medical

problems and impairments, depression, sleep disturbances, or psychosocial problems; and may be treated with multiple drugs with unwanted side effects. The diagnosis of the neuropathic pain syndrome and the presumptive underlying mechanisms is the first important step and requires a thorough assessment. The diagnosis of neuropathic pain is not always easy, and often neuropathic pain coexists with other types of pain, particularly in palliative care. Whenever possible, the underlying disease should be treated. Whether or not the underlying mechanisms causing the pain can be treated, symptomatic treatment of pain and related disability should be offered. Realistic expectations for the outcome of a given treatment should be discussed with the patient, explaining that often only partial pain relief from neuropathic pain can be expected.

As analgesic therapies are applied, the effects are unpredictable and patients with the same disease or same symptom may respond differently to the same treatment. There is little evidence to support the use of specific drugs for specific symptoms and at the present time, treatment of neuropathic pain is a 'trial-and-error' process. Although a mechanism-based treatment approach has been suggested, future trials will tell whether pain mechanisms can be identified in an individual patient, and whether specific symptoms and signs, or clusters, will be able to predict response to certain treatments.

Treatment algorithm

Although a general treatment algorithm may be proposed, each treatment has to be individualized to each patient, taking into account all co-morbidities and drug interactions. Most randomized controlled trials are performed in patients with diabetic polyneuropathy and post-herpetic neuralgia, and to what extent a treatment, which is found effective in one neuropathic pain condition, can be expected to relieve other conditions, is unknown (Dworkin et al., 2011). Based on experience, it seems likely that efficacy demonstrated in one condition can be extrapolated to others (Hansson and Dickenson 2005). There are clearly exceptions, however, and the existing studies, albeit very limited, suggest that some disorders, such as HIV-related pain, may be more difficult to treat, although these studies may have had low assay-sensitivity because of high placebo responses.

During the course of pain treatment, the level and character of the pain, and side effects should be monitored. If there is no effect of a first-line drug, the treatment should be switched to another first-line drug, then ultimately to a second line drug. In case of partial pain relief, another drug with complementary mechanisms can be added. Treatment algorithms for neuropathic pain have recently been updated (Attal 2010; Attal et al., 2010; Dworkin et al., 2010).

First-line treatments

In patients with trigeminal neuralgia, carbamazepine and oxcarbazepine are the first drug choices. In other neuropathic pain conditions, tricyclic antidepressants, SNRIs (duloxetine or venlafaxine), or calcium channel $\alpha_2\delta$ agonists (gabapentin or pregabalin) are the first drug choices. In patients with focal peripheral neuropathy with allodynia, topical lidocaine patch is also a first-line drug. Antidepressants may be the first drug choice in patients with depression, and both TCAs and calcium channel $\alpha_2\delta$

agonists may be considered in patients with sleep disturbances. Pregabalin may be the first choice in patients with anxiety.

Second-line treatments

Opioids (including tramadol) may be considered if there is no, or insufficient, effect of first-line drug classes and may be first line in episodic pain or in patients with co-existing cancer-related non-neuropathic pain. Switching from one opioid to another may improve pain relief. Combination therapy may be considered in patients with insufficient effect from one drug.

Visceral pain

Victor T. Chang

Introduction to visceral pain

Visceral pain is pain that arises from in or around internal organs. This chapter provides a brief overview of visceral nociception and pain pathophysiology, visceral pain syndromes, and therapeutic approaches.

Visceral nociception

The central nervous system receives sensory information from visceral organs and their surrounding tissues through afferent nerves that run in parallel with the efferent autonomic nerves that comprise the sympathetic and parasympathetic systems. Visceral nerves are predominantly unmyelinated C fibres and some thinly myelinated A fibres. The larger nerves within which these afferents run include the vagus, the pelvic nerves, and the spinal nerves.

The vagus nerve conveys efferent parasympathetic activity and information from the visceral organs in the chest and the abdomen, up to the level of the proximal colon. Vagal nerve cell bodies are located in the nodose and jugular ganglia and terminate in the nucleus tractus solitarius in the dorsal medulla. Emerging data suggests that the vagus nerve may convey nociceptive information related to mucosal inflammation (Kollarik et al., 2010). The parasympathetic nerves in the lower bowel and pelvic organs carry afferent fibres that innervate these structures. The cell bodies are in pelvic ganglia. These nerves proceed as pelvic nerves to the sacral cord.

The sympathetic system similarly has afferent fibres running in parallel to the efferent sympathetic nerves. The cell bodies of the sensory fibres from the abdominal viscera are found in the coeliac, hypogastric, and sacral plexuses, and impulses proceed from these structures to the dorsal horn of the thoracolumbar spinal cord. The coeliac plexus is the largest prevertebral ganglion and typically is located anterior to the crura of the diaphragm and L1. There are usually two coeliac ganglia, but up to five have been noted (Ward et al., 1979); the ganglia vary in location (Yang et al., 2011). The superior and inferior hypogastric plexus are located in the retroperitoneum from L4 to S1, and carry visceral afferent impulses from the pelvic viscera and the left colon to the dorsal horn. The superior hypogastric plexus is located anterior to L5 and the Inferior hypogastric plexus at the level of the sacrococcygeal junction. For further anatomical details, readers are referred to Bonica et al. (2001) and Wesselman et al. (1997).

Afferent fibres from the periphery project primarily to second order neurons in laminae I, II, V, and X in the dorsal horn. In contrast to input from somatic structures, this visceral input has wide arborization in the spinal cord; fibres extend to other segments and the contralateral cord. Furthermore, unlike somatic pathways, the second order visceral afferents may also project to other adjacent segments and join other contralateral tracts to the brain, such as the spinothalamic, spinomesencephalic, and spinoparabrachial tracts. An ipsilateraldorsal column pathway has been described where spinal neurons in lamina X ascend by the dorsal columns to the contralateral thalamus by the gracile or cuneate pathways (Willis et al., 1999).

In the brain, visceral nociceptive fibres project to the thalamic ventral posterolateral and posteromedial nuclei, and then the somatosensory cortex, prefrontal cortex, perigeniculate areas of the anterior cingulate cortex, amygdala, and laterally to the insula. The density of visceral fibre projection to the somatosensory cortex is significantly less than for cutaneous fibres.

There are features that distinguish the anatomical organization of the visceral nociceptive system from that of the somatosensory system. Among the most important are the following: The innervation density in the periphery is much lower for visceral nerves than somatic nerves. Both visceral and somatic afferent nerves may converge on the same second order neurons in the dorsal horn of the spinal cord, but the visceral sensory afferent nerves project to a larger number of levels in the spinal cord than somatic nerves, and to the contralateral side, and one visceral sensory neuron may innervate two different visceral organs, especially in the pelvis (Christianson et al 2007).

The vast majority of visceral sensations never reach consciousness and the relationship between conscious experience and visceral nociceptor activity, like many other elements of visceral neural functioning, remain an area of investigation (Robinson and Gebhart, 2008). Functionally, visceral nociceptors are thought to be polymodal, potentially responsive to different kinds of noxious stimuli, such as distention, ischaemia, and electrical stimulation (Ness and Gebhart, 1990). From work on bowel preparations, there also may be mechanosensory, chemosensory, and temperature receptors. Three kinds of mechanosensory nociceptors have been described: those that respond to a range of distention pressures including normal pressures (tonic), those that respond to high levels of distention (high threshold), and those that are silent but become activated in the presence of inflammation. These nociceptors are located in the different layers of the walls and muscles of internal organs (Brierley, 2010). Chemoreceptors and thermoreceptors are present in the mucosa and the muscular layers.

The various components of the sensory system transmit different types of information, and concurrent activation of these components may account for the symptoms that commonly accompany pain. For example, the afferent nerves running with the sympathetic nerves carry acute nociceptive input, whereas activation of afferents travelling in the vagal pathway may contribute to the nausea and bloating that often occurs with abdominal

pain. In the mouse, differences in afferent fibre composition have been found between colonic lumbar splanchnic and pelvic nerves (Brierley et al., 2004), and bladder splanchnic and pelvic nerves (Xu and Gebhart, 2008).

The visceral nociceptive system, like the somatic pathways, has a complex neurochemistry. In the rat, for example, there are specific pelvic nerve fibres that transmit pain, are capable of sensitization, and respond specifically to kappa opioids (Gebhart, 2000). Cell bodies in the nodose ganglion stain positively for transient receptor potential voltage-gated (TRPV) channel 1 and calcitonin gene-related peptide (CGRP), and are less likely to stain for isolectin B4. Other visceral nociceptors do not stain for any of these or other peptides. In the digestive tract, the majority of afferent fibres stain for CGRP, and members of the TRPV receptor family (Christianson and Davis, 2010). Although it is possible to identify likely nociceptors on the basis of this neurochemical staining, functional response to noxious stimuli remains the most reliable way to identify a visceral nociceptor (Robinson and Gebhart, 2008).

Many types of ion and voltage-gated channels also have been identified in visceral nociceptors. Among those that appear important are sodium channels that are tetrodotoxin resistant.

In the brain, functional magnetic resonance imaging images suggest that the regions activated by somatic pain are also activated by visceral pain, but in a slightly different pattern (Strigo et al., 2003; Dunckley et al., 2005). One study suggested that pregabalin may affect brainstem processing of visceral pain (Sikandar and Dickenson, 2011). The locus coeruleus complex, the periaqueductal grey area and the rostral ventral medulla activate descending pathways, and there is evidence for some visceral pain states that the descending spinal pathways can exhibit both inhibitory and facilitatory effects on nociception. These signals are mediated by pre- and post-alpha 2 adrenergic receptors and presynaptic 5-HT$_3$ receptors (Sikandar and Dickenson, 2012). Other potential mediators include the autonomic nervous system, the hypothalamic pituitary tract (Knowles and Aziz, 2009), and hormones such as oestrogen (Sanoja and Cervero, 2010).

Pathophysiology of visceral pain

Like somatic pain, visceral pain presumably occurs as a result of many potential mechanisms. Although understanding of these mechanisms is still very limited, speculation has focused on three broad types: peripheral activation, peripheral sensitization, and central sensitization.

Peripheral activation

Physiologic stimuli include distention, inflammation, torsion, and ischaemia. In the laboratory, additional stimuli include electricity, and the application of various inflammatory and noxious substances, such as hydrochloric acid, bradykinin, and capsaicin.

In the heart, ischaemia leads to a drop in the pH and increased lactate levels. Acid sensing ion channel 3 (ASIC 3) is activated by acidaemia (Yagi et al., 2006) and sensitized by lactate (Immke and McCleskey, 2001). TRPV channels may also be activated by ischaemia (Pan and Chen, 2004).

In the gut, afferents may be activated by physical stimuli, such as high distention pressures or contractions (Sarna, 2007), or the release of compounds that serve as ligands for receptors, such as substance P, CGRP, and products from inflammatory cells.

Mechanosensory transduction may be mediated by TRPV channels (Brierley et al., 2008, 2009), while chemosensory transmission may be mediated by serotonin, TRPV receptors (Brierley et al., 2010), tetrodotoxin resistant sodium channel Na$_v$1.8 (Cervero and Laird, 2004), and ASIC channels. Another relevant mechanism is cleavage and activation of the proteinase activated receptor (PAR) by trypsin. In pancreatic cancer, an inflammatory perineural invasion by pancreatic cancer cells leads to hypertrophy and increased arborization of the sensory nerves (Bapat et al., 2011), a process which also occurs in chronic pancreatitis. While much of this knowledge pertains to animal models of visceral pain, studies in human tissue support these findings (Peiris et al., 2011).

In the bladder and other pelvic organs, distention leads to ATP release, which in turn binds to and activates purinergic receptors P2X2/3 on the afferent nerves (Wang et al., 2005).

Peripheral sensitization

Peripheral sensitization refers to changes in the functioning of a primary afferent nerve that may include a reduced threshold to peripheral activation, spontaneous activation, or an increase in the magnitude of the response after it is activated. This sensitization may accompany inflammation or exposure to specific compounds, or follow peripheral nerve trauma. Visceral afferent nerves are sensitized by inflammatory or adrenergic compounds (Bueno and Fioramonti, 2002) and this may persist long after the initial event. Experimentally, this is accomplished by applying irritants or excitatory compounds such as ATP, bradykinin, or capsaicin. Recent studies suggest that cytokines and other mediators of inflammation can lead to peripheral sensitization (Benson et al., 2012).

This phenomenon may be relevant to the concept of visceral hyperalgesia. Ongoing work is aimed at defining the roles of a wide array of inflammatory products and candidate receptors for different organs and nerves, with interest in the role of serotonin receptors, sodium channels, nitric oxide and TRPV channels (Christianson et al., 2009; Page et al., 2009; Blackshaw et al., 2010).

Central sensitization

Central sensitization is operationally defined as an amplification of neural signalling within the central nervous system. Like peripheral sensitization, it is a process that can result in the experience of spontaneous pain, the perception of pain related to non-noxious stimuli, or hypersensitivity to noxious events. Examples of visceral pain that are believed to be related to central sensitization include oesophageal non-cardiac chest pain and chronic pancreatitis (Woolf, 2011). The *N*-methyl-D-aspartate (NMDA) receptor is important for central sensitization to visceral pain (Willert et al., 2004).

Clinical aspects of visceral pain

In the United States, unexplained abdominal pain is the most frequent cause of medical visits by the general population (Shaheen et al., 2006). In two large surveys of cancer pain patients, 16% of patients had purely visceral pain, mixed somatic and visceral pain occurred in 12%, and mixed visceral and neuropathic pain was noted in 3% (Caraceni et al., 1996; Grond et al., 1996).

Pain that occurs in association with injury to visceral structures may have distinctive clinical features (Cervero and Laird, 1999). If it is related to obstruction or injury to hollow viscus, the pain

tends to be poorly localized and described as vague, gnawing, or crampy; the pain may become intermittently severe in association with visceral contractions. In contrast, injury to solid organs or to organ capsules or related fascia tends to be better localized and described as sharp or stabbing; it. All types of visceral pain may be referred in specific patterns and also may be associated with autonomic symptoms, such as nausea and vomiting. Visceral pain may be accompanied by highly aversive emotional reactions.

In a comparison of pain caused by cutaneous heat with pain caused by oesophageal balloon distention, subjects undergoing oesophageal distention used a wider range of descriptors, more affective descriptors, and reported more anxiety (Strigo et al., 2002). Descriptors used by patients in experimental studies include nauseating, suffocating, and deep. Burning pain has been described for oesophageal and bladder pain.

Referred pain

Because visceral and somatic afferent fibres can converge on the same lamina in the spinal cord, nociceptive impulses from a visceral site may be processed by higher brain centres as emanating from the corresponding somatic site, or viscerosomatic 'referred' pain. The referral sites are specific: in balloon distention studies, oesophageal distention leads to painful sensations in the chest and back (Strigo et al., 2002), distention of the cervix leads to perceived pain in the lower abdomen and the lower back (Bajaj et al., 2002), and bladder distention is referred to the suprapubic area (Ness et al., 1998). The area of referred pain can increase over time or with evolution of the visceral injury. Hyperalgesia and allodynia on stimulation of the skin or gentle palpation may develop in the area of referred pain.

Three general patterns of visceral referral pain have been identified (Fig. 13.4.1). The first is pain in the thoracic region referred from cardiac or oesophageal injury. The second is pain in the upper abdominal wall, which may be referred from the upper abdominal organs (stomach, pancreas, and liver). The third is pain in the lower abdominal wall related to injury of pelvic organs, including colon, bladder, or uterus; the kidney also may refer pain to this location. Other referral sites are equally well known. For example, injury to the region of the porta hepatis may refer pain to the region of the ipsilateral scapula and injury to the diaphragm may refer pain to the ipsilateral shoulder.

Visceral pain also may be referred to other visceral organs. This phenomenon originally was termed viscero-visceral referral; more recently, it has been known as cross organ sensitivity (Brumovsky and Gebhart, 2010). Afferents from different visceral organs can converge at the spinal, brainstem, or thalamic levels. For example, coronary artery disease and disease of the biliary tree have a common afferent input into the T5 spinal level, and afferents from the intestine and pelvis may converge at the T10–L1 spinal level. Although the clinical significance of this phenomenon remains to be determined, it raises the possibility that pain that localized to one organ may be related, at least in part, to a disorder affecting another (Giamberardino et al., 2010).

The complex pain complaints that may occur as a result of visceral disease are mirrored by the potential for equally complex physical findings. Referral sites can become tender and demonstrate cutaneous hypersensitivity—allodynia, hyperesthesia, or hyperalgesia. Some patients experience tenderness that predominates at the referral site. For example, the finding of cutaneous allodynia along the lower abdomen can be the most prominent finding initially in those with injury to pelvic organs (Jarrell et al., 2011). Appreciation of these phenomena will reduce the risk that an evaluation for the source of a pain will go astray.

Visceral pain syndromes

Numerous visceral pain syndromes have been identified and can be categorized by region of the body affected by the pain-producing disorder (see Chapter 13.1). The following syndromes are representative.

Pain related to thoracic disorders

Many serious illnesses affect thoracic viscera, including the heart, its blood supply, and the great vessels; the lungs, airways, and pleura; or other mediastinal structures such as lymph nodes. The pain syndromes that result are highly variable and determined by the location of injured viscera, the nature of the injury, the course of the illness, pain referral patterns, and other factors.

Persistent pain is usually ipsilateral to the affected hemithorax. Mediastinal injury also can be broadly distributed across one or both hemithoraces, or can result in pain that is experienced more focally in the region of the thoracic spine, across one or both shoulders, or substernally.

Pain syndromes related to thoracic disease often have a time course determined by the progression of the underlying illness. Some, such as refractory angina, may have a prolonged and fluctuating course. Refractory angina may complicate ischaemic heart disease and may co-occur with congestive heart failure. The prevalence of this pain syndrome is expected to increase as patients with heart disease live longer and the population ages (Kim et al., 2002; McGillon et al., 2012).

Pain related to intra-abdominal disorders

For specialists in palliative medicine, the visceral pain disorders related to intra-abdominal disease most likely to be encountered include pain related to a neoplasm in the upper mid-retroperitoneum, such as the pancreas; the diffuse pain associated with bowel obstruction; and pain related to injury of specific structures, such as capsular pain.

Pain may arise from an inflammatory perineural invasion by pancreatic cancer cells (Bapat et al., 2011) and has been reported in up to 75% of patients with advanced pancreatic cancer. Risk factors for the development of abdominal pain are tumour size, invasion of the anterior capsule, and invasion of intrapancreatic nerves (Okusaka et al., 2001). Pain severity may have prognostic significance in patients with resectable pancreatic cancer (Ceyhan et al., 2009). Patients complain of a boring, well-localized upper abdominal pain that may radiate to the back. Most patients ultimately have a component of pain shooting towards the mid-thoracic spinal level; a small minority of patients have back pain without the anterior component. Physical exam may demonstrate an abdominal mass and inability to lie flat. Computed tomography (CT) scans and endoscopic ultrasound are helpful in defining the anatomy of the lesions and the coeliac plexus.

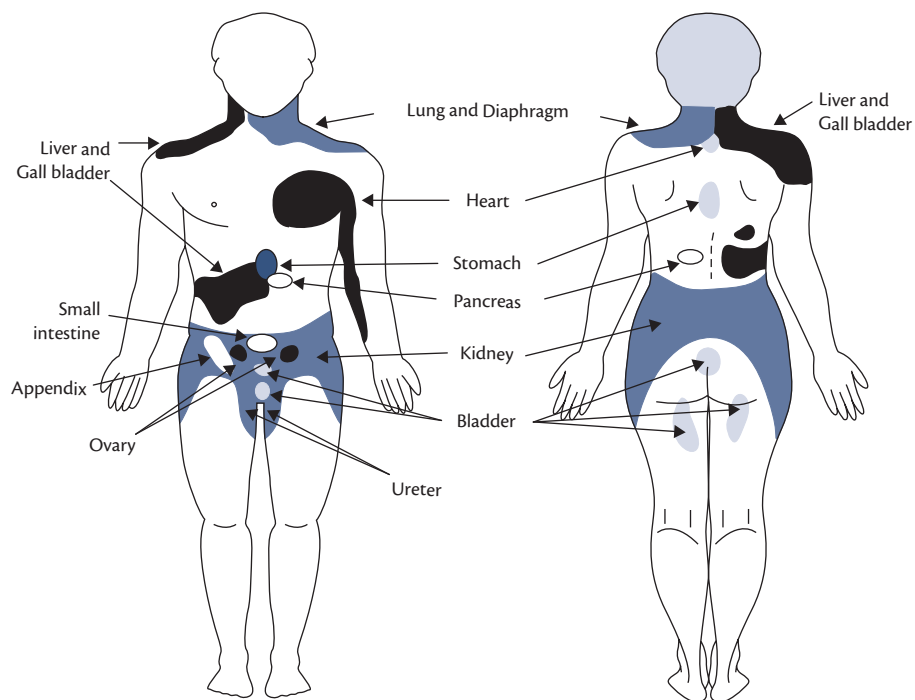
Bowel obstruction is characterized by fluctuating abdominal pain, distention, regurgitation or nausea and vomiting, and absence of bowel movements. Chronic obstruction is seen most commonly in patients with ovarian, cervical, or gastric primary sites. Sometimes, the main site of the obstruction can be localized and mechanical


Fig. 13.4.1 Patterns of referred pain from visceral organs.

strategies, such as stenting or surgical decompression, may be considered. In the context of advanced illness, the goals of care usually focus on symptom relief. The pain is usually crampy and may rise and fall during the day. The distress associated with the pain may be intense, driven by the associated symptoms, inability to eat, and concerns about progressive illness or impending death.

Some pain syndromes are causally related to capsular injury. These include the hepatic distention syndrome and pain from large adrenal masses. Marked and/or rapid enlargement of the spleen and lymph nodes can also lead to pain. In the hepatic distention syndrome, patients complain of a steady pressure sensation in the right upper quadrant. Physical examination shows an enlarged liver and imaging demonstrates hepatic lesions. Patients with massively enlarged adrenal glands from tumours will complain of flank discomfort, which may radiate to the ipsilateral inguinal region.

Enlarged retroperitoneal lymphadenopathy can cause severe back pain, which can be focal or diffuse. This pain syndrome is most prevalent among those with lymphomas or germ cell tumours. Lymphadenopathy was the most common cause of visceral pain in a study of patients with haematological malignancies (Niscola et al., 2007). Patients with lymphomas may experience a flare of pain related to enlarged lymph nodes after drinking alcohol (Atkinson et al., 1976). In patients with long standing myeloproliferative diseases and splenomegaly, splenic infarction may develop and result in left upper quadrant pain, which is often characterized as a continuous pain with exacerbations of stabbing pain. The spleen is usually prominent on examination, and its size may prevent patients from bending or sitting.

Other abdominal pain syndromes are less common. Abdominal pain from herpes zoster infections has been reported in bone marrow transplant recipients, sometimes accompanied by a complex of syndrome of inappropriate antidiuretic hormone secretion (SIADH), and rash (David et al., 1998; Koc et al., 2000). Zoster also can cause a more typical dermatomal neuropathic pain (Tribble et al., 1993). Some pain syndromes are related to antineoplastic therapies. For example, persistent abdominal pain may follow tumour embolization procedures involving lesions in the liver, kidney, spleen, or uterus; in the acute phase, pain often is associated with fever, nausea, vomiting, and leucocytosis (Brown et al., 2009). No risk factors have been identified (Patel et al., 2000), and symptoms usually resolve with supportive care after a few days. Radiation-related pain syndromes include radiation enteritis, radiation proctitis, and radiation prostatitis. Finally, pain has been associated with placement of oesophageal stents (Golder et al., 2001), and there are anecdotal observations suggesting that pain also may accompany biliary or colonic stent placement (Gianotti et al., 2013). Migration of stents can lead to pain associated with visceral perforation (Gould et al., 1988).

Pain related to pelvic disorders

Some of the pain syndromes that occur with intra-pelvic pathology, such as chronic bowel obstruction, were noted earlier. Other pain syndromes also occur from diseases in this region, particularly locally advanced neoplasms affecting gynaecological structures, prostate, or rectum. These disorders may cause persistent perineal or deep pelvic pain, and may be accompanied by tenesmus or by urinary urgency or bladder spasms. Perineal pain within 1 year of surgery for pelvic tumour should be evaluated for relapse and distinguished from patients with phantom pain (Stillman, 1990; Boas et al., 1993).

Therapeutic approaches for visceral pain

The approach to pain management in the patient with a visceral pain syndrome largely parallels the treatment of other types of chronic pain. There are several distinctions, however, as summarized below.

Opioid therapy is the mainstay approach for chronic pain that is moderate or severe. In rodent studies of bladder and colon distention, mu and kappa agonist opioids inhibited mechanoreceptor responses (Su et al., 1997a, 1997b); subsequent work points to a kappa-like receptor in visceral afferents. Morphine also affects modulation of visceral pain through its effect on the rostroventral medulla in the rat (Friedrich and Gebhart, 2003). Although some of these preclinical findings suggest that kappa agonist opioids may be preferable in visceral pain, there is no clinical evidence to substantiate this. Oxycodone interacts with both kappa and mu receptors, and in a small randomized comparison of oxycodone with morphine in patients with pancreatic cancer, no difference was seen (Mercadante et al., 2010). However, there are suggestive experimental human data. In a human experimental model with different types of pains, oxycodone did provide better pain relief than morphine in patients with visceral pain (Staahl et al., 2006). A comparison of oxycodone with KR665, a kappa opioid agonist, using a similar experimental design showed more pain relief with KR665 (Arendt-Nielsen et al., 2009). A study of another kappa specific opioid, asimadoline, in patients with irritable bowel syndrome showed improvement in the asimadoline arm (Mangel et al., 2008). More research is needed to determine whether there may be selective opioid effects related to receptor binding profile. The development of kappa receptor opioid agonists remains an area of great interest (Vanderah, 2010).

Patients with visceral pain resulting from obstruction of a hollow viscus often are considered for trials of adjuvant analgesics intended to reduce spasm of smooth muscle. Most of the data comes from studies of oesophageal spasms, biliary colic, renal colic, irritable bowel syndrome and overactive bladder, and comparatively little has been studied in populations with serious illnesses and the use of non-opioid and opioid analgesics continues to be emphasized. Indeed, non-steroidal anti-inflammatory drugs have been recommended for biliary colic (Colli et al., 2012). Based largely on anecdotal experience, anticholinergic agents, such as hyoscine (scopolamine), are used for pain related to bowel obstruction (Ripamonti et al., 2000; Tytgat, 2008); dicyclomine, which has both anticholinergic and muscle relaxant properties, has been used for irritable bowel syndrome (Ruepert et al., 2011); and oxybutynin, another anticholinergic drug, has been used for patients with bladder spasm (Kennelly, 2010; Madhuvrata et al., 2012).

With the identification of relevant neurotransmitters, interest in new classes of medications has increased (Bueno et al., 2007; Blackshaw et al., 2010; Burnstock, 2012). A trial of tetrodotoxin has been promising (Hagen et al., 2011), for example, and other agents have been considered in specific disease states. These include JAK-2 inhibitors (Hagen et al., 2010; Mesa et al., 2013) for patients with symptomatic myelofibrosis, steroids for capsule distention and for bowel obstruction (Philip et al., 1995; Feuer and Broadley, 2000), octreotide for bowel obstruction (Mercadante and Porzio, 2012) or capsule distention (Pistevou-Gombake et al., 2003), intravenous phentolamine for pancreatic cancer (Yasukawa et al., 2007), and ranolazine for angina (Yasukawa et al., 2006). Readers

are referred to Davis (2012) and Holzer and Holzer-Petesche (2009) for more details.

Some visceral pain syndromes may be best approached through specific interventions. The challenge in these cases often relates to an informed balancing of potential benefit against the burdens of the approach and the risks in the context of advanced illness. Offering a strategy of shared decision-making, which may involve both the patient and the family, appears to be the best approach.

Stents have been increasingly used as a non-surgical means of relieving oesophageal obstruction (Madhusudhan et al., 2009), bowel obstruction (Nagula et al., 2010; Larssen et al., 2011), and pain from pancreatic cancer-related duct stenosis (Costamagna et al., 1999). Surgical interventions include thoracic splanchnicectomy for upper abdominal pain (Krishna et al., 2001) and intractable angina (Khogali et al., 1999), and surgical decompression for bowel obstruction (Feuer et al., 2000; Kucukmetin et al., 2010).

So-called interventional pain procedures involve injections or infusions through catheters that re intended to block afferent input from a painful site. The coeliac plexus block is commonly employed in an effort to interrupt pain transmission from upper abdominal structures. There are numerous techniques, the most common of which include radiographically guided bilateral posterior percutaneous injections and an endoscopic ultrasound-guided transoesophageal injection. A neurolytic solution, such as phenol or alcohol, is injected, and successful cases experience pain reduction that typically lasts until death. An important but unresolved issue is timing of the block relative to titration of medications (De Oliveira et al., 2004).

Other interventional approaches are used to manage various types of visceral pain. For example, bilateral superior hypogastric block can relieve intra-abdominal and pelvic pain, but extensive retroperitoneal disease is a risk factor for poor pain control (Plancarte et al., 1997; Cariati et al., 2002). Ganglion impar block, sacral nerve root blocks, and saddle blocks may be useful in patients with visceral perineal pain (Plancarte, 1983; De Medicis et al., 2001; Slatkin and Rhiner, 2003) (see Chapter 9.8).

Rarely, neurosurgical approaches are considered for refractory visceral pain. For example, a T10 myelotomy for pelvic visceral pain can be performed by transecting the dorsal column pathway surgically (Viswanathan et al., 2010) or with CT guidance (Vilela Filho et al., 2001) (see Chapter 9.8).

Other pain therapies used very uncommonly in visceral pain involve implantation of devices. Spinal cord stimulation has been studied in small cohorts as a way to implement modulation of the dorsal columns and improve pain control in chronic pancreatitis (Kapural et al., 2011), intractable angina (Mesa and Yakovlev, 2008; Taylor et al., 2009), and testicular pain (Nouri and Brish, 2011). Neuraxial analgesia involves placement of an intrathecal or epidural catheter for long-term infusion of various analgesic compounds, including opioids, local anaesthetics, clonidine and others. There are a variety of techniques, and if the local expertise exists to evaluate them for the patient with refractory pain, there may be advantages in doing so given the flexibility of the approach and its' lack of risk relative to neurolysis (see Chapter 9.9).

Finally, radiofrequency ablation has been employed for visceral pain resulting from recurrent bladder cancer (Campbell et al., 2005) and rectal cancer (Lefevre et al., 2008). It presupposes an ability to identify the peripheral neural anatomy close to the size

of the structure involved, a task that may prove difficult when the anatomy has been distorted by locally advanced disease.

For patients with cancer, antineoplastic therapy may have analgesic consequences. Radiation therapy is used commonly for pain, including visceral pain. For example, radiation has been used to palliate pain from hepatic metastases (Bydder et al., 2003), pancreatic cancer (Morganti et al., 2003), recurrent gynaecological cancers (Smith and Koh, 2001), bladder cancer (Yi et al., 2007), and from an enlarged spleen in myeloproliferative disease (McFarland et al., 2003).

Visceral pain is associated with emotional reactions and psychological approaches to pain control should be considered as important adjuncts to pharmacotherapy and interventions, as they are in other types of pain. In patients with angina pectoris, angina during daily life was associated more with the psychological distress associated with chest pain than with inducible myocardial ischaemia, whereas chest pain during exercise stress testing was related to myocardial ischaemia (Sullivan et al., 2008). In patients with gastrointestinal cancer pain, communication with caregivers and ambivalence in expressing emotion were important determinants of pain severity, mediated in part by the catastrophizing response (Keefe et al., 2003; Porter et al., 2005). Conversely, self-efficacy of the caregiver during interactions with the patient was associated with decreased pain. Interventions to assist the patient and the caregiver may be helpful in patients with visceral pain (see Chapter 9.11).

Conclusion

Distinguishing features of the visceral pain system have been delineated at many levels. Organ-specific and tissue-specific nociceptive signalling, and the pathophysiological changes that affect these processes and sustain pain in the setting of illness, are undergoing investigation and may inform specific treatment strategies for these pain syndromes in the future. For the present, there are numerous therapeutic options and the expectation should be that most patients can achieve satisfactory relief if treatment is carefully considered and implemented appropriately.

Management issues in chronic pain following cancer therapy

Martin Chasen and Gordon Giddings

Introduction to management issues in chronic pain following cancer therapy

The extended phase of cancer survivorship commences after completion of initial anti-cancer treatment and includes regular follow-up examinations with or without maintenance or intermittent anticancer therapy. The permanent survival phase follows the extended phase and continues until death (Levy et al., 2008).

The American Cancer Society have stated that their goal is to make cancer into a chronic disease state in which long-term control is possible, even in the absence of a conventional cure (Burton et al., 2007). At a global level, the incidence of 26 cancers in 2008 was estimated at 12.7 million new cancers by GLOBOCAN series of the International Agency for Research on Cancer (World Health Organization (WHO), 2008). Survival at 5 years after diagnosis is the widely used benchmark for prevalence. Accordingly, there were an estimated 24.6 million people worldwide living with cancer in 2002 (Parkin et al., 2005; WHO, 2005). As of January 2008, it is estimated that there are 11.9 million cancer survivors in the United States. This represents approximately 4% of the population, with approximately 15% of these cancer survivors being diagnosed 20 or more years earlier (Howlader and Noone, 2009).

Improved cancer surveillance, more accurate diagnoses, more efficacious treatment, as well as longer follow-up, have led to an increased life expectancy for patients and increased number of 'cancer cured' people. It is predicted that this number of cancer survivors will increase in the future. A public health effort to address cancer survivorship supports the Healthy People 2010 goal to increase the proportion of cancer survivors who are living 5 years or longer after diagnosis to 70% (US Department of Health and Human Services, 2010).

The report from the Institute of Medicine 'From Cancer Patient to Cancer Survivor: Lost in Transition' mentions that although the number of patients surviving cancer is increasing, it is unknown what this will mean to the health and well-being of these people (National Research Council, 2005).

Survivors face numerous physical, psychological, social, spiritual, and financial issues following their diagnosis and treatment and for the remaining years of their lives. The health-care challenges of survivors are being now recognized as unique. In addition to the acute effects of the surgical, radiation, and chemotherapy treatments, many permanent phase survivors are at risk for developing late or long-term side effects from their primary treatments. These long-term effects have a bearing on obtaining optimal physical, psychological, and cognitive functioning for survivors—which is the goal of rehabilitation for patients with cancer (Chasen and Dippenaar, 2008). Survivors of cancer have significantly poorer health outcomes across many burden of illness outcomes for many years after the diagnosis of cancer (Miaskowski and Dibble, 1995; Siddall and Cousins, 2004). More than 6 million survivors are older than 65 years, thus translating into a growing elderly patient population of cancer survivors who suffer from co-morbidities that affect their general well-being (Deimling et al., 2007). For many survivors, a high prevalence of physical symptoms, in addition to symptoms in other life domains will diminish their quality of life (Alfano and Rowland, 2006).

Pain is recognized as impacting on all dimensions of quality of life (Cleeland, 1984; Miaskowski and Dibble, 1995; Siddall and Cousins, 2004; Burton et al., 2007) and is one of the most distressing symptoms for patients with cancer (Patrick et al., 2003; Sun et al., 2008). Pain, may, in some cases of head and neck cancer patients predict for survival (Funk et al., 2012). Up to 40% of 5-year cancer survivors report pain (Nelson et al., 2001; Anderson et al., 2002). Experiencing pain was related to poorer general health ($p = 0.001$) and physical ($p < 0.001$), role ($p < 0.01$), and social ($p < 0.001$) functioning in a group of patients who had survived cancer (Green et al., 2011).

Patients under-recognize pain and are often unsure if optimum pain control is achievable (Green et al., 2002, 2003). They are concerned about distracting attention away from treatment and believe that pain is indicative of progressive disease (Turk, 2002; Green et al., 2003, 2009; Greenberg et al., 2003; Stewart et al., 2003; Howlader and Noone, 2009). In addition, members of the interdisciplinary team often fail to assess the patient's pain adequately or to recognize under reporting (Anderson et al., 2000; Nelson et al., 2001). Many professionals lack knowledge of the principles of pain relief, side effect management, or understanding of key concepts like addiction, tolerance, dosing, and communication (Green et al., 2009). Epidemiological data including incidence and prevalence of chronic pain in the different cancer types have not been reported consistently and pain treatment strategies such as the WHO pain ladder has not been validated for patients with cancer who have chronic pain (Burton et al., 2007).

Aetiology of pain in cancer survivors

Chronic pain in cancer survivors can arise because of damage to tissue caused by the cancer and/or the cancer therapy: surgery, chemotherapy, steroids, hormones, and radiation (Table 13.5.1). In addition, survivors may have pain from chronic conditions such as post-herpetic neuralgia, rheumatic diseases and diabetic neuropathy. At one centre, up to 40% of visits to a Cancer Survivors Pain and Palliative Care Program were due to chronic pain.

Chronic pain in cancer survivors can be divided into three pathophysiologic categories: somatic, visceral, and neuropathic (Levy et al., 2008):

1. Somatic pain occurs as a result of excitation of nociceptive receptors in the skin, serosa, and musculoskeletal system. This pain is usually confined, sharp, and aggravated by movement. Examples of somatic pains in cancer survivors include osteoporotic fractures, musculoskeletal imbalance with degenerative arthritis, and avascular necrosis of the femoral head.

2. Visceral pain is generated by nociceptive receptors in the walls of both visceral hollow and solid organs. These receptors respond to stretching and produce an ache over the organ as well as a referred pain. Examples include partial small bowel obstruction from adhesions and odynophagia from oesophageal narrowing.

3. Neuropathic pain arises from injury to the peripheral and/or central nervous system, and can be both spontaneous and evoked by a stimulus. Neuropathic pain is the most common type of pain in cancer survivors and it poses a challenge due to the severity, persistence, and resistance to simple analgesics. The description by patients is vivid and includes: 'itching', 'pins and needles', 'electric', 'holding a snow ball', 'burning', 'hot poker iron', amongst others. Neuropathic pain is localized to specific dermatomes, nerve root distribution, or peripheral, distal extremities (Levy et al., 2008).

4. Chronic neuropathic pain, resulting from nerve injury, is a challenging clinical problem which often cannot be adequately treated by current analgesics without unacceptable side effects. It greatly reduces quality of life, even more so than other chronic pain states with a negative impact on mobility, function, mood, and general well-being (Jensen et al., 2007). The prevalence of neuropathic pain is likely to be underestimated but studies from North America, Europe and the United Kingdom have found between 8% and 17% of the population may suffer from pain of predominantly neuropathic origin (Torrance et al., 2006; Toth et al., 2009; Doth et al., 2010). Neuropathic pain associated with cancer treatment is an increasing challenge. As the incidence of cancer increases and survival improves with better oncological management, there is an increasing number of patients having to live with the long-term effects of treatment-related neuropathic pain such as chemotherapy-induced peripheral neuropathy (CIPN) or scar pain (Cavaletti et al., 2011; Naleschinski et al., 2012).

CIPN affects up to 96% of patients who receive potentially neurotoxic chemotherapy (e.g. platinums, taxanes, vinca-alkaloids, and bortezomib), resulting in dose-reduction or early cessation of potentially life-prolonging treatment for up to 50% (Vasey et al., 2004; Richardson et al., 2006; Argyriou et al., 2008; Storey et al.,

2010). Symptoms are commonly in a glove and stocking distribution and include spontaneous pain, paraesthesia, allodynia (non-painful stimuli causing pain), hyperalgesia (increased sensitivity to painful stimuli), hypoaesthesia (numbness), and impaired proprioception, causing difficulty with day-to-day functioning such as fastening buttons, handling coins, walking and driving. One year following cessation of treatment approximately 50% of patients still have symptoms which both limits future treatment options for patients with relapsed/metastatic disease and leaves many with long-term pain or disability despite being cured of cancer. In our centre 57% of colorectal cancer patients still had symptoms of neuropathy 6 months after completing treatment with curative intent (WHO, 2005).

Estimates for persistent neuropathic pain after cancer surgery vary, with post-mastectomy and post-thoracotomy pain occurring in 30–60% of patients (Kehlet et al., 2006). One large study after breast cancer surgery found almost half of patients had persistent pain 2–3 years later, with this being moderate to severe in nearly a quarter of (Gartner et al., 2009). In our own centre approximately 30% of patients had persistent post-mastectomy pain, with a threefold increase in risk conferred by adjuvant chemotherapy (Sheridan et al., 2012). Recent guidelines suggest the use of objective quantifiable tests such as Quantitative Sensory Testing as clinical biomarkers to strengthen the diagnosis of neuropathic pain, which is made on history and examination (Smith et al., 2007; Cruccu et al., 2010; Haanpaa et al., 2011).

Treatment of neuropathic pain relies on early identification, understanding of the initiating and sustaining pathophysiological mechanisms and use of a range of therapeutic approaches (Attal et al., 2011). Evidence is accumulating which suggests the neurosensory characteristics of the pain may be the most important factor in predicting a treatment response, rather than the underlying aetiology (Dworkin et al., 2011; Selph et al., 2011). Current systemic therapy is mainly oral antidepressants or anticonvulsants; however, treatment often requires titration over months and is limited by variable efficacy and unacceptable side effects (Liu and Qin, 2011).

Chronic pain by disease type

Head and neck cancer

Cervical lymph node metastases in this setting have been treated commonly with radical neck dissection, which involves the removal of the ipsilateral spinal accessory nerve (cranial nerve CN) XI), internal jugular vein, and sternocleidomastoid muscle, in addition to ipsilateral cervical lymph node groups. Though performed commonly, this procedure carries with it significant morbidity.

The 'shoulder syndrome' manifests as continuous pain, shoulder tilt and drop, limitations in shoulder retraction, anterior flexion movements and active shoulder abduction, winged scapula and abnormal electromyographic findings (Ewing and Martin, 1952). Compromise or injury to the spinal accessory nerve (CN XI) can result in sensory paraesthesias and numbness. It has been observed that patients who have undergone neck dissections sparing the spinal accessory nerve, report less shoulder and neck pain than those in whom it was sacrificed. Spinal accessory nerve preservation has also been correlated with lower consumption of analgesics (Terrell et al., 2000).

Table 13.5.1 Sources of chronic pain in cancer survivors

	Chemotherapy/corticosteroids	Surgery	Radiation	Hormonal	Bisphosphonates	Cancer
Type of pain	Two major types: 1. *Acute paraesthesias* 2. *Chronic dysaesthetic pain*—often presents as 'stocking-glove' distribution	Chronic postoperative pain Characterized by type of surgery: thoracotomy breast surgery modified-radical neck dissection limb amputations nephrectomy inguinal lymph node dissection Common mechanism: central sensitization	*Several types of pain* Plexophathies Peripheral nerve entrapment Myelopathy Enteritis Proctitis Cystitis Visceral strictures Osteoradionecrosis Accelerated osteoporosis Secondary malignancies	Osteoporosis secondary to hormonal treatments of breast and prostate CA Cancer-therapy related bone loss is severe and occurs at a higher rate than typical osteoporosis	Usually well tolerated May increase risk of osteonecrosis of the jaw (ONJ) Incidence range: 1–11% 3% > 2 years 11% > 4 years	
Characteristics	*Acute paraesthesias* Typically resolves once chemotherapy is discontinued 15–50% of cases become chronic *Chronic paraesthesias* Risk of chronic pain due to cumulative toxicity *Agents with prominent neurotoxic side effects* Cisplatin, oxaliplatin, vincristine, vinblastine, paclitaxel, docetaxel	*Variability in pain incidence* Phantom breast pain: 13–25% Phantom limb pain: 30–80% Typically presents 2–12 months post-surgery Intensity of acute postoperative pain predicts chronic pain	Manifest months or years after treatment is completed		ONJ symptoms: localized pain, swelling, loosening of teeth, exposed bone, non-healing oral ulcers, purulent gingival discharge, numbness or heaviness of the jaw Chronic and diffuse bone pain may also occur	
Effects	*Chronic peripheral neuropathy* Risk of deconditioning and musculoskeletal pain *Myopathy* Somatic pains and weakness			Increased risk of vertebral and non-vertebral fractures; resulting in pain and disability Aseptic necrosis of the femoral heads and hip Fractures		

Nonetheless, chronic pain has been demonstrated even with sparing of the spinal accessory nerve, as evidenced by electromyographic studies. This is most commonly secondary to expansive dissection, vigorous traction, intraoperative trauma, and ischaemia (Sakorafas et al., 2010). Morbidity is compounded if there is a delay in the diagnosis post surgery.

Osteonecrosis of the jaw is a known potential adverse effect of head and neck irradiation. It can be exacerbated by the use of steroids and chemotherapeutic agents, infection, periodontal disease, and poor dental hygiene. It has been associated more recently with the use of high doses of intravenous bisphosphonates in several studies, with the mandible being the most commonly affected site.

Rectal cancer

Patients who have had radiation to the pelvis for rectal cancer can be at risk of the development of 'pelvic pain syndrome'. Aetiologies for this syndrome may include chronic radiation enteritis or proctitis, chronic cystitis, pelvic insufficiency fractures, and neuropathies which may manifest as burning perineum syndrome (Levy et al., 2008).

Chronic radiation enteritis can happen in up to 15% of patients receiving abdominal or pelvic irradiation. The onset of symptoms may occur up to 18 months post radiation treatment, and commonly include crampy, colicky abdominal pain accompanied by tenesmus, bloody diarrhoea, emesis, and anorexia or weight loss.

Cystitis, the product of chronic effects of bladder irradiation, results from endothelial ischaemic damage and interstitial fibrosis, and may lead to a diminution in bladder capacity. Clinically, urgency and dysuria may be observed.

Pelvic insufficiency fractures are an uncommon side effect of chemotherapy and radiation treatment for rectal cancer, however they can lead to significant morbidity. Pain is usually intense and of acute onset, most commonly affecting the abdomen, low back, pelvis, hip, buttock or thigh. Studies indicate a 3-year average of 3.1%, and females and Caucasians appear to be at higher risk (Herman et al., 2009). Burning perineum syndrome refers to pain that has developed in the perianal region as a result of radiation that may expand to encompass the scrotum or vagina. It is a rare complication, and onset is usually 6 to 18 months following radiation (Minsky and Cohen, 1988).

Sarcoma

Depending on the disease presentation, limb-sparing surgery may be an option for soft tissue sarcomas occurring in an extremity, and thus amputation may not be necessary. Certain situations will, however, dictate limb amputation.

One of the more frequent complications post amputation is phantom limb pain (PLP), the perception of painful sensations in an amputated extremity. Though the exact mechanism is unknown, it is believed to be secondary to spinal plasticity and cerebral reorganization following an insult. Onset is typically within days to weeks of amputation, but can be delayed for months or years. It has been shown to occur acutely in over half of amputees, with higher levels of extremity amputation increasing the risk of greater pain intensity. Incidence is higher following traumatic amputation as opposed to surgical amputation (Ramachandran and Hirstein, 1998). Other risk factors include the presence of pre-amputation pain, persistent stump pain, noxious intraoperative stimuli and acute postoperative pain (Ramachandran and

Hirstein, 1997). PLP is less common in children and congenital amputees. Phantom limb pain can be varied in presentation, but may be shooting, stabbing, cramping, burning, or itchy in nature. Pain is often localized to the distal portion of the amputated extremity, and many patients report that the affected limb is in a contorted or awkward position. Some patients have also reported exacerbations with cold temperature, stress, fatigue, urination, and defecation. Psychological factors are not correlated with its occurrence, but may be exacerbating rather than causative in nature.

Genitourinary

Prostate cancer

The treatment modalities available for prostate cancer have expanded within the last several years. Standard treatment is androgen deprivation therapy, either surgical (orchidectomy) or medical (gonadotropin-releasing hormone (GnRH) agonist treatment). The intended outcome of GnRH agonist treatment is hypogonadism, which is a significant cause of acquired osteoporosis in males. GnRH agonists have been shown to decrease bone mineral density of the hip and spine by approximately 2–3% per year during initial treatment. Similarly, surgical orchidectomy for prostate cancer is often followed by severe osteoporosis and increased risk of hip fracture and vertebral fracture. Risk factors include Caucasian race, low bone mineral density, and treatment duration of at least 1 year with GnRH agonists (Smith et al., 2005; Saylor et al., 2011). This increased risk starts almost immediately and can persist for several years (Daniell, 1997).

Chronic testicular pain is a well-known potential complication of treatment for testicular cancer. This includes chronic pelvic pain syndrome (pelvic pain either continuous or recurrent for at least 6 months) and phantom testes syndrome (pain in the removed testis), with the presence of preoperative pain in the removed testes as a positive risk factor (Puhse et al., 2010). A higher incidence of genital pain during and after intercourse has also been recorded (Puhse et al., 2008).

Breast cancer

Treatments for breast cancer now commonly include surgery for axillary node dissection and primary tumour staging, radiation, hormonal (anti-oestrogen) therapy, and/or chemotherapy. Up to half of patients post mastectomy experience chronic pain, which can lead to significant encroachments on a patient's quality of life due to physical and emotional distress. Chronic neuropathic pain following mastectomy has been well documented and can be characterized by four different types of pain syndrome:

1. *Phantom breast syndrome* (PBS). PBS is a condition in which patients have the sensation of residual breast tissue which is often painful, but can also include non-painful sensations. Patients may complain of persistent pain and discomfort, numbness or tingling, pressure, burning, and throbbing among other neuropathic symptoms. Onset may be delayed up to one year post surgery, and the condition can persist for several years following surgery (Jamison et al., 1979) with an incidence ranging between 13% and 44% (Jamison et al., 1979; Kroner et al., 1989, 1992). Common risk factors for the development of PBS are severe acute postoperative pain and greater postoperative use of analgesics (Tasmuth et al., 1996). Other factors believed

to contribute include age under 40 years, psychosocial status, premenopausal state, parity, and those who have had a preoperative history of breast sensations (Staps et al., 1985; Gartner et al., 2009). In addition, it is important to remember that patients who have undergone both breast-conserving surgery or reconstructive breast surgery can also have a post-surgical pain syndrome, consisting of various neuropathic components.

2. *Neuroma pain* is pain in the area of a surgical scar on the breast, chest, or arm aggravated or intensified by touch or percussion. A neuroma is a benign growth of nerve tissue at the severed ends of sensory nerves, which may become entrapped by scar tissue. It can result in dysaesthesia to the overlying skin secondary to atypical connections of regenerating nerves. The estimated prevalence of neuroma pain is approximately 23–49%.

3. *Intercostobrachial neuralgia* (ICN) refers to post-surgical pain experienced in the distribution of the intercostobrachial nerve either with or without axillary node dissection. This most commonly results in pain, allodynia or hyperalgesia in the axilla, anterior chest wall or medial upper arm. Given the substantial inter-individual variation in distribution of the intercostobrachial nerve, the risk of damage to the nerve is relatively high, regardless of surgical procedure or method. Prevalence estimates range as high as 40% (Granek et al., 1984; Smith et al., 1999).

4. *Other nerve injury pain*. It is postulated that other nerves may be involved in the development of post-mastectomy pain syndrome. This is evidenced by the prevalence of chronic post-surgical pain in patients who have undergone mastectomy without accompanying axillary node dissection and with documented sparing of the intercostobrachial nerve (Carpenter et al., 1999).

5. *Radiation-induced pain syndromes*. It has been well documented that adjunctive radiation in breast cancer patients increases their risk of developing a chronic pain syndrome. The most common cause of pain in this setting includes radiation-induced plexopathy, especially brachial plexopathy. Brachial plexopathy is often heralded by numbness and paraesthesias of the hands and fingers, followed by weakness and increasing pain. It is thought to result from a combination of direct cell damage from ionizing radiation and progressive ischaemic changes which may lead to fibrosis surrounding the nerves of the brachial plexus, fibrous thickening of the neurilemmal sheath, demyelination, and fibrous replacement of nerve fibrils (Qayyum et al., 2000). Onset of symptoms of plexopathy may be delayed for months to years in some cases. Other less common causes include osteoradionecrosis of the chest wall, fractures, and secondary malignancies (Paice, 2011).

6. *Peripheral neuropathy*. The most common cause of peripheral neuropathy in the breast cancer population is the use of chemotherapeutic agents. Those that have been most frequently implicated include vinca alkaloids (e.g. vincristine), taxanes (paclitaxel and docetaxel), and platinum-derived compounds such as carboplatin. Peripheral neuropathy is often the dose limiting side effect of these agents (Reyes-Gibby et al., 2009). Symptoms can include numbness, tingling, pain, and other paraesthesias. The majority of breast cancer patients do experience improvement in their neuropathic symptoms over time;

however, in some patients it is irreversible. Sensory polyneuropathy is the usual presentation, but it can progress to cranial nerve palsies, motor weakness, and autonomic dysfunction (Rowinsky et al., 1993).

7. *Pain related to breast implants and surgical reconstruction*. There is some evidence to suggest that women who have undergone breast reconstruction are at a higher risk post surgery for chronic pain than those who have not. One study found the incidence of pain at 1 year following mastectomy with reconstruction to be appreciably higher (49%) than those with mastectomy alone (31%) or who had undergone breast reduction (22%). Breast reconstruction also correlated with higher pain intensity (Wallace et al., 1996) with submuscular implant placement associated with more chronic pain than subglandular implants. There has been no demonstrated relationship between the type of implant used (saline vs silicone) and the development of chronic pain (Wallace et al., 1996).

Lung cancer

Chronic post-thoracotomy pain syndrome (PTPS) is a persistent or recurrent pain in the area of a thoracotomy incision for at least 2 months following surgery (International Association for the Study of Pain, Subcommittee on Taxonomy, 1986). It is believed to be secondary to intercostal nerve damage as well as suboptimal control of acute pain in the immediate postoperative period. Aggressive rib retraction may also contribute by leading to costovertebral and costochondral dislocation. Neuroma formation and tumour recurrence have also been cited. The syndrome is characterized by significant burning pain with other associated neuropathic features postoperatively with a very slow resolution in the following months and years. Unfortunately, it does not appear to decrease appreciably with time. There is a relatively high incidence of ipsilateral arm and shoulder dysfunction. The incidence of PTPS is reported at approximately 80% at 3 months, 75% at 6 months, and 61% 1 year after surgery (Perttunen et al., 1999). One study found that approximately 30% of patients continued to report pain at 5 years post thoracotomy with no significant decrease in pain intensity (Dajczman et al., 1991). Preoperative epidural analgesia has been shown to be more effective at reducing the incidence and intensity of the resultant chronic pain than postoperative epidural analgesia (Obata et al., 1999).

Haematological/stem cell transplantation

Haematological malignancy survivors are at an increased risk of developing chronic pain syndromes due to several potential treatment related complications. These pain syndromes are of particular concern in the setting of stem cell transplantation, given the treatment intensity. Patients may experience significant bone pain as a result of prolonged steroid therapy as treatment for graft-versus-host disease. This may lead to an increased incidence of osteonecrosis and osteoporosis. Haemorrhagic cystitis is another painful condition, which can result from certain conditioning regimens, especially those containing cyclophosphamide and total body irradiation. The immune-suppressing calcineurin inhibitors used prophylactically post stem cell transplant to prevent graft rejection (i.e. cyclosporine, tacrolimus) can have neurotoxic side effects with an incidence between 5% and 30%. Profound immune suppression post transplant leaves patients susceptible to

a number of opportunistic infections, such as herpes zoster, with the potential subsequent development of post herpetic neuralgia (Niscola et al., 2008).

Treatments

Despite numerous advances in the course of the last several years, the management of chronic pain in cancer survivors is often suboptimal, secondary to the complex neurophysiology of many chronic pain syndromes and a relative paucity of education and resources within many oncological settings. It requires an interprofessional approach that details a comprehensive assessment with ongoing reassessment to guide the implementation and integration of pharmacological and non-pharmacological measures. This facilitates the elucidation and revision of the pain source, alteration of the perception of pain, and inhibition of pain transmission to the central nervous system (Ferrer-Brechner et al., 1985), thereby helping to optimize patient quality of life.

Opioid therapy is one of the foundations of cancer pain treatment. Its role in the management of neuropathic as well as nociceptive pain has been confirmed in several clinical trials (Eisenberg et al., 2005). Though morphine remains the most widely used opioid, there is presently no evidence to suggest that one opioid is better than another as a first-line agent. Opioid therapy can be administered through several routes, including oral, transdermal and, most commonly, parenteral. Opioids can also be delivered via the buccal, submucosal, and intranasal routes (rapid onset opioids), and rectally for the control of episodes of breakthrough pain, in addition to regularly scheduled or long-acting preparations. Methadone may have a distinctive role in the management of chronic pain in cancer survivors due to its action as an opioid agonist and *N*-methyl-D-aspartase (NMDA) receptor antagonist, which can inhibit central sensitization and may moderate allodynia and hyperalgesia in certain neuropathic pain syndromes. In occasional situations, neuraxial (epidural or intrathecal) delivery of opioids may be appropriate for some particularly challenging pain syndromes when resources permit.

When opioids are used as a singular treatment, higher doses may be required. This may lead to adverse effects such as constipation and sedation, as well as long-term complications, which can include tolerance, opioid-induced neurotoxicity, physical dependency, and pituitary axis suppression. Clearly in susceptible individuals, psychological dependence may become an issue. Optimal management of neuropathic pain usually involves the administration of a neuropathic analgesic medication, used either alone or in combination with opioids for synergistic effect, which may reduce the risk of opioid-induced neurotoxicity. Those used most commonly in this setting include antidepressants, anticonvulsants, and non-steroidal anti-inflammatory drugs (NSAIDs).

Tricyclic antidepressants (TCAs) such as nortriptyline and desipramine are used most commonly in the setting of neuropathic pain, as they have a lower incidence of anticholinergic and cardiac side effects (QT prolongation) as compared to amitriptyline. Usually days to weeks of treatment are required before a measurable degree of analgesia is achieved. Newer classes of antidepressants including serotonin and norepinephrine (noradrenaline) reuptake inhibitors (i.e. duloxetine and venlafaxine) can also have a role in the modulation of neuropathic pain, however selective serotonin reuptake inhibitors (SSRIs) have not been proven to be as effective (Sindrup et al., 2005). (See Chapter 13.3.)

Anticonvulsant medications commonly used in the management of neuropathic pain include gabapentin, carbamazepine, and pregabalin. Carbamazepine is thought to exert its analgesic effect through the reduction of conductance in sodium channels and may have a particular role in the management of trigeminal neuralgia. Gabapentin and pregabalin are similar in their mechanism of action, which appears to be delivered via interaction with the α2-δ protein subunit of voltage-gated calcium channels. Pregabalin displays linear absorption as opposed to gabapentin, giving it a more predictable dose response range and a generally faster time to therapeutic titration. The efficacy of other anticonvulsants for neuropathic pain has not been reliably established in clinical trials.

Anti-inflammatory agents (NSAIDs, steroids) have been employed in several chronic pain syndromes in cancer survivors. They are mostly used in association with opioids for musculoskeletal pain; however they are not viable options for long-term treatment due to side effects. Other potential treatments being explored include topical analgesics such as lidocaine and the NMDA receptor antagonists such as ketamine. These treatments require further research.

Non-pharmacological management of chronic pain in the cancer survivor

Non-pharmacological treatment options should be used in combination with medications where appropriate, with a view to minimizing medication side effects and optimizing function and quality of life.

The basic concept of a true multidisciplinary, interdisciplinary treatment team to manage and address the challenges and the various needs of cancer survivors, including pain, is a natural progression based on the cancer rehabilitation philosophy. The latter's objective being, through an interdisciplinary approach, to empower individuals who are experiencing loss of function, fatigue, pain, malnutrition, psychological distress, and other symptoms, as a result of cancer or its treatment to improve their own quality of life (Chasen and Dippenaar, 2008). Such teams have shown efficacy in treating chronic pain in the general population (Shealy, 2013). The results have been profound with at least one-third returning to work, their average pain intensity decreasing an average of 70% and their mood improving in 90% of patients. This same interdisciplinary treatment prototype also can be applied to cancer survivors (Robbins et al., 2003). Team members should include physicians, nurses, physical, occupational, and vocational therapists in addition to dietitians, social workers, and psychologists. The different disciplines involved in the care of these patients constitute the team. It is vital that communication within the team is open, direct, and supportive. Herein lies the strength of collaboration between team members. They will learn of the different assessment approaches, the importance that patients place on various symptoms and the effects these symptoms have on the domains of the patients' quality of life, specifically relating to pain. With the patient and the caregiver placed as the end target of all therapeutic interventions, the combined collaborative efforts of the team are synergistic in their effect. Regular roundtable discussions are a key component of this teamwork (Chasen and Jacobsen, 2013). At times, spiritual

counsellors or religious personnel can be of importance. In addition, group educational sessions during which dialogue is encouraged is important to empower participants to play an active role in their own management. Attention to all symptoms including, loss of appetite, loneliness, fatigue and their relationship to pain are all key components that need to be addressed. Social isolation, existential distress, and family disharmony should all be considered an integral cause of pain. The adult 'Damocles syndrome', characterized by a state of long-term uncertainty, stress, and anxiety of having disease recurrence, experienced by the patients who have survived cancer and their families must also be considered. Cancer survivors can be physically de-conditioned after the treatments which have caused weight loss, muscle loss (sarcopenia), muscle weakness, and also be psychologically de-conditioned which expresses as a result of a change in body image, a loss of previous role within the family and work spheres, as well as having to face morbidity and mortality. All of these factors contribute to the 'total pain' of the patient. Patients with chronic pain are prone to develop 'maladaptive behaviours' (McCracken and Eccleston, 2003). These behaviours are manifested by the following cycle. Pain causes diminished activity. This leads to progressive de-conditioning, which gives rise to reduced socialization, altered sleep/awake cycle and medication and drug abuse.

Within the expertise of the various members of the interdisciplinary rehabilitation team, cancer survivors with chronic pain are instructed and trained to build stamina and endurance to counter the muscle de-conditioning, to recognize stressful situations and utilise learned, effective coping strategies. The effect of exercise training and comprehensive health improvement programmes, has been suggested to improve quality of life, particularly in chronic breast or chest-wall pain (Wong et al., 2012). By building on past, successful experiences of the patient, existential meaning can be found and utilized in order to surmount current suffering.

Other types of pain

For patients experiencing moderate to severe pain following neck dissection, acupuncture resulted in an improvement of a third of patients on a composite scale. Biogenetics as developed by Shealy, synthesizes techniques of self- regulation with emphasis on positive attitude, a belief in self, relaxation, hypnosis, massage, yoga, and transcutaneous electrical nerve stimulation (TENS), which may help to build strength and stamina (Pujol and Monti, 2007). Psychosocial interventions can include hypnosis, cognitive behavioural therapy, desensitization strategies, guided imagery, and mindfulness-based stress reduction (Keefe et al., 2005).

Conclusion

Pain can be a common experience for many cancer survivors and may develop due to a number of aetiologies. The experience and perception of pain is affected by not only physical but also psychological, cognitive, cultural, and environmental factors, which are specific to each individual. The repercussions of pain which is managed suboptimally can be extensive, and in some cases even lead to increased mortality. Substantial improvements have been made in the outcomes and survival rates of patients with many different types of cancer over the past several years, yet with this the complexity of their pain syndromes continues to increase. Though

many cancer survivors can return to relatively satisfactory levels of quality of life, chronic pain can remain a persistent issue for some, and may be underreported and therefore diagnosed and treated suboptimally. It is recognized that cancer survivors experience a greater incidence of comorbidities and psychosocial sequelae. The evidence base is increasing for a number of treatments for cancer survivors to address their pain issues and improve their quality of life. Each cancer survivor is unique and responses to pain management strategies can be diverse. Additional resources should also be focused on equipping patients with the skills to cope with chronic or persistent pain, thereby creating a more efficient transition from active treatment to survivorship. Empowerment of the cancer survivor is a key element of any successful strategy as is collaboration among team members. Respect for survivors' individuality is also paramount to any successful outcome.

SECTION 14

Cancer-associated disorders

Neurological problems in advanced cancer

Augusto Caraceni, Cinzia Martini, and Fabio Simonetti

Introduction to neurological problems in advanced cancer

Neurological complications are frequent in populations with advanced cancer. An adequate neurological assessment is always important in addressing pain, cognitive symptoms, and peripheral and central nervous system (CNS) complications.

Intracranial hypertension

General aspects

Intracranial pressure (ICP) is the result of the balance between the liquid (cerebrospinal fluid (CSF), blood interstitial fluid) and solid content of the cranium. It is not constant but depends on systemic blood pressure; its changes are maintained within narrow limits. The normal brain can tolerate small variations usually without clinical consequences.

An adult's cranium is a fixed vault so an increase in one of the three components—brain, blood, CSF—causes a reduction in one of the others.

Pathological processes, such as tumours, abscesses, or haematomas, increase intracranial contents that compress brain parenchyma. They also disrupt the blood–brain barrier, which may lead to increased intracranial blood volume. If this occurs slowly, there may be no increase in ICP, at least temporarily. This is due to compensatory mechanisms, such as enhanced CSF reabsorption, reduced intracranial blood volume, and increased drainage through the lymphatic and circulatory system. When these mechanisms are insufficient or if the process is acute, ICP rises rapidly and may cause death, with or without brain distortion or herniation (see below).

Clinical findings

The clinical picture of increased ICP is characterized by an altered state of consciousness, headache, nausea and vomiting, papilloedema, and, at times, focal signs. An altered state of consciousness is the most frequent sign, starting with psychomotor retardation, and slowing of verbal and motor responses. This can progress to stupor and then coma.

Headache progresses and can be severe. It usually is diffuse, more intense in the supine position, and worse in the morning immediately after awakening. It can awaken the patient from sleep, and also is worsened by head movements, cough, and the Valsalva manoeuvre. Nausea and vomiting frequently accompany the headache. Vomiting may be projectile in children with posterior fossa lesions, which can directly stimulate the trigger zone in the fourth ventricle.

Papilloedema is a specific sign of increased ICP but its sensibility is low, so it often is absent, even in severe cases. Among the focal signs that occur frequently in those with increased ICP, the most frequent is diplopia due to paralysis of the abducens nerve. This nerve, with its long intracranial course, is particularly sensitive to traction or compression. Other signs may occur in either the sensory or motor systems. Seizures also may occur in the setting of increased ICP.

In children, increased ICP often is accompanied by non-specific findings or may manifest as irritability, labile mood, negativity, or aggressive or hostile behaviours. A focal sign relatively more common in children is the 'sunset' sign; downward ocular deviation, eyelids retraction due to compression of the quadrigeminal plate.

Acute pressure symptoms

In the setting of intracranial hypertension, the physiological fluctuation in ICP can be interrupted suddenly by abnormal pressure waves, including waves of very high pressure, or plateau waves (Lundberg, 1960). These pressure waves, which usually last seconds to minutes, may be accompanied by acute pressure symptoms that are sudden acute neurological symptoms or worsening of general neurological conditions (Box 14.1.1).

Herniation

Dural reflections of the falx cerebri and tentorium cerebelli divide the cranial box into compartments, and raised ICP can result in pressure gradients between compartments. These pressure gradients can, in turn, lead to shifts of brain parenchyma or herniations: subfalcial, tentorial, upward cerebellar, and cerebellar pressure cone. These can be merely a relief for crowding or a sign of overfilled sovratentorial and posterior fossa compartments, but when they occur rapidly, or interfere with CSF circulation and cause hydrocephalus, they can be life-threatening.

Brain oedema and treatment of increased ICP

Brain oedema

In both primary and secondary brain tumours, oedema is an important cause of increased ICP. The underlying pathogenic mechanism of oedema is the loss of osmotically active substances

> **Box 14.1.1** Signs and symptoms of ICP waves
>
> ◆ Altered state of consciousness, agitation, delirium
> ◆ Headache, neck pain
> ◆ Focal or generalized seizures
> ◆ Cerebellar fits (opisthotonus)
> ◆ Decerebration (hypertonus, extension, and internal rotation of four limbs)
> ◆ Amaurosis, mydriasis
> ◆ II, IV, VI nerve paralysis, conjugated eye deviation
> ◆ Nystagmus, tinnitus
> ◆ Myoclonus of face and limb muscles
> ◆ Dysarthria, dysphagia
> ◆ Pyramidal signs, paraesthesiae
> ◆ Cardiovascular or respiratory disturbances, yawning
> ◆ Hyperthermia, face cyanosis, flushing, pallor, sweating
> ◆ Nausea, vomiting, hiccup, sialorrhoea, diarrhoea, incontinence.

such as albumin from the circulatory system into the brain interstitial tissue, which is caused by disruption of the blood–brain barrier within the tumour and in the surrounding cerebral parenchyma. According to the classic classification (Klatzo, 1967), there are four broad types of brain oedema:

◆ *Vasogenic oedema* is caused by an increase of the extracellular space. It results from increased capillary permeability and can be produced by any lesion that damages the blood–brain barrier.

◆ *Cytotoxic oedema* is caused by an increase of intracellular volume. It results from ischaemic or hypoxic cellular damage. Cellular dysfunction of the ion pump system produces intracellular accumulation of sodium followed by influx of extracellular fluid. It is now referred to as cellular swelling.

◆ *Interstitial oedema* is caused by an increase of the extracellular space due to blockade of CSF reabsorption at any level.

◆ *Osmotic oedema* is caused by an increase in the water content of the brain parenchyma due to plasma hypo-osmolarity. This may occur, for example, in water intoxication or in SIADH.

Tumour-induced brain oedema is sustained mainly, at least initially, by vasogenic mechanisms. Interstitial and osmotic oedema are rare and do not apply to the perturbations produced by a tumour.

Treatment of increased ICP

Conservative management of cerebral oedema has two main goals: maintenance of cerebral perfusion pressure (CPP) and reduction of vasogenic oedema (Rosner et al 1995). CPP is defined as mean arterial pressure minus ICP. Intracranial processes can impair CPP by increasing ICP and disrupting cerebrovascular autoregulation. The consequences of reduced CPP are cerebral ischaemia, compensatory and dilatation of cerebral vessels, with further increase of ICP. Since hypovolaemia reduces arterial pressure and therefore CPP, the patient with elevated ICP does not require fluid restriction, but should be kept euvolaemic with adequate fluid intake.

Interventions that assist in maintaining CPP and reducing vasogenic oedema are varied. Consideration of these interventions depends on the goals of care. Aggressive management strategies, such as assisted ventilation to lower the partial pressure of carbon dioxide may not be considered when the goals are purely palliative.

Positioning: a neutral head position should be adopted, with the head at least 30° above the heart to facilitate venous drainage from the head.

Infusion of hypertonic solutions: rapid reduction of ICP and cerebral oedema with hypertonic solutions has been utilized since 1925 (Howe, 1925). Nowadays, used hyperosmolar solutions are mannitol, and hypertonic saline (Ropper, 2012).

Hyperosmolar solutions are only effective if the blood–brain barrier is intact; action is by removal of water from normal brain parenchyma, as ICP is lowered in proportion to the volume of undamaged brain. There is little value on oedema around a lesion where the blood–brain barrier is damaged. In addition such solutions do not have a role in asymptomatic cerebral oedema.

Mannitol is the most commonly used agent (Ropper, 2012). Its activity is based initially on an increase in blood flow, leading to improved cerebral perfusion. Only later does it create an osmolar gradient between blood and brain and extract water from the cerebral compartment. Usually more water than sodium is eliminated, resulting in hypovolaemia and hyponatraemia. There is no interaction between mannitol and glucose metabolism. There are a number of other actions associated with the therapeutic effect of mannitol, including a diuretic effect, an increase in red cell deformability, and a rapid reduction of the diameter of arterioles and small veins of the brain surface. Mannitol is not metabolized and is excreted by the kidneys; with moderate reduction of glomerular filtration, it can accumulate in the central compartment. Although it can be administered orally, bioavailability is very poor and the usual approach is intravenous (IV) infusion, aiming to achieve concentrations higher than 5 mmol/L, which are active osmotically and persist for 4–6 hours. Mannitol 18% or 20% solutions are used and the suggested dose regimen for both adults and children is 1 g/kg delivered over 15–30 minutes immediately, then 0.25 g/kg every 6 or 8 hours. The regimen can vary according to the severity of symptoms and the presence of acute and symptomatic brain herniation. Daily doses should never be higher than 150–200 g/day. Renal disease, congestive heart failure, and intracerebral haemorrhage may contraindicate the use of mannitol. Mannitol therapy should never extend for more than 3–4 days. Salt and water balance should be monitored carefully to avoid dehydration and hypotension. Hyperosmolality should also be prevented by cessation of therapy at values of 320 mOsmol/kg.

Hypertonic saline used in the past only for craniocerebral trauma is now used for increased ICP not responsive to mannitol. It is as effective in lowering ICP as mannitol. Besides osmotic action, it has a vasoregulatory immunological action. Doses: NACL 3%: 5–10 mL/kg in 5–10'; NACL 23.4%: 30 mL/dose, repeatable. When hypertonic solution is used for a longer period than a few days, a risk for rebound effect exists. This rebound effect is, in part, a consequence of the osmotic agents entering the intracranial compartment, with inversion of the osmotic gradient between blood, extracellular fluid, and brain.

Table 14.1.1 Relative potency of different drugs

	Anti-inflammatory activity	Duration of action, hours	Equivalent dose, mg
Cortisone	0.8	8–12	25
Prednisone	4	12–36	5
6 α-Methylprednisolone	5	12–36	4
Dexamethasone	25	36–54	0.75
Betamethasone	30	36–54	0.75
Cortisol	1	8–12	20

Corticosteroids: corticosteroids initially gained a wide application in treating ICP (Galicich and French, 1961). The mechanism of action is based fundamentally on their ability to block the outflow of blood components from the capillary bed into the brain tissue at the site of blood–brain barrier damage. Dexamethasone does not reduce the water content of the swelling brain tissue (as mannitol does), and reduction of ICP does not occur before 48–72 hours. Nonetheless, it is common to observe a clinical improvement before this and within the first 24 hours.

Doses and administration schedules of corticosteroids have never been established by specific guidelines. It is, therefore, worthwhile considering the relative potency of the different drugs and their pharmacological characteristics (Schimmer and Parker, 2006) (Table 14.1.1).

Sodium retention activity is 1 for cortisol, 0.8 for hydrocortisone, 0.8 for prednisone and methylprednisolone, and 0 for betamethasone and dexamethasone.

Dexamethasone is found in higher concentrations within the CSF compared with other corticosteroids because it is less bound to plasma proteins. This should be taken into account when switching from one steroid to another, in addition to the data shown in Table 14.1.1. The dose of dexamethasone used in metastatic or primary brain tumours varies according to the clinical findings and degree of oedema, from 4 mg every 6 hours to 96 mg/day in patients with more severe symptoms or impending herniation. Once the patient is stabilized clinically, the total dose can be given in one or two daily doses, as suggested by the drug's pharmacokinetic profile. In children, the suggested initial dose of dexamethasone is 1 mg/kg followed by doses of 0.4–1 mg/kg in one or more daily doses. Clinical experience suggests that higher doses can be administered safely, if needed.

Although it is common for steroids to be continued indefinitely, continuation of steroid therapy must always be under constant review. Steroids should not be continued if there is no clear medical indication for therapy, or the clinical benefit is exceeded by side effects. Steroid side effects are significant and some may add to the disability of patients (e.g. weakness due to myopathy). Box 14.1.2 lists the side effects of corticosteroids. Although not all are relevant to short-term management of symptoms in palliative care, many can seriously impact on the quality of life of patients and require careful balancing with therapeutic effects. If a steroid is no longer indicated, it should be tapered and discontinued.

Seizures in patients with advanced illness

A seizure is a transient occurrence of signs or symptoms due to abnormal excessive or synchronous neuronal activity in the brain (Fisher et al., 2005).

Seizures are encountered not infrequently in palliative medicine. They may be caused by structural disease of the brain, non-structural causes, or both. Structural problems include metastatic cerebral lesions and infectious causes. The most common non-structural causes include metabolic derangement and drug toxicity (Delanty et al., 1998).

Seizure definition and classification

Seizures are classified according to their electroencephalographic (EEG) features as partial or focal, which applies to any seizure related to an initiating focus that can be identified in a specific brain area, and generalized, which refers to seizures that appear to begin bilaterally. Seizures that originate as truly generalized electrical discharges are defined as primary generalized seizures; those that begin locally and evolve into generalized tonic–clonic seizures are termed secondary generalized seizures.

Depending on the level of consciousness during attacks, partial or focal seizures are classified as follows:

Simple partial seizures are associated with a normal level of consciousness. Only a selective area of the cortex participates in the seizure activity, causing symptoms that depend on the function of that part of the cortex. Therefore, partial motor, sensory, autonomic, and affective seizures are possible. At times when symptoms of this kind precede the onset of a generalized seizure they are called an 'aura'.

Complex partial seizures combine focal symptoms with an altered state of consciousness. These are the most common type of seizures in adults and probably the most common encountered in palliative care. The patient seems awake but is not meaningfully engaged with the environment. If there is verbal output, questions are not answered appropriately and the patient may repeat words or sentences. Eyes can be fixed or rolling purposelessly. The patient may be immobile or engaged in repetitive behaviours (motor automatisms), such as grimacing, snapping fingers, chewing, running, or undressing. If physically restrained, behaviours can become hostile or aggressive. The seizure lasts on average 3 minutes and is followed by a post-ictal phase, which can include somnolence, delirium, and headache, and can last for several hours. After complete recovery, the patient has no recall of the event, but sometimes may remember the aura. The partial complex seizure can itself be preceded by an aura, which may be equivalent to a simple partial seizure.

Generalized seizures can be non-convulsive, which also are called absence or *petit mal*; or convulsive, which are known as tonic–clonic or *grand mal* seizures.

Generalized tonic–clonic (grand mal) seizures start with a sudden loss of consciousness, at times accompanied by shouting (due to forced air expiration by sudden contraction of the diaphragm). Diffuse muscle rigidity follows, which is accompanied by cyanosis. After a short time, myoclonus and muscle fasciculations occur and the patient can bite his or her tongue. The latter clonic phase typically lasts 2 minutes or less, but more prolonged episodes can occur. At the end, post-ictal phase presents with deep sleep and slow deep breathing. Later the patient gradually awakens, often complaining of headache.

Box 14.1.2 Acute and chronic side effects of corticosteroids

- *Infections (especially relevant if associated with chemotherapy)*: reactivation of tuberculosis, candida, pneumocystis pneumonia.

- *Metabolic disturbances*: hyperglycaemia, electrolyte imbalances, fluid retention, hyperlipidaemia.

- *Dystrophic reaction*: delay in wound healing, purpura, dermal atrophy, acne.

- *Myopathy*: weakness affects mainly the pelvic girdle muscles, but also head flexor and shoulder muscles are affected. Muscle enzymes and electromyogram are normal. On the contrary, cretinuria is elevated. Myopathy occurs as early as 2 weeks of starting dexamethasone, manifesting with difficulties in climbing stairs and standing from a sitting position. Some authors suggest that substitution with non-fluorinated steroids (methylprednisolone or prednisone) is effective in reducing myopathic effects.

- *Bone*: osteoporosis probably due to the reduced intestinal absorption of calcium and reduced tubular reuptake with increased calciuria. These mechanisms cause hypocalcaemia, which reflects on parathyroid activation and subsequent increased bone re-absorption. Phenobarbital causes osteopathy and so it is preferable to use different anticonvulsants in combined therapies.

- *Aseptic bone necrosis* (usually of the femoral head). Two hypotheses have been proposed to explain this complication. Fat embolism due to altered lipid metabolism and osteomedullary ischaemia. Bone necrosis has been seen after relatively short-term treatment with dexamethasone (cumulative doses of 220 mg) (McCluskey and Gutteridge, 1982).

- *GI side effects*: peptic ulcer disease: the use of steroids alone in patients in good general condition is not associated with damage to the GI tract. There are, however, specific risk factors that are associated with peptic ulceration and bleeding, such as, very high doses, systemic neoplasm, previous peptic ulcer, and combined use of non-steroidal anti-inflammatory drugs (NSAIDs). It is also well known that patients with intracranial lesions are at risk of GI bleeding (Cushing, 1932). Prophylaxis with proton pump inhibitors is therefore suggested in patients at increased risk.

- *Hiccup*: chronic hiccup has been observed in association with the use of dexamethasone or high-dose methylprednisolone. The physiopathology of this effect is unknown (LeWitt et al., 1982).

- *Psychiatric* (Vanelle et al., 1990): euphoria with mild insomnia. Hyperalert reaction: anxiety can be associated with confusion. Steroid psychosis: can have hypomanic, depressive, and psychotic features with high inter- and intraindividual variability. This reaction is usually seen within 2 weeks of therapy at doses above 40 mg of prednisone per day. The steroid dose should be tapered and symptoms usually subside spontaneously in about 3 weeks.

- *Anaphylaxis*: has been observed after IV methylprednisolone (Freedmann et al., 1981).

- *Ocular toxicity*: glaucoma (Garbe et al., 1997), cataract.

- *Perineal burning sensation* (Baharav et al., 1986).

- *Endocrine effects*: adrenal suppression is seen after 10 days of therapy with doses in excess of 7.5 mg prednisone per day. It is therefore useful to follow some practical suggestions to minimize this effect (Helfer and Rose, 1989). Morning administration matches the physiological zenith of adrenocorticotropic hormone (ACTH) secretion while evening administration favours the inhibition of ACTH secretion. Single administration should be preferred and when possible on alternate days. Before withholding therapy, it is important to check adrenal function (morning cortisol and response to ACTH stimulation).

- *Steroid withdrawal syndrome*: this syndrome can occur with sudden discontinuation of therapy and includes, pseudo-rheumatism, headache, lethargy, nausea, vomiting, postural hypotension, and papilloedema (Dixon and Christy, 1980).

- *Epidural lipomatosis*: this complication can cause slowly developing spinal cord compression (Jalladeau et al., 2000).

- *Pseudo-tumour cerebri*: papilloedema and headache can occur without focal neurological signs and normal CSF. It has been described in patients with Addison's disease and after steroid withdrawal and it has also been reported after chronic steroid use (Walker and Adamkiewicz, 1964).

Treatment

Prophylactic therapy of seizures in palliative medicine usually should not be undertaken if the patient has never had seizures. Although prophylactic anticonvulsant treatment in patients with primary brain tumours or metastases may be considered in selected cases, very few studies have addressed the efficacy of this approach and one randomized clinical trial confirmed that prophylactic treatment did not prevent seizures in patients with brain metastases who had never had seizures (Glantz et al., 1994).

Pharmacological therapy

The ideal anticonvulsant drug for palliative care should have no metabolic interactions, lack significant side effects, and also have parenteral formulations, so few drugs are available. General characteristics of antiepileptic drugs (AEDs) are summarized in Table 14.1.2 together with the recommended dosage. Blood levels of some anticonvulsants should be monitored because of the unpredictability of metabolic changes and drug interactions, but it must be remembered that clinical response and not blood levels should guide dosage.

Table 14.1.2 Main indications and therapeutic dosing schedules of some anticonvulsants used in palliative medicine

Drug	Indication	Therapeutic daily dose	Schedule
Phenobarbital	Broad spectrum	1–5 mg/kg in adults; 3–8 mg/kg in children	Every night at bedtime
Phenytoin	Broad spectrum and status epilepticus	200–400 mg in adults; 4–8 mg/kg children	q8–12 h
Sodium valproate	Broad spectrum and status epilepticus	1000–3000 mg in adults; 30–60 mg/kg in children	q12 h
Levetiracetam	Broad spectrum and status epilepticus	750–3000 mg in adults; 20–60 mg/kg in children	q12 h
Lacosamide	Refractory focal seizures or secondary generalized, and refractory status epilepticus	200–400 mg; 4–12 mg/kg in children	q12–24 h

Phenobarbital is available in oral and parenteral formulations. It is effective in both partial and generalized tonic–clonic seizures. It is metabolized by liver cytochrome P450 and has a very slow plasma clearance (4–5 days), which can be prolonged by liver disease. It has a wide therapeutic index but can cause drowsiness, ataxia, and severe rash (Stevens–Johnson syndrome and the more extensive toxic epidermal necrolysis, Lyell syndrome). It can interfere with the metabolism of several chemotherapy agents and in chronic use is associated with pseudo-rheumatism, which can worsen the symptoms of a concurrent steroid-induced osteoporosis.

Phenytoin is the first-line drug in simple and complex partial seizures, and in generalized tonic–clonic seizures. Dosing can vary from 4 to 8 mg/kg/day in two to three daily administrations, preferably after eating. The IV formulation of phenytoin, or fos-phenytoin, can be systemically loaded and provide rapid control of seizures. The advantages of phenytoin are the relative lack of sedative effects, and good tolerability at higher than recommended doses. Side effects due to chronic use include ataxia, gastrointestinal (GI) disturbances, gingival hypertrophy, hirsutism, osteoporosis, and megaloblastic anaemia. The use of phenytoin also may be problematic due to variation in blood levels produced by the administration of many other drugs that interfere with liver metabolism, absorption, or protein binding. Interactions have been demonstrated with ciclosporin, cis-platinum, and paclitaxel. Significant pharmacokinetic interaction is found with concurrent dexamethasone, which can reduce phenytoin plasma levels by 50%. Severe allergic reactions involving rash, hypersensitivity reactions, liver toxicity, and myelosuppression have been reported, but are rare.

Sodium valproate is active in most types of generalized seizures (tonic, myoclonic, absence, tonic–clonic), including secondary generalized partial seizures. Doses start at 250–500 mg/day and are increased by 250 mg/week up to 1000–3000 mg/day. In children, the initial dose is 10–15 mg/kg/day, increased by the same incremental

doses. Dose escalation can occur more quickly if needed, and an IV formulation is available in some countries, which can allow tolerable loading doses. Common side effects of sodium valproate are tremors, sedation, ataxia, GI symptoms, and thrombocytopenia. Liver enzymes and blood ammonia can be increased. Although severe liver toxicity can occur (usually in the first 6 months of therapy), all reported cases occurred in children under the age of 3 years who also were receiving other anticonvulsants.

Levetiracetam is used for partial and secondary generalized tonic–clonic seizures. The drug is well tolerated, and the most frequent side effects are somnolence, asthenia, and dizziness. The starting dose may be the same as the minimally effective dose of 750–1000 mg/daily, increasing to 40–40 mg/kg in children and 3000 mg in adults.

Lacosamide is approved as adjunctive treatment for focal seizures, with or without secondary generalization, that do not respond to other AEDs. Lacosamide does not affect the plasma concentration of carbamazepine, sodium valproate, clonazepam, and levetiracetam, but its tolerability may be adversely affected by a sodium-blocking AED such as carbamazepine, sodium valproate, lamotrigine, or topiramate. Lacosamide usually does not cause sedation, and cardiac side effects are comparable to those of other AEDs, but dizziness is frequent, especially at high doses. The drug is well absorbed after oral administration and it may be started at dose of 50 mg twice a day, increasing weekly by 100 mg up to a maintenance dose of 200–600 mg/day.

Status epilepticus

Mechanistically, status epilepticus represents the failure of the natural homeostatic seizure-suppressing mechanisms responsible for seizure termination (Engel, 2006). As defined for adults and children older than age 5, status epilepticus is a seizure that lasts 30 minutes or more, or two or more seizures that occur without complete recovery of consciousness in between. Although the definition requires a continuous seizure for 30 minutes, it should be recognized that the likelihood of spontaneous resolution of a seizure becomes small after 5 minutes. For this reason, the treatment used for status epilepticus should be considered whenever a seizure lasts 5 minutes or more.

Clinical characteristics of status epilepticus

Status epilepticus may be classified by the type of seizure (Engel, 2006). The broadest classification distinguishes non-convulsive status epilepticus from convulsive status epilepticus. Non-convulsive status epilepticus can manifest as an absence type and as a partial complex type. The most common convulsive status epilepticus in populations with advanced illness presents as continuous or repeated tonic–clonic seizures. *Non-convulsive status epilepticus* is characterized by EEG seizure activity without convulsive activity. It is a significant cause of impaired consciousness in patients with complex toxic–metabolic encephalopathies, occurring in 8% of comatose patients, according to recent data (Towne et al., 2000).

Partial complex non-convulsive status epilepticus may be particularly challenging to diagnose and treat. Seizure activity may fluctuate and often originates from a temporal cortical area that may not be evident on routine EEG. The syndrome may present as a confusional state with variable clinical findings. It may be continuous or frequently recurrent, or discontinuous, with recurrent

Table 14.1.3 Suggested algorithm for the management of status epilepticus in supportive care patient when cardiorespiratory problems and drug–drug interaction are a concern

Minutes	Treatment
0	Stabilize the patient: ABC, protect Airway—ensure Breathing—maintain the Circulation.
> 5 Additional drug therapy may be not required if seizure stops and the cause of status epilepticus is treated	*Lorazepam* IV, 0.1–0.15 mg/kg in children and 4–8 mg in adult (depending on body weight), at a rate of 2 mg/min; may repeat once after 20 minutes, **or** *midazolam* IV 0.2 mg/kg as bolus, continuous venous infusion of 0.1–0.6 mg/kg/h. Midazolam is well absorbed also IM and SC, and can be given at the same doses when venous access in not feasible; *midazolam* as oral or atomized nasal preparations is also an alternative, at dose of 0.5 mg/kg, 2.5 mg for children, 6–12 months old; 5 mg 1–4 years; 7.5 mg 5–9 years; 10 mg for children 10 years or older, **or** IV *diazepam* 0.15–0.25 mg/kg, at rate of 5 mg/min, until a total of 20 mg in adults; may repeat once after 5min; *rectal diazepam*, 0.5 mg/kg or 2.5 mg for children 6–12 months old; 5 mg for 1–4 years; 7.5 mg 5–9 years; 10 mg for children 10 years, or more. **then** IV *valproic acid* 20–30 mg/kg infused over 15 minutes. However, higher doses, up to 25–60 mg/kg, at 3 mg/kg/min, have been used without serious side effects. This bolus must be followed by continuous infusion of 1–2 mg/kg/h*, **or** IV *levetiracetam*: 20–30 mg/kg in 100 mL of NaCl 0.9% or 5% glucose infused in 30 minutes: then, after 12 hours, the same in two divided doses. **If status epilepticus does not respond, consider** IV *phenytoin* 15 (in the elderly)–20 mg/kg, at infusion rate of no more than 50 mg/min in adults or 1 mg/kg/min in children (monitor for hypotension and electrocardigraphic QT prolongation), in *normal saline*, followed by a dose of 4–8 mg/kg/daily oral or IV. If ineffective, give supplemental IV *phenytoin* 5 mg/kg, which can be repeated up to a total dose of 30 mg/kg. * *In some guidelines, phenytoin is suggested before valproic acid, but a number of papers have documented the successful use of IV valproate in status epilepticus, without serious cardiovascular side effects; fosphenytoin is better tolerated than phenytoin, but is not available in all countries.* **and** *phenobarbital* IV, 20 mg/kg, infusion rate of 60 mg/min; caution with respiratory depression, mostly in patients treated before with benzodiazepines; if ineffective, supplemental IV *phenobarbital* 5–10 mg/kg
> 60: refractory status epilepticus	**First consider:** *Lacosamide: children* 2–2.5 mg/kg infused in 15 minutes then the same dose bid; *adults*: 200–400 mg in 15 minutes, then 200 mg twice a day *Otherwise refractory status epilepticus* to be treated in intensive care unit, where the patient can be treated with general anaesthesia, propofol, pentobarbital, or others drugs (Fernandez and Claassen, 2012)

partial complex seizures and recovery of consciousness between episodes. The duration of a status episode is highly variable and can be as long as weeks. In 40% of cases, the episode is shorter than 24 hours; in another 40%, the episode lasts from 1 to 10 days. The clinical manifestations may take the form of a prolonged delirium, with or without psychotic behaviours and automatisms, or have a more baffling presentation. Some patients have minimal difficulty answering questions but demonstrate affective changes, such as fear, or paranoid ideation.

Convulsive status epilepticus takes the form of continuous or frequently recurrent abnormal motor movements with alteration of consciousness. The risk of cerebral damage and serious complications, including cerebral oedema with increased ICP and acute brain herniations acidosis and rhabdomyolysis, usually demands an emergent approach to management (Chen and Wasterlain, 2006). Treatment has a high rate of success if initiated early, before neuronal injury and time-dependent pharmacoresistence develop. A suggested algorithm for the management of status epilepticus is given in Table 14.1.3.

Lorazepam (Riviello et al., 2013) is considered the drug of choice for the initial emergent management of convulsive status epilepticus. The mean time to clinical effect is 3 minutes. The half-life is 10–15 hours, but effective brain levels are maintained for 8–24 hours. It has no active metabolites. It should be infused IV not faster than 2 mg/min, to reduce the risk of respiratory depression. It is well absorbed also after intramuscular (IM) administration.

Diazepam enters the brain in a few seconds but because of its high lipid solubility, redistribution to all body tissues is rapid, with a consequent fall in brain concentration. Its anticonvulsant effect is therefore very brief and a second dose may be necessary after only 20–30 minutes. Rectal formulations are available. Recommended doses are 10 mg in adults and 5 mg (0.5 mg/kg) in children. Rectal administration at these doses does not cause respiratory depression. After IM administration, absorption is very variable and unpredictable and this route should generally be avoided.

Midazolam is water soluble, has a very short half-life, and has no active metabolites. Its onset of action is 3 minutes after IV administration, and 5 minutes and 15 minutes, respectively, after IM

and oral administration. The good IM absorption is an important advantage in cases of difficult venous access or in pre-hospital setting (Silbergleit et al., 2012). In refractory status epilepticus, the initial dose is 0.2 mg/kg (concomitant use of opioids or recent use of other benzodiazepines involves lower doses, i.e. 0.05 mg/kg) followed by 0.05–0.5 mg/kg/h IV infusion. Higher dose may be used in refractory status epilepticus without significant morbidity.

Sodium valproate is available as a parenteral formulation and provides an alternative to phenytoin. Studies confirm the efficacy and safety of valproate infusion, including infusion at high doses in patients with repetitive seizures. Valproate is relatively contraindicated in cirrhosis or hepatic failure, and liver function should be monitored during therapy. However, fatalities have been reported only in children under 2 years who were concurrently treated with other anticonvulsant drugs.

Levetiracetam: IV levetiracetam seems to be effective and safe in the treatment of acute repeated seizures and status epilepticus in children (McTague et al., 2012). It can be used as first choice or add-on if sodium valproate has been already in use or fails. This drug has no interactions because it has no hepatic metabolism.

Phenytoin when given intravenously, has a relatively rapid onset of action (10–20 minutes). It has no sedative effects, does not cause respiratory depression, and has a long duration of action. It may be used to abort the seizure in benzodiazepine-refractory status epilepticus. In the latter situation, it may be given IV infusion at a rate that should not exceed 50 mg/min. After diluting phenytoin in saline, the solution should be infused within 1 hour. The loading dose usually is 20 mg/kg but could be less, and is 15 mg/kg in elderly patients. A loading dose of 15–20 mg/kg can be also administered orally but poor gastric tolerability limits the use of this route in some patients. Side effects may be related to excessively fast infusion rates, as may occur in emergency situations, and include cardiac arrhythmias, hypotension, and CNS depression. The 'purple glove syndrome' is due to the high pH of the drug (–13), which manifests as blue discolouration and distal oedema near the site of infusion about 2 hours after administration. After the loading dose, the duration of the therapeutic effect is about 24 hours. Blood levels can be checked 120 minutes after the end of the infusion.

IV phenobarbital is an option if benzodiazepines, valproic acid, levetiracetam, or phenytoin fail. The peak clinical effect is delayed for 20–60 minutes after administration.

Lacosamide has been used as add-on treatment in refractory status epilepticus when standard drugs failed, and it was effective and safe (Sutter et al., 2013).

Delirium

Delirium has been defined as a transient organic brain syndrome characterized by the acute onset of disordered attention and cognition, accompanied by disturbances of cognition, psychomotor behaviour, and perception (Caraceni and Grassi, 2011) (see also Chapter 17.5). Delirium is considered to be a single taxonomic entity, and the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (DSM-IV) proposes specific diagnostic criteria for its diagnosis and confirms that delirium is to be considered primarily a disturbance of consciousness (Box 14.1.3) (APA, 2000).

Delirium may be considered to be a stereotyped response of the brain to a spectrum of insults and as a distinctive state on

---

Box 14.1.3 Summary of DSM-IV criteria for diagnosing delirium due to a general medical condition

A. Disturbance of consciousness with reduced ability to focus, sustain, and shift attention.

B. Change in cognition (such as memory deficit, disorientation, language disturbances, or perception disturbances not better explained by a pre-existing stabilized or evolving dementia).

C. The disturbance develops over a short period of time and tends to fluctuate during the course of the day.

D. There is evidence from the history, physical examination, or laboratory findings that the disturbance is caused by the direct physiological consequences of a general medical condition.

---

the continuum between normal wakefulness and stupor and coma (Engel and Romano, 1959). Other terms for this condition include 'encephalopathy' and 'acute confusional state'. The latter descriptions are used commonly by neurologists to describe acute changes in mental status.

Clinical diagnosis

The diagnosis of delirium requires that consciousness and attention are assessed together with cognitive function and performance. The Mini Mental State Examination (MMSE) is the most widely used method and can be applied to bedside patient assessment. It assesses cognitive function but is not a diagnostic tool. It screens for cognitive failure and can be abnormal in dementia as well as in delirium, or in other disorders that affect cognitive performance.

In contrast to the MMSE, the Confusion Assessment Method is a diagnostic system that can be used to apply the DSM criteria for the diagnosis of delirium. It is very sensitive and specific when applied by trained personnel (Inouye et al., 1990). More recently the Nursing Delirium Screening Scale (NUDESC) has been proposed as a useful instrument for screening delirium cases to be used by nurses; its role in palliative care still needs to be elucidated fully (Gaudreau et al., 2005).

The Delirium Rating Scale (DRS) (Trzepacz et al., 2001) and the Memorial Delirium Assessment Scale (MDAS) (Breitbart et al., 1997) are instruments specifically designed to assess delirium and its severity. These tools can be used to evaluate a range of symptoms that occur in patients with delirium.

Subtle changes frequently precede the onset of delirium. These minor symptoms and behavioural changes may go unnoticed, only to be recalled later in family or staff interviews. A patient who becomes restless, anxious, depressed, irritable, angry, or emotionally labile may be manifesting these premonitory symptoms of delirium. The differential diagnosis is complex, however, and includes adjustment disorder and any of a large number of neurological conditions, including dementia.

The first of the DSM-IV diagnostic criteria for delirium relates to disturbance of consciousness and impaired attention. This disturbance can be highly variable, characterized by increased or decreased arousal, or merely by distractibility and reduced responsiveness. Three clinical variants of delirium have been described based on the type of arousal disturbance: hypoalert–hypoactive, hyperalert–hyperactive, and mixed type (with fluctuations from hypoalert to hyperalert) (Liptzin and Levkoff, 1992; Caraceni and Grassi, 2011).

Attention is affected also by specific changes in the patient's ability to concentrate, which can be subtle. Attention disturbances may be evidenced by an inability to maintain a conversation or to attend to its flow, language abnormalities, and difficulties in writing (Wallesch and Hundsaltz, 1994).

The second DSM criterion for delirium relates to the presence of changed cognition. This may take the form of disorientation, memory deficits, or disturbances of language, reasoning, or perception. It is important to recognize that a diagnosis of delirium may be established in the presence of any one of these cognitive abnormalities.

Language abnormalities are frequent in delirium and are often compounded by the presence of incoherent reasoning. Language may lack fluency and spontaneity, and conversation may be prolonged and interrupted by long pauses or repetitions. Writing abilities are affected early and more severely than other language-related skills (Chédru and Geschwind, 1972; Macleod and Whitehead, 1997). Delirium affects reasoning and patients frequently demonstrate irrelevant or rambling thinking, abnormal conceptualization, and altered insight.

Perceptual abnormalities (hallucinations and illusions) and delusions, but also may be typical of delirium, especially in some subtypes such as delirium tremens or other types of hyperactive delirium. These disturbances in perception are systematically assessed in the DRS and the MDAS.

Delusions may be associated with hallucinations. These delusions are frequently poorly organized and characterized by paranoid features (Wolf and Curran, 1935; Lipowski, 1990).

Delirium can interfere significantly with family and staff understanding of patient's suffering. A small study of 14 patients with cancer pain and severe cognitive failure found that during episodes of agitated cognitive failure, pain intensity, as assessed by a nurse, was significantly higher than the patient's assessment had been before and after the episode (Bruera et al., 1992). Upon complete recovery, none of these patients recalled having had any discomfort during the episode.

The third and fourth criteria for diagnosis of delirium relates to the time course and organic aetiology of the disturbance. For diagnosis, there must be evidence confirming that the disturbance has developed over a short period of time and tends to fluctuate during the course of the day. Fluctuation in the clinical manifestations of delirium is usually apparent in disturbance of the sleep–wake cycle. The phenomenon known as 'sundowning' refers to the worsening of symptoms toward evening and probably has to do with sleep–wake abnormalities that are aggravated by environmental factors. The organic aetiology will be discussed below.

In addition to mental status changes, neurological examination of the patient with delirium may identify findings associated with diffuse brain dysfunction, such as multifocal myoclonus and asterixis. Some findings may be relatively specific for one or more aetiologies. For example, tremulousness is typical of alcohol withdrawal states; miosis and mydriasis suggest opioid toxicity and anticholinergic toxicity, respectively; and tachypnoea may be a manifestation of a central process, or of sepsis or hypoxaemia.

Frequency

Prevalence of delirium ranges from 20–30% of patients when admitted to palliative care services to 60–80% of those in the last days of life (Caraceni et al., 2000; Hosie et al., 2013), figures are higher than in the hospitalized elderly population (Francis et al., 1990). Altered mental state is the second most common reason for neurological consultation at a tertiary cancer centre (Clouston et al., 1992; Ljubisavljevic and Kelly, 2003).

In a study by Gagnon et al., 20% of 89 consecutively hospitalized cancer patients were delirious on admission and, among the others, 32% developed delirium subsequently (Gagnon et al., 2000). In a sample of 104 patients admitted to an acute palliative care unit, Lawlor et al. diagnosed delirium in 44 patients (42%), and of the remaining 60, delirium developed in 45% (Lawlor et al., 2000). Reversal of delirium occurred in 46 (49%) of 94 episodes in 71 patients and terminal delirium occurred in 46 (88%) of the 52 deaths (Lawlor et al., 2000). Reversibility of delirium was observed in 27% of episodes occurring during hospice admission (Leonard et al., 2008).

Aetiological factors in delirium and multifactorial risk model

Risk factors

Disease-related and sociodemographic factors that may predispose to delirium or predict its occurrence have not been well documented in cancer patients. In one study, dyspnoea, anorexia, presence of brain metastases, performance status, and physician estimated prediction of survival were associated with the diagnosis of delirium but only univariate statistics were applied (Johnson et al., 1992).

Inouye and colleagues have proposed a multifactorial model for delirium in the hospitalized elderly (Inouye et al., 1999). The model involves the interaction between 'baseline vulnerability' and 'precipitating factors. In this model, baseline vulnerability is defined by the predisposing factors at the time of admission to hospital, and the precipitating factors are the noxious events that occurred during hospitalization. The factors that Inouye et al. specifically demonstrated to be contributory to baseline vulnerability in the elderly include visual impairment, severity of illness, cognitive impairment, and an elevated serum urea nitrogen/creatinine ratio of 18 or greater (dehydration) (Inouye et al., 1999). Other studies have implicated risk factors, including, age, dementia, depression, alcohol abuse, the preoperative use of anticholinergic drugs, poor functional status, and markedly abnormal preoperative serum sodium, potassium, or glucose levels (Schor et al., 1992; Gaudreau et al., 2005). Among medications, neuroleptics, opioids, and anticholinergic drugs (Schor et al., 1992; Caraceni et al., 2000, 2011; Gaudreau et al., 2005) have also been implicated as risk factors for delirium.

Aetiology

In cancer patients, the potential aetiologies of delirium, as distinct from 'risk factors', may be divided into direct effects related to tumour involvement and indirect effects. The latter category includes drugs, electrolyte imbalance, cranial irradiation,

Box 14.1.4 Aetiological factors implicated in the onset of delirium in patients with cancer

- Primary CNS tumour
- Secondary CNS tumour:
  - brain metastases
  - meningeal metastases
- Non-metastatic complications of cancer:
  - metabolic encephalopathy due to hepatic, renal, or pulmonary failure
  - electrolyte abnormalities
  - glucose abnormalities
  - infections
  - haematological abnormalities
  - nutritional deficiency (thiamine, folic acid, vitamin B_{12} deficiency)
  - vasculitis
  - paraneoplastic neurological syndromes
- Toxicity of antineoplastic therapies
- Chemotherapy and biological therapies: methotrexate, cis-platin, vincristine, procarbazine, asparaginase, citosina arabinoside, 5-fluorouracil, ifosfamide, tamoxifene (rare), etoposide (high doses), nitrosurea (high doses or arterial route), bevacizumab, rituximab
- Radiation to brain: acute and delayed encephalopathy
- Toxicity of other drugs
- Anticholinergics: belladonna alkaloids, scopolamine, atropine, hyoscine
  - drugs with established anticholinergic activity: tricyclic antidepressants, diphenhydramine, promethazine, triesifenidile, chlorpromazine, and other neuroleptics: hyoscine butylbromide
  - anxiolytics, hypnotics
  - steroids, opioids, digitalis, ciprofloxacin, aciclovir, ganciclovir, NSAIDs, anticonvulsants, H_2 blockers, omeprazole, interferons, interleukins, ciclosporin, levodopa, lithium
- Other diseases not related to neoplasms:
  - CNS diseases or trauma
  - cardiac disease
  - lung disease
  - endocrine pathology
  - alcohol or drug abuse or withdrawal.

organ failure, nutritional deficiencies, vascular complications, paraneoplastic syndromes, and many other factors (Box 14.1.4).

A survey of 140 confused cancer patients referred for a neurology consultation demonstrated a single cause of the altered mental status in 31% and multiple causes in 69%; the median number of probable contributing factors in each patient was three (Tuma and DeAngelis, 2000). Drugs, especially opioids, were associated with altered mental status in 64% of patients, metabolic abnormalities in 53%, infection in 46%, and recent surgery in 32%. A structural brain lesion was the sole cause of encephalopathy in 15% of patients. Two-thirds of the patients in this survey recovered cognitive function when the cause of the delirium was treated.

In the study by Lawlor and colleagues of 104 patients with advanced cancer admitted to a palliative care unit (Lawlor et al., 2000), the median number of precipitating factors was three, and 49% of patients had delirium that was reversible. Although the use of psychoactive medications, predominantly opioids, was the precipitating factor that was independently associated with reversibility of the delirium, the authors concluded that more than one factor (e.g. opioid medication and dehydration) usually requires attention if the delirium is to be reversed (Lawlor et al., 2000). In the study by Gaudreau et al. (2005) the use of opioids at doses of 90 mg of daily oral morphine or more was associated independently at multivariate analysis with the risk of delirium. Other studies have demonstrated that drug interactions with opioid metabolism and metabolic failure (especially renal impairment) can produce unexpected toxicities, especially in the patient with advanced disease (Fainsinger et al., 1993; Bortolussi et al., 1994; Caraceni and Grassi, 2011).

Cognitive compromise is probably one of the most common presenting symptoms or signs of brain (Posner, 1995) and leptomeningeal metastases (Weitzener et al., 1995). Non-convulsive epileptic status, which can occur in association with complex metabolic problems and also with ifosfamide encephalopathy, is a condition that also can result in altered consciousness manifesting with delirium (Towne et al., 2000).

In reviewing the causes of delirium, it is important to recognize that many are common and potentially reversible in the population with advance illness. These factors include, among others, dehydration, borderline renal function, infections, metabolic disturbances, drug withdrawal, and the use of psychoactive medications such as opioids (Tuma and DeAngelis, 2000; Gaudreau et al., 2005; Leonard et al., 2008; Caraceni et al., 2011).

General assessment recommendations

Clinical assessment should include careful physical and neurological examination. Specific mental status assessment can follow the above-mentioned recommendations and can be helped by the systematic use of the NuDESC MMSE, DRS, MDAS, or CAM (Inouye et al., 1990; Breitbart et al., 1997; Trzepacz et al., 2001; Gaudreau et al., 2005). Aetiological screening should involve a rational and stepwise implementation of procedures (Table 14.1.4). The completeness of the list is not incompatible with a policy of avoiding procedures which are considered inappropriate for the individual patient.

Treatment

Symptomatic management often is required both in reversible and irreversible cases, and is based on non-pharmacological and pharmacological therapies.

Environmental interventions

In a classic study by Inouye et al., systematic reorientation and a risk-modifying protocol reduced the incidence of delirium among

Table 14.1.4 Screening process for delirium aetiology in advanced cancer

Toxic factors	Bedside screen of medication profile
	Urine or blood drug screening
Sepsis	Temperature
	Blood/urine and other cultures for infection screen
	Leucocyte count
	Urinalysis
	Red cell count
Glucose-oxidative brain deficiency	Pulse oximetry
	Blood gases and acid–base balance
	Blood glucose
Electrolyte imbalances	Serum electrolytes (Na, K, Cl, Mg, Ca)
Renal failure	Urea, creatinine, creatinine clearance
Liver failure	Liver function tests
	Ammonia
CNS vascular, infectious or structural lesion	Disseminated intravascular coagulation screening and coagulation profile
	CSF examination: blood, glucose, proteins, lymphocytes, leucocytes, malignant cells, culture
	Brain CT or MRI
Paraneoplastic disease	Autoantibodies anti-Hu, Yo, Ma, etc.
Cofactor deficiency malnutrition	Vitamin B_{12} levels—administer Vitamin B_1 1 g/day[a]
Endocrine dysfunction	Thyroid hormone and thyroid-stimulating hormone
	Adrenal function

[a] Because the determination of vitamin B_1 levels is problematic, it is reasonable to supplement vitamin B_1 in every patient with poor nutritional status.

elderly hospitalized patients (Inouye et al., 1999). A calm, quiet environment, with good light, is important to allow for potential recovery and to help the patient to reorientate to time and space. The process may be further assisted by placing a clock or calendar where the patient can see them, and by permitting the patient to see or touch a well-known object from the patient's house. Presence in the room of family members can be advantageous.

Communication with patient and family

In managing the delirious patient, a close collaboration between staff and family is fundamental. Special attention needs to be focused on communication. Family members may be particularly stressed by observing the change of the patient's usual behaviour and by a new barrier to communication. The family must be informed about the characteristics of delirium, including fluctuation of cognitive function, its relationship with the disease conditions, potential for reversibility, role of therapies, and short-term prognosis.

Family members may require special care as they react to what they interpret as the patient's suffering or pain. The behaviour of families, particularly those strained by the burden of caregiving,

can swing from requests to withdraw medication to advocating sedation; caregiver distress may be compounded by personal problems in facing suffering and death (Buss et al., 2007; Morita et al., 2007; Caracenie and Grassi, 2011).

It is very important to clarify the potential aetiological role of existing therapies. For example, it is customary to blame opioid medications for mental changes that are actually caused by the complex interaction of several factors.

In communicating with the patient, the clinician should show empathy and to ask simple questions ('Do you feel confused?'). The patient may be fearful and should be reassured. As needed, logic and rational communication should be supplanted by more direct non-verbal communication. The patient should be encouraged to communicate with well-known family members, and this communication should focus more on affective aspects than on discussions that could confuse or frighten the delirious patient.

Pharmacological therapy

Agitated delirium often requires pharmacological treatment to control behaviours that could result in harm for the patient and others, and to treat hallucinations or delusions that may be contributing to patient suffering. The treatment of hypoactive deliria is more debatable and will depend on individual clinical judgement.

The usual first-choice drug for agitated delirium is haloperidol (Canadian Coalition for Seniors' Mental Health, 2006; Campbell et al., 2009), since it has relatively low sedating potency and fewer anticholinergic and cardiovascular effects than other neuroleptics. Table 14.1.5 gives guidelines for the use of haloperidol and alternative drugs.

Haloperidol has been used via IV infusion, although it is not licensed for this route of administration (Canadian Coalition for Seniors' Mental Health, 2006). Very high IV doses have been safely administered. Therapeutic effects in hyperactive delirium typically are seen at doses of 6–12 mg/day; difficult cases may require higher doses or sedation with other drugs. Careful titration of the dose at the bedside is the most important recommendation to improve outcome. ECG monitoring should be considered before and during haloperidol therapy to monitor possible prolongation of the Q–T interval that can occasionally occur with most neuroleptics; torsade de pointe has been described as a rare complication of haloperidol administration via the IV and oral routes (Jackson et al., 1997).

Alternative neuroleptics can be used if greater sedation is desired or haloperidol is contraindicated. Droperidol and chlorpromazine are relatively sedating, and recently, risperidone, clozapine, quetiapine, ziprasidone, and olanzapine have been used (Caraceni and Grassi, 2011). Benzodiazepines are first-choice agents in the treatment of delirium related to alcohol or other sedative-hypnotic withdrawal. They also can be added in cases of delirium when anxiolytic and sedative effects are considered particularly desirable or in cases unresponsive to neuroleptic medications. They should be used cautiously, however, because they can worsen delirium, especially in the elderly (Campbell et al., 2009), they should not be used in hepatic encephalopathy.

In the management of delirium in the setting of advanced illness, more than one drug may be needed. In one case series of 39 patients, only 20% could be managed by haloperidol alone (Stiefel et al., 1992). When sedation is necessary to control symptoms, the combination of an opioid with a neuroleptic and an antihistamine

Table 14.1.5 Pharmacological therapy of delirium (regimens suggested for general guidance; each case will need specific dose adjustment)

Haloperidol; oral	0.5–5 mg every 8–12 h; a dose of 2 mg/day can be efficacious in mild cases
Haloperidol; SC, IM, or IV	0.5–2 mg per dose titrating dose to clinical effect hourly IV infusion 0.2–1 mg/h with careful titration to clinical effect can be used in difficult cases. ECG monitoring is recommended
Chlorpromazine; oral, IM, or IV	12.5–50 mg every 8–12 h. More sedating, anticholinergic, and hypotensive effects; ECG monitoring is mandatory
Clozapine; oral	12.5–50 mg at night (monitoring of blood cell count is needed) very sedative, has less extrapyramidal effects than other neuroleptics
Risperidone; oral	From 0.5–1 mg/day up to 2–4 mg/day. It has extrapyramidal effects
Olanzapine; OS IM	5 mg every night at bedtime to be titrated up to clinical effect
Quetiapine; OS	25 mg every 12 h More sedating, orthostatic hypotension, to be titrated to effect, useful in mild cases with insomnia
Lorazepam; oral, SL, or IV	0.5–2 mg every 6–8 h if sedating anxiolytic effects required
Midazolam; SC or IV	20–100 mg 24 h IV or SC continuous infusion for sedation in refractory cases. 3–5 mg IV priming dose if rapid sedation is required. Start IV infusion with 1 mg/h, dose should be frequently titrated to effect
Promethazine; IM or IV	50 mg every 8–12 h; antihistamine more sedative; useful if sedation desired and for night-time sleep

Table 14.1.6 Cancer-related and treatment related neurological diagnoses in 851 patients with cancer

Diagnosis	Percentage
Brain metastasis	15.9
Metabolic or drug-related encephalopathy	10.2
Pain associated with bone metastasis	9.9
Epidural tumour	8.5
Tumour plexopathy	5.8
Leptomeningeal metastasis	5.1
Chemotherapy peripheral neuropathy	3.2
Radiculopathy	2.7
Base-of-skull metastasis	2.7
Seizures due to metastasis	2.7
Seizures not due to metastasis	1.8
Paraneoplastic syndromes	1.2
Intracranial haemorrhage related to thrombocytopenia	1.3
Radiation myelopathy	1.2
Radiation plexopathy	1.1
Intracranial haemorrhage from tumour	0.6

A total of 1042 diagnoses were given with up to three per patient. Among the non-cancer-related diagnoses, cerebrovascular disease, headache, and degenerative spine disease were the most common diagnoses.

Source: Data from Clouston, P.D. et al., The spectrum of neurological disease in patients with systemic cancer, Annals of Neurology, Volume 31, Issue 3, pp. 268–73, Copyright © 1992.

such as promethazine can be particularly effective. Alpha 2 agonists (clonidine or dexmedetomidine) can be useful to obtain controlled sedation; they can be used in combination with neuroleptics and opioids and do not have respiratory depressant effects. Their use in palliative care is still based on personal experience (Alfonso and Reis, 2012).

Other neurological complications of cancer

Neurological complications are estimated to occur in up to 20% of patients with cancer. In a large consultation survey conducted at a comprehensive cancer centre, the most frequent complaints were pain and altered mental status (Table 14.1.6) (Ljubisavljevic and Kelly, 2003).

Brain metastases

Pathology

Intracranial metastases are found at autopsy in about 25% of patients who died of cancer (Posner, 1995). Other common intracranial lesions involve the skull and meninges. There is evidence that the incidence of brain metastases and leptomeningeal metastases is increasing, because of better control of systemic disease and longer survival, which allow 'sanctuary' cells in the CNS to evolve into clinically significant lesions. Lung cancer, melanoma,

and breast cancer are the primary tumours most frequently associated with metastatic spread to the brain parenchyma. Tumours such as melanoma usually cause multiple lesions, while breast cancer more often causes single lesions (some 50% of breast cancer patients have a single lesion and 20% two lesions). Brain metastases can cause symptoms by compression, local destruction, irritation of brain tissue, brain oedema, and bleeding. The most common effect of a metastatic lesion is brain oedema and increased ICP. Focal symptoms can be due to oedema or bleeding. As discussed previously, typical presentations include cognitive failure, focal signs, seizures, and the syndrome of intracranial hypertension.

Clinical course

After clinical presentation of a brain metastasis, the median survival is about 2 months if no treatment is given, depending on tumour type (Posner, 1995). Patients who have access to brain radiotherapy and respond favourably to this modality usually die of their systemic disease. Patients who do not receive radiotherapy or do not respond often die of direct effects of the brain metastasis (Boogerd et al., 1993).

The signs and symptoms of brain metastases are highly variable. Symptoms can present progressively and deceptively, or alternatively, can be sudden, and 'stroke-like'. It should be remembered that in many patients formal neurological tests of strength and mental function will reveal signs of changes in the CNS that are not otherwise apparent (Posner, 1995).

Headache is an important symptom of brain metastasis. The headache usually is aching in quality and moderate to severe in intensity. It is caused by compression or traction of intracranial pain-sensitive structures. With supratentorial lesions, it is often bifrontal, although it can occur on one side—always that of the tumour.

Headache occurs more frequently during the night and in early morning, and is more severe with infratentorial lesions that affect CSF circulation, causing hydrocephalus and increased ICP.

Treatment

The treatment of a brain metastasis requires a careful assessment of the type of cancer and its sensitivity to radiation and chemotherapy, the neurological status of the patient, the extent of systemic disease, symptoms, and other complications and comorbidities, expectations concerning quality of life with and without treatment, and both the goals of care expressed at the time of diagnosis and the broader values of the patient. It should be understood that the provision of supportive treatment only is among the therapeutic options available.

Surgery is indicated only for single metastases with limited or no systemic disease, especially with radio-resistant tumours (Kaal et al., 2005). Whole-brain irradiation produces neurological improvement in the majority of patients but survival after treatment is only 4–6 months. Metastases from breast and lung cancers usually have a relatively good response to radiotherapy, showing both clinical and radiological improvement. Clinical improvement in the absence of radiological improvement is relatively common during treatment of metastases from melanoma, colon cancer, or renal cancer.

Newer techniques for focal radiation may be of benefit. Focal brain irradiation or 'radiosurgery' can have a role in treating single, or occasionally two, brain metastases, sometimes in combination with whole brain irradiation. The aim of this strategy is eradication of disease from the brain and radiosurgery is used as a substitute for surgery in this context (Kaal et al., 2005).

Corticosteroids

Treatment with steroids is recommended for all symptomatic patients with brain metastases or primary brain tumour. The main therapeutic effect is probably related to a reduction in peri-tumoral oedema from partial restoration of the blood–brain barrier. Steroids are also recommended for all patients undergoing brain irradiation. Treatment should start 48 hours before radiation. A regimen of dexamethasone 8–16 mg/day in one single administration, which is tapered beginning the 2nd week of radiation is recommended. Tapering should be gradual (2–4 mg every 5th day).

Higher steroid doses can be given acutely if symptoms recur (e.g. restarting 16 mg/day) or if there are signs of increased ICP or cerebral herniation (e.g. 16–100 mg IV once, followed again by tapering). If a steroid cannot be discontinued, the dose should be tapered to the minimum required for symptom control. Dexamethasone taper and discontinuation should always be attempted after completion of radiation treatment, since in most patients steroids are not necessary to preserve neurological function.

Spinal cord compression

Pathology

Most cases of epidural spinal cord compression in populations with cancer are caused by a vertebral body metastasis invading the epidural space posteriorly and compressing the spinal cord or cauda equina. Invasion of the epidural space through the intervertebral foramina by a paraspinal lesion also can occur, and is relatively more likely in lymphoma and neuroblastoma; the absence of a bony lesion on radiography in these cases can lead to misdiagnosis. Very rarely, spinal cord syndromes are due to epidural or cord metastases.

Spinal cord, including conus medullaris, and cauda equina lesions have similar aetiologies, mechanisms, and clinical implications, and are therefore usually considered together.

Clinical course

Epidural spinal cord compression is a frequent problem in patients with cancer, occurring in 25% of patients with lung cancer, 16% with prostate cancer and 11% of patients with myeloma. It is a neurological emergency, as functional outcome is dependent on the degree of neurological impairment at diagnosis, the promptitude of therapy and the initial response to therapy. Other factors important in prognosis are tumour histology and rate of progression of the neurological symptoms. The importance of early diagnosis cannot be overemphasized; symptoms are usually present for some weeks before the neurological emergency occurs. Pain precedes other neurological symptoms in almost every case, but diagnosis is often delayed until the onset of neurological symptoms and signs.

Pain of long duration, which suddenly changes its characteristics, should prompt re-evaluation and spinal imaging. Pain in a crescendo pattern is particularly worrying, as are pain aggravated by lying down, pain associated with the Valsalva manoeuvre, and radicular pain (pain occurring or radiating in a dermatomal distribution).

Other clinical features, are impaired deambulation for lower limb paralysis, ataxia or sensory loss, and altered function of bladder, and less frequently, bowel.

The occurrence of a Lhermitte's sign also should raise concern about the possibility of tumour compression of the spinal cord. A Lhermitte's sign, also described as 'barber's chair sign' in the British literature, is a shock-like sensation passing down the trunk and one or more extremities when the neck is flexed. It also may occur spontaneously or be precipitated by sudden limb movements, or by coughing or sneezing. It is due to demyelination or compression of the posterior column of the spinal cord in the cervical or upper thoracic regions. Lhermitte's sign is frequent in multiple sclerosis, but it is not uncommon in cancer-related spinal cord dysfunction. In the cancer population, the differential diagnosis ranges from relatively benign conditions such as transient radiation myelopathy and cisplatin injury, to severe complications such as cord compression and progressive radiation myelopathy (Ventafridda et al., 1991).

Diagnosis

Neurological examination discloses signs related to the location of the compressive lesion. If the spinal cord is involved (typically with lesions at or above, the T12–L1 spinal level), signs are consistent with myelopathy and usually begin with paraesthesiae, or sensory loss in the feet, which ascends as the compression worsens. Weakness of hip flexors, and then other lower extremity muscles, also occurs. The sensory signs are helpful in defining the level of the compression (Table 14.1.7) (Hellmann et al., 2013). If the lesion is at the T12–L1 level, a conus medullaris syndrome may be the presenting phenomenology, with early loss of sphincter control and 'saddle'

Table 14.1.7 Localizing signs with spinal cord lesions

Sign	Clinical level		
	Cord	**Conus and epiconus medullaris**	**Cauda equina**
Motor	Paraparesis usually flaccid	If epiconus involved L5–S3 weakness	Never pyramidal signs
	Pyramidal signs can be present	If conus S2–S3 weakness	Often asymmetrical weakness
Reflexes	Absent or hyperactive	Patellar hyperactive	Hypoactive
		Ankle hypoactive	Asymmetrical
Babinski sign	Usually present	Present only if lesion of epiconus	Never present
Sensory	Symmetrical level of dermatomal level sensory loss (locates compression within two dermatomes, or more, above the sensory level)	If conus S2–S5 'saddle' sensory loss If epiconus L4–S5	Asymmetrical findings in the lower extremities and perineum
Sphincter control	Can be initially preserved	Early involved sometimes selectively	Can be preserved

sensory symptoms or signs. A more caudal lesion causes a cauda equine syndrome, which is usually prominently asymmetric, with weakness or sensory changes affecting one leg more than another.

Emergency imaging of the spinal cord and canal should be carried out in patients with cancer and back pain who have symptoms of myelopathy (including conus medullaris) or cauda equine syndrome.

Ideally, this should be done when the characteristic back pain is noted and before significant neurological signs ensue (Portenoy et al., 1989).

Figure 14.1.1 summarizes the clinical and radiological findings that should prompt either immediate treatment or spinal cord imaging with magnetic resonance imaging (MRI), the results of which will dictate the treatment modality (Hellmann et al., 2013). Although MRI is the best imaging procedure in these patients, myelography or computed tomography (CT) still has a place when MRI is unavailable. There may be multiple lesions and the whole spine should be evaluated.

Treatment

If the goals of care support aggressive treatment of epidural spinal cord or cauda equine compression, corticosteroids and radiation should be offered (Ingham et al., 1993; Spinazzé et al., 2005) (see also Chapter 12.3). Steroids can reduce pain, preserve neurological function, and improve functional outcome after definitive treatment (Sorensen, et al., 1994). Dexamethasone in high doses is recommended for high-degree lesions, as shown by severe or rapidly progressing neurological abnormalities, or by MRI evidence of a severe lesion). A low-dose regimen should be used for low-degree lesions, as suggested by stable or slowly progressing neurological findings, or by MRI or myelography. One high-dose regimen included an initial IV bolus of 100 mg followed by a tapering schedule of 96 mg orally for 3 days and subsequent halving of the dose every 3rd day until the end of radiation treatment (Spinazzé et al., 1994; Posner, 1995). The use of such high doses for severe epidural spinal cord compression has been questioned (Vecht et al., 1989), and lower doses between 16 and 32 mg are often clinically used. If surgery is considered, posterior laminectomy alone is now seldom if at all indicated (Findlay, 1984). A more rational surgical approach for anteriorly compressing lesions is vertebral body resection (Harrington, 1988), but the procedure requires intact vertebral elements above and below the affected level to stabilize the spine after surgery. Surgery is the first choice where the site of the primary tumour is unknown, where there is relapse after radiation treatment, and in cases of spinal instability or vertebral
Fig. 14.1.1 Algorithm for the evaluation of back pain in the patient with cancer.

displacement. It should also be considered when neurological symptoms progress during radiotherapy, in plegia of rapid onset, and when the tumour is not likely to be radiosensitive.

Some series showed impressive results with vertebral resection. In one series, 13 of 36 paraplegic patients regained ambulation (Harrington, 1988). One controlled clinical trial suggests that surgery can be the first choice for selected patients with better prognoses (Patchell et al., 2005). Careful individual indication is key, prognosis and expected quality of life should influence the decision.

Leptomeningeal metastases

Pathology

Leptomeningeal metastases (also known as carcinomatous meningitis or meningeal carcinomatosis) are caused by the dissemination of cancerous cells throughout the subarachnoid space. These cells can reach the meninges through the general circulation or the perineural spaces along nerve roots, by direct invasion from epidural lesions, or by direct seeding from existing brain tumours (Chamberlain, 2006). Meningeal involvement can be multifocal or diffuse, and either visible on imaging as discrete masses or not visible on imaging because of microscopic infiltration.

Clinical course

Leptomeningeal metastases were once considered an unusual complication of systemic cancer (1–8% of cases at autopsy) (Posner, 1995) but these are increasingly seen nowadays, usually as a result of breast or lung cancer, lymphoma, leukaemia, or melanoma. Life expectancy is usually short, ranging from 3 to 6 months in patients who have received intensive treatment. Many patients are not offered treatment and their survival is shorter (Posner, 1995; Chamberlain, 2006).

The clinical findings associated with leptomeningeal disease may relate to CNS or peripheral nervous system dysfunction, or some combination. The clinical syndromes are highly variable. The pathophysiology includes abnormality in the flow and absorption of CSF (which can result in hydrocephalus), direct involvement of the cranial and peripheral nerve meningeal sheets, competition with brain metabolism, invasion of the brain parenchyma or nerve roots, and areas of focal ischaemia.

The most common symptoms are headache, change in mental status, and radicular-type pain (Posner, 1995; Formaglio and Caraceni, 1998; Chamberlain, 2006), but cranial nerve involvement, seizures, polyradiculopathy, and cauda equina syndrome also occur in varying combinations. Multiple symptoms, from involvement of different levels of the neuraxis, are often seen.

Diagnosis

Diagnosis is usually confirmed from examination of the CSF (Chamberlain, 2006). While malignant cells may not be apparent in the first sample of CSF, other abnormalities are usually found, such as high opening pressure, high protein content, increased white cell count, or low glucose content. In one series, only 3% of the first samples were completely normal (Chamberlain, 2006). Other markers and immunocytochemical techniques have not been found to have clinical value (Chamberlain, 2006). Repeated lumbar punctures often are

Fig. 14.1.2 MRI, gadolinium enhanced. The white enhancement of the meningeal sheath around the cauda equina (left side, arrow) and the thecal sac (right side arrow) due to meningeal infiltration.

needed to establish the diagnosis. Contrast-enhanced MRI also can be useful (Formaglio and Caraceni, 1998) (Fig. 14.1.2), as the only sign of leptomeningeal metastases may be slight enhancement of the meninges due to blood–brain barrier disruption or focal enlargement of roots.

Therapy

Traditionally, treatment modalities have been based on a combination of corticosteroids, radiotherapy, and intrathecal or intraventricular chemotherapy. Systemic chemotherapy may also be helpful in some cases with appropriate tumour histology. In one series, only 23% of treated patients could be regarded as long-term survivors. Intrathecal chemotherapy did not achieve better results than systemic chemotherapy (median survival 23 months) (Siegal et al., 1994; Chamberlain, 2006), and caused a treatment-related leucoencephalopathy in 58% of cases. The role of intrathecal chemotherapy is questionable particularly in solid tumours.

Base of the skull and cranial nerve syndromes

Lesions at the base of the skull are commonly caused by metastasis from breast, prostate, and other tumours (Greenberg et al., 1981) or from local invasion by advanced head and neck tumours (Vecht et al., 1992) (see Chapter 13.1). Symptoms secondary to bone lesions are commonly associated with alterations of cranial nerve function. Headache at the site of the lesion or referred to the vertex or to the entire affected side of the head is also frequent (Greenberg, 1981; Posner, 1995). The best imaging procedure for all these syndromes is CT scan with bone window studies. Treatment with radiation is indicated, to control pain and neurological dysfunction. Any combination of pain related to the involvement of the cranial and facial bone and of the trigeminal nerve associated with other cranial nerve dysfunction should receive careful clinical evaluation (Foley, 1979; Greenberg et al., 1981; Weinstein et al., 1986; Vecht et al., 1992).

Trigeminal nerve and the 'numb-chin syndrome'

The most common presentation is a constant dull, well-localized pain related to the underlying disease of bone and other somatic

structures. This pain may be associated with paroxysmal episodes of lancinating or throbbing pain. The quality of the pain only rarely can mimic classical trigeminal neuralgia, an atypical facial pain is more common (Cheng et al., 1993). Atypical trigeminal pain and sensory abnormalities in the peripheral distribution of the V nerve, occasionally associated with incomplete lesions of the VII nerve, have been reported with different facial neoplasms (Cheng et al., 1993).

Involvement of the mental nerve does not usually produce pain but can cause the 'numb chin syndrome' of mental anaesthesia. This is a sign of disease of the jaw or, more frequently, of the base of the skull, leptomeninges carcinomatosis, and local perineural spread of lip carcinoma. The symptom can occur months before the discovery of a bony lesion (Burt et al., 1992).

Glossopharyngeal nerve

The typical patient has throat and neck pain, which radiates to the ear and is aggravated by swallowing. Pharyngeal and other carcinomas of the neck can present with odynophagia with reflex otalgia. Severe pain may be associated with syncope (Weinstein et al., 1986). Although it has been described with leptomeningeal disease, it commonly results from local nerve infiltration in the neck or base of the skull.

Radiculopathy

Radiculopathy is usually caused by the compression of nerve roots by vertebral, paraspinal lesions, or by leptomeningeal metastases. The pain of a root lesion is usually focal and radiates in the distribution of the affected root. It is sometimes difficult to distinguish a polyradiculopathy from a plexus lesion; CT and MRI are useful for imaging non-bony paraspinal lesions. MRI is necessary for imaging the epidural space.

Herpes zoster and post-herpetic neuralgia are common in patients with cancer and should always be considered in the differential diagnosis of painful radiculopathies.

Cervical plexopathy

Infiltration of the cervical plexus by tumour can be a result of compression by head and neck neoplasms or metastases to cervical nodes. Symptoms usually include local lancinating or dysaesthetic pain referred to the retro-auricular and nuchal areas, the shoulder, and the jaw. Sensory abnormalities define the affected (greater auricular and greater occipital) nerves (Vecht et al., 1992). The differential diagnosis should include post-radical neck dissection syndrome. The diagnosis in patients with head and neck cancer may be difficult because of the postoperative and post-radiation changes often found in these patients. CT or MRI scan is appropriate, and imaging of the cervical spine and paraspinal structures is very important in distinguishing between bony lesions, cervical radiculopathy, and epidural spinal cord compression.

Brachial plexopathy

Five per cent of the neurological consultations at a comprehensive cancer centre were found to be initiated by brachial plexopathy (Burt et al., 1992). It occurs most often with breast and lung carcinoma, and with lymphoma. The plexus can be compressed or infiltrated by tumour lying in contiguous structures, such as axillary or supraclavicular nodes, or the apex of the lung. Pain is the first symptom in 85% of patients (Kori
Fig. 14.1.3 MRI image. Lung tumour in the upper lobe compressing the lower trunk of the brachial plexus. Pain was reported in the inner aspect of the arm and paraesthesiae in the 5th and 4th finger. Left side: the arrows show the tumour mass invading the tissue planes in the area of the brachial plexus. Right side: the tumour is invading the left upper lobe, the arrows show the tumour invading one thoracic vertebral body.

Saunders Company, with permission from Elsevier, http://www.sciencedirect.com/science/journal/08898588

et al., 1981), preceding other neurological symptoms or signs by weeks or months.

Breast and lung malignancies typically affect the lower plexus (C7–T1) (Fig. 14.1.3) and cause pain in the shoulder, elbow, hand, and the fourth and fifth finger. Lung tumours can affect the intercostobrachial nerve, giving rise to a pain syndrome and associated sensory disturbances in the axilla (C8–T1–T2). The upper brachial plexus (C5–C6) can also be affected, especially by breast cancer, when pain is usually referred to the paraspinal region, shoulder, biceps region, elbow, and hand; burning dysaesthesia in the index finger or thumb is common. The hallmark of the syndrome is the neuropathic nature of the pain with numbness, paraesthesia, allodynia, and hyperaesthesia.

CT scan with narrow sections and contrast enhancement is effective in imaging soft tissue and bony structures in the plexus area. All patients with symptoms of brachial plexopathy should have a scan of the contiguous paravertebral region before radiation therapy, since extension of disease in this region is common (13/41 cases in one series). MRI is particularly useful in imaging the contiguous epidural space. While use of both techniques can give helpful complementary information in doubtful cases, sometimes neither is helpful even in cases of proven metastatic plexopathy (Krol, 1993). Comparative data on specificity and sensitivity of the two techniques are lacking.

Epidural invasion eventually will occur in some patients with brachial plexopathy (Fig. 14.1.4). Imaging of the epidural space is essential when patients develop Horner's syndrome, panplexopathy, vertebral body erosion, or a paraspinal mass detected on CT scan. These are often hallmark symptoms of tumour progression into the epidural space.

Radiation fibrosis is important in the differential diagnosis of brachial plexopathy in cancer (Table 14.1.8), particularly in patients who have had radiotherapy and who present with upper plexus signs. Positron emission tomography (PET) scan can be very helpful in distinguishing fibrosis from tumour. Pain is often less prominent in patients with radiation-induced plexopathy.

Fig. 14.1.4 MRI image in the same case as shown in Fig. 14.1.3. The tumour is invading the epidural canal and compressing the spinal cord.

Saunders Company, with permission from Elsevier, http://www.sciencedirect.com/science/journal/08898588.

Table 14.1.8 Differential diagnosis of brachial plexopathy

	Tumour infiltration	Radiation fibrosis
Incidence of pain	89%	18%
Severity of pain	Severe in 98%	Mild to moderate
Dose of radiotherapy	—	> 6000 cGy large fractions (> 1900 cGy/day)
Latency	Not indicative	> 6 months, < 5 years
Course	Progressive neurological dysfunction	Progressive weakness
	Pain progression with dysaesthetic quality	Pain stabilizing with onset of weakness
	C7–T1 distribution[a]	C5–C6 distribution
Claude Bernard–Horner syndrome	Can be present	Absent
CT scan findings[b]	Mass with tissue infiltration	Diffuse infiltration of tissue planes
MRI scan findings[b]	High signal intensity mass on T2-weighted images	Low signal intensity lesion on T_2-weighted images
Electromyography findings	Denervation no myokymia	Myokymia

[a] The distribution of the neurological findings can be helpful in some cases but it is not always indicative (see text for more details).

[b] The use of both techniques may provide complementary information. No method is totally credible in differentiating fibrosis from tumour. PET scan nowadays can be an important diagnostic tool.

Although electrodiagnostic studies and imaging may distinguish radiation-induced plexopathy from malignant invasion (Harper et al., 1989), this differential diagnosis sometimes is difficult. In these cases, PET scan can be very useful but, at times, surgical exploration of the plexus is necessary to rule out fibrosis, a new primary tumour, a radiation-induced tumour, or recurrent cancer.

Lumbosacral plexopathy

Lumbosacral plexopathy is one of the most disabling complications of cancer. Although it is commonly associated with colorectal, cervical, and other pelvic malignancies (bladder, uterus, prostate, sarcoma, lymphoma), it can also be caused by breast or lung cancer, or melanoma. Retroperitoneal tumours (e.g. sarcoma, metastatic nodal tumours) may affect the lumbosacral plexus or its roots more proximally.

The presenting symptom in almost all cases (93%) (Jaeckle et al., 1985) is pain in the buttocks or the legs. Pain often precedes other symptoms by weeks or months. It is usually followed by numbness, paraesthesia, weakness, and, later, leg oedema. The pain is usually aching or pressure-like in quality, and is rarely burning or dysaesthetic. In one series (Jaeckle et al., 1985), an upper plexopathy (L1–L4) was found in about one-third of cases, a lower plexopathy (L4–S1) in one-half of cases, and panplexopathy (L1–S3) in about 20% (Table 14.1.9).

Other structures can be involved. These include nerve roots from proximal extension of the tumour, or contiguous structures,

Table 14.1.9 Clinical findings in lumbosacral plexopathy due to cancer

	Upper plexopathy	Lower plexopathy	Panplexopathy
Local pain	Lower abdomen	Buttock, perineum	Lumbosacral
Referred pain	Flank, iliac crest	Hip and ankle	Variable
Radicular pain	Anterolateral thigh	Posterolateral thigh, leg	Variable
Paraesthesiae	Anterior thigh	Perineum, thigh, sole	Anterior thigh, leg, foot
Motor and reflex changes	L2–L4	L5–S1	L2–S2
	Proximal leg weakness	Distal leg weakness	Weakness can affect different muscle groups and reflexes
	Patella reflex	Ankle reflex	
Sensory loss	Anterolateral thigh	Posterior thigh, sole	Anterior thigh, leg
Tenderness	Lumbar	Sciatic notch, sacrum	Lumbosacral
Positive SLRT			
Direct	50%	50%	83%
Reverse	15%	50%	83%
Leg oedema	41%	37%	83%
Rectal mass	25%	43%	15%
Anal sphincter weakness	0	50%	0

SLRT, straight leg raising test or Lasegue manoeuvre.

such as the sympathetic chain or the psoas muscle. Selective involvement of the L1, iliohypogastric, ilioinguinal, or genitofemoral nerves can produce pain and paraesthesia in the inguinal and scrotal region.

A sacral plexopathy, often overlapping a sacral polyradiculopathy, can be produced from direct extension of a presacral mass invading the sacrum, as sometimes occurs with rectosigmoid and bladder carcinomas. The coccygeal plexus is usually affected in patients with sphincter dysfunction and perineal 'saddle' sensory loss.

Tumour is often found in the lumbar vertebrae, sacrum, or pelvis of patients with lumbosacral plexopathy (45/76 patients) and epidural extension is also common, especially with retroperitoneal tumours. Hydroureter or hydronephrosis is extremely common at diagnosis (Jaeckle et al., 1985; Thomas et al., 1985).

Lumbosacral plexopathy can occur after pelvic irradiation. Thomas et al. (1985) reported that radiation-induced lumbosacral plexopathy very rarely presents with pain and has a median latency of 5 years from radiotherapy. Motor involvement is bilateral in 80% of cases and electromyography can be a useful diagnostic tool. Other differential diagnoses include leptomeningeal carcinomatosis, and cauda equina compression.

MRI and CT scanning both image the lumbosacral plexus effectively. CT gives more information on the bony structures, while MRI is more accurate for soft tissues. The assessment should extend from L1 through the true pelvis (Jaeckle et al., 1985), and should include the spine and adjacent pelvic soft tissues.

Mononeuropathy

Mononeuropathy is less common than plexopathy or radicular lesions (Anoine and Camdessanche, 2007). It is caused by compression or infiltration of a nerve by bony lesions, or by soft tissue masses in the limbs. Intercostal nerve neuropathy from invasion of the chest wall is the most common of the mononeuropathies caused by cancer. Obturator, femoral, and sciatic neuropathies are seen when tumour involves the soft tissue along the nerve distribution in the pelvis and thigh. Peroneal mononeuropathy can occur with bony lesions of the head of the fibula and sarcoma of the popliteal fossa. Ulnar and radial neuropathies result from bony lesions in the elbow or humerus. These mononeuropathies must be distinguished from traumatic or compressive lesions, and from nutritional–metabolic lesions of nerves.

Palliative treatment of peripheral nerve compression

Management of pain is often difficult in these syndromes; opioids are indicated and adjuvants for neuropathic pain should be used for specific indications. Clinical experience suggests that dexamethasone can be particularly effective for pain due to compression and oedema of peripheral nerves.

Peripheral polyneuropathy

Polyneuropathy in cancer patients can be caused by chemotherapy, metabolic disturbance or nutritional deficiency, or paraneoplastic syndromes (Box 14.1.5) (Lipton et al., 1991; Anoine and Camdessanche, 2007).

Peripheral neuropathy is characterized by a stocking-glove distribution of negative sensory and positive sensory symptoms. Loss of sensation may predominate, or there may be painless paraesthesia or distressing burning dysaesthesia, allodynia, and hyperalgesia. Early sensory loss and later motor signs (weakness) are

Box 14.1.5 Polyneuropathies and peripheral neuropathies

Related to cancer

- Myeloma associated neuropathies
- Paraneoplastic sensory neuronopathy (Denny-Brown)
- Sensory-motor peripheral neuropathy
- Nutritional factors (cachexia-associated neuromyopathy[a]), vitamin B_{12} folate, deficiency, piridoossine
- Cancer-related metabolic dysfunction: hepatic, renal
- Infiltration of peripheral nerves (lymphomas, leukaemias)[b]
- Vascular (haemorrhagic or ischaemic) peripheral nerve lesion.[b]

Related to chemotherapy and radiation

- Vincristine
- Vinblastine
- Vinorelbine
- Cisplatin
- Oxaliplatin
- Paclitaxel
- Suramin
- Epothilones
- Thalidomide
- Bortezomid
- Radiation to limbs with worsening of vincristine neuropathy.

Non-cancer related

- Metabolic dysfunction: diabetes.

[a] Very frequent.
[b] Mononeuritis multiplex.

---

characteristic of some drug-induced sensorimotor neuropathies (vincristine, paclitaxel). Sensory involvement can be selective in neuropathies associated with cisplatin or paraneoplastic syndromes. Often the only early sign of polyneuropathy is reduction or loss of the ankle reflex. Muscle cramps may be associated with neuropathy and can sometimes be prominent symptoms in vincristine neuropathy. Muscle cramps are relatively frequent in cancer.

Paraneoplastic sensory neuropathy and sensory neuropathy caused by vincristine or paclitaxel is often more painful than that caused by cisplatin. Cisplatin induces a sensory neuropathy mainly affecting the cells of the dorsal root ganglia. There is predominant involvement of the large fibre functions (proprioception), which causes sensory ataxia rather than pain. Vinca alkaloids and paclitaxel produce a mostly sensory axonopathy with some motor component. New antineoplastic drugs that interfere with specific metabolic pathways, such as bortezomid, also have distinct toxic effects on the peripheral nervous system (Anoine and Camdessanche, 2007).

Clinical examination is usually sufficient for diagnosis of a polyneuropathy, although nerve conduction studies and

electromyography may provide additional information (Lipton et al., 1991). Treatment is palliative, with analgesics and adjuvants.

Paraneoplastic neurological syndromes

Paraneoplastic neurological syndromes (PNSs) are a group of neurological disorders that occur in patients with malignant tumour in which an immune-mediate mechanism and not a direct effect of the cancer is the cause. PNSs are rare, affecting less than 1/10 000 of patients with cancer, except Lambert–Eaton myasthenic syndromes (LEMSs) which affect about 3% of patients with small cell lung cancer, and myasthenia gravis, which affects about 15% of patients with tymoma. They can affect central or peripheral nervous systems, neuromuscular junction, or muscle (Darnell and Posner, 2003; Viaccoz and Honnorat, 2013) (Table 14.1.10)

Many PNSs are now recognized. For some of them with well-characterized onco-neuronal antibodies, the nature of the tumour is suggested by the antibody itself; for others the mechanism of the disease is less known, but all are severe and can affect patients' quality of life, even if the underlying tumour is healed or stable. The specific antibodies and their pathogenic role need to be evaluated carefully by highly specialized professionals (Darnell and Posner, 2003; Viacozz and Honnorat, 2013).

In general, neurological symptoms and signs develop acutely and are severe. Subtle, long-lasting symptoms are not usually caused by paraneoplastic syndromes. Only examination of CSF and immunofluorescence techniques for testing circulating autoantibodies can aid diagnosis because MRI scans are often normal and only LEMSs and myasthenia gravis have neurophysiological classic features.

The clinical course is independent of that of the original tumour, which in 50% of cases is found after the onset of neurological symptoms. The associated tumour often is small and slow growing, and may have a relatively benign course. Spontaneous remissions have been seen, but the syndrome is usually irreversible.

Endocrine and metabolic complications of advanced cancer

Mark Bower, Louise Robinson, and Sarah Cox

Paraneoplastic syndromes

Hypercalcaemia

Hypercalcaemia is the commonest life-threatening metabolic disorder associated with cancer. It usually occurs in patients with advanced disseminated malignancy and produces a number of distressing symptoms. The treatment of hypercalcaemia of malignancy frequently ameliorates these symptoms, and for this reason the diagnosis should always be sought.

Pathogenesis

Three related mechanisms contribute to hypercalcaemia:

1. increased osteoclastic bone resorption

2. decreased renal clearance of calcium

3. enhanced calcium absorption from the gut.

All three occur in malignancy and contribute to a greater or lesser extent. Bone resorption in malignant hypercalcaemia is universal and related to both local factors produced in response to metastases and humoral factors produced by tumours. It is mediated by osteoclasts that resorb bone at their ruffled border where cellular proton pumps secrete hydrogen and chloride ions that dissolve hydroxyapatite. In addition, osteoclasts produce lytic proteases including lysosomal proteases, metalloproteinases, and cystine proteases that dissolve bone matrix. Decreased renal calcium excretion occurs with low glomerular filtration rates and/or increased tubular reabsorption of calcium in response to parathyroid hormone or its relatives. Haematological neoplasms rarely produce 1,25-dihydroxycholecalciferol ($1,25(OH)_2D_3$, calcitriol) causing increased gastrointestinal absorption of calcium.

RANKL/RANK/OPG

The final common pathway of osteolysis at the molecular level involves a triad of osteoprotegerin (OPG), receptor activator of nuclear factor kappa B (RANK) and receptor activator of nuclear factor kappa B ligand (RANKL). Bone destruction in the presence of osteolytic skeletal metastases is not caused directly by tumour cells but by osteoclasts. The tumour cells either directly produce RANKL or stimulate bone stromal cells to produce RANKL. RANKL is an osteoclast activating factor that stimulates the RANK membrane receptor on osteoclast precursors. In conjunction with macrophage colony stimulating factor, RANKL causes the differentiation of precursors into osteoclasts and the fusion and activation of osteoclasts into functional multinucleated osteoclasts that mediate bone resorption. OPG is a soluble decoy receptor for RANKL that inhibits RANK by competing for RANKL binding. OPG production is decreased in myeloma and metastatic prostate cancer. This RANKL/RANK/OPG equilibrium is disrupted by cytokines, chemokines and prostaglandins, uncoupling the usual homeostatic balance between osteoclastic bone resorption and osteoblastic bone formation. In addition, osteotropic factors such as $1,25(OH)_2D_3$ and parathyroid hormone-related protein (PTHrP) as well as interleukins 1 and 6 enhance RANKL expression and diminish OPG expression.

Parathyroid hormone

In most cases of malignancy-associated-hypercalcaemia, cytokine-mediated osteoclastic bone resorption appears to be the dominant factor; however, in up to 20% of cases no bone metastases are present, so-called humoral hypercalcaemia of malignancy. In these patients, ectopic secretion of factors by the tumour accounts for the disturbance of calcium homeostasis. Humoral hypercalcaemia of malignancy resembles primary hyperparathyroidism biochemically, with hypercalcaemia, hypophosphataemia, renal phosphate wasting, increased tubular resorption of calcium, and enhanced osteoclastic bone resorption. Although true ectopic secretion of parathyroid hormone (PTH) has been described in non-parathyroid tumours, it is very rare indeed.

Parathyroid hormone-related protein

PTHrP is a 16 kDa peptide that resembles PTH in bioactivity but has different immunoreactivity. PTHrP (1-141) and PTH bind same PTH receptor 1 with equal affinity. Whilst PTH is only expressed in parathyroid glands, PTHrP is found in several tissues including keratinocytes, placenta, breast tissue, parathyroid glands, fetal liver and brain. PTHrP plays a central role in endochondrial bone formation, breast morphogenesis and transplacental calcium flux (Lanske et al., 1996; Vortkamp et al., 1996; Strewler et al., 2000).

PTHrP immunoperoxidase staining is strongly positive in human squamous cell carcinomas from various sites (Danks et al., 1989). Moreover, PTHrP mRNA expression was detected in all tumours from patients with humoral hypercalcaemia of malignancy but not in any tumours from normocalcaemic patients (Honda et al., 1988). Furthermore, cancer patients with hypercalcaemia have elevated serum PTHrP measured by immunoassay (> 2.5 pg/mL) (Budayr et al., 1989). Thus PTHrP assays may facilitate the diagnosis of the cause of hypercalcaemia (Hutchesson et al.,

1993). PTHrP may also have a limited role as a prognostic tumour marker, predicting the development of bone metastases in women with breast cancer (Bouizar al., 1993).

At least 80% of patients with solid tumours and hypercalcaemia have elevated serum levels of PTHrP (Wysolmerski and Broadus, 1994) including over 60% of patients with bone metastases (Grill et al., 1991). Nevertheless, PTHrP cannot explain all the biochemical findings in humoral hypercalcaemia of malignancy. In contrast to primary hyperparathyroidism, there is impaired intestinal calcium absorption, low $1,25(OH)_2D_3$ levels and osteoclastic bone resorption is far more prominent. These features suggest that other factors (probably cytokines) have an important role in humoral hypercalcaemia of malignancy, even in the absence of bone metastases.

Vitamin D

Gut absorption of calcium and vitamin D levels generally are suppressed in patients with humoral hypercalcaemia of malignancy. However, a number of cases of Hodgkin's disease, non-Hodgkin's lymphoma, and human T-cell lymphotrophic virus type 1 (HTLV-1)-associated adult T-cell leukaemia/lymphoma (ATLL) have been reported with ectopic production of $1,25(OH)_2D_3$ resulting in hypercalcaemia (Seymour and Gagel, 1993). The mechanism is thought to involve extra-renal hydroxylation of $25(OH)D_3$ by 1 alpha-hydroxylase to $1,25(OH)_2D_3$ (Davies et al., 1994) and this has implications for therapy. Hypercalcaemia of malignancy is usually associated with low calcium absorption and hence dietary calcium restriction is unnecessary; however, with elevated $1,25(OH)_2D_3$ levels, a low-calcium diet is needed to control hypercalcaemia.

Epidemiology

One in ten cancer patients develops hypercalcaemia and malignancy accounts for about half the cases of hypercalcaemia amongst hospital inpatients. Hypercalcaemia occurs most frequently with myeloma, breast, lung, and renal cancers, and up to 20% of cases occur in the absence of bone metastases. Most patients with hypercalcaemia of malignancy have disseminated disease and 80% die within 1 year. The median survival is just 3–4 months. Thus hypercalcaemia is usually a complication of advanced disease and its treatment should be directed at symptom palliation, but occasionally patients with myeloma or metastatic breast cancer present with hypercalcaemia.

Clinical features

The clinical manifestations of hypercalcaemia are myriad and many symptoms that may have been attributed to the underlying malignancy may resolve on correction of the hypercalcaemia. Although the severity of symptoms is not correlated with degree of elevation of serum calcium, most patients initially develop malaise and lethargy followed by thirst, nausea, and constipation before neurological (drowsiness and confusion) and cardiological features appear (Table 14.2.1). A diagnosis of hypercalcaemia can only be made by biochemical investigation and all symptomatic patients with malignancy should have their serum calcium measured if treatment is likely to be appropriate.

Treatment

In parallel with the advances in the understanding of the pathogenesis of hypercalcaemia have come improvements in therapy, especially the introduction of bisphosphonates that are more effective, less toxic, and easier to administer. They represent a

Table 14.2.1 Clinical features of hypercalcaemia of malignancy

General	Gastrointestinal	Neurological	Cardiological
Dehydration	Anorexia	Fatigue	Bradycardia
Polydipsia	Weight loss	Lethargy	Atrial arrhythmias
Polyuria	Nausea	Confusion	Ventricular arrhythmias
Pruritus	Vomiting	Myopathy	Prolonged P–R interval
	Constipation	Hyporeflexia	Reduced Q–T interval
	Ileus	Seizures	Wide T waves
		Psychosis	
		Coma	

major improvement in palliative therapy for cancer patients. The treatment of hypercalcaemia should be determined on the basis of attributable symptoms and the corrected serum calcium calculated from the formula:

$$\text{Corrected calcium} = \text{measured calcium} + ([40 - \text{serum albumin (g/L)}] \times 0.02)$$

Rehydration followed by the administration of calcium lowering agents is the mainstay of therapy. Low calcium diets are unpalatable, impractical and exacerbate malnutrition. They have no place in palliative therapy. Drugs promoting hypercalcaemia (thiazide diuretics, vitamins A and D) should be withdrawn.

Intravenous fluids

Dehydration due to polyuria and vomiting is a prominent feature of hypercalcaemia and intravenous rehydration is an essential component of acute therapy for severe or symptomatic hypercalcaemia. Although large volumes of fluid will lower serum calcium, patients rarely achieve normocalcaemia and careful monitoring to avoid fluid overload is necessary. In view of this, 2–3 L per day of fluid is now the accepted practice with daily serum electrolyte measurement to prevent hypokalaemia and hyponatraemia. Loop diuretics are often prescribed as an adjunct to intravenous fluids and cause calciuresis. However there is little evidence of any benefit and they may exacerbate hypovolaemia, hypokalaemia, and hypomagnesaemia and are best avoided.

Corticosteroids

Glucocorticoids have been widely used in cancer-related hypercalcaemia and rapidly inhibit osteoclastic bone resorption *in vitro* as well as reducing calcium absorption from the gut. However, their limited clinical benefit is chiefly confined to tumours that respond to the cytostatic effects of steroids, such as myeloma, lymphoma, leukaemia, and, occasionally, breast cancer when hypercalcaemia occurs as a flare effect caused by endocrine therapy. Thus their role in severe hypercalcaemia is limited to haematological malignancies and oral prednisolone 40–100 mg/day is usually effective in these circumstances, although it may take 4–10 days to lower the serum calcium.

Bisphosphonates

Bisphosphonates are synthetic pyrophosphate analogues characterized by a phosphorus–carbon–phosphorus bond, making them resistant to enzymatic hydrolysis. They reduce bone resorption by binding hydroxyapatite crystals with a high affinity and inhibiting

osteoclast function leading to disappearance of the ruffled border, decreased acid production, and altered enzyme activity (Sato et al., 1991; Zimolo et al., 1995). In hypercalcaemia of malignancy, bisphosphonates cause a gradual fall in serum calcium over a few days. Bisphosphonates do not alter PTHrP levels, renal calcium reabsorption, RANKL, or OPG levels and so they may fail to control humoral hypercalcaemia of malignancy without bone metastases (Walls et al., 1994; Zojer et al., 2005). There is a correlation between the responsiveness to pamidronate and plasma PTHrP levels; non-responders have levels above 75 pg/mL. Hence PTHrP measurement may identify patients requiring higher or more frequent doses of bisphosphonates (Zimolo, 1994).

The most commonly prescribed bisphosphonate is pamidronate, administered as a single infusion of 90 mg administered at 1 mg/minute, irrespective of the serum calcium level, and repeated every 3–4 weeks (Hillner et al., 2003). First-generation bisphosphonates (e.g. etidronate, clodronate) have been superseded by more potent third-generation preparations including ibandronate (4 mg intravenous infusion over 2 hours) (Ralston et al., 1997; Pecherstorfer et al., 2003) and zoledronate (Body et al., 1999; Major et al., 2001) that are effective in humoral hypercalcaemia of malignancy. Zoledronate corrects hypercalcaemia in more patients, faster and for longer than pamidronate, as well as only requiring a 15-minute infusion (Major et al., 2001). The differences between pamidronate and zoledronate are not marked, however, and the choice is based largely on cost and convenience. In our unit, intravenous pamidronate is used for inpatients whilst outpatients are treated with the briefer zoledronate infusions. A randomized study comparing ibandronate and pamidronate suggested similar efficacy but longer duration of normocalcaemia with ibandronate, although the study used stratified dosing based on serum calcium levels (Pecherstorfer et al., 2003).

In addition to these actions, intravenous bisphosphonates have valuable analgesic activity in patients with metastatic bone pain and reduce skeletal morbidity in patients with breast cancer and myeloma. Osteonecrosis of the jaw is a recognized complication of bisphosphonate therapy associated with prolonged use, older age, and a history of recent dental extraction. Symptoms can mimic dental problems and patient may develop severe pain. The usual management is with antibiotics and surgical debridement (Migliorati et al., 2006).

Calcitonin

Calcitonin is secreted by the parafollicular cells of the thyroid gland, although its physiological role in calcium homeostasis remains undefined. In much higher pharmacological doses, calcitonin reduces osteoclastic bone resorption and increases calciuresis, thereby reducing serum calcium. It is effective in around a third of patients and usually causes a fall in calcium within 4 hours (compared to 48 hours for bisphosphonates), but normocalcaemia is rare and the effect is short lived, usually requiring daily repeat dosing. Doses of up to 8 IU/kg salmon calcitonin may be injected subcutaneously or intramuscularly every 6–12 hours and this therapy has minimal toxicity (nausea is the most frequent side effect and occasional hypersensitivity reactions are seen).

Plicamycin

Plicamycin (formerly mithramycin), a cytotoxic antibiotic, is toxic to osteoclasts by blocking RNA synthesis and hence reduces bone resorption, producing prompt and effective lowering of serum calcium. It is administered as an intravenous bolus or 2-hour infusion at a dosage of 25 micrograms/kg. It produces normocalcaemia within 3 days in 80% of patients and is usually repeated weekly. The disadvantage of this highly effective treatment is its toxicity; cumulative nephrotoxicity and hepatotoxicity occur and thrombocytopenia is common; nausea is frequent and may be reduced when plicamycin is given as an infusion. Plicamycin is now used very rarely.

Phosphates

Oral phosphates may be effective in mild hypercalcaemia, by a combination of effects on calcium metabolism. The usual recommended dose is 0.5–3 g/day phosphate (as sodium cellulose phosphate powder) and this frequently causes nausea and diarrhoea. Intravenous phosphate is a highly effective therapy for acute life-threatening hypercalcaemia and the onset of hypocalcaemic action is more rapid than with any other agent. However, the severe toxicity of parenteral phosphate includes extensive extraskeletal calcification and hence it has been abandoned in all but exceptional cases. Recommended dosing is 1.5 g (50 mmol) elemental phosphate diluted in 1 L of saline over 6–8 hours and should preferably be given in intensive care where the patient's cardiac and renal function can be monitored closely.

Gallium nitrate

Gallium nitrate is incorporated into bone, rendering hydroxyapatite less soluble (Bockman et al., 1990). It inhibits bone resorption directly without killing osteoclasts and is not associated with the nausea or myelosuppression caused by plicamycin. Gallium is highly effective, producing normocalcaemia in 80% of patients with hypercalcaemia of malignancy. Randomized double-blind trials have demonstrated the superiority of gallium compared to calcitonin (Warrell et al., 1988), etidronate (Warrell et al., 1991), and pamidronate (Cvitkovic et al., 2006). The main drawback of gallium is that it requires continuous intravenous infusion (100–200 mg/m^2 per day) for 5 days and it causes nephrotoxicity. Gallium nitrate is not licensed in the United Kingdom.

Future approaches

Two promising new approaches are emerging for the management of hypercalcaemia of malignancy. Denosumab is a fully human monoclonal antibody to RANKL that is used in the management of postmenopausal women with osteoporosis (McClung et al., 2006) and reduces skeletal events in patients with bone metastases and myeloma (Fizazi et al., 2009; Henry et al., 2011). Denosumab is currently under trial for hypercalcaemia of malignancy. Circulating levels of ionized calcium ion are monitored and regulated via cell surface calcium sensing receptors (CASR). Calcium sensor mimetics or calcimimetics are small organic molecules that potentiate the effect of calcium on the CASR and suppress PTH secretion. Cinacalcet, the first drug in this class, alleviates hypercalcaemia in secondary hyperparathyroidism (Block et al., 2004) and parathyroid carcinoma.

Treatment summary

Symptomatic or severe hypercalcaemia requires intravenous rehydration with 2–3 L per day followed by a single infusion of pamidronate at 1 mg/minute according to the corrected serum calcium. This combination will control hypercalcaemia in most patients simply, promptly, and with minimal toxicity. The majority of patients will remain normocalcaemic for 2–4 weeks
Fig. 14.2.1 Pro-opiomelanocortin (POMC)-derived peptides. CLIP, corticotropin-like intermediate lobe peptide; Enc, encephalin; MSH, melanocyte stimulating hormone; LPH, lipotropin; POC, pro-opiocortin; POMC, pro-opiomelanocortin.

with encouragement of oral hydration. In the absence of effective treatment of the malignancy, however, hypercalcaemia will recur and the serum calcium should be rechecked every 3–4 weeks. Maintenance pamidronate infusions over 2 hours or zoledronate over 5 minutes can be managed on an outpatient basis. Second-line therapy for humoral hypercalcaemia of malignancy resistant to bisphosphonates should probably be with gallium nitrate, although this is rarely available.

Cushing's syndrome

Whilst ectopic secretion of adrenocorticotrophic hormone (ACTH) by non-endocrine derived tumours is not uncommon, clinically overt paraneoplastic Cushing's syndrome is rare. ACTH and at least nine other active peptide hormones are produced from the pro-opiomelanocortin (*POMC*) gene.

Pathogenesis

The *POMC* gene can produce numerous different peptides as a consequence of using alternative gene promoters and post-translational modification and many of these products have been identified in

tumours. The main peptide products include the melanocyte stimulating hormones (α-MSH, β-MSH, and γ-MSH) and the N-terminal peptide precursor (NPP or pro-γ-MSH), the corticotrophins (ACTH and corticotropin-like intermediate peptide or CLIP), the lipotropins (β-lipotropin or β-LPH and γ-LPH) and the endorphins (β-endorphin and met-encephalin). It is remarkable that all these peptides are derived from a single gene (see Fig. 14.2.1).

Excessive ACTH production, whether as ACTH or the larger peptide pro-ACTH, leads to Cushing's syndrome. Melanocyte-stimulating hormones (MSHs) regulate skin pigmentation by affecting directly dermal melanocyte growth and melanin production. Hence ectopic secretion of any peptide containing MSH may lead to generalized hyperpigmentation but this symptom is rarely distressing. No clear clinical correlates have been described that relate to excessive production of endorphins or lipotropins.

Epidemiology

Ectopic ACTH secretion by a tumour accounts for only 5–15% of cases of Cushing's syndrome and the cancer is frequently occult

at presentation (Boscaro et al., 2001; Barbosa et al., 2005). For this reason the differential diagnosis between an ACTH secreting pituitary adenoma and ectopic ACTH production is important clinically although biochemical overlap often makes distinguishing them difficult. Half the cases of ectopic ACTH syndrome are due to lung cancer, divided evenly between small cell lung cancer and bronchial carcinoids (Isidori et al., 2006). Islet cell tumour of the pancreas (16%), and thymic carcinoids (10%) make up most of the remaining cases (Beuschlein and Hammer, 2002). The levels of ACTH may decline in response to chemotherapy or radiotherapy (Abeloff et al., 1981), but any correlation between declining ACTH levels and tumour response is only anecdotal, and elevation of ACTH may persist in long-term survivors following chemotherapy (Hansen et al., 1980a).

Clinical features

The typical presentation is of a middle-aged, male smoker with features of severe hypercortisolism and hypokalaemic metabolic alkalosis. Patients have muscle weakness or atrophy, oedema, hypertension, mental changes, glucose intolerance, and weight loss. When ectopic ACTH production arises from a slower growing tumour (e.g. bronchial carcinoid or thymoma) the other classical features of Cushing's syndrome may be present including truncal obesity, moon facies and cutaneous striae, often making the clinical distinction from pituitary-dependant Cushing's disease impossible. Furthermore, biochemical tests do not always differentiate reliably a pituitary corticotroph adenoma from an ectopic tumour as the source of ACTH.

Diagnosis

In addition to the clinical features, the diagnosis of Cushing's syndrome may be confirmed by demonstrating abnormality of at least two of these first-line tests: elevated 24-hour urinary free cortisol, failure of cortisol suppression in the low-dose overnight dexamethasone (1 mg at midnight and plasma cortisol measured at 8 a.m.) test, and raised late evening salivary cortisol (Nieman et al., 2008). After establishing the diagnosis, an elevated plasma ACTH supports the diagnosis of ACTH-dependent Cushing's syndrome due to a pituitary adenoma (Cushing's disease) or ectopic ACTH secretion by a tumour. Failure of 8 am cortisol to suppress, following high-dose dexamethasone (2 mg four times daily for 2 days, or 8 mg at midnight) and very high levels of ACTH (> 200 pg/mL), suggest an ectopic source of ACTH. However, half of the cases of ectopic ACTH from carcinoid tumours suppress with high dose dexamethasone and have ACTH levels in the lower range. In difficult cases, a corticotrophin-releasing hormone (CRH) stimulation test, selective venous catheterization of inferior petrosal venous sinus with ACTH estimations, and two-site directed IRMA for pro-ACTH and ACTH measurements may be necessary to determine the source of ACTH (Orth, 1995; Boscaro et al., 2001). Recently both somatostatin analogue scintigraphy (de Herder et al., 1994) and [99]technetium methoxyisobutylisonitrile (MIBI) imaging (Jacobsson et al., 1994) have been used for localization of ectopic ACTH-producing tumours.

Further difficulties in differential diagnosis have arisen with the description of ectopic CRH secretion by tumours giving rise to Cushing's syndrome (Carey et al., 1984). In these circumstances, ectopically secreted CRH stimulates the normal pituitary to secrete excess ACTH resulting in Cushing's syndrome.

Treatment

The mainstay of palliative therapy for Cushing's syndrome due to ectopic ACTH production is inhibition of steroid synthesis, although inhibition of ACTH release and blocking glucocorticoid receptors have also been attempted. Several steroid synthesis inhibitors are available and successful use in these circumstances has been reported with ketoconazole, metyrapone, mitotane, etomidate, and octreotide. On rare occasions, laparoscopic bilateral adrenalectomy or adrenal artery embolization may be necessary to control symptoms (Boscaro et al., 2001).

The imidazole antifungal ketoconazole inhibits the first step in cortisol biosynthesis by inhibiting cytochrome P450 (CYP) 11A1 enzyme that catalyses side chain cleavage, as well as some of the other enzymes that catalyse adrenal steroidogenesis. It is the best tolerated of the steroid synthesis inhibitors, with potential side effects including nausea, headaches, pruritic rashes and liver failure. Case reports document its successful use in Cushing's syndrome due to ectopic ACTH secretion (Hoffman and Boigham, 1991; Winquist et al., 1995) and it is effective in half the patients with ectopic ACTH secretion (Tritos and Biller, 2012).

Metyrapone inhibits 11-β-hydroxylase (CYP11B1), the final step in cortisol and corticosterone synthesis and has been shown to be effective in ectopic ACTH syndrome at doses of 250–750 mg four times a day. The short half-life of metyrapone and gastrointestinal toxicity (chiefly nausea) are drawbacks and very high levels of ACTH may over-ride the effects of metyrapone. For these reasons it has been suggested that metyrapone should be used in conjunction with ketoconazole.

Mitotane is an adrenal cytotoxic which irreversibly inhibits 11-β-hydroxylase and 18-hydroxylase thus reducing glucocorticoid, mineralocorticoid and androgen production. It produces focal atrophy and necrosis of the zona fasiculata and zona reticularis. Doses of 1–12 g/day in four divided doses have been used and it is active also against primary adrenal cancers. Mitotane is a toxic drug with gastrointestinal side effects (anorexia, nausea, vomiting, diarrhoea) reported in 80% of patients and lethargy and somnolence in 40% (Wajchenberg et al., 2000). Mitotane often takes several weeks to effect cortisol levels.

Etomidate is an intravenous anaesthetic that also inhibits 11-β-hydroxylase and has been used to control hypercortisolaemia in patients unable to take oral medication (Johnson and Canada, 2007).

Octreotide, a long-acting somatostatin analogue that activates predominantly somatostatin receptor (SSTR) 2, may suppress ectopic ACTH secretion via SSTR on pituitary corticotrophs and ectopic ACTH secreting tumours (Woodhouse et al., 1993; Pivonello et al., 2005). Whilst the effects of octreotide in Cushing's disease are limited, a new somatostatin analogue, pasireotide which has broader receptor activation (including SSTR 1, 2, 3, and 5) has shown promise (Feelders et al., 2010).

Mifepristone is a progesterone partial agonist that inhibits the type 2 glucocorticoid receptor that has been used successfully in both Cushing's syndrome patients and those with ectopic ACTH secretion (Castinetti et al., 2009).

Treatment summary

The initial treatment for ectopic ACTH secretion should be ketoconazole 200 mg three times a day rising to 400 mg three times

a day. If this fails to control cortisol levels, add metyrapone 250 mg two or three times a day rising to doses of up to 4.5g a day. Further options thereafter include mitotane, octreotide, mifepristone, or pasireotide. The efficacy of treatment must be monitored as hypoadrenalism may ensue and this is most easily achieved by measuring 24-hour urinary cortisol excretion. As levels return to normal in these patients, hormone replacement therapy is frequently necessary. Regimens similar to those used in Addison's disease should be used (e.g. hydrocortisone 20 mg at 8 a.m. and 10 mg at 6 p.m., fludrocortisone 0.05–0.15 mg daily).

Syndrome of inappropriate antidiuresis

Hyponatraemia, usually defined as serum Na+ less than 135 mmol/L, is a common finding in association with advanced malignancy and many factors may contribute, including cardiac and hepatic failure, hyperglycaemia, and diuretics. However, the detection of concentrated urine in conjunction with hypo-osmolar plasma suggests abnormal renal free water excretion and the presence of the nephrogenic syndrome of inappropriate antidiuresis (SIAD) (Feldman et al., 2005). This acronym is more suitable than 'SIADH' since there is no vasopressin secretion in approximately 15% of cases (Verbalis, 1989).

Pathogenesis

The vasopressin gene encodes a peptide product that includes both the nine-amino acid arginine vasopressin (AVP) and a 90-amino acid peptide, vasopressin-specific neurophysin II (NP II). The AVP-NP II polypeptide is transported by axonal streaming from the hypothalamus to the posterior pituitary gland where it is cleaved and secreted as AVP and NP II. Three AVP receptors have been identified (V_{1A}, V_{1B}, and V_2); V_2 receptors are located on renal collecting duct cells and mediate the antidiuretic activity. Following ligand binding, V_2 receptor activation results in the insertion of aquaporin-2 (AQP2) water channels into the apical plasma membrane of collecting duct cells. Aquaporins are a group of membrane channels that allow the passage of free water but not ions across cell membranes. Thus enhanced AQP2 expression in the collecting ducts increases water reabsorption and leads to reduced free water excretion.

Epidemiology

Stimulation of hypothalamic–pituitary secretion of AVP or a direct effect on distal nephrons accounts for most cases of SIAD. However, in paraneoplastic SIAD, tumours secrete ectopic AVP or vasopressin-like peptides (Smitz et al., 1988). SIAD is most frequently associated with small cell lung cancer or carcinoid tumours but has also been described in gastrointestinal and genitourinary cancers as well as lymphomas and sarcomas (Ellison and Berl, 2007). Among 523 patients with small cell lung cancer, 9% had clinically evident SIAD, 32–44% elevated plasma AVP, and 53–68% abnormal renal handling of water loads (Comis et al., 1980; Hansen et al., 1980b). Although correction of hyponatraemia may correlate with tumour response (Cohen et al., 1978; Vanhees et al., 2000) complete restoration of normal renal water handling is rare even when complete remission is achieved (Srensen et al., 1987).

Clinical features

Significant symptoms of hyponatraemia appear at plasma sodium levels below 120 mmol/L with confusion progressing to stupor, coma, and seizures as levels fall. Nausea, vomiting, and focal neurological deficits may also occur. The clinical features depend both on the levels of plasma sodium and the rate of decline; with gradual falls in sodium the brain cells are able to compensate against cerebral oedema by secreting potassium and other intracellular solutes. Asymptomatic hyponatraemia, therefore, suggests chronic SIAD rather than acute SIAD. The division into chronic and acute SIAD is of therapeutic importance as their management differs (Hojer, 1994).

Diagnosis

The diagnosis of SIAD requires the demonstration of plasma hyponatraemia and hypo-osmolality in the presence of concentrated urine and normal extracellular fluid volume (Box 14.2.1). There are a number of causes of SIAD, including ectopic AVP production by tumours, and several may play a role in hyponatraemia in patients with advanced malignancy. Pulmonary, meningeal, and cerebral infections are common causes and drug-induced SIAD may also present in patients with cancer. Most drugs cause SIAD by stimulating hypophyseal secretion of AVP, although prostaglandin synthesis inhibitors directly inhibit renal tubular excretion of free water. The list of drugs implicated is long and includes morphine, phenothiazines, tricyclic antidepressants, and non-steroidal anti-inflammatory drugs, all frequently used in palliative care, as well as the cytotoxic drugs vincristine and cyclophosphamide, and nicotine. The possibility of drug-related SIAD should always be considered before invoking ectopic AVP secretion by tumours and in most cases the hyponatraemia resolves when the drug is stopped. When SIAD presents with no identifiable cause, a thorough search for occult malignancy (especially small cell lung cancer) should be undertaken, as SIAD may be the presenting symptom and may precede radiological evidence by up to 1 year (Cohen et al., 1984).

Treatment

The management of SIAD depends upon the rate of onset of hyponatraemia and the presence of neurological complications. Acute SIAD with an onset over 2–3 days and falls in serum

---

Box 14.2.1 Diagnosis of syndrome of inappropriate diuresis (SIAD)

Essential criteria to establish this diagnosis

1. Plasma hypo-osmolality (plasma osmolality < 275 mOsm/kg H_2O and plasma sodium < 135mmol/L)

2. Concentrated urine (plasma osmolality > 100 mOsm/kg H_2O)

3. Normal plasma/extracellular fluid volume

4. High urinary sodium (urine sodium > 20 mEq/L) on a normal salt and water intake

5. Exclude (a) hypothyroidism, (b) hypoadrenalism (c) diuretics.

Supportive criteria for this diagnosis

6. Abnormal water load test (unable to excrete > 90% of a 20 mL/kg water load in 4 hours, and/or failure to dilute urine to osmolality < 100 mOsm/kg H_2O)

7. Elevated plasma arginine vasopressin.

sodium in excess of 0.5 mmol/L per day are associated with neurological sequelae and require prompt correction by intravenous hypertonic saline. In contrast, the mainstay of therapy for chronic asymptomatic SIAD is fluid restriction, with or without demeclocycline, urea or aquaretic vaptans.

Acute hyponatraemia with neurological symptoms has a mortality of 5–8%, partly reflecting the underlying pathology. Rapid correction of hyponatraemia by intravenous hypertonic saline, causes osmotic demyelination, leading to central pontine and extrapontine myelinosis. Central pontine myelinosis usually presents 1–2 days after correcting hyponatraemia with quadriparesis and bulbar palsy and is related to the rapidity of correction of sodium. A safe balance between over-zealous correction causing irreversible myelinosis and the considerable mortality of uncorrected SIAD is required (Ellison and Berl, 2007). Hypertonic saline infusions should correct serum sodium at a rate of 0.5 mmol/L per hour although a correction rate of up to 2 mmol/L per hour is said to be safe (Ayus et al., 1982). The total rise in serum sodium should not exceed 25 mmol/L and correction should stop once the serum sodium exceeds 120 mmol/L and symptoms have resolved. To achieve a correction rate of 0.5 mmol/L per hour requires $0.3 \times$ body weight in kg (mmol Na^+/hour). Hypertonic (twice normal) saline solution of 1.8% contains 0.3 mmol/L Na^+. So the correct rate of infusion is 1 mL/kg body weight per hour of 1.8% sodium chloride (Adrogue and Madias, 2000). Although more complex formulae may prove more accurate, they tend to be more difficult to calculate (Nguyen and Kurtz, 2005).

The mainstay of treatment of chronic asymptomatic SIAD is fluid restriction: intake should be limited to 500 mL/day and urine output should not exceed 500 mL/day. This takes several days to influence hyponatraemia. In the context of palliative care, fluid restriction is frequently undesirable as it is unpleasant for patients and onerous for their carers.

The tetracycline analogue demeclocycline (desmethylchlortetracycline) causes nephrogenic diabetes insipidus and alleviates chronic SIAD. Demeclocycline administered orally in two divided doses equivalent to 900–1200 mg/day will reverse chronic SIAD over 3–4 days and should be followed by a maintenance dosage of 600–900 mg/day. The main side effects are gastrointestinal disturbances and hypersensitivity reactions, although reversible nephrotoxicity may occur with prolonged use, especially when hepatic function is impaired.

Urea is an osmotic diuretic increasing free water excretion and reducing natriuresis by raising intramedullary urea levels. It controls SIAD when given intravenously or orally but is poorly tolerated. Oral urea should be given once daily at a dose of 30 g, dissolved in orange juice to mask the taste. There is no need to fluid restrict patients treated with oral urea because of its diuretic properties (Decaux et al., 1993).

Recently non-peptide vasopressin receptor antagonists have been developed including oral selective V_2 receptor antagonists (tolvaptan, satavaptan, and lixivaptan) and intravenous V_{1A}/V_2 receptor antagonists (conivaptan). This class of drugs has been christened the vaptan aquaretics in recognition of their different mechanism of diuresis compared to the saliuretic actions of more familiar diuretics. In conjunction with modest fluid restriction vaptans have proven safe and effective in the treatment of chronic euvolaemic hyponatraemia (Decaux et al., 2008; Robertson, 2011). Oral tolvaptan and intravenous conivaptan are currently licensed for the treatment of euvolaemic hyponatraemia (Gross et al., 2011).

Non-islet cell tumour hypoglycaemia

Tumour-related hypoglycaemia is a frequent complication of pancreatic beta islet cell tumours which secrete insulin, but occurs uncommonly with non-islet cell tumours, usually due to secretion of insulin-like growth factors (Gorden et al., 1981).

Pathogenesis

The two insulin-like growth factors (IGF-1 and IGF-2) share sequence homology with insulin and influence cellular growth, differentiation and metabolism. In many cases of non-islet cell tumour hypoglycaemia, tumours secrete an abnormal precursor of IGF-2 (known as big IGF-2) (Zapf et al., 1992). Unlike insulin, IGFs are bound to at least six IGF plasma binding proteins and normally bind to two cell surface receptors (IGFR-1 and IGFR-2). At high levels of IGF-2 there is a specificity spill-over so that lower affinity binding to insulin receptors occurs, causing hypoglycaemia.

Rarely, non-islet cell tumour hypoglycaemia has been reported to be due to insulin secretion by cervical cancers (Seckl et al., 1999) and the production of antibodies to insulin (Redmon et al., 1992) and insulin receptors (Walters et al., 1987).

Epidemiology

Non-islet cell tumours associated with hypoglycaemia are usually large (average 2.4 kg), retroperitoneal or intrathoracic, often with liver invasion, and growing over several years. Histologically, half these tumours are mesenchymal (mesothelioma, neurofibroma, fibrosarcoma, leiomyosarcoma, rhabdomyosarcoma, neurofibrosarcoma, haemangiopericytoma, and spindle cell carcinoma), 20% hepatoma, 5–10% adrenal carcinoma (chiefly androgen-secreting), and 5–10% gastrointestinal tumours.

Clinical features

Hypoglycaemia may be a presenting symptom, but more commonly occurs with advanced disease. The clinical manifestations comprise cerebral hypoglycaemia and secondary secretion of catecholamines. Neurological findings include agitation, stupor, coma, and seizures which usually follow exercise or fasting and occur most often in the early morning and late afternoon. Focal neurological deficits may be present.

Tumour-related hypoglycaemia should be differentiated from other causes of hypoglycaemia including drugs (e.g. sulphonylureas), hypoadrenalism, hypopituitarism, and liver failure. In advanced malignancy the most common cause of hypoglycaemia is continued oral hypoglycaemic medication in long-standing diabetics.

Treatment

Reversing life-threatening or symptomatic hypoglycaemia requires intravenous glucose infusion. Hyperosmolar glucose solutions in excess of 10% should be administered via central lines; serum glucose levels require frequent monitoring to ensure optimal correction of hypoglycaemia. Up to 2000 g/day may be required to control tumour-related hypoglycaemia. Debulking surgery and effective chemotherapy frequently improve paraneoplastic hypoglycaemia and should therefore be considered even in

a palliative context. Dietary supplementation with frequent feeding, including during the night, may control symptoms of mild paraneoplastic hypoglycaemia. Corticosteroids in high doses, parentral glucagon and human growth hormone have all been of benefit in some patients, whilst diazoxide, which inhibits insulin secretion, and somatostatin have been ineffective (Teale and Wark, 2004). Arterial embolization of tumours may also palliate paraneoplastic hypoglycaemia.

Future approaches

The discovery of the role of IGFs in the pathogenesis of non-islet cell tumour hypoglycaemia suggests that IGF antagonists may reduce the dependence on continuous glucose infusions to control hypoglycaemia (Pollak, 2012).

Enteropancreatic hormone syndromes

Enteropancreatic hormone production is relatively uncommon in malignancy; however, there is a variety of clinical syndromes associated with hormone secretion by endocrine tumours of the pancreas and less frequently tumours arising in other organs. The majority of pancreatic islet cell tumours are malignant (with the exception of most insulinomas) and frequently metastases are present at diagnosis. Surgical excision of small localized tumours is optimal treatment and unresectable malignant secretory tumours may respond to chemotherapy. However, in many patients the distressing clinical manifestations arising from excessive secretion of gastrointestinal peptides require palliation and this may be difficult to achieve. These tumours often secrete more than one polypeptide hormone and may switch hormone production during follow-up.

Treatment

The clinical manifestations listed according to the major hormone product of secretory endocrine tumours are shown in Table 14.2.2,

along with palliative endocrine manoeuvres. The control of insulinoma-related hypoglycaemia is similar to the management of paraneoplastic hypoglycaemia (see above), except that diazoxide may be a valuable additional agent in insulinoma. Diazoxide inhibits insulin release from beta islet cells but may cause salt and water retention and so is usually prescribed with chlorothiazide. Palliation of acid hypersecretion in Zollinger–Ellison syndrome is achieved most effectively by proton pump inhibitors. High-dose histamine H_2 receptor antagonists may also be useful. The symptomatic control of other secretory tumours has been revolutionized by the introduction of long-acting somatostatin analogues.

Somatostatin, a widely distributed neuroendocrine peptide, acts via five receptors, has a short duration of action, and requires intravenous administration (Kulke and Mayer, 1999). These shortcomings have been overcome by the use of an eight-amino acid synthetic analogue octreotide that is given by subcutaneous injection. A depot formulation of octreotide (Sandostatin® LAR®) and a longer-acting analogue lanreotide (Somatuline LA®) are now available.

The control of clinical symptoms associated with enteropancreatic hormone hypersecretion can be achieved by 100–600 micrograms octreotide subcutaneously daily in many patients with endocrine pancreatic tumours. Once adequate symptom control has been achieved, patients may switch to the longer acting Sandostatin® LAR® or lanreotide. The response to octreotide depends upon the presence of somatostatin receptors on tumours and this has been exploited for tumour localization using *in vivo* scintigraphy with labelled octreotide (Ricke et al., 2001). Somatostatin analogues provide valuable palliation in insulinomas, glucagonomas, gastrinomas, and VIPomas but fail generally to control tumour growth. Octreotide therapy is well tolerated; although initially abdominal cramps and diarrhoea

Table 14.2.2 Clinical manifestations of secretory endocrine tumours

Tumour	Major feature	Minor feature	Common sites	Malignant	MEN associated	Palliative therapies
Insulinoma	Neuroglycopenia (confusion, fits)	Permanent neurological deficits	Pancreas (β cells) > 99%	10%	4–5%	Frequent feeding Glucose Glucagon Diazoxide and chlorothiazide Octreotide (if scan +ve)
Gastrinoma (Zollinger–Ellison syndrome)	Peptic ulceration	Diarrhoea, Weight loss Malabsorption Dumping	Pancreas (δ cells) 25% Duodenum 70%	> 50%	20–25%	Gastrectomy Proton pump inhibitors H_2 receptor antagonists Octreotide
VIPoma (WDHA or Werner–Morrison syndrome)	Watery diarrhoea Hypokalaemia Achlorhydria	Hypercalcaemia Hyperglycaemia Hypomagnesaemia	Pancreas (α–δ cells) 90% Neuroblastoma SCLC Phaeochromocytoma	> 50%	6%	Octreotide Glucocorticoids Potassium and bicarbonate during attacks
Glucagonoma	Migratory necrolytic erythema Mild diabetes mellitus Muscle wasting Anaemia	Diarrhoea Thromboembolism Stomatitis Hypoaminoacidaemia Encephalitis	Pancreas (α cells) 99%	> 70%	1–20%	Octreotide Oral hypoglycaemics Prophylactic anticoagulation

H_2, histamine type 2; MEN, multiple endocrine neoplasia; SCLC, small cell lung cancer; VIP, vasoactive intestinal polypeptide; WDHA, watery diarrhoea, hypokalaemic achlorhydria.

may occur, significant steatorrhoea and malabsorption have not been observed. Amongst the more recent advances in the management of these tumours is the use of radiolabelled somatostatin analogues (Kaltsas et al., 2005).

Carcinoid syndrome

Carcinoid tumours arise from serotonin-producing cells, principally in the gastrointestinal tract, pancreas, and lungs, but occasionally in the thymus and gonads. The incidence is 1.5 per 100 000 and carcinoid syndrome develops in 6–18% of patients with these tumours and these patients almost invariably have hepatic metastases (Feldman, 1987; Modlin and Sandor, 1997; Kulke and Mayer, 1999). The features of carcinoid tumours vary by their sites of origin (see Table 14.2.3).

The cardinal feature of carcinoid syndrome is the combination of diarrhoea and flushing and may be associated with endomyocardial fibrosis, asthma, and pellagra. One-third of patients develop late cardiac manifestations, typically involving the right side of the heart and leading to pulmonary valve stenosis and tricuspid valve regurgitation. Asthma and pellagra are less common. The pellagroid rash arises secondary to diversion of tryptophan for 5-hydroxytryptamine (5-HT) synthesis rather than nicotinamide production (Vinik et al., 1989). The clinical features are mediated by several potentially active substances secreted by carcinoid tumours including 5-HT, 5-hydroxytryptophan, kallikrein, tachykinins (substance P, neuropeptide K), prostaglandins, catecholamines, and histamine. The diagnosis is established by measuring the urinary excretion of 5-hydroxyindoloacetic acid. However, platelet 5-HT levels are a more sensitive diagnostic test and are unaffected by diet (Kema et al., 1992). Tumour localization may be achieved using somatostatin receptor scintigraphy or by positron emission tomography (PET) scanning after injecting ^{11}C-labelled 5-hydroxytryptophan (Jensen, 2000).

Pharmacological control of carcinoid syndrome is primarily achieved by inhibiting the synthesis, release and peripheral action of circulating tumour products, principally 5-HT. The choice of drugs remains empirical in view of the varied profiles of substances released by tumours. Parachlorophenylalanine and methyldopa block 5-HT synthesis, but are poorly tolerated and, therefore, rarely used. There are seven families of serotonin receptors (5-HT_{1-7}) but the relevance of the different receptors to the clinical manifestations is uncertain and is obscured by the secretion of multiple products by these tumours. Cyproheptadine (4–7 mg three times daily) blocks 5-HT_2 receptors and improves diarrhoea in 60% of patients and flushing in 47% with a mean duration of response of 8 months. In contrast, ketanserin (40–160 mg once daily) ameliorates flushing in 50% but only 20% derive relief from diarrhoea. Selective 5-HT_3 receptor inhibitors have been shown to reduce diarrhoea in carcinoid syndrome. Metoclopramide and cisapride stimulate gastric motility via the 5-HT_4 receptor and antagonists of this receptor, which are in development, may prove useful in palliating carcinoid syndrome.

Somatostatin analogues are the first line of treatment for patients with carcinoid syndrome. Octreotide in doses of 50–150 micrograms two or three times daily, subcutaneously, reduces 5-HT secretion and activity. It controls both flushing and diarrhoea in the carcinoid syndrome and produces initial relief of symptoms in 80% of patients (Kvols and Reubi, 1993). Sandostatin® LAR® and lanreotide, a related peptide, are long-acting analogues that have been found to be efficacious (di Bartolomeo et al., 1996; Rubin et al., 1999; O'Toole et al., 2000). Tumour shrinkage rarely occurs however, and the effects of treatment diminish with time.

Palliative debulking surgery may be offered to selected patients with metastatic disease, as it can delay the development of the carcinoid syndrome. Hepatic artery embolization similarly can produce good symptom palliation. Chemotherapy and alpha interferon have also been used successfully to palliate symptoms in carcinoid syndrome (Jensen, 2000). Interferon alpha is of benefit for carcinoid tumours that are somatostatin receptor negative (Oberg, 2000) but adding interferon to somatostatin analogues does not improve outcomes (Faiss et al., 2003). ^{131}I-met-iodobenzylguanidine has been used in patients with disabling symptoms in whom other therapeutic options have failed (Taal et al., 1996). Targeted agents including the mammalian target of rapamycin (mTOR) inhibitors such as everolimus (Yao et al., 2008a), and vascular endothelial growth factor receptor (VEGFR) inhibitors such as bevacizumab have been investigated (Yao et al., 2008b).

Symptom palliation in carcinoid syndrome includes therapy of diarrhoea (codeine phosphate, loperamide or diphenoxylate), β_2 adrenergic agonists for wheezing, and avoiding precipitating factors to reduce flushing (including alcohol and some foods).

Phaeochromocytoma

Catecholamine secreting tumours arise from the adrenal medulla (phaeochromocytomas) or other neural crest-derived tissues. Phaeochromocytomas derive from chromaffin cells of the sympathetic nervous system, usually in the adrenal medulla but occasionally in sympathetic ganglia (paragangliomas).

Table 14.2.3 Comparison of carcinoid tumours by site of origin

	Foregut (2–33% carcinoid tumours)	Midgut (75–87% carcinoid tumours)	Hindgut (1–8% carcinoid tumours)
Site	Respiratory tract, pancreas, stomach, proximal duodenum	Jejunum, ileum, appendix, Meckle's diverticulum, ascending colon	Transverse and descending colon, rectum
Tumour products	Low 5-HTP, multihormones[a]	High 5-HTP, multihormones[a]	Rarely 5-HTP, multihormones[a]
Blood	5-HTP, histamine, multihormones[a], occasionally ACTH	5-HT, multihormones[a], rarely ACTH	Rarely 5-HT or ACTH
Urine	5-HTP, 5-HT, 5-HIAA, histamine	5-HT, 5-HIAA	Negative
Carcinoid syndrome	Occurs but is atypical	Occurs frequently with metastases	Rarely occurs
Metastasises to bone	Common	Rare	Common

[a] Multihormones include tachykinins (substance P, substance K, neuropeptide K), neurotensin, PYY, enkephalin, insulin, glucagon, glicentin, VIP, somatostatin, pancreatic polypeptide, ACTH, α-subunit of human chorionic gonadotrophin.

5-HT, 5-hydroxytryptamine (serotonin); 5-HTP, 5-hydroxytryptophan; 5-HIAA, 5-hydroxyindole acetic acid.

Phaeochromocytomas commonly secrete norepinephrine and epinephrine but also occasionally significant quantities of dopamine. The catecholamines cause intermittent, episodic, or sustained hypertension and other manifestations including anxiety, tremor, palpitations, sweating, flushing, headaches, gastrointestinal disturbances, and polyuria. These symptoms are all attributable to excessive adrenergic stimulation, and when surgery and chemotherapy are unable to control the disease, palliative treatment is usually achieved by alpha and beta adrenergic receptor blockade. However, phaeochromocytomas rarely secrete other peptide hormones which cause symptoms refractory to adrenergic inhibition. Initial treatment should be alpha blockade to control hypertension (e.g. phenoxybenzamine 10 mg twice daily, gradually increasing the dosage until symptoms are palliated) followed by beta blockade to control tachycardia (e.g. propranolol 20–80 mg three times daily). This combination will control symptoms in most patients. If palliation is not achieved despite full adrenergic receptor blockade, α-methylparatyrosine (metirosine 250 mg twice daily increasing up to 4 g/day) may be used, but is only available on a named patient basis in the United Kingdom. Metirosine is a competitive inhibitor of tyrosine hydroxylase, the rate limiting enzyme in catecholamine synthesis, and reduces catecholamine production by up to 75%, but it is poorly tolerated due to sedation, extrapyramidal effects, and diarrhoea. The noradrenaline (norepinephrine) analogue metiodobenzylguanidine (MIBG) is taken up by catecholamine synthesizing tissues and ^{131}I-MIBG is useful for imaging phaeochromocytomas. At higher doses ^{131}I-MIBG may be used as therapy for phaeochromocytoma and neuroblastoma (Lenders et al., 2005).

Gonadotrophin secretion

Follicle-stimulating hormone, luteinizing hormone, and human chorionic gonadotrophin (hCG) may be secreted by pituitary, trophoblastic, or germ cell tumours and ectopically by tumours arising in other organs. All three gonadotrophins share the same β subunit with thyroid stimulating hormone but have a unique α subunit that confers biological activity. Excess gonadotrophins may result in precocious puberty in children, secondary amenorrhoea in women, gynaecomastia in men, and, rarely, hyperthyroidism.

Precocious puberty

Central precocious puberty occurs with central nervous system tumours secreting gonadotrophins. Incomplete or peripheral precocious puberty may result from hCG secretion by germinomas, teratomas, chorioepitheliomas, and hepatomas and oestrogen or testosterone production by adrenal, testicular (Leydig cell), and ovarian (granulosa thecal cell) tumours. The treatment of precocious puberty includes psychological counselling for boys with increased aggression and excessive masturbation. Medical therapy is required to control both the psychosocial aspects and sustained effects on skeletal maturation. Central precocious puberty is amenable to gonadorelin analogues which lead to pituitary gonadotrophin receptor desensitization resulting in suppressed luteinizing hormone and follicle-stimulating-hormone secretion. The management of incomplete precocious puberty is more difficult and requires the use of antiandrogens (e.g. flutamide, bicalutamide, cyproterone acetate and spironolactone) and

inhibitors of androgen synthesis (e.g. ketoconazole, dutasteride and finasteride).

Amenorrhoea

Secondary amenorrhoea occasionally may be a consequence of gonadotrophin, prolactin, oestrogen, or androgen-secreting tumours although iatrogenic causes are far more common. The vasomotor symptoms may be palliated by hormone replacement therapy and dyspareunia caused by vaginal atrophy may be alleviated by topical oestrogen preparations.

Gynaecomastia

Gynaecomastia results from elevation in the oestrogen:androgen ratio and is most often a consequence of drug therapy, either chemotherapy (alkylating agents, vinca alkaloids, nitrosoureas), antiemetics (metoclopramide and phenothiazines), antiandrogens (cyproterone acetate, flutamide, bicalutamide), or gonadorelin analogues (goserelin, leuprorelin, buserelin, and triptorelin). Occasionally, tumours secreting oestrogens or gonadotrophins may be responsible. Testicular Leydig cell tumours and feminizing adrenocortical tumours may secrete oestrogens, whilst peripheral aromatization of circulating androgens to oestrogens, is a feature of Sertoli cell tumours, trophoblastic germ cell tumours, sex cord tumours of the testes, and hepatocellular cancers. Elevated circulating oestrogen levels induce ductal, lobular, and alveolar growth of the breast. HCG-secreting tumours (including testicular tumours, non-small cell lung cancers, hepatoma, and pancreatic islet cell tumours) stimulate oestradiol production by interstitial and Sertoli cells of the testes resulting in gynaecomastia. Symptomatic therapy for gynaecomastia includes discontinuation of any incriminated drugs and treatment of the primary tumour. Tamoxifen, clomiphene, topical dihydrotestosterone, and danazol have all been used, as have liposuction, subcutaneous mastectomy, and low-dosage radiotherapy for palliation of painful gynaecomastia (Braunstein, 1993; Di Lorenzo et al., 2005).

Hyperthyroidism

On account of the structural similarities to thyroid stimulating hormone, hCG has intrinsic thyrotropic action via a thyroid stimulating hormone receptor spill-over effect (Fradkin et al., 1989) but clinically overt hyperthyroidism only occurs with tumours secreting very large quantities of hCG, usually trophoblastic tumours (Giralt et al., 1992). The hyperthyroidism resolves after successful tumour therapy, so palliation of the hyperthyroidism should be with drugs (e.g. carbimazole) rather than radioactive iodine or thyroidectomy.

Prolactin

Ectopic prolactin secretion from non-pituitary tumours is very rare and uncommonly causes galactorrhoea. Small cell lung cancer and renal cell cancer causing hyperprolactinaemia and galactorrhoea may be treated by the dopaminergic agonist bromocriptine.

Oxytocin

The molecular biology of oxytocin resembles that of AVP with similar genes, precursor proteins, and transport by axonal streaming. Furthermore, ectopic secretion of both oxytocin and its carrier protein neurophysin I have been demonstrated in small cell

lung cancer, usually in conjunction with ectopic AVP production. Although water intoxication and hyponatraemia may follow oxytocin infusions in obstetrics, ectopic oxytocin secretion does not contribute to SIAD or any other clinical symptoms.

Pyrexia

Pyrexia is a common feature of advanced cancer and is usually attributable to infection or drugs. In one study of fever of unknown origin, 15% of cases were attributed to malignancy (Vanderschueren et al., 2003a), although amongst cancer patients, infection, chemotherapy, or other treatments account for most cases of pyrexia. Paraneoplastic pyrexia is a diagnosis of exclusion established after other causes of fever have been excluded. Lymphoma, leukaemia, renal cancer, hepatoma, myxoma, and osteogenic sarcoma account for most cases of paraneoplastic fever (Zell and Chang, 2005). Although neither C-reactive protein nor erythrocyte sedimentation rate differentiate paraneoplastic pyrexia from infection (Kallio et al., 2001), resolution of fever with naproxen 250 mg twice daily was diagnostic of paraneoplastic pyrexia in some (Chang, 1987), but not all, studies (Vanderschueren et al., 2003b).

Pathogenesis

Pyrogenic cytokines (including tumour necrosis factor, IL-1, IL-6, and interferons) stimulate the synthesis and release of prostaglandin E_2 from the hypothalamus which mediates thermal homeostasis. Tumour-related pyrexia is a consequence of pyrogenic cytokine production by neoplastic cells or normal cells in response to tumours.

Therapy

Definitive tumour therapy resolves paraneoplastic pyrexias in most cases of lymphoma. Sponging, ice-packs, and fans may relieve discomfort. Pharmacological agents such as paracetamol, aspirin, non-steroidal anti-inflammatory drugs, and steroids are effective antipyretics. Advances in the understanding of the pathogenesis of paraneoplastic pyrexia propose a role for cytokine antagonists in therapy.

Non-paraneoplastic complications

Hyperglycaemia

Aetiology

The prevalence of hyperglycaemia in cancer patients is higher than in the general population. Hyperglycaemia is both a risk factor for cancers and a consequence of their treatment. Diabetes mellitus increases the risk of cancers of the pancreas, liver by up to twofold, and to a lesser extent is a risk factor for other cancers (Vigneri et al., 2009; Gallagher and LeRoith, 2011). Several mechanisms may contribute to hyperglycaemia in advanced cancers, including increased gluconeogenesis and Cori cycle activity (conversion of muscle derived lactate to glucose), diminished glucose tolerance, and insulin resistance (Nelson et al., 1994; Poulson, 1997). These changes may arise as a consequence of hepatic dysfunction, altered glucose metabolism by tumour cells, and the secretion of insulin antagonists. Cancer treatments associated with glucocorticoid use, androgen receptor inhibition, or immunomodulation with cytokines, also predispose to the development of hyperglycaemia. Furthermore, the frequent use of corticosteroids in palliative medicine may contribute, since one in five patients on high-dose steroids will develop steroid-induced diabetes mellitus.

Treatment

The conventional treatment of diabetes advocates tight control of blood sugar to delay the onset of both macrovascular and microvascular complications. In contrast, the aims of therapy in palliative care of advanced cancer are to minimize symptoms associated with hypoglycaemia or marked hyperglycaemia. For this reason a higher range of blood sugar is usually advocated, although symptomatic hyperglycaemia (persistent blood sugar > 15 mmol/L) should be avoided (Poulson, 1997). As disease progresses, oral hypoglycaemic agents or insulin dose generally will need to be reduced with falling nutritional intake.

Steroid-induced diabetes, which occurs frequently in advanced cancer, is usually asymptomatic and requires no therapy; however, monitoring should be instituted for patients on moderate or high doses of exogenous glucocorticoids. If symptomatic hyperglycaemia develops, a short-acting sulphonylurea may be useful (e.g. gliclazide 40–80 mg once daily.)

Hypothalamic–pituitary–adrenal dysfunction

Dysfunction of the hypothalamic–pituitary–adrenal axis can occur as a direct result of cancer or as a consequence of treatment.

Growth hormone

Growth hormone deficiency occurs as a dose-dependent effect of cranial radiotherapy. It often presents years later with reduced bone and muscle mass, poor exercise tolerance, and diminished myocardial function (Sklar and Constine, 1995). Measurements of growth hormone, IGF-1, and gonadal function establish the diagnosis. Tumours of the pituitary or craniopharnyx can also cause growth hormone deficiency.

Sex hormones

Similarly, head and neck radiotherapy can affect sex hormone production, directly causing hyperprolactinaemia and gonadotrophin deficiency, or indirectly by disrupting growth hormone, thyroid, or adrenal function. Hyperprolactinaemia inhibits secretion of pituitary gonadatrophin causing secondary hypogonadism and occurs in 60% of brain tumour patients treated with cranial radiotherapy (Constine et al., 1993). Sex hormone deficiency may alter libido and affect metabolism of bones and lipids. Specialist assessment for sexual dysfunction is recommended, as there may be multifactorial causes.

Adrenocorticoid function

Adrenal function may be disrupted by bilateral metastases, infection in the immunocompromised, haemorrhage, surgery, chemotherapy, or other drugs which affect CYP enzymes (e.g. ketoconazole). Metastases to the adrenal glands are common, however clinically significant hypoadrenalism is rare, as over 80% of the adrenal tissue needs to be replaced to disrupt function (Cedermark and Sjoberg, 1981). Hypoadrenalism presents with profound weakness, gastrointestinal upset, hypotension, psychiatric manifestations, and, rarely Addisonian, crises. Standard replacement therapy is hydrocortisone 20 mg at 800 a.m. and 10 mg at 6 p.m. with fludrocortisone 0.05–0.15 mg daily.

Thyroid function

Thyroid function can be affected by surgery, radiotherapy, and systemic anticancer therapy. Radiotherapy is associated with hypothyroidism, transient hyperthyroidism related to an

autoimmune thyroiditis, and thyroid cancer (Wasnich et al., 1973; Tami et al., 1992). Euthyroid sick syndrome, characterized by low serum triiodothyronine levels, occurs commonly with advanced malignancy but rarely causes clinical illness (McIver and Gorman, 1997).

Metabolic bone disease

Osteoporosis can be precipitated by glucocorticoids and chemotherapy (e.g. cisplatin) which cause renal loss of calcium, magnesium, and phosphate. In premenopausal women treated for breast or ovarian cancer and men with prostate cancer treated with androgen inhibition, osteoporosis is common (Gralow et al., 2009). Early assessment using bone mineral density measurement and treatment with oestrogens, if appropriate, or bisphosphonates should be considered to reduce the risk of skeletal events.

Renal failure

Renal failure is a common feature of advanced malignancy and many aetiological factors play a role in its pathogenesis (see Box 14.2.2) (Darmon et al., 2006). In the context of incurable malignant disease, reversible causes may be addressed but aggressive treatment, such as renal replacement therapy, is seldom appropriate. Conversely, there is increasing awareness of palliative measures and end-of-life care amongst nephrologists treating patients with end-stage renal failure (Poppel et al., 2003).

Potentially reversible metabolic causes of renal failure include urate nephropathy, hypercalcaemia, and tumour lysis syndrome

---

Box 14.2.2 Causes of renal failure in malignancy
◆ Infiltration by tumour
◆ Fluid depletion
◆ Electrolyte imbalance:
• uric acid (tumour lysis syndrome)
• hypercalcaemia
• paraprotein (e.g. myeloma)
• amyloid (e.g. myeloma)
• lysozyme (e.g. acute myelomonocytic leukaemia)
• mucoprotein (e.g. pancreatic adenocarcinoma)
• nephrogenic diabetes insipidus (e.g. leiomyosarcoma)
◆ Urinary tract obstruction
◆ Iatrogenic
• chemotherapy
• radiotherapy
◆ Paraneoplastic:
• membranous glomerulonephritis (e.g. carcinomas)
• minimal change glomerulonephritis (e.g. Hodgkin's disease)
• membranoproliferative glomerulonephritis (e.g. non-Hodgkin's lymphoma)
• thrombotic microangiopathy
◆ Pre-existing chronic renal failure.

(Garnick and Mayer, 1978). Prerenal and obstructive renal failure may be reversible, although treatment may be inappropriate if the patient is very frail and antitumour options have been exhausted (Garnick and Mayer, 1978).

Nevertheless, symptomatic management of renal failure is important. Patients may experience nausea, vomiting, drowsiness, and confusion as the kidneys fail. Dry mouth and anorexia are frequent symptoms of advanced cancer and may be exacerbated by renal impairment. Appropriate and sensitive explanation to the patient and family should be accompanied by medication to relieve any unpleasant symptoms. In the context of renal failure, doses or dose frequency of some medications, including opioid analgesics, may need to be reduced or stopped to avoid drug accumulation or deterioration of renal function (see Chapter 15.6). Patients already receiving renal dialysis for pre-existing chronic renal failure may choose to continue, but should be supported to stop dialysis, if this is their wish (Smith et al., 2003).

Obstructive nephropathy may cause colicky pain in addition to the non-specific symptoms of renal failure. Although analgesics and antispasmodics may ameliorate the pain, longer lasting relief of symptoms can be achieved with percutaneous nephrostomy. This procedure, performed under sedation, can be followed by antegrade catheterization of the ureters. Nephrostomy tube insertion is an invasive procedure and is appropriate in selected cases where prognosis may be longer or antitumour treatment is planned (Harrington et al., 1995; Little et al., 2003).

Liver failure

Liver failure in cancer patients is usually a consequence of biliary obstruction, very extensive hepatic metastases, or drug therapy, although paraneoplastic hepatopathy has been described in Hodgkin's lymphoma (Dourakis et al., 1999) and renal cancer (Fang et al., 1992) (see Chapter 10.4). After excluding drug causes, it is important to differentiate obstructive and parenchymal causes, as the approach to palliation differs.

Biliary obstruction may be confirmed by ultrasonography and drainage may be undertaken to relieve jaundice and associated symptoms such as anorexia, nausea, and pruritus (see Chapter 10.4). The diagnosis is important since relief of obstruction can provide symptomatic relief and a prognosis of more than 6 months (Isayama et al., 2004), whereas hepatic failure from parenchymal replacement by malignant disease is likely to lead to death within weeks. Biliary drainage may be obtained temporarily by percutaneous transhepatic biliary drainage or directly by endoscopic retrograde biliary stenting.

Hepatic failure due to massive metastases may produce jaundice, pruritus, anorexia, liver capsule pain, ascites, disturbances of haemostasis, malabsorption, and electrolyte disturbances, culminating in hepatic encephalopathy. The palliative treatment of liver failure needs to be tailored to the particular symptoms of each patient. Liver capsule pain may be helped by non-steroidal anti-inflammatory drugs or corticosteroids together with conventional analgesics. Symptoms of functional gastric outlet obstruction may be relieved by metoclopramide before meals. Nausea secondary to liver failure may require centrally acting antiemetics such as haloperidol. Pruritus may be reduced by using emollients and night sedation. Naltrexone and stanozolol have also been found to be effective in pruritus from intrahepatic cholestasis and obstructive jaundice respectively (see Chapter 11.2).

Hepaticencephalopathyiscausedbyexcessgamma-aminobutyric acid (GABA) activity, ammonia, and other toxins in the central nervous system. Conventional therapies include restriction of dietary protein and sodium, bowel clearance with magnesium sulphate enemas and lactulose, as well as bowel sterilization with the non-absorbed antibiotic rifaximin (Bass et al., 2010). Since hepatic encephalopathy is a terminal event in advanced malignancy, these unpleasant treatments are rarely appropriate. The main symptom of encephalopathy is confusion, and after establishing the cause, familiar company, a light and quiet environment, and a regular routine should be provided, together with explanation, reassurance, and reorientation. Sedation may be necessary if the patient is agitated; haloperidol (1.5–5 mg) or levomepromazine (6.25–150 mg) may be given orally or subcutaneously, and also has antiemetic activity (see Chapter 18.2). Portal hypertension and abnormal coagulation predisposes to gastrointestinal haemorrhage. Major haemorrhage should usually be managed symptomatically (see Chapter 8.7).

Lactic acidosis

In cancer patients, lactic acidosis is most frequently type A, due to impaired tissue oxygenation secondary to hypoperfusion as a consequence of septicaemia shock. Less commonly, type B lactic acidosis occurs with large tumour burdens of haematological cancers. Increased lactate production by tumour cells owing to uncoupled oxidative phosphorylation and glycolysis, and reduced lactate clearance due to liver dysfunction, are implicated in the pathogenesis. Lactic acidosis presents with hyperventilation and hypotension and the diagnosis is established biochemically by the combination of wide anion gap acidosis and raised plasma lactate (> 2 mEq/L). High-volume haemofiltration and intravenous sodium bicarbonate may correct the metabolic acidosis, but should obviously only be used if effective anticancer therapy is available and appropriate (Fall and Szerlip, 2005).

Bowel obstruction

Carla I. Ripamonti, Alexandra M. Easson,
and Hans Gerdes

Introduction to bowel obstruction

In this chapter, malignant bowel obstruction (MBO) is defined as the clinical presentation of patients with symptoms, signs, and radiographic evidence of obstruction to the transit of gastrointestinal (GI) contents caused by cancer, or the consequences of anticancer therapy including surgery, chemotherapy or radiation therapy. Although some authors and investigators restrict the definition of MBO to the sites of obstruction in the small intestine alone, or any part of the bowel beyond the ligament of Treitz, for the purposes of this chapter, MBO will be considered as obstruction at any level from the stomach outlet to the anus. The signs and symptoms of MBO are not always pathognomonic, but when present in conjunction with the clinical history of abdominal and some extra-abdominal malignancies, should raise suspicion for the diagnosis. Similarly, radiographic testing may not always confirm the presence of obstruction in the presence of classical symptoms, while at times the radiographic changes may predate the onset of symptoms. Therefore, clinicians caring for cancer patients should always retain a high index of suspicion for this problem.

MBO is a well-recognized complication of advanced cancer in patients with abdominal and pelvic malignancies. Although it may develop at any time in the disease, it occurs most frequently at the advanced stage, with the highest incidence ranging from 5.5% to 42% in ovarian carcinoma and in 4.4–24% of patients with colorectal cancer depending on when it is measured in the disease trajectory (Castaldo et al., 1981; Krebs and Goplerud, 1983; Baines et al., 1985; Gallick et al., 1987; Fernandes et al., 1988, Beattie et al., 1989; Larson et all., 1989; Lund, 1989; Mercadante, 1997; Ripamonti et al., 2001). This chapter does not deal with bowel obstruction as the primary presentation of cancer, but rather MBO in the setting of advanced disease.

Mechanisms of bowel obstruction

The aetiology may be benign in 10–48% of cases at operation, caused by adhesions or radiation enteritis, or malignant with single-site, multiple-site, or diffuse disease.

The enlargement of the primary tumour or recurrence of abdominal masses, fibrosis, or adhesions may produce extrinsic occlusion of the lumen. Polypoidal lesions or annular narrowing due to disseminated disease may cause an intraluminal occlusion. Infiltration of the intestinal muscles or superimposed inflammation may produce intramural occlusion of the lumen. Intestinal motility disorders due to a deranged extrinsic neural control of viscera may produce delay in intestinal transit, resulting in a clinical picture similar to bowel obstruction, namely pseudo-obstruction. Concomitant disease, such as diabetes, para-neoplastic syndromes, or previous gastric surgery, may also contribute to dysmotility of this kind. Contributing factors include constipation, due to illness and/or to drugs such as those with anticholinergic side effects including opioids. Pain due to opioid-induced constipation, wrongly treated with increased doses of opioids, may result in faecal impaction producing signs consistent with bowel obstruction (Glare and Lickiss, 1992).

Pathogenesis

An occlusion of the lumen prevents or delays the propulsion of the intestinal contents from passing distally. The accumulation of non-absorbed secretions produces abdominal distension and colicky peristalsis to surmount the obstacle in the early stage, corresponding to a subobstructive state, possibly still reversible. Although there is little or no through-movement of intestinal contents, the bowel continues to contract with increased uncoordinated peristaltic activity. As a consequence, the bowel becomes distended, stimulating intestinal fluid secretion, thus creating a vicious cycle of distension–secretion, further stretching the bowel wall. Moreover, in bowel obstruction the abnormally increased flora may also produce gases in the small intestine, contributing to distension and pain (Mercadante, 1995a) (Fig. 14.3.1).

This will produce damage in the lumen with a consequent inflammatory response involving the activation of the cyclooxygenase pathway and the release of prostaglandins, potent secretagogues either by a direct effect on enterocytes or the enteric nervous reflex (Mercadante, 1995a). Vasoactive intestinal peptide (VIP) may be released into the portal and peripheral circulation and mediate local intestinal and systemic pathophysiological alterations as hyperaemia and oedema of the intestinal wall and an accumulation of fluid in the lumen (Nellgard and Cassuto, 1993; Nellgard et al., 1995).

Hypoxia, caused by the reduction in venous drainage from the obstructed segment interfering with oxygen consumption, is the primary stimulus for VIP release and for intraluminal bacterial overgrowth. High portal levels of VIP are known to cause hypersecretion and splanchnic vasodilatation (Basson et al., 1989). Experimental studies have shown that higher VIP content is
Fig. 14.3.1 Distension–secretion–motor activity causing gastrointestinal symptoms. PG, prostaglandins; VIP, vasoactive intestinal polypeptide.
Reproduced courtesy of Carla Ripamonti.

present in the duodenal tissue when compared to colonic tissue content. This may also explain the finding of a redistribution of blood flow between the obstructed segment and the distal sites. Alterations of splanchnic flow are the basis of the appearance of multiple organ failure syndrome caused or worsened by systemic hypotension commonly observed in the late stage of bowel occlusion (Neville et al., 1991). Fluids and electrolytes are sequestered in the gut wall and in its lumen (third space) in the presence of vasodilatation.

Metabolic and septic consequences

The hypovolaemic state may induce functional renal failure due to a decrease in renal flow and, as a consequence, reduced glomerular filtration. Oliguria, azotaemia, and haemoconcentration may accompany dehydration. Metabolic disorders in intestinal obstruction depend on the site and duration of the obstruction and are caused by dehydration, electrolyte losses, and disorders of acid–base balance (Chan and Woodruff, 1992). The respiratory pattern will depend on the level of obstruction. Metabolic alkalosis, hypochloraemia, hyponatraemia, and hypokalaemia will be features of a high-level obstruction, in part due to intestinal stasis of biliary, pancreatic, intestinal, as well as gastric secretions (Mercadante, 1997). There will be acidosis due to ischaemic

lesions or septic complications (Scott Jones and Schirmer, 1989). The increased abdominal distension reduces the venous return and may impair pulmonary ventilation as a result of elevation of the diaphragm.

Sepsis may occur in the late stages of bowel obstruction. It consists of the passage of toxins from the intestinal contents through the intestinal wall into the lymphatic and systemic circulation, or bacterial translocation. This phenomenon results from the increase in endoluminal pressure, stasis, and intestinal ischaemia, together with intestinal gangrene and perforation, commonly observed in the late stages of persisting bowel obstruction. The time course of these events is variable, occurring over several days in malignant mechanical bowel obstruction.

Clinical and radiological diagnosis

In cancer patients, compression of the bowel lumen develops slowly and often remains partial. The level of obstruction determines the different patterns of symptoms (Table 14.3.1). The progression may be slow or fast, from partial obstruction to complete occlusion, each producing a different spectrum of symptoms, differing intensity of suffering, and ultimate outcome. Accumulation and increased production of secretions produce the principal symptoms, namely abdominal pain and distension,

Table 14.3.1 Common symptoms in cancer patients with MBO

Vomiting	Intermittent or continuous	It develops early and in great amounts in gastric, duodenum, and small bowel obstruction and develops later in large bowel obstruction	Biliary vomiting is almost odourless and indicates an obstruction in the upper part of the abdomen. The presence of bad smelling and faecaloid vomiting can be the first sign of a ileal or colic obstruction
Nausea	Intermittent or continuous		
Colicky pain	Variable intensity and localization due to distension proximal to the obstruction; secondary to gas and fluid accumulation most of which are produced by the gut	If it is intense, periumbelical and occurring at brief intervals, may be an indication of an obstruction at the jejunum–ileal level. In large bowel obstruction the pain is less intense, deeper, occurring at longer intervals and spreads toward the colon wall	An overall acute pain which begins intensely and becomes stronger, or a pain which is specifically localized, may be a symptom of a perforation or an ileal or colic strangulation. A pain which increases with palpation may be due to peritoneal irritation or the beginning of a perforation
Continuous pain	Variable intensity and localization	It is due to abdominal distension, tumour mass and/or hepatomegaly	
Dry mouth		it is due to severe dehydration, metabolic alterations but above all it is due to the use of drugs with anticholinergic properties and poor mouth care	
Constipation	Intermittent or complete	In case of complete obstruction there is no evacuation of faeces and no flatus	In case of partial obstruction the symptom is intermittent
Overflow diarrhoea		It is the result of bacterial liquefaction of the faecal material	

Reproduced courtesy of Carla Ripamonti.

vomiting, and constipation (Table 14.3.1). However, distension may be minimal in both jejunal involvement and fixed tumours extensively infiltrating the small bowel. In the presence of a high level of obstruction, such as in stomach, duodenum, or jejunum, vomiting develops early and in larger volumes. Nausea is persistent or occasionally subsides temporarily after an episode of vomiting. Continuous pain is due to a visceral mass growth compressing the intestine, intestinal distension, or hepatomegaly, while severe superimposed colic above the obstruction, in the small or large intestine, may worsen the distress. This activity is variable in intensity and site due to distension proximal to the obstruction. In large bowel obstruction, the pain is generally less intense.

The initial symptoms are frequently abdominal cramps, nausea, vomiting, and abdominal distension that usually present periodically and resolve spontaneously. These episodes are frequently followed by passage of gas or loose stools. GI symptoms caused by the sequence of distension–secretion–motor activity of the obstructed bowel occur in different combinations and intensity depending on the site of obstruction and tend to worsen. Dry mouth is associated with other symptoms, and is the consequence of severe dehydration and metabolic alterations, as well as pharmacological interventions such as anticholinergic drugs. No evacuation of faeces and no passing of flatus are typical features of complete obstruction. The eventual appearance of *paradoxical diarrhoea* results from leakage of faecal fluid from faecal impaction, generally in large bowel obstruction.

Vomiting can be assessed in terms of number of episodes, volume, and overall duration. Other symptoms such as nausea, pain (both colicky and continuous), somnolence, dyspnoea, and, at times even the sensation of hunger can be present and can be evaluated with visual analogue, numerical, or verbal scales.

The assessment of patients with suspected MBO should consider:

- other causes of nausea, vomiting, and constipation
- metabolic abnormalities
- type and dosages of drugs
- nutritional and hydration status
- bowel movements and the presence of overflow diarrhoea
- presence of abdominal faecal masses, distension of the whole abdomen or only above the obstacle, ascites, and painful sites
- presence of faeces in the rectal ampulla (rectal examination).

The diagnosis of intestinal obstruction is established or suspected on clinical grounds and confirmed with abdominal radiographs demonstrating air–fluid levels. Radiologic imaging in the evaluation of patients with the acute abdomen and the confirmation of the diagnosis of MBO has assumed a pivotal role. The preferred radiological procedure has evolved in recent years but it varies in different parts of the world according to the local expertise and the availability of each imaging modality. Table 14.3.2 reports the possible radiological investigations that might be performed in patients with symptoms and signs of bowel obstruction. These should only be used if they are going to directly inform clinical decisions.

Management of bowel obstruction: therapeutic approaches

The management of patients with MBO is one of the greatest challenges for physicians who care for cancer patients. Although MBO is usually associated with advanced-stage disease, when it occurs at the time of initial diagnosis, regardless of the primary site of malignancy, management generally proceeds with curative intent,

Table 14.3.2 Radiological investigations

Plain radiography	The usefulness of abdominal radiography taken is supine and standing position when small bowel obstruction is suspected in questionable; however, it remains an important step in the evaluation of most patients with acute and chronic abdominal symptoms. Plain X-ray can document the air-filled dilated loops of bowel, differential air–fluid levels, or both, but the accuracy for localizing the point and cause of obstruction is low. The sensitivity of plain films in making a decision of small bowel obstruction is 66%
Contrast GI series using barium suspension	Provide excellent radiological definition of the mucosal pattern and luminal patency, particularly in the assessment of the stomach and proximal small bowel but more distal points of small bowel obstruction may not be seen as clearly
	As it is not absorbed, the inability to eliminate it in the setting of obstruction can interfere with subsequent radiographic studies or cause severe impaction, overall in patients with a complete and inoperable bowel obstruction
	Barium small bowel series should be used selectively when acute obstruction has already been ruled out
	In large MBO, barium enema provides a quick, accurate, and inexpensive assessment of the location and cause of obstruction, but it should be used with caution to avoid the retention of the barium proximal to the obstruction leading to dehydration of the barium and potential impaction, especially in patients with incomplete and inoperable large bowel obstruction
	Gastrografin is useful in evaluating small and large bowel obstructions, but it usually only provides good visualization of proximal small bowel obstruction as the water soluble nature of the Gastrografin will result in it being diluted by the excess fluid retained in the distal small bowel
	Retrograde, transrectal contrast studies (enteroclysis) serve to insert the contrast under pressure resulting in full distension of the loops of small bowel, permitting better assessment of the mucosal pattern and patency, and improving the accuracy of diagnosis in small bowel obstruction
CT or MRI	CT provides superior results in the assessment of abdominal symptoms. MRI and CT are useful in evaluating the global extent of disease, to perform a staging and to assist in the choice of surgical, endoscopic, or simple pharmacological palliative intervention for relief of the obstruction

Reproduced courtesy of Carla Ripamonti.

and each patient should be managed according to appropriate principles/guidelines for the underlying malignancy. On the other hand, MBO as part of recurrent disease is often managed with palliative intent; in this context, different factors should be considered to determine the most appropriate treatment.

For patients with recurrent disease, MBO generally occurs in a chronic and slow fashion that results in narrowing of the diameter of the small or large bowel (or both simultaneously).

In the face of a clearly incurable situation, significant patient discomfort and suffering must be balanced with the short life expectancy. The goal in any decision we make needs to impact the quality of life (QOL) of the affected person in a positive way and each assessment and management needs to be tailored to the specific needs of the patients. Fig. 14.3.2 shows the algorithm for assessing and managing a patient with MBO. The physicians need to consider a series of questions when faced with terminal cancer patients (patients no longer responsive to specific oncological therapies) with bowel obstruction:

◆ Is the patient fit for surgery?

◆ Is there a place for stenting?

◆ Is it necessary to use a venting nasogastric tube (NGT) in inoperable patients?

◆ When should a venting gastrostomy be considered?

◆ What drugs are indicated for symptom control?

◆ What is the proper route for drug administration?

◆ What is the role of parenteral hydration and total parenteral nutrition?

Surgical procedures

An open or laparoscopic surgical procedure can successfully relieve obstruction in the appropriate patient (see also Chapter 12.4).

Endoscopic stent placement cannot be done beyond the length of the endoscope, cannot be done for long obstructions, and may not be possible due to previous surgical alterations of the anatomy. Because of a perforation rate of 7–14% and a long-term failure rate of 25–30%, stents are not always the best long-term solution and surgical palliation is likely to provide more durable palliation in patients where there is likely to be a longer survival, as demonstrated in a group of ovarian cancer patients (Abecasis et al., 2001; Dolan, 2011). The selection of patients who will benefit from these procedures is an ongoing challenge and can be done only by multidisciplinary teams working in close collaboration.

Surgical options include complete resection, operative bypass, lysis of adhesions, the creation of a diverting stoma, whether in the small or large bowel, or a combination of these. Complete resection of an obstructing lesion is only beneficial if all tumour in that area can be resected with negative margins, and therefore is most often possible for cancers originating within the digestive tract. In select cases of ovarian or colon cancer, such 'debulking' operation followed by chemotherapy may be of use. In a bypass procedure, if the tumour cannot be resected, but there is healthy non-obstructed bowel before and after the site of obstruction, the two healthy segments can be connected, allowing the bowel contents to go past the blockage. Diverting stomas bring the bowel out to the skin, allowing stool to empty into a bag, and effectively relieving distal obstruction. They can be made of either small or large bowel, and are created out of the most distal unaffected bowel segment. In small bowel stomas, it is necessary to have a minimum of 100 cm of small bowel before a stoma in order to maintain one's nutrition orally. Even so, high small bowel stomas may have high outputs and may cause significant fluid balance problems (Easson, 2007).

Patient selection for surgery

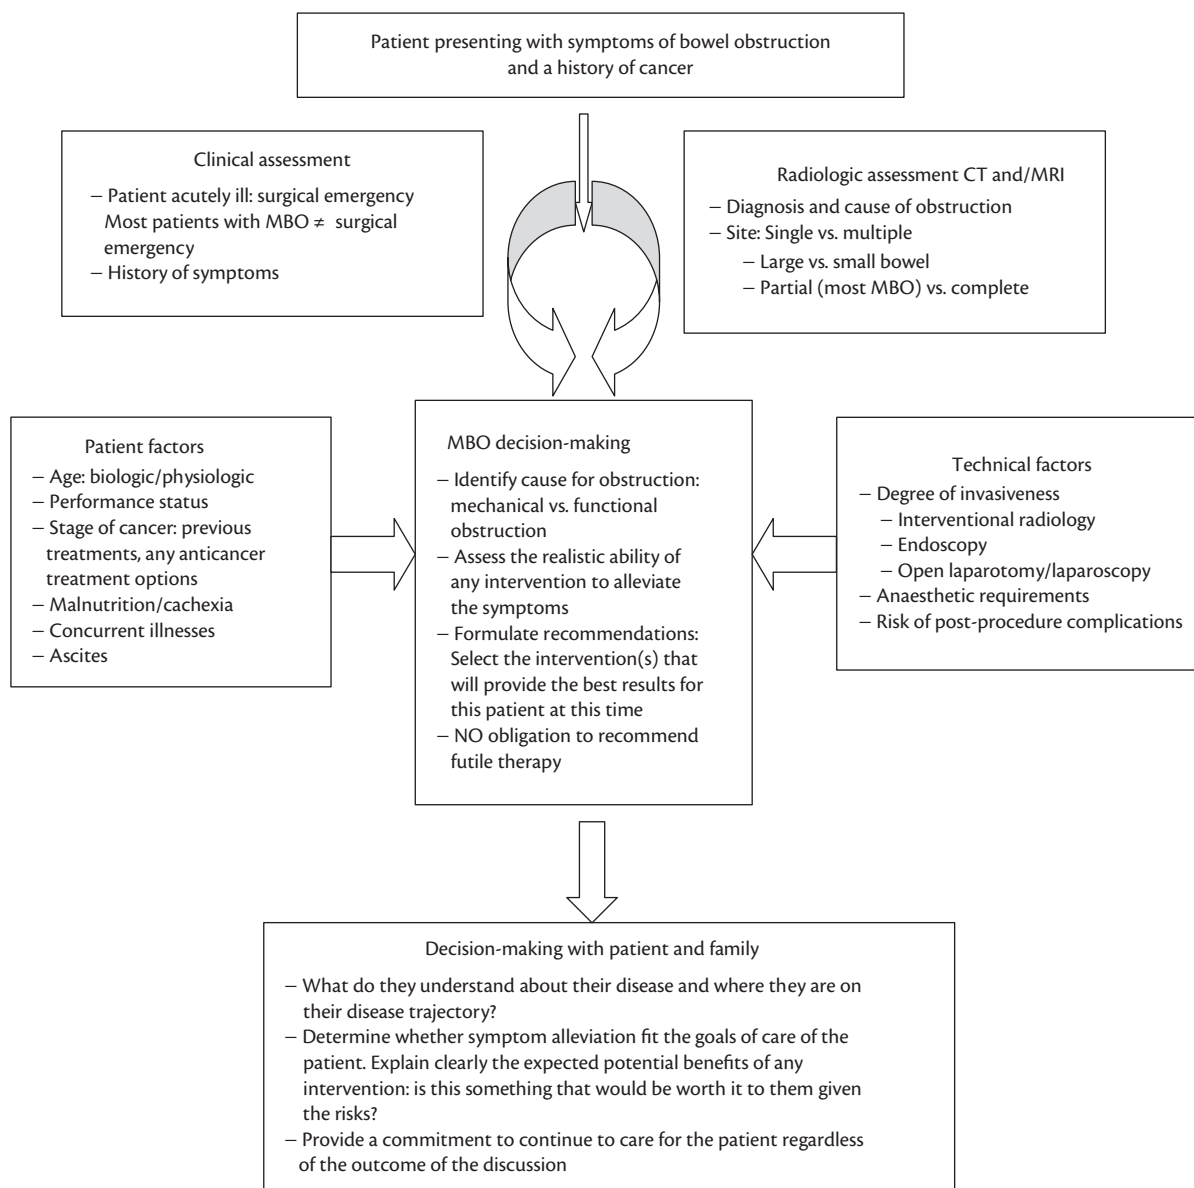
The decision to undergo a palliative procedure is facilitated if the goals and definition of success are clearly defined preoperatively.


Fig. 14.3.2 Distension–secretion–motor activity causing gastrointestinal symptoms.
Reproduced from Lucy Helyer and Alexandra M. Easson, Surgical Approaches to Malignant Bowel Obstruction, *The Journal of Supportive Oncology*, Volume 6, Number 3, pp.105–113, Copyright © 2008, with permission from the authors.

An accepted definition of palliative surgery is surgery used with the primary intent of improving patient QOL and symptoms (Krouse et al., 2002). In approaching these decisions, the patient must first have significant symptoms that, if they could be improved, will improve their QOL. The clinician then reviews which, if any, treatments are appropriate or feasible. The patient's understanding of the nature and prognosis of their underlying illness must be explored, as well as their expectations, goals and values. Their co-morbid medical conditions and expected prognosis are discussed. All treatment options including surgery, endoscopic procedures, interventional radiology, and aggressive medical management should be discussed, along with the complication rates and the expected success of each intervention. This discussion is an extraordinary opportunity to clarify goals of care, including suffering and QOL, adjust reasonable treatment plans,

and deepen the level of trust between the physician and surgeon. The surgeon should be prepared to make a recommendation rather than just providing information (Dunn et al., 2009). These discussions may take time as the patient comes to terms with their disease; fortunately MBO is rarely an emergency and thus the time should be available.

With careful preoperative planning it is possible to determine before the operation in most cases which operation is most likely to succeed; however, the final decision must be made in the operating room. The possibility that no surgical procedure may be possible should also be discussed preoperatively; the patient and family must be prepared for that option and consider advance directives or substitute decision-makers. Finally, there must be a commitment to ongoing care with a clear care plan whatever the outcome of the surgery.

Long-term outcomes from surgery

The likelihood of long-term relief of obstruction after surgery depends on the location of the bowel obstruction, with large bowel obstructions successfully relieved in 80% of cases, compared to 25% if both large and small bowel is involved (Bryan et al., 2004). The number of obstructed sites also affects the likelihood of success; a single site of obstruction has a high likelihood of success when compared to multiple sites of obstruction. It is worth emphasizing that MBO from generalized carcinomatosis is a distinct entity that responds poorly, or not at all, to surgical intervention and these patients are not surgical candidates (Abbas and Merrie, 2007; Helyer et al., 2007; Dolan, 2011).

The selection of patients who will benefit from these procedures is an ongoing challenge. The procedure that is the most likely to successfully relieve symptoms for the greatest length of time with reasonable morbidity is chosen (Krouse et al., 2002). Performance status remains one of the best predictors of lower complication rates and improved survival (Wright et al., 2010); patient factors associated with poor surgical outcomes include advanced age (both physiological and chronological), low albumin, psychological health and social support; and ascites, concurrent illness, and co-morbidities (Medina-Franco et al., 2008; Imai et al., 2010; Henry et al., 2012). Disease factors such as tumour type, grade and extent, time from primary presentation, and history of response to and availability of anti-cancer treatments also affects prognosis and likelihood of success (Henry et al., 2012). In patients with GI malignancy, relief of obstruction with surgery has been shown to increase the likelihood of receiving chemotherapy, with the potential that this may improve survival (Helyer et al., 2007). Several recent papers from large cancer centres have followed patients prospectively with MBO. Significant symptom relief can be obtained by selecting appropriate patients either for surgery or stenting with minimal procedural mortality (Imai et al., 2010; Wright et al., 2010; Chakraborty et al., 2011; Dalal et al., 2011). Henry et al. (2012) recently published two nomograms based on a retrospective analysis of 523 patients, providing a scoring system for 30-day mortality and likelihood of surgical success. Validation of these nomograms in a prospective fashion would be very useful.

Endoscopic procedures

Over the past two decades several endoscopic procedures have been developed in the management of MBO. Tumour ablative techniques were initially investigated including high-energy Nd:YAG (neodymium-doped yttrium aluminium garnet) laser therapy, alcohol injection, photodynamic therapy, and cryotherapy, but the insertion of a self-expandable metal stent (SEMS) and venting gastrostomy are more frequently non-surgical alternatives for relief of symptoms from MBO if intervention is indicated.

Multiple studies have demonstrated that these procedures can be performed both for palliation of symptoms from advanced disease. These treatments may not yet be available in all hospitals, but as the knowledge is disseminated and adopted more widely, they will allow clinicians to have more options to better tailor treatment for their patients according to their own clinical situation and individualized goals of therapy.

Endoscopic stenting for gastroduodenal and proximal jejunal obstruction

Malignant gastric-outlet and duodenal obstruction commonly occurs from neoplastic invasion or extrinsic compression by carcinoma of the stomach, head of the pancreas, gall bladder, and bile duct or from compression by metastatic lymphadenopathy in the porta hepatis from a number of abdominal and extra-abdominal primaries. Obstruction of the proximal jejunum is usually caused by primary jejunal tumours, but similarly can occur as a result of local extension from proximal GI tract cancers or metastases to the peritoneum from intra-and-extra abdominal malignancies.

Endoscopic placement of SEMSs has become the primary endoscopic approach to attempt luminal restoration in such patients. With the use of therapeutic gastroscopes with large operating channels, SEMSs can be inserted directly through the scope. Produced by several manufacturers, they come in several diameters and lengths, allowing clinicians to tailor treatment to the patient's needs. The procedure can be performed under conscious sedation, but because of the frequent presence of significant food retention in the stomach, the risk of aspiration is high, in which case general anaesthesia with airway intubation will help to minimize that risk. Combined endoscopic and fluoroscopic guidance permits accurate placement of stents resulting in quick and effective procedures, short hospital stays, or in selected cases with incomplete obstruction, outpatient procedures.

A number of small retrospective reviews have been published describing short-term results (Yim et al., 2001; Espinel et al., 2006; Chandrasegaram et al., 2012) and several prospective multi-institution series, and meta-analyses (Bryan et al., 2004, 2007; Dunn et al., 2009) report excellent technical and clinical success rates for stent placement for gastroduodenal obstruction as shown in Table 14.3.3 (Dormann et al., 2004; Telford et al., 2004; Kim et al., 2007). Very high technical and clinical success rates are associated with patient reports of improvement or resolution of their symptoms (nausea, vomiting and abdominal pain) while being able to consume at least semi-soft or pureed foods. One multicenter prospective study documented an improvement in ability to eat solid food by day 7 in 75% of patients and 80% by day 28 in a carefully selected cohort (Piesman et al., 2009).

Some comparative studies of treating malignant gastric outlet obstruction (GOO) with endoscopic stent placement versus surgery have shown stenting is associated with shorter hospital stay, lower periprocedural mortality (Lillemoe et al., 1999; Espinel et al., 2006), and more rapid food intake (Espinel et al., 2006; Jeurnink et al., 2007). Stent placement has even been shown to be effective in palliating symptoms from obstruction in the setting of limited degrees of peritoneal carcinomatosis (Mendelsohn et al., 2011).

A prospective study of 27 patients with malignant GOO, examining effects on QOL randomized patients to laparoscopic gastrojejunostomy or endoscopic stent placement and found that stent placement was associated with less pain and shorter hospital stay, with a greater improvement in physical health following stent placement relative to those managed surgically (Mehta et al., 2006). Other prospective non-randomized studies of patient administered questionnaires to quantify the effect of stents on symptoms and QOL noted that patients treated with stents reported significant improvements in nausea, vomiting, ability to eat, and several measures of QOL (Schmidt et al., 2009; Larssen et al., 2011).

Table 14.3.3 Summary of three studies of SEMS in palliation of malignant gastroduodenal obstruction

Reference	N	Outcome	Complications
Dormann et al. (2004) Pooled analysis	606	97% technical success 89% clinical success Med patency N/A	0% mortality 1.2% perforation/bleeding 18% re-obstruction 5% migration
Telford et al. (2004) US multicenter	176	98% technical success 84% clinical success Med patency 146 days	0% mortality 2% perforation/bleeding 6% migration 6% cholangitis
Kim et al. (2007) Radiologists	213	94% technical success 94% clinical success Med patency 270 days	0% mortality 1% bleeding (0% perforation) 17% re-obstruction 4% migration

Endoscopic stenting for obstruction beyond the third part of the duodenum is much more challenging because of the length of standard endoscopes and the more tortuous anatomy. Anecdotal and small series studies have reported success with the use of specialized overtubes designed for deep small bowel intubation, but such procedures are still in need of refinement and dissemination before distal small bowel stenting will become more widely available (Ross et al., 2006; Lennon et al., 2010).

Although endoscopic stenting has been demonstrated to be relatively safe, problems remain that reduce their long-term success rates. Delayed stent failure occurring in up to 18% of cases results in the potential need for reintervention, in some patients (Dormann et al., 2004). The most common causes of delayed stent failure are food impaction or re-obstruction caused by tumour ingrowth. Stent migration also occurs, sometimes in association with cancer treatment. In one study, the presence of ongoing anticancer therapy was reported to be associated with longer stent patency rates but a greater risk of stent migration (Kim et al., 2007). Re-obstruction due to tumour ingrowth can easily be managed with the placement of a second stent or tumour ablation by Nd:YAG laser or argon plasma coagulator (Holt et al., 2004). In comparative studies, those managed with stent did just as well initially as patients managed with surgical bypass, but they had a greater need for re-intervention because of delayed stent re-occlusion (Wong et al., 2002; Jeurnink et al., 2007). This should be considered when decisions on management are being made.

Patients who have slowly progressive disease with a relatively long life expectancy (> 60 days), few comorbidities, and a single site of obstruction near the gastric outlet are probably best managed with surgery. Those that are best suited for endoscopic stenting are patients with a short length of tumour, a single site of obstruction that is located near the pylorus or in the proximal two-thirds of the duodenum, with an intermediate to high performance status and a median life expectancy of greater than 30 days. Patients with a poor performance status, rapidly progressive disease, evidence of advanced carcinomatosis with moderate to severe ascites or multiple levels of obstruction on cross-sectional imaging, and a prognosis of less than 30 days are best served by managing their symptoms pharmacologically or by the insertion of a drainage percutaneous endoscopic gastrostomy (PEG) tube.

Endoscopic stenting for colorectal obstruction

Malignant colon and rectal obstruction occurs as a result of circumferential infiltration of the colonic wall by a primary colorectal cancer, extrinsic compression, or infiltration by nearby tumours, such as ovarian cancer, pancreas or gastric cancer, or from intra-peritoneal spread of tumours originating outside the abdomen, such as metastatic lung, or breast cancer. Regardless of the origin, the clinical manifestations vary depending on the location of obstruction in the colon and rectum. A common presentation is gradual development of constipation bloating and anorexia, eventually resulting in subacute or acute presentation with abdominal distension, abdominal pain, nausea, vomiting, and inability to pass faeces or even flatus. On occasion, patients present with acute obstruction without prior warning symptoms. The more severe cases are in danger of life-threatening bowel perforation and should be managed urgently.

Stent placement in the setting of malignant colorectal obstruction has been reported by investigators from several different countries and can be performed using colonoscopy or interventional radiology techniques using fluoroscopy, with catheters and guidewires (Mainar et al., 1999; Camunez et al., 2000; Law et al., 2000; Arya et al., 2011; Kim et al., 2011; Manes et al., 2011). The prior clearing of the bowel can often not be performed as customarily done for colonoscopy due to the obstruction and risk of perforation with vigorous oral laxatives, but should at the least involve clearing from below the obstruction with enemas.

In the case of the endoscopic approach, a sigmoidoscopy or colonoscopy is performed with the use of a therapeutic scope, which has a large operating channel that would permit the insertion of the constrained stent. In some cases the endoscope can be advanced through the area of obstruction, but in many cases with severe obstruction the 11–13 mm endoscopes are too large to pass the point of obstruction, but stent insertion can be facilitated with the use of guidewires or with concurrent fluoroscopic guidance to ensure accurate placement. Once properly aligned, the stent can be released from the insertion catheter, expanding spontaneously against the tumour stricture, gradually expanding the lumen. A successful stent deployment usually results in immediate passage of air and liquid faeces through the point of obstruction. This translates to rapid relief of symptoms for most patients, permitting resumption of oral intake. In some cases this procedure can be performed as an outpatient procedure, particularly for those with subacute obstruction.

Multiple retrospective studies and several pooled analyses of results have been published demonstrating the positive results of endoscopic and radiographically guided colorectal stent placement in treating malignant colon obstruction in selected patients

(Mainar et al., 1999; Camunez et al., 2000; Law et al., 2000; Khot et al., 2002; Sebastian et al., 2004; Arya et al., 2011; Kim et al., 2011; Manes et al., 2011; Meisner et al., 2011). On average, stent placement for palliative relief of malignant colorectal obstruction results in relief of symptoms in about 91% of patients with less than 4% risk of macroscopic perforation and 0.5% risk of death from complications caused by the procedure (Sebastian et al., 2004). In one retrospective study of long-term results from the Mayo Clinic, Rochester, Minnesota, mean stent patency was reported to be 145 days, and 88.5% of 122 patients treated with endoscopic stenting remained free of obstruction until death (Small et al., 2010). This group reported overall complications associated with palliative stenting of 24.4%, with 9% perforations, but most of the complications were not associated with the procedure, but rather at a delayed time; a mean of 27 days after stent for perforations and 143 days for reocclusion.

Although there have been few prospective studies comparing stenting with surgery in the palliation of malignant colorectal obstruction (Martinez-Santos et al., 2002; Carne et al., 2004; Xinopoulos et al., 2004), several retrospective studies have shown comparable results, with similar successes in relieving obstruction of about 94% for stent and close to 100% for surgery in selected patients, but with lower complications, shorter hospital stay, and lower hospital mortality with stenting (Nagula et al., 2010; Vemulapalli et al., 2010; Moore-Dalal et al., 2011). In addition to improving symptoms, stenting is also associated with an improvement in QOL (Nagula et al., 2010), even when the obstruction is caused by an extracolonic malignancy (Pothuri et al., 2004; Caceres et al., 2008; Shin et al., 2008; Nagula et al., 2010; Kim et al., 2011).

While most publications report excellent success with stenting there are some limitations to technical success which include a very proximal location which can be difficult to reach with the colonoscope, tortuous tumours which increase the difficulty of traversing the tumour with a guidewire or the stent, and tightly obstructing tumours which impair the ability of the stent to expand. Tumours that are very low in the rectum should not be treated with stenting as this will result in complete loss of continence, so such patients should be managed with surgical diverting colostomy. Stent migration can occur at times. Re-obstruction can occur as a result of tumour ingrowth, or stent occlusion from hard faecal material, but these problems can also be retreated with further endoscopic intervention, and treatment with mineral oil, stool softeners, and laxatives.

Endoscopic drainage gastrostomy and jejunostomy

Many patients with MBO cannot be successfully treated with endoluminal stenting. The presence of peritoneal carcinomatosis with multifocal bowel obstruction will often result in failure of both surgical and endoscopic attempts of luminal restoration. It may be reasonable to consider attempting stenting in the setting of two or three points of obstruction if radiographic evaluation clearly demonstrates functional patency of the rest of the gut; however, many patients who present with peritoneal carcinomatosis will have multiple sites of small bowel obstruction, or both small and large bowel obstruction. Such patients can often be successfully palliated with medicinal approaches, described in this chapter, to reduce gastric and bowel secretions and motility, in conjunction with analgesics. Some however

may experience intractable nausea and vomiting which is only relieved with the insertion of a NGT, or they may wish to continue to experience oral intake. For such people, the insertion of a drainage or venting tube in the stomach or jejunum can help relieve the nausea and vomiting, while allowing them to partake in the social experiences of eating and drinking for the rest of their shortened life (Campagnutta et al., 1996; Pothuri et al., 2005).

Although initial experiences used the same sized tubes that are used for feeding gastrostomies, Pothuri et al. showed that the use of a larger diameter PEG tube, 28 French, was feasible in 98% of patients with advanced recurrent ovarian cancer, even in patients with tumour encasing the stomach, diffuse carcinomatosis, and ascites (Pothuri et al., 2005). These larger tubes can also be used to temporarily palliate obstructive symptoms in patients with MBO still undergoing curative systemic therapy.

In some cases where the stomach has been partially or completely removed, as in Billroth II reconstruction, or where the position of the stomach impairs the insertion of a gastrostomy, a drainage PEJ (jejunostomy) tube can be inserted to serve the same purpose by draining the distended small bowel (Pothuri et al., 2005).

Pharmacological treatment of symptoms

The pharmacological management of MBO in inoperable patients focuses on the relief of nausea and vomiting, pain, and other possible distressing symptoms. It principally consists of a combination of antiemetics, antisecretory drugs, and analgesics whether the person is an inpatient or in the community. The drugs of choice vary widely, pending controlled studies which would give clearer therapeutic guidelines (Baines et al., 1985; Ripamonti et al., 2001).

Vomiting may be controlled either symptomatically, using antiemetic drugs with specific central effects, or with anticholinergic drugs able to reduce GI secretions. In the last years, steroids and somatostatin analogues have been successfully used as antisecretory–anti-inflammatory drugs. Clinical practice recommendations for the management of MBO in patients with end-stage cancer have recently been published by the Working Group of the European Association for Palliative Care (Ripamonti et al., 2001).

Route of administration

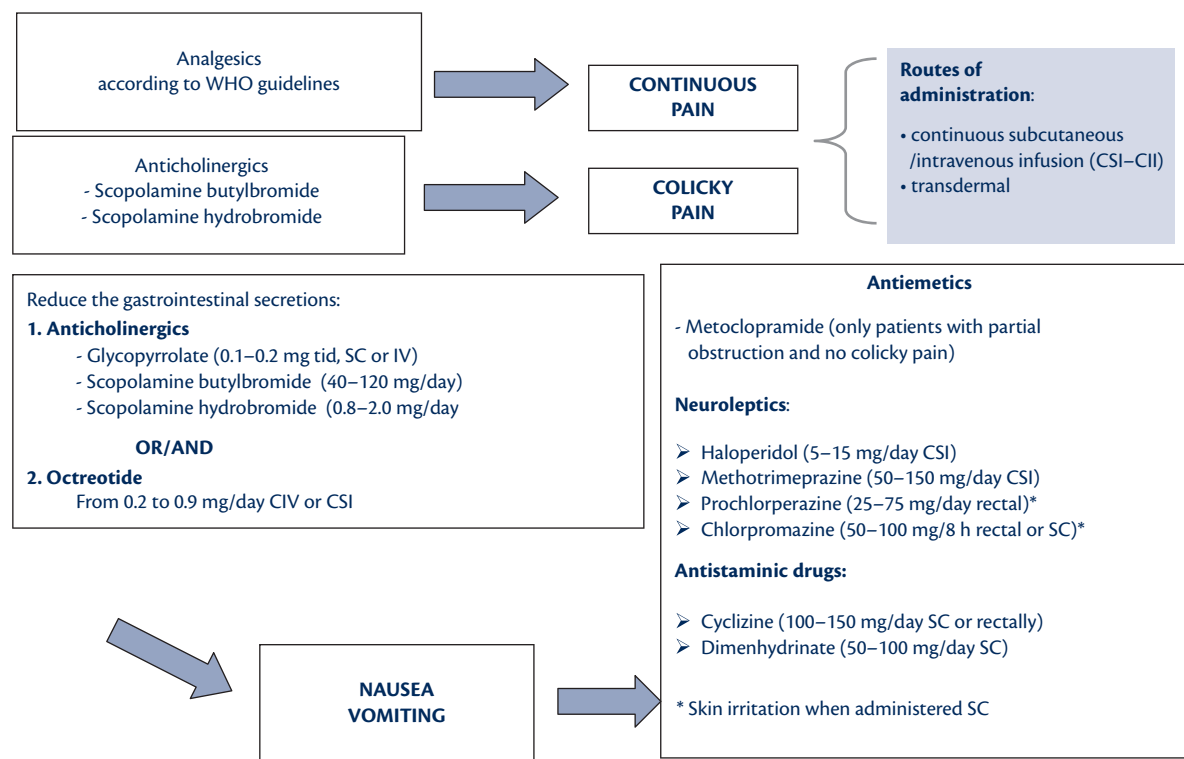
As oral administration is unreliable in most patients with nausea and/or vomiting, in the presence of bowel obstruction, an alternative route, mainly the parenteral one, is preferred. A continuous subcutaneous infusion or regular subcutaneous bolus administration allows a constant drug level to be maintained with similar pharmacokinetics demonstrated with either approach. In the presence of a pre-existing venous line, the intravenous route will be the route of choice. Morphine, haloperidol, cyclizine, and octreotide appear to be compatible in different combinations and can be mixed in the same syringe (Mercadante, 1995c; and Hutchings, 1997; Ripamonti et al., 2001). Rectal and sublingual administration can occasionally be used. Finally, some drugs, such as fentanyl and scopolamine, may be also administered by the transdermal route. Fig. 14.3.3 shows the drugs and their dosages used to control nausea and vomiting in bowel obstructed patients although formal dose ranging studies have not been done.


Fig. 14.3.3 Algorithm for assessing and managing a patient with malignant bowel obstruction. CII, continuous intravenous infusion; CSI, continuous subcutaneous infusion.

Reproduced courtesy of Carla Ripamonti.

The use of symptomatic pharmacological approach should be used in inoperable patients with the following aims:

◆ to relieve continuous abdominal pain and intestinal colic

◆ to reduce vomiting to an acceptable level for the patient without the use of a NGT

◆ to relieve nausea (Baines et al., 1985; Mercadante, 1997; Ripamonti et al., 2001; Ripamonti et al., 2008).

Pain

Opioid analgesics, administered according to the World Health Organization and European Society for Medical Oncology guidelines (World Health Organization, 1996; Ripamonti et al., 2012), are the most effective drugs for the management of abdominal continuous and colicky pain associated with bowel obstruction. The dose of opioids should be titrated against the effect, and most usually be administered parenterally.

Anticholinergic drugs such as scopolamine butylbromide, scopolamine hydrobromide, or glycopyrrolate can be associated to opioids in the presence of colicky pain if the opioids alone are not effective (Ventafridda et al., 1990; De Conno et al., 1991; Fainsinger et al., 1994; Mercadante, 1995b; Mercadante et al., 1997; Ripamonti et al., 2001) (Fig. 14.3.3).

Nausea and vomiting

Nausea and vomiting can be managed using two different pharmacological approaches (Fig. 14.3.3):

1. Administration of drugs that reduce GI secretions such as anticholinergics (hyoscine hydrobromide, hyoscine butylbromide, glycopyrrolate) and/or somatostatin analogues (octreotide) (Ventafridda et al., 1990; De Conno et al., 1991; Mercadante, 1995b; Mercadante et al., 2000; Ripamonti et al., 2000, 2001; Porzio et al., 2011).

2. Administration of antiemetics acting on the central nervous system, alone, or in association with drugs to reduce GI secretions. Metoclopramide is the drug of choice in functional intestinal obstruction, but it is not recommended in the presence of complete bowel obstruction because it may increase nausea, vomiting, and colicky pain. It is a prokinetic acting at the level of acetylcholine and dopamine receptors, thus stimulates the musculature of the GI tract. Other antiemetics are the butyrophenones, antihistaminic-antiemetic, and phenothiazines (prochlorperazine and chlorpromazine (Ripamonti et al., 2001) (Fig. 14.3.3). Haloperidol, a dopamine antagonist and a potent suppressor of the chemoreceptor trigger zone, is considered to be the antiemetic drug of first choice when the obstruction is complete. Haloperidol can be combined with scopolamine butylbromide and opioid analgesic in the same syringe.

There are no comparative studies on the efficacy of these different approaches. Generally, physicians are guided by drug availability, costs, and local practice.

Corticosteroids have been used as well because of their anti-inflammatory effect. There is no consensus regarding which is the most effective steroid in this condition, however dexamethasone and methyl-prednisolone are the most commonly used. A systematic review showed a tendency but no definite significant reduction in symptoms in the steroids group compared to the placebo. In terms of mortality, there was no difference between both

groups (Feuer and Broadley, 1999), but the number of participants was relatively small.

In a meta-analysis of randomized controlled trials, histamine-2 antagonists and proton pump inhibitors (omeprazole, lansoprazole, pantoprazole, and rabeprazole) were compared for their ability to reduce the volume of preoperative gastric secretions in patients. Both drugs were able to reduce the gastric secretions, but ranitidine was the most potent (Clark et al., 2009).

Somatostatin and its analogues have been shown to inhibit the release and activity of GI hormones, modulate GI function by reducing gastric acid secretion, slow intestinal motility, decrease bile flow, increase mucous production, and reduce splanchnic blood flow. They reduce GI contents and increase absorption of water and electrolytes at intracellular level, via cyclic adenosine monophosphate and calcium regulation. The inhibitory effect of octreotide on both peristalsis and GI secretions reduces bowel distension and the secretion of water and sodium by the intestinal epithelium, thereby reducing vomiting. The drug may theoretically address hypersecretion and distension (Riley and Fallon, 1994).

Several uncontrolled studies have examined the use of octreotide in reducing GI secretions, nausea, and vomiting in patients with MBO (Ripamonti et al., 2001; Ripamonti and Mercadante, 2004; Shima et al., 2008; Hisanaga et al., 2010; Correa et al., 2011). In many cases NGT can be removed. Reported effective doses range from 100 to 600 micrograms per day either as a continuous infusion or as intermittent subcutaneous boluses. Octreotide has been co administered with numerous other agents including morphine, haloperidol and scopolamine butylbromide.

Controlled trials include two large studies of sustained release lanreotide, one large study of octreotide, and two smaller studies of octreotide (Mercadante et al., 2000; Ripamonti et al., 2000; Mystakidou et al., 2002; Laval et al., 2012; Mariani et al., 2012). Mystakidou and colleagues studied 68 people in a double blind, randomized controlled trial comparing octreotide to hyoscine butylbromide. Both arms received regular chlorpromazine. There was less nausea and vomiting at day 3, but not at day 6. Like the study by Hisanga et al., pain was not reduced in the octreotide arm (Mystakidou et al., 2002; Hisanaga et al., 2010).

More recently, studies have also looked at the use of long-acting octreotide in patients with advanced malignancies who developed MBO at some point during the course of the disease (Matulonis et al., 2005; Massacesi and Galeazzi, 2006). The efficacy and safety of octreotide long-acting release (LAR) at the dose of 30 mg on day 1 and ocreotide for 2 weeks was evaluated in a pilot study of 15 patients with advanced ovarian cancer. Of 13 evaluable patients, three patients had reductions in GI symptoms, two had minor response, four patients had no response, and four had progressive symptoms. No significant toxicities were due to LAR (Matulonis et al., 2005).

Recently Mariani et al. (2012) investigated the somatostatin analogue lanreotide as symptomatic treatment for inoperable bowel obstruction due to peritoneal carcinomatosis in 80 patients. The patients with inoperable MBO due to peritoneal carcinomatosis and two or more vomiting episodes daily or NGT who were previously treated with intravenous corticosteroids and proton pump inhibitors were randomly assigned to one 30 mg injection of lanreotide (43 patients) or placebo (37 patients) in a 10-day,

double-blind parallel-group phase. The primary end point was the proportion of patients responding on day 7: one or fewer episodes of vomiting per day or no vomiting recurrence after NGT removal. More patients receiving lanreotide than placebo were responders; this difference was not statistically significant for the intention-to-treat population.

These findings are reflected in another recent study combining regular monthly lanreotide with immediate-release octreotide for the first 6 days of the study in a placebo controlled, double-blind, randomized controlled trial (Laval et al., 2012). The study sought to measure vomiting on days 10–13 with success being defined as fewer than two episodes of vomiting per day for those four days. On an intention-to-treat basis, 37.5% (12/32) of patients on somatostatin analogue arm responded and 28.1% (9/32) in the placebo. This difference was not statistically significant.

Two of the three largest studies of a somatostatin analogue in the setting of MBO showed no additional benefit over and above a placebo (Mystakidou et al., 2002; Laval et al., 2012; Mariani et al., 2012).

Nutrition in the person with bowel obstruction

From the patient's view, the most important consequence of a bowel obstruction, no matter its cause, is the disruption of the ability to eat normally. This fundamental function is essential to maintain health and social ties, and when it is not possible, is a significant source of distress to the patient and more often, their caregivers. Patients with bowel obstruction mostly have little desire to eat, because it exacerbates their symptoms, and caregivers often do not understand that forcing nutrition on such a patient is of little benefit. Severe malnutrition is defined as at least one of the following risk factors: weight loss of 10–15% or more within 6 months; body mass index (BMI) of 18 kg/m^2 or lower, and serum albumin of 30 g/L or less (without evidence of renal and/or liver dysfunction) (Braga et al., 2009). The natural consequence of reduced intake is loss of weight and muscle mass, occurring over time, the cause is often multifactorial, whether from mechanical obstruction, anti-cancer treatments (chemotherapy/radiation), ascites, or cachexia. Cachexia is a catabolic metabolic state common in advanced illness, where intrinsic muscle, protein, and fat are metabolically breaking down (MacDonald et al., 2003). Associated with inflammation, hormonal changes, and the production of tumour factors, it can be difficult to diagnose. However, cachexia is not reversible by increasing nutritional intake, represents end-stage disease, and therefore interventions to improve oral intake will not be helpful. Unfortunately, in advanced cancer patients, cachexia and mechanical obstruction are often seen together and it can be difficult to identify if the weight loss can be reversed if the mechanical obstruction is relieved.

The use of parenteral nutrition in unrelieved MBO from advanced cancer is therefore generally not recommended. The exception may be for patients who are severely malnourished (BMI < 18.5–22 kg/m^2 depending on age), in whom a surgery is planned, and who cannot be enterally fed. Parenteral nutrition starting 7–10 days preoperatively may decrease the rate of postoperative infections, length of stay in hospital, and postoperative mortality. The postoperative duration of parenteral nutrition in such patients should be defined preoperatively and should be short (7–10 days). Short-term postoperative total parenteral nutrition (TPN) may be

used for malnourished patients who required emergency surgery and therefore could not receive TPN preoperatively (Braga et al., 2009). For those patients with advanced cancer and poor nutritional status who will not have surgery, TPN is considered ineffective if there is no mechanical bowel obstruction. Also, TPN does not have a role as a supplement while patients are on either chemotherapy, radiation treatment or both therapies simultaneously and also are able to receive oral or enteral nutrition adequately (Bozzetti et al., 2009). Once the patient can eat, the value of oral nutritional support programmes for advanced cancer patients is unclear. In advanced head and neck cancer patients undergoing radiation, the group randomized to the nutritional support programme lost less weight but had an overall poorer outcome (Rabinovitch et al., 2006), and a review of nutritional support programme in lung cancer patients demonstrated no survival benefit (Rueda et al., 2011).

Conclusions

Bowel obstruction secondary to cancer or its treatments is encountered relatively frequently in supportive care as well as in hospice/palliative care practice, carries a poor prognosis, and is associated with significant symptoms. Careful clinical assessment and an understanding of the patient's disease trajectory are crucial in recommending the best way of providing palliation. In someone with a single-level obstruction and good functional status, surgery should be offered. Those with multilevel obstruction are almost never surgical candidates and should be managed with changes in oral intake and medications.

Skin problems in oncology

Sharon Merims and Michal Lotem

Introduction: skin in disease

Perception of reality is based on visual inputs, and part of living experience is a reflection of what meets the eye. The skin is the largest and most visible organ of the body. It can be a passive participant in states of disease or be directly involved by disease or by its treatment. The skin may manifest the disease or subtly hint at its existence. For the physician, the skin may be a diagnostic aid, though often enigmatic. For the patient, the skin is part of what his sense of illness derives from. In contrast to disease progression, which can be occult or more of an abstract notion, skin manifestations are easily perceived, measured, and followed. They focus attention and cause distress that often outsize their real risk, being a constant reminder of the harboured disease. In those with cancer particularly, the most alarming aspect of skin involvement may be the threat of disfigurement. When a distressing skin symptom is addressed and treated successfully, the patient may derive a renewed sense of hope that reflects on the motivation to participate actively in therapy.

Skin structure and function

The basic function of the skin is to serve as a barrier, separating the human body from the external environment. The skin is made up of three distinct layers:

Epidermis

The epidermis comprises mainly keratinocytes. Intercalated among them are the immigrant cells:

- melanocytes that produce melanin
- Langerhans cells, which serve as antigen presenting cells
- Merkel cells, which have neuroendocrine features and take part in mechano-reception.

Columnar keratinocytes at the base of the epidermis form the germinative layer of the skin, which is known as the basal layer. These keratinocytes undergo a process of differentiation while they move upwards towards the surface (Chu et al., 2008a). A small proportion of keratinocytes is constantly dividing to replace cells that are injured and removed. A pathological state associated with inflammation results in an increased turnover of keratinocytes.

Differentiating keratinocytes produce and contain keratin filaments arranged in bundles that anchor each keratinocyte to adjacent cells and produce adherent forces that resist external traction. Cellular adhesion is lost at the surface of the skin, where keratinocytes detach as flakes and scales, which are usually unnoticeable.

The regenerative potential of the skin is harboured in colony-forming cells that reside in the hair follicles (Oshima et al., 2001). In states of damage to the skin, it is these cells that generate a new epidermal covering.

The epidermis is anchored to the dermis through a basement membrane complex. This highly specialized basal lamina acts as a highly selective pathway for the migration of cells and transport of macromolecules. The basal cells are anchored to the basal lamina through an array of tonofilaments and hemidesmosomes. Epidermal integrity may be disrupted by any pathology that weakens keratinocyte adhesion or damages the basal lamina. Depositions of antibodies against proteins or collagen subtypes that build these structures can split the epidermis and lead to the formation of blisters. Excessive accumulation of fluids in the dermis can generate similar forces and damage skin integrity by distending the intercellular matrix, causing cells to detach from each other.

The skin appendages are specialized differentiated subunits with unique functions. They include the hair follicle, sebaceous gland, and the eccrine and apocrine sweat glands. The hair sebaceous unit in humans mainly serves a social function. The sweat glands are part of the thermoregulatory mechanism of the body.

Dermis

The dermis is a network of collagen and elastin fibres embedded in an amorphic extracellular matrix of mucopolysaccharides, which nests below the epidermis. The fibres and extracellular matrix of the dermis are synthesized by fibroblasts—cells that are dispersed throughout the dermis. The dermis also contains the blood supply for the non-vascularized epidermis tissue. Two webs of capillary blood vessels, deep and superficial, stretch along the dermis to oxygenate and nourish both layers. Parallel lymphatic vessels remove fluids from the skin back into the intravascular compartment. Trafficking immune cells traverse the lymphatic channels to and from regional lymph nodes as part of a screening and defence process against invasion. Inflammation of the skin—dermatitis—results in oedema of the dermis, vasodilatation, and accumulation of leucocytes and lymphocytes in the dermis.

Subcutaneous fat

This adipose tissue serves as a layer of padding and thermal isolation. In states of starvation and cachexia, the subcutaneous fat is severely depleted and the skin is exposed to pressure without the protective effect of fat.

Skin manifestations of neoplastic disease

The skin may be adversely affected by any serious medical illness, often as a secondary process related to infection, trauma, nutritional deficiencies, and other factors (see below). Disease-specific skin involvement occurs commonly in some conditions, and is best characterized in cancer.

Skin of the patient with advanced cancer is unique compared to other organs of the body. While the sequela of metastatic spread to internal organs often is replacement of normal tissue and resultant organ failure, widespread replacement of skin with a neoplasm is uncommon. Yet, even a local disruption of skin integrity can cause deterioration in the quality of life, debilitation, and even mortality. Other aspects of neoplastic disorders affecting the skin include accumulation of abnormally produced metabolites, adverse effects to treatment, and paraneoplastic syndromes.

Direct invasion of skin by tumour

Metastases to the skin are not an infrequent occurrence in cancer patients. In a retrospective series of 4020 metastatic cancer patients, 10% had skin involvement (Lookingbill et al., 1993). The skin may be involved with the primary tumour or may be the target of systemic metastatic spread (Brenner et al., 2001).

Direct invasion of the skin results from an uncontrolled local-regional disease, as in melanoma and breast cancer, where the tumour invades the superficial lymphatic vessels and infiltrates the skin. This commonly appears as discrete nodules, but can also form a diffuse pattern similar to oedema. An inflammatory plaque also may occur, which is often mistaken for erysipelas until diagnosed correctly. Any aggressive tumour that arises in an adjacent organ may directly extend to the overlying skin. The pressure of a tumour mass interferes with cutaneous blood supply and may lead to ulcerating wounds, which discharge foul smelling necrotic material and may require daily washing and the use of hydrocolloids or absorbent dressings. Metastatic cancer of the umbilicus, known as 'Sister Mary Joseph's nodule', has long been recognized as a clinical manifestation of intra-abdominal tumours that extend via the umbilical vessels into the peri-umbilical skin. Incisional metastases are also a common cause of abdominal skin involvement (Lookingbill et al., 1993).

Haematogenic spread to the skin may also occur with dermotropic distant metastases. Breast cancer, lung cancer, melanoma, and colon cancer are common neoplasms that tend to involve the skin (Brownstein and Helwig, 1972a). Common locations of skin metastases are the scalp, chest, and abdominal wall and less frequently to the limbs (Brownstein and Helwig, 1972b). Dermal metastases are more likely to cause pain and ulceration than metastases to the subcutaneous fat. Diagnosis of skin metastases is simple in the context of a patient already diagnosed with metastatic cancer.

Discoloration

The colour of the skin is based on the reflection of chromophores, which are normal constituents of skin that may form abnormal deposits as part of disease. Brown discoloration is intuitively attributed to melanin. Generalized melanosis—darkening of the skin because of a 'shower' of single melanoma cell dissemination—may occur with advanced melanin-producing metastatic malignant melanoma (Schuler et al., 1980). Dark urine often accompanies this condition.

Mild darkening of the skin may be seen with adrenal insufficiency, with adrenocorticotropic hormone-producing tumours such as primary tumours of the pituitary gland, or with other malignant tumours metastatic to the pituitary gland. Increased melanization of the basal layer, leading to hyperpigmentation, may be a side effect of chemotherapeutic agents (Alley et al., 2002). It may occur in skin overlying a vein used for chemotherapy, even if administered with no apparent extravasation injury; this is typical for 5-fluorouracil (5-FU). Bleomycin, busulphan, capecitabine and hydroxyurea can cause generalized persistent hyperpigmentation (Singal et al., 1991). Drug-induced hyperpigmentation may be limited to mucosae, nails, palms, and soles.

Brown discoloration may also result from haemosiderin sedimentation. Widespread inflammation of the skin from any cause results in post-inflammatory hyperpigmentation and persistent brown tint. Yellowish orange discoloration is associated with states of hyperbilirubinaemia.

Pruritus

One of the most distressing skin symptoms of advanced cancer is pruritus. In severe cases, it can lead to sleep deprivation and contribute to significant psychological distress. Biliary obstruction and cholestasis are the most common causes of pruritus in advanced disease, but many other factors may be important. The cancer itself can cause pruritus; the mechanism is unknown and possibly related to serotonin. Numerous other conditions, including common treatments such as systemic or intrathecal opioids (Ruan, 2007), also can cause or worsen the symptom.

Topical therapies for immediate itch relief include 1% menthol in cream base or lotion. Systemic therapy usually is required for better symptom relief, however, but unfortunately, first-line therapies, such as antihistamines, often have limited effectiveness and other types of therapies should be considered, if available.

The anticholestatic agent, cholestyramine, is effective for cholestatic pruritus but is of limited use in total biliary obstruction (Bosonnet, 2003). It chelates intestinal bile acids, thereby reducing the enterohepatic circulation of bile salts. Treatment consists of 4 g before meals, but some patients may find the preparation nauseating. Ursodeoxycholic acid (UDCA) exerts anticholestatic effects in various cholestatic disorders. Several potential mechanisms could explain its beneficial effects, including protection of injured cholangiocytes against the toxic effects of bile acids and stimulation of impaired hepatocellular secretion (Paumgartner, and Beuers, 2002).

Paroxetine, a selective serotonin reuptake inhibitor, may show some positive effect in cancer-related pruritus, and rifampicin, acting as a hepatic enzyme inducer, also has been reported to relieve itching (Tandon et al., 2007). Continuous infusion with

granisetron, a 5-hydroxytryptamine type 3 receptor (5-HT$_3$) antagonist, also has been reported to relieve cancer-related pruritus (Porzio et al., 2004). Oral opioid mu-receptor antagonists (such as naltrexone and nalmefene) may be beneficial but cannot be used when an opioid analgesic is needed for pain. Topical application of naltrexone was recently reported as having anti-pruritic effects and the advantage of avoiding withdrawal (Bigliardi et al., 2007). For patients with good performance status, phototherapy using ultraviolet B spectrum is a good option (Seckin et al., 2007), but takes several weeks to exert its beneficial effect.

Dryness and erythroderma

General dryness, xerosis, is a common skin condition in cancer patients. Xerosis may follow chemotherapy administration, a period of decreased food intake, or hypoproteinaemia. Gentle flakes or larger scales generate an ichthyosiform appearance. Lack of elasticity of the drying skin creates cracking lines over the trunk and lower limbs, resulting in itching and soreness. Daily use of emollient may be helpful and should be encouraged.

The term 'erythroderma' refers to general redness of the skin. It often is associated with exfoliation and is, essentially, an end stage of many skin diseases, including psoriasis and papulo-squamous disorders. It also is a clinical hallmark of Sézary syndrome, which is a rare variant of cutaneous T-cell lymphoma. In the wider oncological context, erythroderma may accompany leukaemia and lymphoma (Robak and Robak, 2007), and, less commonly, solid tumours. The mechanism is unknown and it is sometimes managed with emollients and systemic steroids.

Radiation-induced toxicities

Radiation effects on the skin are usually divided into acute and chronic. Early effects occur during the course of radiation and the weeks thereafter, and late effects occur months and years later. The acute effects are thought to result from germinative cell failure to reproduce and replenish epidermal keratinocytes (Hopewell, 1990). Specifically, radiation destroys a section of the basal keratinocytes, stimulating non-cycling basal cells into a cycling phase; continued destruction of basal cells from ongoing radiation treatment overwhelms this process, however, and causes extensive injury. Radiation also damages dermal vasculature and leads to capillary disruption, extravasation, extracapillary cell damage, and inflammatory responses. The local release of histamine and serotonin induce vasodilation and hence erythema, oedema, and a burning sensation. Hair growth is interrupted as hair follicles revert to a resting phase and new hairs are shed. Complete hair loss depends on the total dose and fractionation of the radiation. Sweat and sebaceous glands can be permanently destroyed after approximately 30 Gy in fractions of 2 Gy per day.

Acute radiodermatitis

Clinically, the acute phase of radiation injury can present as an acute radiodermatitis. Erythema and oedema are the first to occur, appearing after 1–2 weeks of treatment and peaking around week 3–4. Dry desquamation and moist desquamation then ensue, and in severe cases erosions, and even ulcers, may develop and be associated with severe pain. Areas of skin folding are at particular risk of developing severe reactions.

Acute radiodermatitis varies in severity and is dependent on radiation energy, total dose and fractionation, the use of bolus material that reduces the skin-sparing effect of megavoltage units, and the individual's sensitivity (Denham et al., 1995). Co-morbidities, older age, and previous sun damage to the irradiated skin are aggravating factors (Porock, 2002). Addition of an electron beam boost to enhance the dose to the tumour is often associated with severe local skin reactions.

There is no effective prophylaxis for radiodermatitis. Daily washing with mild soaps, and avoiding the use of deodorants and electric razors, may help, and the basic care consists of ointments, creams, and lotions to moisten the skin, ease the burning sensation, restore elasticity, and prevent breakage and erosions. It is important to note that the vehicle of the beneficial preparation may be as influential in its effectiveness as the active component in it. Gels are soothing but increase drying. Fatty ointments protect well from moisture loss, but may increase itching. Corticosteroid creams and ointments may reduce vasodilation and inflammation, but have no preventative effect and their advantage over non-steroidal preparations is doubtful. Oil-in-water emulsions are a good option (such as Biafine® and aqueous creams), and calendula oil, sucralfate, and barrier films have been tried with favourable effects (McQuestion, 2006). Ulcers and erosions are treated with silver sulfadiazine (Silverol®) and hydrophilic dressings such as Tegaderm® and Vaseline® gauze.

Chronic radiodermatitis

Delayed damage to the skin is primarily a function of radiation effects on the vasculature. An initial wave of dermal atrophy is seen within 4–6 months. A second phase of dermal thinning tends to develop after more than 52 weeks, often accompanied by the appearance of telangiectasia (Hopewell, 1990). The skin is seen to appear thin and tight, hyperpigmented, and dry. Marked fibrosis may limit flexibility or movement. Radiation-induced skin necrosis and chronic ulcers may develop and persist indefinitely, especially over the scalp and leg. Trauma, chronic friction, and pressure contribute to the development of radiation ulcers. Keratoses and squamous cell carcinoma (SCC) may develop. Histopathology is often required to differentiate SCC from non-neoplastic radionecrosis.

For chronic radiodermatitis, the basic treatment for intact skin consists of oil-in-water emollients and prevention of trauma. Radiation ulcers are resistant to treatment and a realistic goal would be to prevent secondary infection, pain, and fetid smell. This can be achieved with the use of hydrocolloids, but the prospects of healing are limited.

Radiation recall

Radiation recall refers to inflammatory reactions triggered by the administration of cytotoxic chemotherapy, which develop in previously irradiated areas, mainly in the skin. The radiation could have been delivered days to years ago. Typically, chemotherapy is acutely followed by a well circumscribed erythema that perfectly fits the radiation field of the past treatment. The histopathology of this area reveals mixed non-specific inflammatory infiltrate. The most common chemotherapeutic agents implicated in radiation recall are anthracyclines and taxanes. Gemcitabine, a nucleotide analogue, was implicated recently in several cases (Friedlander et al., 2004).

Radiation recall may not require any special treatment. Withdrawal of the offending agent produces prompt improvement. If treatment is necessary, corticosteroids or the use of non-steroidal anti-inflammatory agents may help (Azria et al., 2005).

Paraneoplastic syndromes with skin manifestations

Paraneoplastic syndrome refers to a pathological state generated by cancer in an organ or system that is not directly affected by tumour. The syndromes may be due to the production, by the tumour or by the host, of substances that directly or indirectly cause disease, or by depletion of essential substances. There is a variety of paraneoplastic syndromes involving the skin and these skin manifestations can precede or follow the diagnosis of cancer, indicate a recurrence of disease, or have no correlation with the course of the neoplasm. In the patient with advanced illness, the discomfort caused by skin manifestations is often overshadowed by the neoplastic disease itself.

The most common paraneoplastic syndrome associated with skin pathology is dermatomyositis (DM). This is a systemic illness that primarily affects skeletal muscle and skin. It has been associated with almost every type of solid tumour, including ovarian, pancreatic, lung, stomach, or colorectal (Hill et al., 2001). Among adults older than 40 years who have melanoma or lymphoma, the disorder is especially common, affecting 15–50% of patients (Braverman, 2002).

In 1992, Sigurgeirsson et al. established the connection between DM and cancer. The relative risk of cancer in their series of 392 patients was 2.4 in males and 3.4 in females. In another series, the two independent predictive factors for malignancy (p < 0.05) in patients with DM were an older age at onset (> 45 years) and male sex (Chen et al., 2001). This connection with cancer distinguishes DM from polymyositis, which in the latter study had only a slight and statistically non-significant association with cancer.

The characteristic and possibly pathognomonic cutaneous features of DM are the heliotrope rash and Gottron's papules. The heliotrope is a violaceous rash with or without oedema involving periorbital skin. Gottron's papules are slightly elevated; violaceous papules and plaques are mainly found over the finger joints but also may be found overlying the elbows, knees, and feet. Other characteristic features include a slight scale and, on some occasions, a thick psoriasiform scale; telangiectasia; an erythematous eruption in a photosensitive distribution; and periungual changes.

The diagnosis of DM is based on the clinical presentation. Electrophysiological or laboratory evidence of myopathy, including elevations of creatine kinase, aldolase, lactic dehydrogenase, or alanine aminotransferase, are supportive. An evaluation of malignancy should be considered in all adult patients with a consistent syndrome (Callen, 1982).

Corticosteroids are the mainstay of DM therapy. In resistant cases, immunosuppressive agents, such as methotrexate, azathioprine, cyclophosphamide, mycophenolate mofetil, chlorambucil or ciclosporin, may be helpful in inducing remission. Skin lesions may persist even when positive systemic effects prevail. Skin pathology may be ameliorated by topical steroids or topical immunosuppressants, such as 0.1% tacrolimus ointment.

Skin toxicities of chemotherapeutic agents

The skin, hair, nails, and mucous membranes are composed of rapidly dividing cells and are therefore a natural target for toxicities and adverse effects of anti-cancer drugs. Cancer therapy has widened extensively during recent years. New molecular targeting therapies and monoclonal antibodies now comprise a larger part in the arsenal of anti-neoplastic drugs. Alongside new indications and combinations of these drugs, novel toxicities also appeared, including skin toxicity. Common skin toxicities of chemotherapy will be detailed first followed by those of the widely used epidermal growth factor receptor (EGFR) inhibitors.

Common adverse effects of chemotherapeutic agents

The potential effects of conventional chemotherapeutic agents are extremely diverse. Multiple syndromes have been defined and there is large inter-individual variation in presentation and severity.

Alopecia

The rapidly dividing and proliferating cells of hair follicles are targeted by many chemotherapies, and the resultant alopecia is one of the most common and distressing side effects of these drugs. Paclitaxel and doxorubicin are major causes of alopecia in the oncology clinic. Scalp hair is affected to a larger extent than the slowly growing eyelashes, eyebrows, and body hair.

Mucositis

Mucositis includes damage to mucous membranes, most frequently of the oral cavity, and is characterized by redness, swelling, white exudates, and in severe cases, ulceration. Difficulty in chewing, swallowing, and speech may arise. Patients avoid food intake and oral medications to avoid flares of pain. In severe cases, the patient may not be able to drink water due to distressing pain.

Almost all anti-neoplastic agents are associated with mucositis, but the severity is dependent on patient-related factors, the specific drugs employed in treatment, and varied comorbidities. Patient susceptibility to mucositis may be genetically determined, perhaps related to the expression levels of pro-apoptotic and anti-apoptotic genes (Sonis et al., 2004). Drugs that are administered continuously by slow-release mechanisms, such as continuous 5-FU, daily capecitabine, and liposomal doxorubicin, are relatively likely to produce mucositis. Other drugs with high rates of mucositis include methotrexate, cytarabine, and taxanes. Myeloablative conditioning prior to stem cell transplantation may cause severe stomatitis. The severity of mucositis may be greatly worsened by the occurrence of mucosal candidiasis secondary to reduced immunity. Superimposed herpes simplex infection also may severely complicate chemotherapy-induced stomatitis; extensive erosive components and circumscribed ulcers should raise the suspicion of herpes simplex virus infection. Damaged mucosal barriers give rise to a higher rate of septicaemia.

Prevention of chemotherapy-related oral complications is difficult. Good dental and oral hygiene are helpful. Daily chlorhexidine mouthwash is often recommended as a preventative, but its efficacy is doubtful. Povidone-iodine, NaCl 0.9%, water salt soda solution, and chamomile mouthwash also have been recommended and are not associated with dental staining typically produced by chlorhexidine (Potting et al., 2006). Topical non-steroidal anti-inflammatory agents and corticosteroids have been used

with varying success, and mucosal protectants, such as sucralfate, have yielded inconsistent results (Pfeiffer et al., 1990; Nottage et al., 2003). Systemic administration of granulocyte macrophage colony-stimulating factor apparently reduces the development of radiation- and chemotherapy-related mucositis (Stokman et al., 2006). Palifermin (recombinant human keratinocyte growth factor) was recently shown to decrease the severity and duration of oral mucosal injury induced by intensive chemotherapy for haematological malignancies (Spielberger et al., 2004); data on the use of this drug in those with solid tumours are limited and its use is not advocated as there is a theoretical risk of stimulating tumour growth. In some cases pain may be so excruciating as to require opioid analgesics.

Nail changes and paronychia

Although less commonly encountered than alopecia and mucositis, nail changes can significantly interfere with manual activities and locomotion, due to their sensitive locations. Taxanes, especially docetaxel, are the major offenders, and cause nail abnormalities in 30–40% of patients (Hussain et al., 2000). Recently, paronychia was reported to occur with the new EGFR inhibitors (Hu et al., 2007). Discoloration, nail bed bleeding, and detachment of the corny material from the nail plate (onycholysis) may occur (Nicolopoulos and Howard 2002). The development of onycholysis seems to be unrelated to the drug dose or frequency of administration. In some cases, purulent exudates may accumulate beneath the nail and soft tissue swelling of the nail bed ensues.

There is a tendency for nail changes to resolve gradually over weeks, despite continued treatment (Flory et al., 1999). Nail changes may be partly reduced by soaking the tips of the fingers in ice water. Topical disinfectants like povidone iodine and 6% peroxide, and topical antibiotics can reduce secondary bacterial infection.

Hand–foot syndrome

Also known as toxic acral erythema and palmar–plantar erythrodysaesthesia syndrome, hand–foot syndrome is a common skin reaction among patients treated with conventional chemotherapy. The earliest sign is painful erythema of the palms, soles, and fingers that later becomes oedematous, changes colour to violet, then dries off and desquamates. In severe cases, blisters develop, later leaving erosive surfaces, with considerable impairment in function. Hand–foot syndrome is often a dose-limiting toxic effect, especially for liposomal doxorubicin. Pharmacologic agents that have been evaluated for hand–foot syndrome include pyridoxine or vitamin B_6, dexamethasone, amifostine, and COX-2 inhibitors. As of now, there are no established preventative strategies or treatments.

Chronic graft-versus-host disease

Allogeneic haematopoietic stem cell transplantation remains the major therapy that can consistently eradicate all evidence of chronic myeloid leukaemia, which is the most common indication of this treatment. The success of allogeneic stem cell transplantation depends on the degree of human leucocyte antigen (HLA) matching. The therapeutic success is offset by a large percentage of patients who develop clinical graft-versus-host disease (GVHD). GVHD is initiated when immunocompetent T cells from the graft react against the immunocompromised host via recognition of alloantigens displayed by host antigen-presenting cells. Th1

cytokines secreted by activated donor T cells are responsible in part for the acute phase changes, while Th2 cytokines, including interleukin (IL)-4 and IL-5 generate some of the chronic phase pathology (Okamoto et al., 2000; Hofmeister et al., 2004). Early withdrawal of post-transplant immunosuppression and use of donor lymphocyte infusions to incite a graft-versus-malignancy effect in patients with residual or progressive disease enhance acute and chronic GVHD. The majority of patients with chronic GVHD have had prior acute GVHD. In addition to the skin, the organs and systems that may be involved by GVHD include gastrointestinal tract, liver, respiratory tract, musculoskeletal system, and haematopoietic system. In HLA-matched marrow grafting with primarily methotrexate-based prophylaxis, skin (65–80%), mouth (48–72%), liver (40–73%), and eye (18–47%) involvement are most commonly reported (Sullivan et al., 1991).

The cutaneous hallmark of chronic GVHD is a lichenoid eruption, an erythematous, papular rash that resembles lichen planus and leaves hyperpigmented spots when resolved. In sclerodermatous GVHD the skin is thickened, tight, and fragile (Higman and Vogelsang, 2004). Atrophic patches of lichen sclerosus are often described. Poor wound-healing and ulcerations occur on areas subjected to tension or trauma. Hair loss and reduced sweating occur as a result of dermal fibrosis. Brittle hair, fingernails, and toenails develop and premature greying of hair may occur. Ocular GVHD presents with irritation, burning, dry eyes, or photophobia from irreversible destruction of the lacrimal glands (Higman and Vogelsang, 2004). Salivary gland dysfunction leads to xerostomia. Mucosal involvement by lichenoid eruption causes food sensitivity and in severe cases can develop to ulceration, especially at the biting line.

Basic skin lubrication to maintain flexibility, and eye and mouth wetting preparations are required in the management of GVHD. Antimicrobial agents against complicating herpes simplex infection also may be required. Extracorporeal photopheresis was reported to improve refractory GVHD, and effect that may be due to an increase in regulatory T cells that suppress autoreactivity (Biagi et al., 2007).

Skin toxicities of molecular targeted therapies

The newer molecular targeted therapies have greatly expanded treatment options for diverse types of cancer. Skin toxicity is a major problem associated with these drugs.

Epidermal growth factor receptor inhibitors

The EGFR inhibitors comprise monoclonal antibodies with varied modes of action. Some (e.g. cetuximab and panitumumab) target the extracellular ligand-binding domain of epidermal growth factor, thereby preventing binding of the ligand to the same receptor. Others (e.g. erlotinib and gefitinib) target the intracellular tyrosine kinase domain of the receptor. Yet others act by competing with adenosine triphosphate binding at the tyrosine kinase site.

Skin eruptions are the most common and sometimes distressing side effect of this category of drugs. Studies indicate that 45–100% of patients experience some type of cutaneous side effect (Perez-Soler and Saltz, 2005; Shepherd et al., 2005). The characteristic rash is composed of acneiform pustules on a background of seborrheic dermatitis-like erythematous plaques with oily scales. The typical distribution is on the face, upper chest and back, and less often the scalp. Unlike acne, closed and open comedones will not appear, and in contrast to steroid-induced acne, the EGFR inhibitors may induce oily scales and dried pus crusts with severe

dermatitis rather than small pustular lesions which are prominent on normal skin. The rash begins during the first week of treatment and may vary in severity with repeated treatments, tending to increase initially and then partially decrease. A correlation between the clinical response to the drug and the presence of skin rash has been observed (Saltz et al., 2004).

Microscopically, the acneiform rash associated with the EGFR inhibitors is characterized by T-lymphocyte infiltration around the follicular infundibulum, which can be followed by superficial lymphocytic perifolliculitis. The latter condition can lead to follicular rupture and suppurative superficial folliculitis. Although secondary bacterial infection can occur, the pathology is directly related to the inhibition of the EGFRs on epidermal cells and is non-infectious.

Although most patients receiving EGFR inhibitors (EGFRIs) experience these toxicities, few controlled studies have been conducted to determine the best practices for their management. Instead, much of the literature contains prevention and treatment recommendations based on case reports or studies with small samples sizes and nonrandomized patient allocation. Nonetheless, comprehensive supportive care prevention and treatment recommendations for EGFRI-induced dermatological toxicities have been proposed (Lacouture et al., 2011). Hydrocortisone 1% combined with moisturizer, sunscreen, and doxycycline 100 mg twice daily recommended for the first 6 weeks of therapy, based on data from randomized clinical trials. Although prophylactic minocycline 100 mg daily is another effective agent in reducing the number of lesions during the first 8 weeks, doxycycline appears to have a more favourable safety profile, especially in patients with renal dysfunction; minocycline is less photosensitizing, however, and is preferable in geographic or seasonal locations with a high UV index. Oil-free moisturizing creams are used to relieve dryness and itching, and in severe cases, antihistamines can ameliorate pruritus. Dose reduction should be considered in non-remitting, severe skin symptoms (Lynch et al., 2007).

Non-specific tyrosine kinase inhibitors

Multikinase inhibitors have entered the clinic in the treatment of multiple systemic cancers. Two of these drugs, sorafenib and sunitinib, have become first-line agents for the treatment of advanced renal cell carcinoma and have brought hope to patients not responding to more traditional therapies. Dermatological side effects occur in more than 90% of patients treated with these drugs (Chu et al., 2008b) and the toxicities that appear overlap those observed with traditional chemotherapeutic agents, including mucositis, alopecia, and xerosis.

One of the most common reactions caused by the multikinase inhibitors is a hand–foot skin reaction (HFSR), which is distinct from the hand–foot syndrome caused by more traditional chemotherapy agents. Clinically, HFSR appears in the first 2–4 weeks of treatment as hyperkeratotic lesions with superficial blistering and callus formation usually affecting the flexural surfaces of the digits. The lesions typically have a peripheral halo of erythema. This is in contrast to the acute erythema, swelling, and desquamation seen in hand–foot syndrome. HFSR symptoms include paraesthesia, burning, pain, and decreased tolerance to contact with hot objects. The associated pain can have a large impact on health-related quality of life and impair the patient's activities of daily living. More severe involvement may require dose reduction,

temporary interruption in treatment, or even cessation of therapy (Porta et al., 2007).

There are no randomized controlled trials examining the treatment of HFSR. The goal of treatment should be focused on a balance between the patient's health-related quality of life and the continued administration of potentially life-prolonging therapy. Removal of pre-existing calluses and keratotic skin is recommended prior to initiation with sorafenib or sunitinib. Other preventive recommendations include orthotic devices to normalize weight-bearing and prevent friction, avoidance of friction and trauma to the hands and feet, especially during the first 2–4 weeks of treatment, and thick cotton socks and gloves to protect the hands and feet. For hyperkeratotic areas, agents that decrease keratinocyte proliferation can be used, including urea 20–40% cream, tazarotene 0.1% cream, and fluorouracil 5% cream. For erythematous areas, clobetasol propionate 0.05% ointment is recommended. Topical 2% lidocaine can help with pain, as can systemic medications, such as non-steroidal anti-inflammatory drugs, opioids, and perhaps pregabalin (Lacouture et al., 2008).

Imatinib mesylate

Imatinib mesylate selectively inhibits BCR/ABL-mediated oncogenic signalling and non-specific tyrosine kinases, such as c-kit and platelet-derived growth factor (PDGF) receptor. This drug has is well established as effective for Ph+ chronic myeloid leukaemia (CML); in the chronic phase of this disease, it induces complete haematological response in over 90% of patients and complete cytogenetic response in 50–80% of patients. Imatinib-related non-haematological side effects are reported in less than 10% of CML patients and include oedema, weight gain, nausea, vomiting, and muscle cramps. Cutaneous reactions are well-recognized events, occurring mostly in patients treated at doses of 600 mg/day and higher, either in stable or progressive disease.

A wide spectrum of dermatological toxicities has been associated with imatinib, among which a maculopapular rash is the most common event. In addition, a variety of pigmentary abnormalities of the skin and mucosal surfaces have been reported. Hypopigmentation is well recognized and paradoxical hyperpigmentation has only rarely been documented (Balagula et al., 2011). Inhibition of the PDGF receptor, which is expressed on blood vessels and negatively regulates transcapillary transport, may be responsible for an imatinib-mediated increase of dermal interstitial fluid pressure, capable of inducing oedema and subsequently erythema and desquamation. Generally, the majority of skin reactions are self-limiting or easily managed; occasionally, oral steroids are needed to continue therapy (Breccia et al., 2005) or therapy must be discontinued.

Selective BRAF inhibitors

BRAF is a human gene that makes a protein known as B-Raf and is associated with oncogenesis. Selective inhibitors, such as vemurafenib and dabrafenib, are approved for treatment of late-stage melanoma. These drugs generally are well tolerated and severe toxicities occur infrequently. Cutaneous side effects are common, however. In a recent multicenter, phase III study of vemurafenib in 336 patients, the most common grade 2 or 3 side effects induced by BRAF inhibition were arthralgia, exanthema (up to 18%), fatigue, photosensitivity (12%), cutaneous squamous cell carcinoma (12%), keratoacanthomas (8%), nausea, alopecia (8%),

Fig. 14.4.1 Skin toxicities of B-RAF inhibitor vemurafenib. (A) Generalized keratosis pilaris; (B) histopathology of (A) showing lamellar hyperkeratosis and follicular plugging; (C) hyperkeratotic plaques on heels and metatarsal heads; (D) warty papule on upper eyelid.

pruritus (7%), and hyperkeratosis (6%) (Chapman et al., 2011). In a phase IIA trial, cutaneous squamous cell carcinoma occurred in eight of 92 patients (9%) with metastatic melanoma who received dabrafenib (Trefzer et al., 2011) (see Fig. 14.4.1).

In our experience the most common skin manifestation seen in patients treated with selected BRAF inhibitors is follicular accentuation clinically resembling generalized keratosis pilaris which was also observed by others (Wang et al., 2012). In a small number of patients, vitiligo was observed and rarely grade 3 vasculitis with pyrexia, leucocytosis, and elevated creatinine.

Immunotherapies

Targeted immunostimulatory drugs also have recently entered the therapeutic arena. They, too, are associated with cutaneous toxicities.

Ipilimumab

Ipilimumab is a novel, targeted, human immunostimulatory monoclonal antibody that blocks cytotoxic T-lymphocyte antigen4 (CTLA-4), an immune-inhibitory receptor expressed on activated T cells. Ipilimumab is well tolerated as an outpatient infusion therapy and multiple studies have confirmed significant activity against melanoma. A randomized trial has documented a survival benefit when ipilimumab was compared to a gp-100 vaccine-only arm (Hodi et al., 2010). Therapeutic responses peak between 12 and 24 weeks, with slow responses continuing up to and beyond 12 months. The major drug- related adverse effects (10–15% grade 3 or above) are immune related and consist most

commonly of rash, colitis, hypophysitis, thyroiditis, and hepatitis. Skin eruptions are mostly macula-erythematous (Di Giacomo et al., 2010). Pruritus often accompanies the eruption and may continue beyond clearing. In most patients, severity of the skin manifestations is mild and only rarely does skin toxicity necessitate treatment discontinuation (Weber et al., 2012). Vitiligo, an autoimmune-induced skin reaction, also has been observed in patients treated with ipilimumab. In contrast to the weak association between immune-related toxicities and tumour response in patients receiving IL-2 or interferon-alpha, this association appears to be much stronger for patients receiving ipilimumab (Bouwhuis et al., 2011).

Skin problems of bedridden patients

The patient with advanced illness who spends most of the day in bed is at risk for debilitating effects on many systems, including the skin. Immobilization, decreased body hygiene, urinary incontinence, and spilled body fluids expose the patient to the development of decubitus ulcers, hair follicle and sweat gland occlusion, irritant contact dermatitis, and skin infections caused by yeasts and dermatophytes.

Fungal skin infections

Tinea corporis and cruris

The typical presentation of tinea consists of large, confluent polycyclic or psoriasiform plaques extending over the buttocks, lower back,

inguinal region, inner aspects of the thigh, pubic region, genitalia, and perianal skin. A common causative agent is the dermatophyte, *Trichophyton rubrum*. Although the clinical picture is useful for diagnosis, KOH skin scraping may reveal hyphae. Tinea corporis may resemble psoriasis, seborrheic dermatitis, and nummular eczema.

Topical agents such as the allylamines, imidazoles, tolnaftate, butenafine, or ciclopirox usually are effective in the treatment of tinea. In resistant cases, fluconazole 150 mg weekly for 4–6 weeks or terbinafine 250 mg daily for 2 weeks can be effective.

Mucocutaneous candidiasis

Candida albicans is an opportunistic human pathogen that produces skin infection. Debilitated and immune-compromised patients are at greatest risk. The non-albicans *Candida* species have been detected more frequently in clinical isolates in recent years, particularly from oropharyngeal cultures in patients who are HIV positive. White patches over buccal mucosa and a yellow velvety membrane over the tongue typically appear in oral candidiasis (also called 'oral thrush' and 'black hairy tongue') (Samaranayake and Yaacob, 1990). Once sloughing occurs, the tongue may appear red and atrophic. Angular cheilitis, or fissuring of the angles of the mouth, may accompany the oral infection.

Nystatin suspension, amphotericin B, and clotrimazole oral preparations are helpful (Hay, 1999). However, immune compromised hosts often do not respond to topical treatment. A short course of systemic fluconazole 100–200 mg daily for 5–10 days may expedite relief.

Other forms of skin infection with pathogenic *Candida* species include nail involvement and peri-ungual inflammation and intertriginous eczema. Treatment usually mirrors that used in mucocutaneous candidiasis.

Vaginal candidiasis

The clinical picture of candidal vulvovaginitis is quite similar to that of oral infection. The symptoms include irritation and discomfort associated with a creamy discharge (Sobel, 1984). Skin lesions may spread from the vulva to the groin area. Small 'satellite' pustules overlie intertriginous patches of the outer labial skin and groin region. The infection usually can be cleared using topically applied nystatin or miconazole. Alternatively, oral treatment with single-dose fluconazole or itraconazole for 3–5 days is effective.

Diaper dermatitis

Urinary incontinence leads to prolonged periods of wetness and soaking of the skin. Maceration of the skin and barrier damage enhances the irritant effect of urine and faeces. Inflamed patches evolve over affected regions, usually the buttocks and genitalia, and cause a burning sensation. Erosions may aggravate the pain. Preventive use of 5% dexpanthenol and zinc oxide ointments may restore the barrier and protect skin from the irritant effect of stool, urine and sweat (Wananukul et al., 2006). Topical corticosteroids are advocated when painful and disturbing dermatitis has already occurred, but should be combined with the barrier restoring agents and discontinued once improvement is detected.

Pressure ulcers

Immobilization puts the cancer patient at an immediate risk of developing pressure ulcers. Other factors, such as older age,

malnutrition, dehydration, immune suppression, cancer-related coagulopathy, hypoperfusion of skin, and increased susceptibility to skin infections, all can contribute to a significantly increased level of morbidity and deterioration (McDonald and Lesage, 2006). In the hospice population, 14%–28% develop ulcers, similar to the prevalence of this disorder in long-term care settings (2.3–28%) (Cuddigan et al., 2001).

Pressure ulcers often become a major source of distress for the patient, and for the caregiver, because of unsightliness, pain, odour, exudates, bleeding, and the potential of infection. Areas that are most affected are those subject to pressure. In the supine patient, for example, the most common ulcer affects the sacrum region.

The exact aetiology of pressure ulcers is unclear. Prolonged pressure obstructs capillaries, leading to dermal hypoxia and ischaemia. The ischaemia results in necrosis that progresses from superficial discoloration to full-thickness skin loss.

The key to good wound care is prevention, if possible. Frequent repositioning and weight support for better distribution of pressure on body parts is necessary. Alternating pressure mattresses and absorbing overlays aid in achieving this goal. Careful assessment for early evolving pressure wounds must be done on a daily basis.

When a pressure ulcer occurs, local wound care consists of absorbent dressing (activated charcoal, cellulose, or soft alginate), local and systemic infection control (metronidazole and antibiotics, respectively), and surgical debridement.

Conclusion

While there is much that cannot be changed during the course of a life-limiting illness, such as cancer, many dermatological aspects can be addressed successfully. It is important to give dermatological aspects of disease their appropriate attention, because these can be the ones that may be dealt with efficiently, using simple and effective treatments. The dermatologist is an important participant of the multidisciplinary team. An ambitious approach to seemingly minor aspects of disease can improve the patient's quality of life and provides a message of care, attention, and respect.

Palliative issues in the care of patients with cancer of the head and neck

Barbara A. Murphy, Lauren A. Zatarain, Anthony J. Cmelak, Steven Bayles, Ellie Dowling, Cheryl R. Billante, Sheila Ridner, Kirsten Haman, Stewart Bond, Anne Marie Flores, Wisawatapnimit Panarut, and Bethany M. Andrews

Introduction to palliative issues in the care of patients with cancer of the head and neck

By convention, head and neck cancer (HNC) refers to tumours arising from the epithelial lining of the upper aerodigestive track. This includes patients with tumours of the oral cavity, larynx, pharynx, paranasal sinuses, and salivary glands. There are approximately 50 000 cases of HNC diagnosed annually within the United States. The vast majority of tumours (> 90%) are squamous cell carcinomas. Risk factors include use of tobacco, alcohol, and areca nuts; viral infection with human papilloma virus (HPV) or Epstein–Barr virus (EBV); and mucosal irritation by ill-fitting dentures or roughened dental edges (Blot, 1988). Due to higher rates of smoking and heavy drinking in males, HNC affects men disproportionately. Previously considered to be a disease of older adults, the epidemic of HPV-associated oropharyngeal cancers has led to a striking increase in HNC among middle-age adults.

Patients with HNC experience a wide array of palliative problems (Murphy et al., 2007a, 2007b). Symptoms may be related to the tumour, acute toxicities of treatment, or the long-term sequelae of therapy. Although some symptoms are common to all cancers, HNC patients experience a host of unique problems which require special consideration. In addition, palliation is a major issue throughout the disease trajectory. Symptoms are usually present at the time of diagnosis and remain problematic through the terminal phase. For those patients who are cured, long-term biopsychosocial sequelae may persist for years. Thus, assessment and treatment of palliative issues is an intrinsic and vital component of care for the HNC patient. This chapter will address the palliative issues unique to this cohort of patients. It has been divided into four sections: 'Presenting symptoms, evaluation, and treatment', 'Quality of life and psychosocial issues', 'Functional deficits' (speech and voice), and 'Specific symptom control issues'. The

reader is referred to other chapters in this text to address general symptom control problems.

Presenting symptoms, evaluation, and treatment

Presenting symptoms

Presenting symptoms are often the result of encroachment of normal structures within the upper aerodigestive system and may be predictive of the primary tumour's location. Early in the disease process, symptoms may mimic routine complaints seen by a primary care physician, such as sore throat, nasal congestion, hoarseness, swollen glands, and ear ache. Symptoms, particularly in patients with risk factors of smoking and alcohol use, not resolving or improving spontaneously within 3 weeks of conservative measures warrant additional attention and specialty evaluation in order to limit diagnostic and treatment delays (Alho et al., 2006).

History and physical examination

Assessment begins with a comprehensive history and physical examination. Particular attention should be paid to identification of symptoms or functional deficits that require palliation or intervention. Patients with a known head and neck primary carcinoma carry an additional 5–15% risk of a synchronous primary elsewhere in the aerodigestive tract (Braakhuis and Leemans, 2005).

A thorough examination involves inspection and palpation of each region of the head and neck. A complete cranial nerve exam is necessary to assess signs of perineural spread or extension into the skull base. Otoscopy evaluates the possibility of serous effusion, which may herald a mass in the nasopharynx obstructing the Eustachian tube. Nasal exam begins with anterior rhinoscopy to assess the vestibule, turbinates, and septum. Bimanual

palpation of the oral cavity and oropharynx may identify unvisualized submucosal masses and assesses for contiguous extension of visible primaries. Tumours of the base of tongue and tonsil are often missed because they are not immediately evident on simple visualization but are identifiable by palpation of a firm mass within the region. Larynx visualization is either accomplished with mirror examination or with a fibreoptic scope. The use of a fibreoptic scope through a transnasal route also allows for additional inspection of the nasopharynx, posterior soft palate, larynx, and hypopharyngeal inlet. Attention should be given to subsites of laryngeal involvement and the impact on vocal cord mobility, for this ultimately will impact overall tumour stage. Palpation of the neck with attention to nodal basins may suggest extracapsular extension if fixed to underlying carotid artery or deep neck musculature.

Radiographic and laboratory assessment

Computed tomography (CT) scans and magnetic resonance imaging (MRI) are routinely used in the assessment of head and neck carcinoma. MRI can be valuable in assessing skull base involvement and perineural spread of tumour, while CT scans are more useful for bone evaluation and nodal assessment. Work-up must include an evaluation for potential distant metastatic disease. Chest radiographs or CT of the chest are used to rule out metastatic disease or a second primary tumour. Increasingly, positron emission tomography (PET) scans are used as a part of the staging work-up and may be particularly useful in evaluating an unknown primary tumour (Rudmik et al., 2011). PET scans are used for follow-up where they may be helpful in distinguishing post-treatment scar tissue from recurrent disease (Nayak et al., 2007). Blood counts and complete metabolic profile screen for organ system dysfunction.

Endoscopy

Operative endoscopy is commonly performed to completely assess extension of tumour not easily viewed in the office setting. Additionally, due to the complexity and overlap of mucosal folds within the oral cavity, oropharynx, pharynx, and hypopharynx, standard images often fail to delineate the exact location of a tumour. Operative endoscopy offers the opportunity to manipulate the region and define the site of origin and extent of the tumour. Mapping of the tumour becomes critical in assessing resectability and defining the potential defect that would be created so a reconstructive effort may be planned. A panendoscopy procedure may be of value in high-risk patients to identify second primary tumours (Rodriguez-Bruno et al., 2011).

Treatment and outcome

The staging process must be carried out in a thorough and deliberate fashion since both treatment and outcome are heavily dependent on the extent of disease and the site of primary. Patients with early stage tumours ($T_{1-2}N_0M_0$) have a cure rate of between 70% and 90% with either radiation or surgery (Shah and Lydiatt, 1995). Unfortunately, the majority of patients present with locally advanced disease (T_{3-4} or N+). Patients with locally advanced disease or unresectable tumours are usually treated with combined modality therapy. Patients with resectable disease are treated with surgery followed by radiation therapy (with or without concurrent chemotherapy) in order to eliminate microscopic residual disease. In some patients, surgical-based treatment may lead to severe functional compromise. Patients at particular risk for poor functional outcome with a surgical approach include those patients with laryngeal, hypopharyngeal, and base-of-tongue primaries. In this cohort of patients, a radiation-based treatment approach may be undertaken in order to avoid surgical morbidity (Forastiere et al., 2003). Depending on the stage, site of primary, smoking history, and HPV status, the 3-year survival for patients with resectable locally advanced disease varies from 30% to 90%. Historically the long-term survival for unresectable patients using aggressive chemoradiation is low, approximately 20–30% (Adelstein et al., 2000). In the subset of unresectable HPV positive patients who are non-smokers, the survival is higher (Ang et al., 2010). Combined modality therapy for locally advanced disease is associated with increases in both acute and long-term toxicities. The clinician is therefore challenged to provide sufficient symptom control to ensure completion of this aggressive therapy. In addition, attempts to minimize long-term sequelae of treatment through rehabilitation, nutritional counselling, and general support services are mandatory.

Quality of life and psychosocial issues

Quality of life and symptom burden

Quality of life (QOL) is a global construct that reflects a patient's general sense of well-being. It is influenced by numerous factors including beliefs, expectations, and personal experience (Osoba, 2000). There are four core domains included in health-related QOL: function, emotional, social, and physical well-being. It is important that QOL be distinguished from symptom assessment. Symptom assessment is directed at a specific problem or a related group of problems. Symptoms are a component of QOL assessment, but the emphasis of QOL assessment is on the overall sense of well-being, not specific contributing factors. The relationship between symptom burden and QOL is complex and may change over time as patients adapt to symptom control issues. Over the past decade, numerous tools have been developed to assess QOL and symptoms in patients with HNC (Murphy et al., 2007c): Functional Assessment of Cancer Therapy (FACT/FACIT) (Cella et al., 1993), European Organization for Research into the Treatment of Cancer Quality of Life Questionnaire (EORTC QLQ-30) (Sherman AC, 2000), Vanderbilt Head and Neck Symptom Survey (VHNSS) (Cooperstein et al., 2012), and the MD Anderson Symptom Survey—Head and Neck (Rosenthal et al., 2007).

Worth noting is the general trajectory of QOL in patients undergoing therapy for locally advanced disease. Regardless of the treatment approach used, patients with HNC experience an initial drop in QOL post-treatment. The QOL then rises slowly towards baseline levels as acute symptoms abate, function improves, and as patients adapt to new physical limitations (So et al., 2012).

Comorbid disease and ageing

Two of the primary risk factors for HNC include smoking and drinking, which may lead to comorbid disease (Blot et al., 1988). Between 30% and 90% of HNC patients have at least one comorbid disease at presentation with moderate to severe morbidities present in 8–55% of patients (Paleri et al., 2010). In the HNC population, comorbid disease is associated with decreased overall

survival (Piccirillo et al., 2002) and holds true across the age spectrum (Singh et al., 1998; Reid et al., 2001). In addition, patients with comorbid disease experience increases in treatment-related toxicities and are more likely to die of competing causes such as co-morbid illness, second primary tumours, or treatment-related toxicity (Rose et al., 2011). Of interest, patients who have completed therapy for HNC have an increase in the number of post-treatment comorbidities indicating that treatment may contribute to the identification, development, or worsening of comorbidities (Yung and Piccirillo, 2008).

An extensive medical evaluation is mandatory for all patients prior to initiating therapy. In particular, clinicians should carefully assess those comorbidities that have been identified as 'prognostic for survival'. Patients with multiple comorbidities may be suitable for less aggressive therapy. Since ageing is associated with decrements in organ function that may predispose to the development of toxicity, elderly patients should be screened for function loss (Bond et al., 2012a).

Socioeconomic status

Family issue

HNC patients identify the family as their primary social support, followed by friends, health-care providers, and self-help groups (Hutton and Williams, 2001). Families play an important role in helping patients control the side effects of HNC and its treatment, as well as providing psychological support. HNC patients who do not have family support have worse adaptation and increased distress (de Leeuw et al., 2001). Social support is associated with improved health-related quality-of-life (Karnell et al., 2007).

From a family systems perspective, dysfunction or illness in one family member affects other family members, because a family unit functions as an interconnected whole (Firedman et al., 2003). Depression affects both patients and their caregivers (Wisawatapnimit et al., 2005). Caregiver burden is emerging as an important issue in the HNC population (Wisawatapnimit et al., 2006). HNC and side effects of treatment (in particular, facial disfigurement) negatively impact the QOL of patients and their partners (Vickery et al., 2003).

Both patients and their family reported similar concerns about fear of cancer recurrence (Watt-Watson and Graydon, 1995; Wisawatapnimit et al., 2006). However, there were some differences in concerns between HNC patients and their family members that highlight the importance of also assessing family members. Patients' concerns focused on their physical, functional, and social problems. On the other hand, family caregivers were concerned about their caregiver roles and about taking care of themselves (Watt-Watson and Graydon, 1995). Thus, individuals' concerns varied depending on their roles, and differences appear to increase with time after the surgery (Deschler et al., 2004).

Social issues

Disfigurement as a result of disease and treatment related is commonly experienced by HNC patients (Katz et al., 2000). Because of the highly visible nature of HNC-associated disfigurement, patients are particularly susceptible to experiencing body image disturbance. Body image concerns may exist before, during, or after treatment (He, 2008), with prevalence rates of 41–77% in the HNC population. Body image disturbance is characterized by dissatisfaction with appearance, anxiety, and depression (Katz et al., 2003).

Disfigurement leads to major social problems, most commonly altered social interaction and communication difficulties. HNC patients with visible scars and distorted features often feel stigmatized. There is a reluctance to participate in public activities such as speaking and eating, particularly in layngectomized patients. Moderate to severe effects on social activities occur in 60% of HNC patients (Epstein et al., 1999), with little improvement over time from treatment (de Graeff et al., 1999).

Financial issues, insurance, and work-related issues

In studies of HNC patients, over half of patients were unable to return to work after treatment (Taylor et al., 2004). Common causes for discontinuation of work include fatigue, eating issues, pain, and appearance (Buckwalter et al., 2007). Work-related issues result in a significant decrease in household income for 41.7% of patients (Vartanian et al., 2006), leading to financial consequences. Driving related to work is reduced, with approximately two-thirds of patients avoiding driving during therapy and less than one-third of patients driving less after therapy completion (Yuen et al., 2007).

Inadequate resources may impact both QOL and survival. Within the United States, HNC patients without insurance or those covered by Medicaid present with more advanced disease (Chen et al., 2007) and are at increased risk of death. Patients with a lower socioeconomic status have worse treatment outcomes than patients with a higher socioeconomic status (Boyd et al., 1999). Aggressive social work involvement is needed from the time of diagnosis and throughout treatment to aid the patient and the treatment team and optimize therapeutic outcome.

Functional deficits

HNC may profoundly affect two vital life functions: swallowing and vocalization. Abnormalities in swallowing and voice may be the result of either progressive tumour or treatment-related sequelae. For some patients, functional damage due to tumour may be irreparable; however, contemporary treatment regimens attempt to provide patients with a curative treatment that limits function loss. Access to appropriate rehabilitation services is critical for maximal functional outcomes; thus, the speech-language pathologist (SLP) should be considered an integral member of the multidisciplinary team.

Swallow dysfunction

Swallowing is a complex series of mechanical processes that allows for nutritional intake. A number of symptoms have been identified that herald swallow dysfunction. These 'trigger symptoms' include: (a) inability to control food, liquids or saliva in the oral cavity, (b) pocketing of food in the cheek, (c) excessive chewing, (d) drooling, (e) cough, choking or throat clearing with swallowing, (f) abnormal vocal quality after swallowing (wet or gurgled voice), (g) build-up or congestion after a meal, (h) complaint of difficulty swallowing, (i) nasal regurgitation, or (j) weight loss (Murphy and Gilbert, 2009). The presence of these trigger symptoms should initiate a swallow evaluation.

The two main instrumental assessments for swallowing evaluations include the modified barium swallow (MBS) and the fibreoptic endoscopic evaluation of swallowing (FEES). The MBS has been considered 'the gold standard' for swallowing assessment because it shows the entire oropharyngeal swallow as well

as the aetiology of aspiration. FEES is an endoscopic procedure for the assessment of sensory and motor swallowing function. It may be used to evaluate airway protection as well as bolus transport. The MBS and the FEES provide information to the clinician regarding the effectiveness of diet modification and compensatory strategies that may be utilized to improve swallowing safety and function.

Studies on baseline swallowing abnormalities in patients with newly diagnosed HNC are mixed (Pauloski et al., 2000). The degree of impairment is site specific with hypopharyngeal and laryngeal patients experiencing the most impaired swallowing. Therefore, it is prudent to have a high index of suspicion for dysfunctional swallow at baseline and to refer patients for swallow assessment if any concerning signs or symptoms are present.

Patients who undergo surgery of an organ involved in deglutition should expect some alteration in function (Russi et al., 2012). The degree of functional deficit is largely dependent on site and extent of surgery, as well as reconstruction type (Logemann and Bytell, 1979). The only parameters prognostic for swallowing outcome are the percentage of oral and tongue base resected (McConnel et al., 1994). Abnormalities in oral and oropharyngeal swallow are noted by MBS and scintigraphy in more than half of patients at 6 months post treatment (Borggreven et al., 2007). Factors predictive for poor swallow outcome include comorbid condition, T3 or T4 tumours, and combined resection of the base of tongue and soft palate.

Dysphagia and odynophagia occur in patients who undergo primary or adjuvant radiation therapy. Common acute radiation induced toxicities contributing to dysphagia include mucositis, tissue oedema, xerostomia, and hyperviscous secretions. These side effects interfere with eating ability and overall swallow function. Most acute toxicities resolve slowly within 4–12 weeks of completing therapy; unfortunately, late effects may begin to appear simultaneous with the resolution of acute toxicities. The most commonly identified swallowing abnormalities include decreased tongue base retraction, decreased laryngeal elevation, decreased epiglottic inversion, decreased pharyngeal wall motion, and aspiration. Attempts have been made to limit radiation-induced dysphagia by avoiding or limiting the dose of radiation to critical structures involved in deglutition. These structures have become known as dysphagia-aspiration-related structures (DARS). Unfortunately, review of the literature fails to demonstrate conclusive evidence that conformal radiation decreases dysphagia (Roe et al., 2010).

One of the major complications of dysphagia is aspiration. Aspiration may lead to acute episodes of pneumonia or to chronic pneumonitis with associated decreased pulmonary function (Nguyen et al., 2007). Postoperative pneumonia is associated with increased morbidity, mortality, and hospital-related costs (Semenov et al., 2012). Aspiration is also a common late effect of therapy in up to 44% of patients (Campbell et al., 2004).

Patients with severe dysphagia may require a feeding tube for nutritional support during and immediately after completion of therapy. Early trials using primary chemoradiation therapy reported high rates of percutaneous endoscopic gastrostomy (PEG) feeding tubes 1–2 years post-treatment. It is now recognized that placement of a feeding tube for nutritional support may result in decreased use of muscles of deglutition, leading to disuse atrophy. In fact, periods of nil by mouth for as little as 2 weeks predict poorer swallowing outcomes (Gillespie et al., 2004). Patients are now encouraged to continue to swallow or to perform swallow exercises throughout the course of treatment and recovery in order to maintain pharyngeal function. Advancement to an oral diet is advocated as quickly as possible. In addition, SLPs should be actively involved in the care of HNC patients across the treatment trajectory.

Voice

The ability to communicate is a critical human function and vocalization is our most important communication method. Without an intact voice, patients experience a decrease in social interactions and ability to perform activities of daily living. Treatment of HNC often necessitates resection of structures critical to the production of normal speech, resonance, and voice. In general, greater extents of resection result in more severe communication disorders. Primary or adjuvant radiation may also affect vocalization.

Disordered speech may occur due to structural changes in lips, tongue, teeth, and hard palate. Altered articulation of bilabial sounds /b,p,m/, and labiodental sounds /f,v/ occur with reconstruction of labial structures and subsequent nerve paralysis. In the case of advanced disease, total glossectomy severely alters articulation. Loss of or extraction of teeth associated with tumour involvement or radiation therapy, or mandibular osteoradionecrosis, can negatively impact articulation and overall intelligibility. Hard palate defects resulting from maxillary involvement of tumour potentially affect the production of lingua-alveolar sounds /t,d,n,l/ and lingual-palatal sounds /sh,zh,ch,j/. Often a flap is used to close the defect.

Disordered resonance may occur due to tumour involvement or its treatment. Surgical resection of the soft palate creates velopharyngeal insufficiency. Similarly, when tumour involvement disrupts cranial nerves IX or X, the resulting unilateral palatal paralysis creates a velopharyngeal gap. There is inability of the soft palate to contact the posterior pharyngeal wall creating a constant air leak in the vocal tract. The abnormal leak of air through the nose during speech production results in hypernasal voice quality. Behavioural therapy or surgical correction of velopharyngeal gaps may facilitate articulation of speech sounds sufficient to reduce nasality and optimize intelligibility.

Voice disorders in HNC patients arise from neurologic abnormalities induced by tumour and surgical resection of the tumour. The voice disorder resulting from laryngeal paralysis is extremely debilitating. Most patients present with a very soft, breathy voice quality or even a whisper. Attempts to force enough vocal volume to be heard results in rapid fatigue of laryngeal and respiratory muscles, and patients may avoid communication because of the effort required. Phonosurgery attempts to reposition immobile vocal folds, restoring voice and preventing aspiration (Netterville et al., 1993). Operative procedures which spare some glottic structures and mobility yield varying voice results.

There are several options for communication rehabilitation in laryngectomized patients, including an artificial larynx (electrolarynx), oesophageal speech, or prosthetic speech. An electrolarynx is a device which provides an external sound source, producing a mechanical-sounding voice. The greatest advantage of the electrolarynx is that it provides immediacy of communication with minimal patient training. A second type of speech method is the use of oesophageal speech. This requires long

commitments to therapy but allows for greatest communicative independence. In this method, air is pumped via swallow or inhaled into the cervical oesophagus and immediately exhaled. The pharyngo-oesophageal segment is vibrated by the expelled air and sound is produced, similar to a controlled belch. Prosthetic speech is achieved by creating a trachea-oesophageal tract to allow the insertion of a one-way valve. With the stoma occluded, air from the lungs is shunted through the prosthesis and into the oesophagus. The air vibrates tissue in the superior aspect of the oesophagus to produce sound.

Specific symptom control issues

Airway control

Airway compromise is one of the most distressing symptoms of progressive disease. Obstruction can occur anywhere along the airway but the symptoms and treatment differ depending on the level of obstruction. Initial assessment of the airway begins with an observation of breathing pattern. Sonorous mouth breathing without stridor would suggest obstruction at the level of base of tongue or oral cavity and is palliated with a nasal trumpet and upright patient positioning. Inspiratory or biphasic stridor is more indicative of a fixed laryngotracheal obstruction, often requiring bypass by tracheostomy. Anxiety, agitation, confusion, and claustrophobia are all signs of progressive hypercarbia and air hunger resulting from obstruction and immediate intervention is warranted. Laryngoscopy determines whether a patient may be amenable to intubation in the event of complete airway loss. Additional factors such as trismus and neck immobility complicate intubation. Ultimately for patients with known incurable disease, an honest discussion with the patient about the potential future need for tracheostomy and early placement may avoid emergent intervention under duress.

Auditory function

HNC patients may experience a decrease in hearing as a result of therapy. Sensorineural hearing loss may result from therapy with either radiation or systemic chemotherapy agents such as cisplatin (Bhandare et al., 2007), with 15–31% of patients demonstrating sensorineural hearing deficits 3 months post therapy. Hearing deficits improved over time in only 40% of patients. Predictive factors included age, pre-treatment hearing deficit, dose to cochlea, and concurrent chemotherapy. With the advent of intensity-modulated radiotherapy (IMRT), treatment plans may decrease radiation dose to the cochlea. Patients with a clinically significant sensorineural hearing loss should be referred for hearing aids.

Dermatitis

Patients receiving treatment with external beam radiation can develop severe dermal and soft tissue reactions (Hymes et al., 2006). Acute radiation dermatitis usually begins 2–3 weeks after therapy is initiated. Manifestations include erythema, oedema, blistering, ulceration, and sloughing. Dermal damage begins to heal within 2–4 weeks after radiation is completed. Late dermal effects of radiation occur weeks, months, or years after therapy. Late dermal effects commonly include atrophy, changes in pigmentation, development of telangiectasias, and hair loss. Grading systems are available for both acute and late dermal effects.

Several factors may increase the severity of acute radiation dermatitis. Patients with tracheostomy tubes in place may note increased irritation and ulceration in the peristomal region. Concurrent chemotherapy or epidermal growth factor receptor inhibitors may result in marked increase in radiation dermatitis (Lacouture et al., 2011).

Several guidelines have been developed for treatment for radiation dermatitis. Data supporting recommendations is scant (Bolderston et al., 2006). There is general consensus for cleaning the involved skin with mild soap but insufficient evidence exists for use of topical creams, enzymes, sucralfate or intravenous agents such as amifostine as preventive agents.

Laboratory abnormalities

Hypothyroidism

After primary surgery, neck dissection, or radiation, patients frequently develop hypothyroidism (Sinard et al., 2000). These effects are additive, with rates of hypothyroidism approaching 70% when both lobectomy and adjuvant radiation therapy are employed for laryngeal cancer. The risk for developing clinical or chemical hypothyroidism 3 years post treatment is 15% and 40% respectively, and may be higher with IMRT technologies, particularly if the thyroid gland is not spared. Routine follow-up should include a careful history and physical exam directed towards signs or symptoms of hypothyroidism. Periodic monitoring with a serum thyroid-stimulating hormone is appropriate for any patient who has received radiation to the low neck. For recommendations regarding treatment of hypothyroidism, please reference the American Thyroid Association Standards of Care Committee guidelines (Singer et al., 1995).

Anaemia

Anaemia is a common presenting haematological abnormality in patients with HNC and may worsen throughout the course of treatment. Compelling data demonstrate that anaemia is a strong predictor for outcome with radiation-based treatment regimens (Dische et al., 1986). It is hypothesized that low numbers of circulating red blood cells may increase the fraction of cancer cells that are hypoxic. Hypoxic tumour cells are resistant to radiation therapy and require two to three times higher radiation doses than those required to kill well-oxygenated cells (Gray et al., 1953). Thus anaemia may lead to increased radiation resistance. The absence of anaemia prior to treatment is associated with improvements in overall survival, local regional control, and radiation therapy complications (Cordella et al., 2011).

Studies evaluating erythropoietic agents for management of radiation-induced haematological toxicity raise concern about adverse treatment outcomes. Specifically, there are reductions in loco-regional control rates in HNC patients receiving radiation treated with epoetin beta when compared to placebo (Henke et al., 2003). Based on a re-review of the available data, it has been recommended that erythropoietic agents be used only as specified by regulatory agencies.

Lymphoedema

Lymphoedema is a condition in which excessive fluid and protein accumulate in the extravascular and interstitial space (see Chapter 11.3). This occurs when the lymphatic system can no longer transport the normal fluid and protein load from the blood capillary–interstitial interface into the lymphatic vessels or when

there is increased lymph production. Lymphoedema incidence rates are up to 75% in HNC patients (Deng et al., 2011) and are due to alterations in the structures vital to fluid exchange at the blood capillary–interstitial–lymphatic interface and to the lymphatics related to surgery, radiation, and cancer itself. Lymphoedema may occur before or after surgery and/or radiation treatment.

Presenting symptoms vary depending on the site of involvement. Subtle or overt swelling of the soft tissues of the neck and face are often the first indicator of lymphoedema. HNC patients who develop lymphoedema may also experience other troubling symptoms such as feelings of heaviness, tightness, and stiffness in the swollen areas with the perception that something is stuck in the throat. Soft tissue swelling may progress rapidly over time resulting in fibrosis and impaired range of motion. Lymphoedema of the larynx may result in airway compromise or altered voice quality while pharyngeal oedema may impair swallowing. If swelling appears suddenly or if pre-existing lymphoedema worsens other medical conditions (renal failure, liver failure, cancer recurrence, etc.) should be considered. Thus, a thorough history coupled with a physical assessment is needed to ascertain causative factors and better plan treatment. The history should include onset of swelling, location of swelling, symptoms experienced, and exacerbation/remission patterns of symptoms. The physical assessment should include (a) laryngoscopic evaluation to assess oedema, and (b) careful examination of skin and soft tissues of the face, neck, and shoulders with attention to range of motion and signs of infection or inflammation.

Although controlled trials of lymphoedema therapy are lacking, clinical experience would indicate that appropriate treatment results in improved patient comfort, increased neck and shoulder range of motion, decreased respiratory compromise, improved swallowing function, and decreased risk of infection. Treatment of lymphoedema includes manual lymphatic drainage (MLD), the use of compression garments, and education. MLD should only be undertaken by lymphoedema therapists trained in head and neck drainage techniques. Education should include postural techniques to minimize symptoms, identification and prevention of infections, and exercises to maintain neck and shoulder mobility.

Mood and anxiety disorders

Clinical experience indicates that mental health issues are frequent in the HNC population (see Section 17). Many studies focus on 'psychological distress', which describes the psychological turmoil surrounding the cancer diagnosis and its treatment. However, distress is not synonymous with depressive or anxiety disorder. There are high rates of depressive disorder, alcohol use disorders, and anxiety disorders (Haman, 2008) in HNC patients. Over half of patients have an Axis 1 diagnosis: 27% depressive disorders, 14% anxiety disorders, and 11% with both a depressive and an anxiety disorder. The prevalence of new-onset depression and anxiety after treatment for cancer is 24% and 4%, respectively, with significant negative impacts on QOL.

In order to effectively address this issue, the aetiology of mood disorders in this patient population must be understood. For example, cancer treatment can result in the inability to communicate or impair the ability to eat, leading to social avoidance, depression, and anxiety. A close relationship exists between substance abuse and psychopathology with HNC patients having high rates of substance abuse (past and ongoing). These maladaptive coping strategies both result from and increase the likelihood of depression and anxiety.

Mood and anxiety disorders represent a significant problem in the HNC patient and can negatively impact QOL. They can undermine the ability of the patient to positively change modifiable risk factors (tobacco and alcohol), which can in turn affect disease-free survival. Males with HNC demonstrate some of the highest suicide rates of all cancer patients. In fact, characteristics common to the HNC population such as male gender, advanced disease, little social or cultural support, and limited treatment options all contribute to suicide risk (Kendel, 2007). Physicians who treat HNC must be sensitive to both the physical and psychological sequelae of the diagnosis and treatment.

Mucositis

Oral and pharyngeal mucositis is the most distressing acute complication of radiotherapy for HNC. Incidence rates for all grades of oral mucositis are reported as 60% in standard radiation, and up to 100% in hyperfractionation or accelerated hyperfractionation regimens (Montserrat et al., 2006), with grade 3–4 mucositis rates of 34–57% (Trotti et al., 2003). Oral mucositis clinically presents 10–14 days after radiation therapy is initiated. The initial observation is a transient patchy white discoloration of the mucosa followed by a confluent deep erythema and pseudomembrane formation. The most severe manifestation is frank ulceration of the mucosa.

Risk factors for the development of mucositis include: radiation with special attention to total dose, fraction size, volume irradiated, overall treatment time, fractionation regimen, and the use of concurrent chemotherapy (Murphy, 2007; Bensinger et al., 2008). Mucositis impairs eating, swallowing, and speech, often due to pain. When severe, mucositis may lead to hospitalization for malnutrition or dehydration in up to 15% of cases (Rodríguez-Caballero et al., 2012) and results in treatment interruptions or therapy modifications in 11% of patients (Murphy, 2007; Russo et al., 2008), thus leading to decreased local control and overall survival rates (Rosenthal, 2007). Once radiotherapy treatment has been completed, mucositis spontaneously subsides over a 2–6-week period.

A plethora of traditional treatments for oropharyngeal mucositis have been reported. The Multi-national Association for Supportive Care in Cancer (MASCC) and Cochrane systematic reviews routinely provide updates and generate guidelines on this rapidly expanding database in order to aid clinicians on prevention and treatment of oral mucositis (Keefe et al., 2007; Worthington et al., 2011). Good oral care is a standard component of mucositis management. The foundation of oral care should include regular assessments of oral cavity health and oral pain by dental professionals throughout treatment and follow-up. There is data to support a number of interventions; however, data is conflicting regarding the clinical significance and effectiveness. These interventions include palifermin, amifostine, low-level laser therapy, and multiple other agents for the prevention and treatment of oral mucositis. It is clear that new agents are needed for the prevention and treatment of this acute toxicity. Guidelines are available for review at <http://www.mascc.org>. For further information on treatment of mucositis and other oral cavity lesions, please see Chapter 8.5.

Neurocognitive impairment

HNC patients are at increased risk for neurocognitive impairment before, during, and after treatment. At the time of diagnosis, HNC patients may have baseline neurocognitive impairment due to alcohol abuse or comorbid medical and psychological conditions. Alcohol-dependent patients are at increased risk for greater preoperative neurocognitive impairment (McCaffrey et al., 2007). Almost half of patients have global neurocognitive impairment with the most commonly affected domains being verbal learning, executive function, verbal memory, and processing speed.

Acute neurocognitive impairment in HNC patients during treatment has been studied primarily in the context of delirium. The incidence of postoperative delirium in HNC patients ranges from 13% to 26% (Yamagata et al., 2005) and is attributable to many perioperative causes. HNC patients undergoing primary or adjuvant radiation-based therapies also experience delirium (Bond et al., 2012b), 9% with overt delirium and 45.3% exhibiting subsyndromal delirium (the presence of one or more delirium symptoms without meeting criteria for the full syndrome). Long-term neurocognitive effects of treatment result from incidental brain irradiation, despite improvements in treatment techniques. The pathogenesis of long-term neurocognitive impairment is multifactorial: radiation-induced vascular injury and inflammation, radionecrosis, radiation injury to subcortical white matter, pituitary and hypothalamic dysfunction, cerebral atrophy, and comorbid conditions (Abayomi, 2002).

The implications of neurocognitive deficits for the general management of HNC patients are considerable. Patients report difficulty learning new information and understanding the scope of their disease and treatment. It negatively affects treatment tolerance and compliance, follow-up, and rehabilitation, and leads to increased complications, decreased QOL, and increased psychological distress. Early identification and management of neurocognitive impairment in HNC patients is critical. Therefore, a thorough pre-treatment evaluation for HNC patients should include screening for neurocognitive impairment and associated factors such as alcoholism, depression, and comorbid medical conditions. Patients should be monitored for signs of delirium and ongoing neurocognitive impairment throughout and following treatment.

Nutrition

Nutritional deficits may be present in patients at the time of diagnosis and is prognostic for survival and ability to tolerate treatment (Pai et al., 2012) (see Chapters 4.8 and 10.4). Malnutrition is often multifactorial in nature. Decreased oral intake may be caused by oral pain, difficulty swallowing, or mechanical obstruction by tumour. If functional abnormalities are present, a swallowing evaluation and swallowing therapy may prove beneficial. In patients with mild to moderate swallowing deficits, soft, puréed foods and liquid supplements can stabilize weight loss. Patients with severe swallowing difficulty require more aggressive therapy such as placement of a feeding tube.

Weight loss secondary to treatment is almost universal in HNC patients, with average losses of 6–10% body weight while undergoing therapy. Patients who have extensive surgery resulting in dysphagia undergo PEG tube or nasogastric tube placement. Patients undergoing primary radiation therapy or combined

chemoradiation develop severe mucositis resulting in profoundly diminished oral intake. Weight loss continues through the early recovery phase for most patients. The aggressive use of PEG feeding tubes may minimize weight loss during therapy and improve QOL (Brookes, 1985). However, as noted above, there is concern that prophylactic feeding tube placement may lead to increased rates of long-term feeding tube dependence due to disuse atrophy, loss of normal swallowing reflex, and psychological dependence (Oozeer et al., 2011; Langmore et al., 2012). Thus, patients with a feeding tube should be seen by a licensed SLP so that they may be given appropriate swallowing exercises to maintain swallow function. In addition, patients should be encouraged to transition to oral intake as soon as it is feasible. The placement of a feeding tube does not guarantee adequate caloric or fluid intake and requires considerable time and effort to manage. Elderly or debilitated patients who undergo feeding tube placement may require assistance from caregivers.

Post treatment, nutrition remains an issue of concern for many patients. There are numerous late effects that contribute to the dietary alterations noted in post-treatment HNC patients: (a) swallowing abnormalities due to tumour or treatment, (b) radiation-induced xerostomia inhibiting food bolus formation, (c) dental extractions altering ability to chew, (d) taste alterations causing food aversions, and (e) pain due to mucosal sensitivity. These factors lead to decreased food intake with or without restriction in the consistencies and type of foods ingested. Up to 1 year post treatment, 20% of patients require ongoing use of nutritional supplements and 72% report dietary modifications (Beecken and Calaman, 1994). Due to dietary alterations, a high percentage of patients are deficient in key micronutrients (Murphy et al., 2002), and have decreased energy and protein intake. Non-treatment-related factors which must be considered in the nutritional assessment include co-morbid diseases, the adequacy of socioeconomic support, and the presence of alcohol abuse. Periodic dietary assessment is critical to minimize late treatment effects on nutrition.

In addition to the functional causes of weight loss, patients with locally advanced, metastatic, or recurrent disease have cancer cachexia (Brookes, 1985). Cancers are able to profoundly affect the normal metabolic pathways resulting in weight loss, loss of lean muscle (Tisdale, 2000), and adipose tissue (Innui, 2002). These phenomena are at least partially mediated by cytokines and other pro-inflammatory mediators (Machon et al., 2012). Of note, patients undergoing aggressive therapy with chemoradiation may develop a similar clinical syndrome which is characterized by anorexia, rapid weight loss, loss of muscle mass, loss of subcutaneous fat, fatigue, and generalized weakness (Silver et al., 2007). It may be hypothesized that treatment results in local and systemic tissue damage. The body responds in a stereotypic fashion, activating biological pathways intended to aid in healing and repair. Unfortunately, when the biological response to tissue damage is over exuberant or protracted, repair mechanisms may actually adversely affect the host.

Osteoradionecrosis

Osteoradionecrosis (ORN) may be defined as ischaemic necrosis of bone in a previously radiated area with associated soft tissue necrosis. It presents as exposed bone with failure of mucosa to

heal over 2–6 months. ORN most commonly affects the mandible and usually develops within 6–12 months of completing radiation therapy. Prevalence of ORN in HNC patients is 8.2% (Reuther et al., 2003), with lower reported rates with IMRT due to dose sparing of the mandible (Nguyen et al., 2012b). Rates vary depending upon total radiation dose, fractionation, volume irradiated, follow-up time, status of dentition, and reporting institution. It is more common in edentulous patients; however, ORN is often reported as occurring after dental extractions following irradiation.

Historically, the pathogenesis of ORN has been ascribed to the three 'Hs'—hypoxia, hypocellularity, and hypovascularity (Marx, 1983). More contemporary theories postulate a primary fibroatrophic process including endothelial damage, decreased cellularity, suppressed osteoblastic activity, disorganization of bone remodelling apparatus, avascularity, and fibrosis that leads to poor wound healing after dental trauma and an increased risk of secondary infection from bacterial flora (Chrcanovic et al., 2010).

Careful attention must be paid to the dentition and gingiva before, during, and after radiation treatment. Before initiation of treatment, patients receiving high dose (> 50 Gy) radiation require evaluation by a skilled dentist familiar with radiation side effects. Panoramic radiographs are integral for assessment of osteoradionecrosis (see Fig. 14.5.1). All grossly diseased maxillary and mandibular teeth should be extracted immediately. Antibiotic prophylaxis should be used, and a minimum of 14 days (preferably 21 days) should be allowed for healing prior to onset of radiation.

Prevention of ORN has naturally evolved around minimizing trauma or local irritants that have been shown to precipitate the process. A correlation between higher ORN and continued tobacco and alcohol use exists. Patients are encouraged to use fluoride before bedtime to minimize dental carries. Diseased teeth should be maintained through meticulous endodontic therapy. For periodontally involved or cariously unrestorable teeth, the retention of roots and the use of overdentures are preferable to extractions. ORN can resolve spontaneously with conservative management or may progress ultimately to fistula formation or pathological fracture. Treatment of ORN includes use of hyperbaric oxygen therapy (HBO), administering 100% oxygen under a pressure of greater than 1 atmosphere. Cochrane review found that HBO improved the probability of achieving mucosal coverage and restoration of bony continuity with ORN and prevented the development of ORN associated with dental extraction (Bennett et al., 2012).

Fig. 14.5.1 Osteoradionecrosis of the right mandible after a dental extraction.

Pain

The reader is referred to Section 9 for general management strategies for cancer pain. There are, however, specific problems that confront HNC patients that merit special attention. Head and neck tumours are often deeply ulcerative causing severe somatic pain. Irritation of an ulcerative tumour via speech or swallowing movements makes pain control challenging. Tumour invasion into nerves can lead to refractory pain syndromes. Finally, maxillofacial pain thought to be due to benign processes such as sinusitis, temporomandibular joint dysfunction, or maxillofacial neuralgias can be the first manifestation of carcinomas. Determining the aetiology of pain in the head and neck patient requires familiarity with anatomy and often calls for consultation with the treating otolaryngologist and neuroradiologist.

Patients undergoing surgical resection will experience postoperative pain. Tracheostomy tube placement, loss of vocalization, or severe oral pain hinders effective communication, interfering with pain assessments. As patients recuperate, postoperative pain subsides. However, it is important to emphasize that chronic postoperative pain is common in the head and neck population. Two years following treatment, 26% of patients still experience pain (Chaplin and Morton, 1999), with moderate or severe pain in 14% of patients. Predictors for chronic pain included pain at 3 months post treatment and neck dissection. Patients may develop contractures and tissue scaring in the neck and shoulders, leading to severe and debilitating musculoskeletal pain. Physical therapy consultation can help guide patients in exercises to decrease contractures and preserve function and range of motion (Barrett et al., 1988).

Radiation doses used for the treatment of HNC is high (70 Gy for primary treatment and 50–60 Gy for adjuvant therapy) and are expected to result in significant damage to the mucous membranes, soft tissue, and skin. The severity of symptoms is usually related to the size of the radiation field and the area involved. Patients with large fields, and those receiving radiation to the oral cavity experience severe debilitating mucositis and radiation dermatitis. Mucositis-related pain is often severe and may dramatically impact function. Over the first 6 weeks of therapy, 76% patients experience severe mouth and throat pain, requiring opioid analgesics. The treatment of mucositis-induced pain requires close and frequent monitoring, with aggressive medication titration. Daily nursing assessment with aggressive treatment of mucositis results in decreased pain, improved sleep and eating, and better energy levels (Jannjan et al., 1992). Topical lidocaine solution and mixed opioid/non-opioid tablets are usually adequate during the initial weeks of radiation. By 4–5 weeks, oral and dermal pain begins to increase and swallowing decreases substantially. Fentanyl patches are a very convenient method for administering long-acting narcotics in this patient population. Short-acting liquid narcotics should be used for breakthrough pain. Pain due to radiation mucositis takes weeks to months to resolve.

Pain due to local recurrence is a major palliative issue in terminal HNC patients. More importantly, it may be the first symptom indicating recurrent disease. Pain is the first symptom indicating recurrence in 70% of patients, with a median lag time of 4 months between the onset of pain and the diagnosis of recurrent disease (Smit et al., 2001). Thus, new onset pain in a previously treated HNC patient should be carefully investigated.

Physical therapy examination and treatment

Surgical or radiation-based treatment approaches may result in head and neck specific and generalized alterations of physical performance. Examples of head and neck specific function loss include decreased range of motion in the jaw, neck, and shoulders. Generalized physical function abnormalities include weakness and deconditioning secondary to therapy. Prior to treatment, a baseline physical therapy evaluation will determine physical function and provide pre-treatment exercise programming and education to the patient and caregivers. An individualized home exercise programme targeting postural alignment, active and passive range of motion, muscle strengthening exercises, and balance/coordination activities are recommended.

During the immediate postoperative phase, the home exercise programme should be modified to account for postoperative movement and activity precautions. During this time, isometric exercises of the cervical and associated shoulder muscles help prevent muscle atrophy, excessive oedema, and decrease pain. Surgeries involving sternocleidomastoid resection will result in cervical rotation with the chin pointing toward the involved side. In severe cases, this may also result in cervical flexion, rotation and lateral flexion toward the uninvolved side mimicking torticollis. This dysfunctional movement pattern can be exacerbated with radiation induced tissue fibrosis. Left untreated, the cervical vertebrae lose mobility and abnormal biomechanics are translated up and down the involved vertebral segments. Similarly, a lack of preservation of the spinal accessory nerve will result in 'shoulder syndrome' in which both the sternocleidomastoid and trapezius are affected (Nahum et al., 1961; Cappiello et al., 2005). To compensate for the loss of the trapezius, the smaller scapular stabilizers are overused and can contribute to pain. The physical therapist will use therapeutic exercise, postural re-education, and manual therapy techniques to normalize altered cervical and shoulder biomechanics.

The goals of physical therapy after active cancer treatment are to maximize muscle strength, soft tissue length, postural alignment, endurance, balance/coordination, and scar and tissue mobility. Likewise, physical therapy aims to minimize pain, fatigue, lymphoedema, and improve overall physical function and return the patient to fitness. Trismus may be caused by a variety of mechanisms including the tumour occupying muscle tissue, radiation-induced tissue fibrosis, or muscle spasm of the masseters, pterygoids and/or temporalis muscles, leading to diminished mouth opening. Trismus directly affects nutritional intake and results in weight loss and energy imbalances. Trismus has been effectively treated with physical rehabilitation methods such as sustained stretch devices (e.g. Therabite®, Dynasplint®) and exercise (see Chapters 4.6, 4.9 and 4.10).

Taste alteration

Loss of taste is caused by chemotherapy drugs and radiation. Radiation therapy may result in severe and permanent alteration in taste sensation. Three models have been proposed to explain irradiation-triggered taste dysfunction: (1) disruption of contact between taste cells and nerves via radiation damage, (2) direct damage of taste cells, and/or (3) interruption of production of new taste cells (Nguyen et al., 2012a). Functional taste alteration reported by patients is congruent with taste bud cell degeneration, often beginning within the first week of radiation therapy (Mossman and Henkin, 1978), with more broad taste dysfunction reported by week 3 or 4 (Epstein and Barasch, 2010).

Loss of taste has profound effects on nutrition and QOL. Patients may describe an inability to take nutrition orally due to altered taste sensation. The taste of food may become noxious resulting in nausea and vomiting. Loss of umami taste appears to have the strongest correlation with QOL due to its role in triggering interest in eating via enjoyment and pleasure pathways (Shi et al., 2004). The impact of hyposalivation on taste loss is controversial (Epstein and Barasch, 2010).

The incidence of taste alteration in HNC patients undergoing radiation ranges from 75% to 100% (Comeau et al., 2001). Taste slowly returns over weeks to months after the completion of therapy for the majority of patients. However, some patients have a permanent alteration in taste sensation, especially with accumulated doses over 6000 cGy (Mossman, 1983). Late effects of taste alteration are more prominent than once realized, with 39% patients reporting moderate to severe taste alterations at greater than 6 months post treatment (Cooperstein et al., 2012). To date, there are no known preventative or treatment measures for taste alterations. Although small studies have reported that zinc improves taste alterations, randomized trials failed to demonstrate efficacy (Halyard et al., 2007).

Xerostomia

Xerostomia can be a severe and permanent complication of external beam radiation therapy (Chambers et al., 2007). The degree of xerostomia is related to the amount of salivary gland tissues within the radiation port and dose delivered. Salivary gland function drops rapidly to 5–30% of normal within the first 2–3 weeks of therapy and remains low following completion of radiation for a prolonged period of time (Frazen et al., 1992). The prevalence of xerostomia in HNC patients more than 6 months post radiation ranges from 73% to 93%, with 65% of patients reporting that symptoms are moderate to severe (Dirix et al., 2008). Xerostomia results in numerous symptoms and constitutes the most frequent patient complaint in those receiving radiation, resulting in a profound negative effect on QOL. Xerostomia impacts dietary choices, deglutition, and speech (Logemann et al., 2001; Roh et al., 2005; Brosky, 2007).

A number of palliative and therapeutic interventions can be attempted to improve symptoms of xerostomia. Patients swish and swallow liquids for soothing mucosal surfaces. Sodium bicarbonate rinses help maintain dental hygiene. Caphosol®, a concentrated calcium and phosphate solution, is approved by the Food and Drug Administration (FDA) in the United States for palliation of xerostomia. A number of commercial salivary gland substitutes are available. Although some patients find these products useful, the majority of patients fail to find significant benefit. For an extensive listing of palliative agents, please visit Oral Health in Cancer Therapy at <http://www.doep.org>.

A number of agents are used to increase salivary secretion in patients with established xerostomia. Pilocarpine is a parasympathomimetic that acts as a muscarinic agonist and demonstrates improvements in xerostomia-related symptoms, but not necessarily objective saliva production. Symptom relief is maximal at 4 months, but decreases once the sialagogue is discontinued (Vissink et al., 2010). Pilocarpine has been investigated as a prophylactic treatment during radiation therapy (Wong et al., 1994;

Scarantino et al., 2006). It should be noted that a frequent challenge to xerostomia study outcomes is the disconnect between subjective and objective data, in that patients' assessments of their dry mouth do not always correlate with salivary gland function (Fox et al, 1987).

Amifostine has been FDA approved for reduction in xerostomia in patients undergoing postoperative radiation treatment for HNC when the radiation port includes a large segment of salivary gland tissue (> 75% of both salivary glands included in the radiation port). The rate of acute xerostomia dropped from 78% to 51% and late xerostomia dropped from 57% to 35% (Brizel et al., 2000). A number of subsequent trials have been conducted to delineate more clearly the role of amifostine in the HNC population; however, the results were mixed. A meta-analysis suggests that amifostine decreased acute (odds ratio (OR), 0.24; confidence interval (CI) 0.15–0.36; p < 0.00001) and late xerostomia (OR 0.33; CI, 0.21–0.51; p < 0.00001) (Sasse et al., 2006). Long-term data suggest that amifostine did not compromise locoregional control rates, progression-free survival, or overall survival (Bourhis et al., 2011).

Wound care, fistulas, and carotid rupture

Despite newer reconstructive techniques, patients undergoing adjuvant radiation or combined chemoradiation therapy are at greater risk for wound breakdown as a result of the small vessel arteritis that reduces oxygen tissue exchange. Additionally, patients' preoperative nutritional status and smoking history complicate their wound healing capacity. Pharyngocutaneous fistulas result from wound breakdown if a watertight seal of the pharynx cannot be maintained. Patients who have had a breach of the pharynx during their resection are often maintained with nasogastric feedings to limit the contamination of the suture lines for 1–2 weeks. Fistula formation is usually heralded by erythema of the neck, tenderness, and low-grade fevers. The saliva in the neck must be drained and directed away from the carotid artery. Saliva, with its digestive enzymes, may necrose the great vessels resulting in life-threatening haemorrhage. Additionally, exposure of the vessels to the external environment leads to desiccation and potential carotid rupture. Exposure of the neck vessels or fistula formation represents a surgical emergency. The vessels should be covered with saline-soaked gauze until vascularized tissue can be placed over the vessels. Any continuous bleeding from an exposed area must be taken seriously for it may herald an early leak from the carotid artery and surgical exploration to repair the vessel may be necessary. If a fistula does form, and the great vessels are not exposed, the wound can often be managed conservatively until secondary healing occurs. The wound should be packed with wet to dry gauze dressings twice a day or more frequently if contamination is excessive.

In patients who have unresectable disease in the neck, ulceration of the tumour with necrotic debris may become problematic. Tumour hygiene can be achieved through gentle debridement with hydrogen peroxide. Desiccating powders may be applied if wound remains moist. Intermittent use of antibiotics to cover anaerobic floral contaminants will often assist with sterilizing the field and assist with odour control.

A carotid rupture is an uncommon but catastrophic complication of HNC and its therapy. Carotid rupture may occur in patients undergoing extensive resection, external beam radiation therapy,

brachytherapy, or those with recurrent/advanced cancers of the neck. Although initial retrospective reviews demonstrated carotid rupture rates as high as 14% (Marks et al., 1978), the numbers are much lower with contemporary treatment methods (Downey et al., 1999). When possible, patients with carotid rupture should undergo evaluation with angiography. In patients with controlled tumour, aggressive intervention with surgery or invasive radiologic procedures is indicated. Unfortunately data on the success of radiologic procedures (i.e. balloon occlusion and embolization) are scant (Citardi et al., 1995). In patients with terminal disease, palliative measures are usually undertaken (see Chapter 8.7).

Conclusions

Patients with HNC suffer a variety of cancer- and treatment-related symptom control problems. Some of the palliative issues are unique to the head and neck population. Optimal palliation requires a multimodality team of physicians, nurses, social workers, dentists, physical therapists, and speech/swallowing therapists in order to address the multitude of needs. Since many of these patients have poor social support systems, the treatment team may need to spend substantially more time with the patient to ensure adequate symptom palliation. The added effort and attention can result in improved cure rates, diminished long-term side effects, and decreased distress for the patient and family. For those patients who are destined to die of their disease, adequate medical support can mean the difference between an agonizing death and one that is both physically and emotionally comfortable.

Issues in populations with non-cancer illnesses

15.1

HIV/AIDS

Meera Pahuja, Jessica S. Merlin, and Peter A. Selwyn

Introduction to HIV/AIDS

In the current treatment era, human immunodeficiency virus (HIV) has become a complex chronic disease. This chapter will focus on contemporary palliative care issues in people living with HIV in developed countries, while also acknowledging key differences between developed and developing countries.

A changing epidemic: new needs for palliative care

Early in the epidemic, HIV infection was an inevitable and speedy death sentence. Managing opportunistic infections and end-of-life care was the main focus of HIV disease management. This was done mostly by primary care physicians who quickly learned to be good palliative care physicians, and many palliative care-trained clinicians were deeply involved in end-of-life care for patients with acquired immunodeficiency syndrome (AIDS). In 1996, the era of 'highly active antiretroviral therapy' (HAART) began, with the introduction of powerful protease inhibitor (PI) drugs active against HIV that for the first time significantly slowed the course of the disease. Since that time, increasingly tolerable regimens with smaller pill burdens have been developed; there are now over 35 drugs in five categories of antiretroviral agents, once-daily dosing is generally the norm, and there are two one-pill, once-daily combination drug formulations. In a startlingly short time, AIDS has been transformed in many settings from a rapidly progressive, uniformly fatal illness affecting young adults to a complex, chronic disease with a variable course affecting an ageing population over decades of time (Fig. 15.1.1).

As a result of these rapid changes, patients with HIV who know their diagnosis, are linked to care, and consistently take antiretroviral therapy (ART) can have a near-normal life expectancy. A study of US national HIV surveillance data indicated that life expectancy at diagnosis has increased from 10.5 to 22.5 years from 1996 to 2005 (Harrison et al., 2010). One study found that a 20-year-old individual starting ART could expect to live for another 43 years on average and a 35-year-old could expect 32 more years of life (Antiretroviral Therapy Cohort Collaboration, 2008). A study of a Danish cohort of people living with HIV found that median survival for patients on HAART was more than 35 years from HIV diagnosis (Lohse et al., 2007). Notably, however, this increase in life expectancy has also brought increased morbidity, including co-morbid chronic diseases and complications of ageing that occur earlier in HIV-infected individuals than in their uninfected counterparts (Gallant et al., 2011).

Increased life expectancy, combined with unchanged incidence rates of new HIV infections in the United States (approximately 40 000–50 000/year), also has led to a rise in the prevalence of persons living with HIV/AIDS. By 2009, the prevalence of HIV/AIDS in the United States had increased to an estimated 1.1 million people (Centers for Disease Control and Prevention, 2009a).

The changing nature of HIV disease has in turn expanded the palliative care needs of the population from more traditional end-of-life care into symptom management, co-morbidity disease management, and chronic care-coordination—all in addition to end-of-life care. HIV care in many developed countries now is delivered by infectious diseases specialists, or by primary care practitioners with additional training in HIV and large panels of HIV-infected patients. Because HIV-infected patients have increasingly complex primary care needs, new models of care have emerged, which often include access to an HIV specialist, a care coordinator, and subspecialty care for common comorbidities including liver disease, cardiopulmonary and renal disease, metabolic and bone disorders, malignancies, psychiatric illness, and substance abuse (Gallant et al., 2011). Ironically, as AIDS in the HAART era has become a more chronic, less rapidly fatal illness, palliative care needs have increased, and the need for expertise in palliative care is now expressed by a growing population of patients for longer periods of time. It is important for this palliative care expertise to be reintegrated in the ongoing care of patients with HIV.

In the pre-HAART era, the most common modes of HIV transmission in the United States and much of Europe included sexual contact in men who had sex with men (MSM), and injection drug use (IDU). In 2009, MSM still accounted for 55% of the new cases of HIV in the United States, but heterosexual sex accounted for 30% of the new cases, and IDU accounted for only 9% of the new cases (Centers for Disease Control and Prevention, 2009a). HIV infection disproportionately affects vulnerable populations. In the United States, for example, racial and ethnic minorities account for 71% of the new AIDS cases, 67% of the new HIV infections, and 70% of all AIDS deaths. Historically, poorer communities have higher rates of HIV/AIDS and patients with low socioeconomic status have lower survival rates (Gilman et al., 2012; Mills et al., 2012). Minorities also experience higher death rates even after starting ART (Levine et al., 2007). Though rates have declined in MSM, younger MSM and MSM of colour are still at especially high risk for infection. Women are also disproportionally affected—280 000 are living with HIV/AIDS in the United States (Centers for Disease Control and Prevention, 2009a) These disparities are due to increasing heterosexual transmission,
Fig. 15.1.1 Trajectories of illness over time in chronic, fatal diseases.

delays in HIV diagnosis, and barriers in access/linkage to care (Gilman et al., 2012).

In developed countries, minorities, women, and older people (see below) also are more likely to present with more advanced disease than other populations, which raises important issues for health equity and palliative care. It is critical that these populations have access to HAART while making needed efforts to extend access to palliative care (Selwyn, 2008). Both in the developed and developing world, while advocating for better integration of palliative care with HIV care, it is important to be mindful not to implicitly endorse a double standard of 'HAART for the rich, and palliative care for the poor'.

The HIV-infected population is rapidly ageing. By 2015, half of the HIV-infected US population will be older than 50 (Centers for Disease Control and Prevention, 2009b; Mills et al., 2012). In 2009, more than 15% of both new HIV diagnoses and prevalent HIV infections, respectively, were in patients older than 50 (Centers for Disease Control and Prevention, 2009a). With ageing, HIV-infected patients accumulate comorbidities that were not historically associated with HIV, such as non-AIDS-defining malignancies, end-stage liver disease, atherosclerotic cardiovascular disease, chronic pulmonary disease, bone disorders, age-related neurocognitive decline, and frailty. These disorders appear at a faster rate than their non-HIV-infected counterparts (Onen and Overton, 2011). Frailty-prone HIV-infected patients experience fatigue and decreased mobility, and are at increased risk for bone pain and fractures (Womack et al., 2011).

Some have described a process of 'premature ageing' in HIV/AIDS, although the biological mechanism by which this occurs is not fully understood (Deeks and Phillips, 2009). As a result of this phenomenon, patients with HIV now encounter some of the same issues classically seen in geriatric patients. This accelerated ageing process further complicates the clinical management challenges for an already vulnerable population with multiple medical,

psychosocial, and environmental stressors: all of these issues further amplify the important role for palliative care interventions for HIV disease in the current era (Fig. 15.1.2).

Although advances in ART have increased life-expectancy, overall mortality for those living with HIV remains higher than the general population secondary to a myriad of factors, including delayed diagnosis, poor linkage and retention in care, and increasing co-morbid conditions. Although AIDS-related deaths have decreased, 1.8 million people died of AIDS in 2009 worldwide. In the United States, 15 000 die from AIDS-related causes annually, a number that has not decreased in recent years (UNAIDS, 2010). This underscores the importance of continued excellence in end-of-life care for this population.

Antiretroviral therapy

The two primary measures used to monitor patients with HIV are the CD4+ T-lymphocyte count, a measure of current immune function, and the HIV viral load, a measure of the current level of the virus in the patient's blood. The goal of ART is to achieve suppression of HIV replication such that the viral load is decreased to 'undetectable' levels (generally < 50 or 25 copies of viral RNA/mL, depending on the assay). This allows for immune reconstitution, which is represented by a rise in the CD4+ count and leads to reduced HIV-associated morbidity and mortality (Panel on Antiretroviral Guidelines for Adults and Adolescents, 2012).

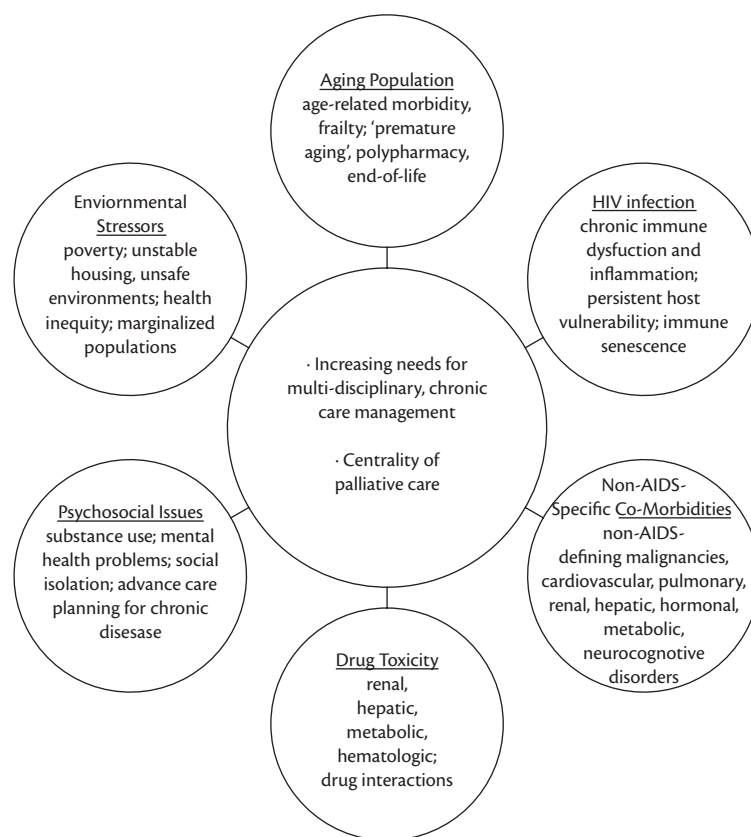
In the developed world, guidelines currently advise considering ART in any patient infected with HIV, particularly those with a CD4 count lower than 500 cells/mm^3, and in all patients with certain conditions (e.g. pregnancy, hepatitis C, HIV nephropathy) (Panel on Antiretroviral Guidelines for Adults and Adolescents, 2012). This means that the majority of patients with HIV, if not all, ideally should be taking ART. This is a guideline, however, and clinicians often consider other factors to guide decisions about ART.


Fig. 15.1.2 Palliative care for HIV/AIDs as a complex, multifactorial chronic disease in an ageing population.

These include factors that influence treatment adherence, such as the patient's willingness to start treatment and the existence of a psychiatric disorder, such as substance abuse, or psychosocial issues.

Current ART guidelines for treatment-naïve patients recommend either: (1) a non-nucleoside reverse transcriptase inhibitor (NNRTI)-based regimen, (2) a ritonavir-boosted PI-based regimen, or (3) an integrase strand transfer inhibitor (INSTI)-based regimen. Each of these regimens includes two additional nucleoside reverse transcriptase inhibitors (NRTIs). Common first-line regimens in treatment-naïve patients include (1) a combination of emtricitabine plus tenofovir (two NRTIs) and efavirenz (NNRTI) in a one-pill once-daily formulation, (2) a two-NRTI combination pill plus a boosted PI (three to four pills once daily), or (3) two NNRTIs plus raltegravir, an INSTI (three pills daily in a twice-daily regimen). Though some of the newly developed medications have more favourable side-effect profiles (see Table 15.1.1), there are still many unknowns regarding their long-term side effects and influence on the development or evaluation of co-morbid conditions.

Adherence/retention

Key factors associated with increased life expectancy of HIV-infected patients include early diagnosis, linkage and retention in care, and adherence to ART regimens. Recent data from the United States suggest the need for improvement. Only 28% of persons with HIV achieved viral suppression (Centers for Disease Control and Prevention, 2011), and of patients who were aware of their HIV diagnosis, only 69% were linked to care and only 59%

were retained in care (Marks et al., 2010). Recent guidelines from the International Association of Physicians in AIDS Care focus on multidisciplinary interventions, such as adherence tools, education and counselling, health system and service delivery interventions, and special guidelines pertaining to vulnerable populations (such as pregnant women, homeless and marginally housed individuals, children and adolescents, and patients with substance use and mental health disorders) to improve entry into care, retention in care, and ART adherence (Thompson et al., 2012), As described below, palliative care interventions, particularly pain and symptom management, also may be especially important in achieving these aims through the provision of comprehensive HIV treatment services.

Co-morbid conditions

Co-morbid conditions which have not been historically associated with HIV, or which have become more common in long-surviving patients, such as cardiovascular, pulmonary, liver, and renal disease, non-AIDS-defining malignancies, frailty and bone disease, are now increasingly prevalent among HIV-infected patients. The accelerated nature of these disorders compared to non-infected patients is an area of active investigation. Multiple factors are suspected, including direct toxicity from the virus itself and/or related chronic inflammatory processes, chronic immunosuppression in patients living longer than in prior eras, toxicity secondary to ART, and increasing rates of smoking in this population. Each of these co-morbid conditions requires primary management, and together, they contribute to an increasing pain and symptom burden for HIV-infected patients.

Table 15.1.1 Classes of antiretrovirals, recommended first-line regimens, and common antiretroviral toxicities

Antiretroviral classes	Toxicities
Nucleoside reverse transcriptase inhibitors (NRTIs)	
Stavudine, (d4T)	Peripheral neuropathy, lipoatrophy, pancreatitis, lactic acidosis, hepatic steatosis
Didanosine (ddl)	Pancreatitis, peripheral neuropathy, nausea/vomiting
Zidovudine (AZT)	Anaemia, headache, nausea
Tenofovir (TDF)	Renal insufficiency, Fanconi syndrome, decreased bone mineralization, nausea, flatulence
Abacavir (ABC)	Hypersensitivity reaction[a], myocardial infarction (studies conflicted but should be used with caution in individuals at risk for myocardial infarction)
Lamivudine (3TC)	Minimal toxicity
Emtricitabine (FTC)	Minimal toxicity, hyperpigmentation/skin discoloration
Protease inhibitors (PIs)	
Lopinavir/ritonavir (LPV/RTV)	Diarrhoea, nausea, hyperlipidaemia, hyperglycaemia, pancreatitis
Atazanavir (ATV)	Indirect hyperbilirubinaemia, rare cardiac conduction abnormalities (PR prolongation), hyperlipidaemia, hyperglycaemia, fat maldistribution
Ritonavir (RTV)	Nausea, vomiting, diarrhoea, abdominal pain, fatigue, taste perversion, hepatotoxicity, headache, hyperlipidaemia, hyperglycaemia, fat maldistribution, circumoral paraesthesia
Darunavir (DRV)	Rash, hepatotoxicity, hyperlipidaemia, hyperglycaemia, diarrhoea nausea, fat maldistribution
Fosamprenavir (FAPV)	Rash, diarrhoea, nausea, headache, hyperlipidaemia, hyperglycaemia, fat maldistribution, transaminase elevation
Non-nucleoside reverse transcriptase inhibitors (NRRTIs)	
Entecavir (ETV)	Rash, nausea
Rilpivirine (RPV)	Rash, depression, insomnia, headache
Efavirenz (EFV)	Rash, neuropsychotic symptoms, transaminase elevation; teratogenic in non-human primates
Nevirapine (NVP)	Rash, hepatotoxicity (increased risk in women with CD4 counts > 250 cells/mm^3, and in men with CD4 counts > 400/mm^3)
Fusion inhibitors	
Enfuvirtide (INN)	Injection site pain and reactions
Integrase strand transfer inhibitors (INSTIs)	
Raltegravir (RAL)	Headache, nausea, diarrhoea
Elvitegravir (EVG)	Headache, nausea, diarrhoea, back pain

Recommended first-line treatment regimens			
	Agents	**Pills/day**	**Dosing schedule**
NNRTI-based	TDF + FTC + EFV	1	Every day
PI-based	TDF + FTC + ATV/RTV	3	Every day
	TDF + FTC + DRV/RTV	4	Every day
INSTI-based	TDF + FTC + RAL	3	Twice a day

3TC, lamuvidine; ABC, abacavir; ATV, atazanavir; AZT, zidovudine; d4T = stavudine; DRV, darunavir; ddl, didanosine; EFV, efavirenz; EVG, elvitegravir; FTC, emtricitabine; ETV, entecavir; FAPV, fosamprenavir; INN, enfuvirtide; LPV, lopinavir; NPV, neviripine; RAL, raltegravir; RPV, rilpivirine; RTV, ritonavir; TDF, tenofovir.

[a] Hypersensitivity reaction seen primarily in patients who test positive for HLA-B*5701 allele; HLA screening recommended before initiation of this agent.

Reproduced from Panel on Antiretroviral Guidelines for Adults and Adolescents, *Guidelines for the use of antiretroviral agents in HIV-1-infected adults and adolescents*, US Department of Health and Human Services, available from http://aidsinfo.nih.gov/contentfiles/lvguidelines/adultandadolescentgl.pdf.

Cardiovascular disease

There is evidence that cardiovascular disease, in particular atherosclerosis and congestive heart failure, occurs earlier in HIV-infected population, and at higher rates, than in HIV-negative individuals (Glass et al., 2006). Some of this prevalence may be explained by a high prevalence of well-known and potentially modifiable risk factors. Smoking has been reported in 40–70% of HIV-infected patients, two- to threefold higher than the rate in the general population (Petoumenos et al., 2011), and HIV-infected patients are more likely to experience dyslipidaemias characterized by elevations in triglycerides, reduced high-density cholesterol, and variable increases in low-density and total cholesterol. In addition to

these modifiable risk factors, HIV infection itself has been shown to increase the risk of atherosclerotic cardiovascular disease (El-Sadr et al., 2006); a combination of HIV viral load, immunological factors, and inflammation may be involved. PIs have also been associated with increased rates of myocardial infarction, which is thought to be secondary to increased rates of dyslipidaemia caused by this class of drugs, and abacavir (an NRTI) has been associated with cardiovascular disease risk as well (Kuritzkes and Currier, 2003; Friis-Moller et al., 2007). Accelerated atherosclerotic cardiovascular disease may be associated with painful or disabling symptoms, similar to patients not infected with HIV.

Pulmonary disease

HIV-infected patients developed numerous pulmonary complications. Some pulmonary opportunistic infections, such as *Pneumocystis jirovecii* pneumonia (PJP; previously *Pneumocystis carinii* pneumonia, PCP), are almost always seen only in HIV-infected patients with low CD4 counts (generally < 200 cells/mm^3); others, such as bacterial pneumonia, particularly pneumococcal pneumonia (Turett et al., 2001), and tuberculosis (Selwyn et al., 1989), are common in HIV-infected patients and may be seen at higher CD4 counts as well (generally < 400 cells/mm^3). There also is evidence in the current treatment era that certain pulmonary comorbidities, such as chronic obstructive pulmonary disease (Madeddu et al., 2013), pulmonary hypertension (Isasti et al., 2013), and lung cancer (Dubrow et al., 2012) may be relatively more common in HIV-infected patients. Whether this is due to higher rates of risk factors such as smoking, or due to the HIV infection itself, is still unknown. Respiratory symptoms experienced by patients with pulmonary comorbidities mirror those experienced by HIV-negative patients, and treatment strategies are similar. Dyspnoea, for example, may be treated with opioids, benzodiazepines, oxygen, and local environmental changes (e.g. open window, fan). Pulmonary comorbidities, like some of the other serious disorders experienced by HIV-infected patients, may cause more symptoms than the infection itself for those receiving successful ART regimens.

Liver disease

End-stage liver disease also is a significant cause of morbidity in HIV-infected patients. There are between 4 and 5 million people co-infected with HIV and hepatitis C virus (HCV) worldwide. Compared to non-HIV infected patients with hepatitis C, co-infected patients experience more rapid progression to fibrosis, increased HCV viral load, higher rates of viral persistence and higher rates end-stage liver disease and death (Operskalski and Kovacs, 2011). There also is evidence that HIV/HCV co-infected patients experience higher rates of neurocognitive impairment, peripheral neuropathy (Aronow et al., 2008), HIV-related kidney disease (Wyatt et al., 2008), and insulin resistance, glucose intolerance, and diabetes (Butt et al., 2009). Symptom burden also is relatively higher in co-infected patients, and studies show increased rates of abdominal pain, mental status change and bleeding risk, all of which may benefit from standard palliative care intervention in addition to disease modifying treatment (Braitstein et al., 2005).

Renal disease

In the pre-HAART era, common disorders of the kidney secondary to HIV disease included HIV-associated nephropathy, HIV-associated immune complex kidney disease, and thrombotic microangiopathy. These disorders remain an issue in those who are diagnosed late in infection or who are not receiving treatment. The risk of HIV-associated nephropathy may increase over time in chronically infected patients. HIV-associated kidney disease is itself an indication for initiation of ART.

Other aetiologies of kidney disease in the current treatment era have emerged. Drug-related nephrotoxicity has been associated with most classes of antiretrovirals, but in particular, with the NRTI tenofovir, and the PI indinavir (Izzedine and Deray, 2007). While indinavir has been replaced by other PIs with better safety profiles, tenofovir is in widespread use as a first-line NRTI (de Silva et al., 2007; Schmid et al., 2007). Serious renal events, such as renal failure and Fanconi syndrome, have been reported in 0.5% of patients taking tenofovir, and 2.2% of patients experience elevations in serum creatinine. There is evidence that older age, reduced renal function at baseline, lower body weight, low CD4 count and other nephrotoxic medications can increase rates of tenofovir-associated nephrotoxicity (Nelson et al., 2007). Tenofovir is thought to cause renal disease secondary to its action on the proximal tubular epithelial cells. This effect on the proximal tubule can also cause hypophosphatemia, which has important implications on bone mineralization and can lead to low bone mass and increased risk for osteoporosis and fractures (Cazanave et al., 2008).

Metabolic bone disease

Bone disease is becoming an increasingly burdensome issue for HIV-infected patients. The aetiology is multifactorial and includes hypogonadism, smoking/alcohol, direct inflammatory effects of HIV, ART (specifically tenofovir), vitamin D deficiency and low body weight. HIV-infected patients with osteoporosis are at increased risk for osteoporosis-related fractures. A recent study found that the prevalence of osteoporosis-related fractures was 60% higher in HIV-infected patients compared with HIV-uninfected patients (Triant et al., 2008).

Early detection of osteoporosis and treatment can reduce the burden of osteoporosis-associated fractures. Current screening guidelines recommend dual-energy X-ray absorptiometry scan for all HIV-infected postmenopausal women and men aged older than 50. Treatment for osteoporosis for HIV-infected patients is similar to HIV-uninfected individuals and includes weight-bearing exercise, muscle-strengthening exercises, smoking cessation, limitation of alcohol intake and adequate intake of calcium and vitamin D. Low vitamin D in particular has been associated with the aetiology of osteoporosis in HIV-infected patients (Walker Harris and Brown, 2012). A recent study found increased risk for vitamin D deficiency and insufficiency related to African American race, Hispanic ethnicity, and exposure to efavirenz and ritonavir (Dao et al., 2011). Despite the high prevalence of vitamin D deficiency, universal screening and treatment is controversial; however, in patients with known history of bone disease and certainly fractures, vitamin D levels should be tested, and if low, repleted (Walker Harris and Brown, 2012). Bisphosphonates have also been shown to improve bone mineral density in HIV-infected patients (Bolland et al., 2007).

Osteonecrosis

Osteonecrosis, or avascular necrosis, is also more common in HIV-infected patients than in the general population. Prevalence

estimates are as high as 4.4% based on imaging studies, although many patients are asymptomatic (Miller et al., 2002). The pathogenesis is controversial; when the femoral head is involved, the pathogenesis may relate to interruption of blood supply, which can lead to instability and, most severely, collapse (Mankin, 1992; Mont and Hungerford, 1995). Risk factors in HIV-infected patients include any lifetime use of systemic corticosteroids, hyperlipidaemia, use of lipid-lowering agents, testosterone supplementation, weightlifting or bodybuilding, anticardiolipin antibodies, previous AIDS-defining illness, low CD4+ cell nadir, longer duration of exposure to ART, pancreatitis, and alcoholism (Scribner et al., 2000; Miller et al., 2002; Mary-Krause et al., 2006).

Osteonecrosis can involve any bone. The femoral head is most common, and the disease may be unilateral or bilateral (Yombi et al., 2009). Patients typically present with groin pain, although pain may also be in the buttock or thigh (Mankin, 1992; Steinberg, 1997; Allison et al., 2003). The recommended initial diagnostic strategy is to perform a plain radiograph of the affected joint. Magnetic resonance imaging is the diagnostic gold standard because of its high sensitivity (> 90%), however, and should be performed if the initial radiograph is negative (Mitchell et al., 1987; Chang et al., 1993; Guerra and Steinberg, 1995; Vande Berg et al., 1997; Sugano et al., 1999; Miller et al., 2002; Allison et al., 2003; Johnson and Decker, 2008).

Treatment depends upon the bone involved and the severity. Asymptomatic disease may be observed, and mild disease may be followed and treated with analgesics and medical management. Patients with more severe disease, efor example, disease involving more than 30% of the femoral head, as well as patients with symptomatic osteonecrosis, should be sent for orthopaedic evaluation. The type of procedure selected (joint-sparing procedures such as core decompression and osteotomy or hip replacement) depends on the severity of disease. In one study of patients with HIV and hip osteonecrosis, 59% underwent a total hip replacement by 10 months after diagnosis (Gutierrez et al., 2006).

Malignancies

Patients with HIV have increased rates of both HIV-related and non-HIV-related malignancies. AIDS-defining malignancies such as Kaposi's sarcoma, non-Hodgkin lymphomas (including Burkitt's lymphoma and primary central nervous system (CNS) lymphoma), and invasive cervical cancer still occur, but their rates have decreased substantially in the current treatment era. However, non-AIDS-defining malignancies, including Hodgkin's lymphoma, multiple myeloma, leukaemia, liver cancer, lung cancer, prostate cancer, invasive anal carcinoma and colon cancer, are increasingly prevalent in this population (Cheung et al., 2005; Palella et al., 2006; Simard and Engels, 2010). In fact, studies show twice the risk of non-HIV-related malignancies in HIV-infected patients compared with the general population (Bedimo et al., 2009). This enhanced risk corresponds to a two- to fivefold increase in risk for cancers such as melanoma, lung cancer, and hepatocellular carcinoma, and an even greater ten- to 30-fold increased risk for anal cancer and Hodgkin's lymphoma.

HIV-infected patients also have a higher prevalence of risk factors for cancer, such as smoking, alcohol consumption, and co-infection with HCV or human papilloma virus (HPV) infection (Silverberg et al., 2009a). Like cervical cancer, anal squamous cell carcinoma is associated with HPV; however, unlike cervical cancer, anal cancer is not considered an AIDS defining illness. Although HIV-infected MSM are at higher risk for anal cancer, there is evidence of an independent association of anal cancer with HIV infection in other patients as well (D'Souza et al., 2008; Piketty et al., 2008). Current guidelines for screening for anal cancer in HIV-infected patients have been borrowed from cervical cancer screening literature and include digital rectal exam and anal cytology testing (Sigel et al., 2011). Though the benefits of screening for anal cancer in HIV-infected patients have not been studied in randomized controlled trials, one observational cohort of HIV-infected MSM found that the median time of progression of high-grade anal intraepithelial neoplasia to cancer was 8.6 months, arguing the need for further study in this area (Kreuter et al., 2010).

The clinical challenge posed by the increasing prevalence of non-HIV related malignancies in HIV-infected patients has been compounded by the serious nature of these diseases. One study found that patients with non-AIDS-defining malignancies experienced a decreased 24-month survival compared to HIV-uninfected patients with equivalent malignancies (Biggar et al., 2005).

Neurocognitive disorders

Despite HAART, HIV-related cognitive disorders, variously described as HIV dementia, HIV encephalopathy and neurocognitive impairment, remain an important part of the disease burden in HIV-infected patients. HIV is a neuroinvasive virus and different HAART regimens have varying degrees of CNS penetration. The number of patients with HIV-related neurocognitive disorders, including HIV dementia and mild neurocognitive impairment, is expected to increase five- to tenfold by 2030 (Cysique et al., 2011). Although HAART can reduce the rates of some neurocognitive disorders, mild cognitive impairment is more difficult to treat, particularly in an ageing population characterized by comorbid disorders of brain function, including Alzheimer's disease. One study of HIV-associated neurocognitive disorders in the pre- and post-HAART eras found that increasing age was a risk factor for mild neurocognitive disorder (Heaton et al., 2011). Further research is needed to characterize the role of accelerated ageing in HIV-infected patients and its impact on HIV-related neurocognitive disorders.

Psychiatric comorbidities

Psychiatric disorders are relatively more common in the HIV-infected population. One study found that the prevalence of psychiatric disorders among HIV patients was more than twice that of non-infected patients (63% vs 30.5%) (Tegger et al., 2008). The most common psychiatric disorder in HIV-infected patients is major depressive disorder, with prevalence estimates as high as 36% (Bing et al., 2001), compared to 4.9% in the general population (Blazer et al., 1994). Generalized anxiety disorder also is common among HIV-infected patients, affecting about 16% (Repetto and Petitto, 2008). In some populations, other psychiatric illnesses, such as schizophrenia, also may be more prevalent. Epidemiologic research also has shown that psychiatric patients with chronic mental disorders such as schizophrenia are at higher risk for acquiring HIV infection (Kalichman et al., 1994).

Psychiatric illness, most significantly depression, has been associated with poor adherence to ART (Dalessandro et al., 2007; Mellins et al., 2009; Gonzalez et al., 2011). Further, a recent study

of 198 HIV-infected patients initiated on HAART at a large academic medical centre in the United States found a higher predicted probability of any psychiatric disorder associated with a slower rate of virological suppression and a faster rate of overall virological failure (Pence et al., 2007). The authors suggest that there would be clinical benefit to screening and treating patients for psychiatric disorders prior to initiating HAART.

Access to mental health care is a vital part of HIV treatment and studies have shown that depressed patients who are started on antidepressants have higher levels of adherence than those that are untreated (Dalessandro et al., 2007). All of these themes suggest the central importance of psychosocial issues and mental health services in the care of patients with HIV/AIDS, and highlight the potential value of multi-disciplinary palliative care team intervention in routine care in this population.

Premature frailty

Frailty is a clinical syndrome that 'reflects biological rather than chronological age' (Onen and Overton, 2011). Frailty has been defined in numerous ways. The most widely accepted definition includes physical parameters only, that is, at least three of five criteria (unintentional weight loss of > 4.5 kg in the past year, exhaustion, low physical activity, weak grip strength, and slow walk time) (Fried et al., 2001). HIV researchers have suggested, however, that a more accurate representation of frailty in HIV-infected patients may include neuropsychiatric comorbidity as well (Onen and Overton, 2011).

The prevalence of premature frailty in HIV-infected individuals may be as high as 20%, even among populations of patients in their 40s and 50s, at least a decade younger than this occurs in non-HIV-infected patients. Premature frailty in HIV-infected patients is associated with having had AIDS and opportunistic infections in the past, lower CD4+ T-cell counts, uncontrolled viraemia, and medical comorbidity. The pathophysiology of this syndrome is not well understood, but may relate to immune dysregulation. Although evidence is limited, exercise seems to improve physical function (Onen and Overton, 2011).

Wasting

Wasting syndrome in HIV-infected patients is much less common in the current HIV treatment era, as fewer patients have advanced disease and active opportunistic infections. However, there is some evidence from more contemporary cohorts that wasting still occurs. To reflect syndromes seen more frequently in the current treatment era, and identify individuals with clinically meaningful weight loss, the Nutrition for Healthy Living Cohort defined wasting as (1) unintentional loss of greater than 10%, (2) a body mass index (BMI) of 20 or below, or (3) unintentional loss of more than 5% of body weight in 6 months that persisted for at least 1 year (Mangili et al., 2006). One study in the early post-HAART era found that the incidence of wasting per 1000 person-years was 7.5 in 1988–1990, 14.4 in 1991–1993, and 22.1 in 1994–1995, and decreased to 13.4 in 1996–1999 (Smit et al., 2002). Another study from the later post-HAART era found that the risk of a 5% weight loss over 6 months was greater in the years 1998–2003 than the years 1995–1997 (relative risk 1.52; 95% confidence interval 1.17–1.97) (Tang et al., 2005), and although seen at all CD4 counts, wasting was associated with lower CD4 count (Forrester et al., 2001) and increased mortality (Tang et al., 2002). The aetiology of wasting is often multifactorial, and can include inadequate nutrient intake secondary to oral and upper gastrointestinal problems, malabsorption, poor appetite, economic constraints, altered metabolism secondary to advanced HIV or opportunistic infections, and/or hormonal disorders such as hypogonadism or hyperthyroidism (Mangili et al., 2006).

In managing wasting, consideration should be given to consultation with an HIV specialist and initiation of ART in patients who are not receiving it. In addition to ART, other medical therapies have shown promise for the treatment of wasting. Moyle et al conducted a randomized, double-blind, placebo-controlled trial and found that 12 weeks of daily recombinant human growth hormone improved lean body mass, physical performance, and quality of life in patients with HIV-associated weight loss or wasting who were on ART (Moyle et al., 2004). Dronabinol, a synthetic delta-9-tetrahydrocannabinol is an approved treatment for HIV-associated weight loss and anorexia in the United States. Although studies have shown increased self-reported appetite and decreased nausea they have not shown significant increases in weight (Beal et al., 1995). Megestrol acetate, a synthetic progestational agent also has potent appetite stimulant properties and increases fat; compared to placebo, men taking 800 mg/day had increased caloric consumption and weight gains of up to 4 kg (Von Roenn et al., 1994).

Hypogonadism is highly prevalent in patients with HIV-associated wasting. Bhasin et al. demonstrated that testosterone replacement and resistance exercise increased lean body mass by 1.4 kg in HIV-infected, hypogonadal patients (Bhasin et al., 2000). Synthetic anabolic agents, such as oxandrolone, also have been shown to be effective in increasing lean body mass (Berger et al., 1996). Resistance exercise itself also has been shown to increase lean tissue in HIV-infected patients (Roubenoff et al., 1999).

Studies have shown that the combination of the above modalities have even further increases on weight gain and potential improvements in quality of life (Storer et al., 2005; Sardar et al., 2010). Effective treatment can be based on careful consideration of the aetiology of the weight loss and side effect profiles of the medical therapies.

Hypogonadism

As noted, low testosterone levels due to hypogonadism, specifically secondary hypogonadism, is a common problem among HIV-infected men in the current treatment era. Although prevalence rates are lower in the current treatment era, up to 6% of HIV-infected men have low testosterone levels (Dube et al., 2007). Hypogonadism increases with age. Relatively low testosterone also may exist in HIV-infected woman, but normative standards and guidelines for diagnosis and treatment are less clear for these patients.

With the ageing of the HIV-infected population, the consequences of male hypogonadism are becoming important primary care issues. Patients with low testosterone levels may report fatigue, depression, and decreased libido; decreased muscle mass and low bone mineral density may worsen (Bhasin et al., 2010). The clinical response to these problems starts with measurement of free and total testosterone levels. Measurement of free testosterone is important, especially since total levels may be normal as HIV-infected patients produce lower levels of sex hormone binding

globulin (Martin et al., 1992; Bhasin et al., 2010). Treatment with testosterone replacement—available in topical, transdermal, and injectable preparations—is indicated in patients with poor libido, low bone mineral density, and low muscle mass. The benefits of testosterone replacement must be carefully weighed against potential risk of prostate cancer and cardiovascular disease (Bhasin et al., 2010).

Substance abuse

Substance use disorders are highly prevalent in the HIV-infected population. Studies report that 40–74% of patients have, or have had, comorbid substance use problems (McGowan et al., 2011). Substance abuse is related to the presence of other psychiatric illness, and recent estimates suggest that substance use and mental health disorders co-occur in at least one-quarter of all patients infected with HIV (Bing et al., 2001). Patients with substance abuse and concomitant psychiatric disorders have lower CD4 counts, and poorer HIV viral suppression and ART adherence (Lucas et al., 2001). While a recent review found that active substance abuse was related to poor adherence, the evidence also suggests that drug users can adhere effectively to medications if they receive structured care, including access to mental health treatment (Malta et al., 2008). All of these mental health and substance use issues pose special challenges and opportunities for palliative care interventions in patients with HIV/AIDS.

Pain and symptom burden

Earlier studies from the pre- and early HAART era documented high levels of pain in patients with AIDS (29–76%), as well as high levels of other non-pain symptoms (10–91% across many studies), with correspondingly high levels of under-diagnosis and under-treatment (Moss, 1990; O'Neill and Sherrard, 1993; Singer et al., 1993; Filbet et al., 1994; Foley, 1994; Larue et al., 1994; Breitbart et al., 1996, 1998; Fantoni et al., 1997; Kelleher et al., 1997; Larue et al., 1997; Wood et al., 1997; Fontaine et al., 1999; Vogl et al., 1999; Mathews et al., 2000). In the pre-HAART era, the aetiology of pain and other symptoms in HIV/AIDS was often due to opportunistic infections, AIDS-associated malignancies, and the systemic effects of progressive, untreated HIV infection. Although symptoms still may be due to these factors, patients in the HAART era also experience pain and other symptoms from numerous other sources, including chronic co-morbidities, frailty, bone disease, ageing-related processes, and the effects of chronic exposure to antiretroviral medications (Table 15.1.2). All of these factors highlight the importance of timely and effective palliative care interventions for the management of pain and other symptoms in patients with HIV/AIDS.

Recent studies have explored the prevalence of pain and other symptoms. A study of 156 ambulatory HIV-infected patients in the United States found that 48.7% reported pain, of whom 51.3% had moderate to severe pain intensity; 57.3% of participants felt that their pain caused moderate to severe interference with their lives (Merlin et al., 2012a). This high prevalence of pain has also been documented in numerous other studies in the current treatment era.

Since early in the epidemic, neuropathic pain has been reported in patients with HIV. HIV distal sensory polyneuropathy (DSP), which is the most common cause of neuropathic pain

in HIV-infected patients, is a length-dependent degeneration of large and small peripheral nerve fibres (Cornblath and McArthur, 1988; Barohn et al., 1993; Griffen et al., 1998; Gonzalez-Duarte et al., 2008). Aetiologies include exposure to older ART regimens (e.g. stavudine (d4T), didanosine (ddI), and zalcitabine (DDC)), or more contemporary regimens such as PIs, and simply HIV infection (Gonzalez-Duarte et al., 2008). Although the prevalence estimates in the current treatment era are lower than in the pre-HAART era, DSP still affects many long-surviving HIV-infected patients, ranging from 4.3% to 21.8%, and the incidence of this disorder may increase in this population over time (Sacktor, 2002; Lichtenstein et al., 2005; Ellis et al., 2010; Evans et al., 2011).

Patients infected with HIV who develop DSP typically present with sensory signs in a stocking-glove distribution. The diagnosis is clinical, and initial workup should include testing for other common causes of neuropathy (e.g. diabetes, vitamin B_{12} deficiency, alcohol use). More invasive tests, such as nerve conduction studies, may be considered if the diagnosis is in question, but are often not needed (Gonzalez-Duarte et al., 2008). Treatment is symptomatic. Drugs with proven efficacy in HIV-infected patients include gabapentin (Hahn et al., 2004) and high-dose topical capsaicin (Estanislao et al., 2004). Although not specifically shown to be effective in HIV-infected patients, other drugs often are tried based on their efficacy in other types of peripheral neuropathy; these include various antidepressants, especially tricyclic antidepressants and duloxetine (a serotonin-norepinephrine (noradrenaline) reuptake inhibitor); opioids also are often employed effectively (Gonzalez-Duarte et al., 2008).

In addition to pain, overall symptom burden remains high for patients in the HAART era. Several recent studies have documented high prevalences of fatigue, weight loss, cough, memory loss, insomnia, depression and paraesthesias (Fontaine et al., 1999; Newshan et al., 2002; Harding et al., 2006, 2010a; Lee et al., 2009; Silverberg et al., 2009b; Cervia et al., 2010; Merlin et al., 2012b). A recent study that administered a 32-item symptom distress measure to patients in three separate outpatient HIV clinics in the United States found that, on average, patients reported 10.9–12.7 symptoms (Karus et al., 2005). The most common symptoms in this study were pain, lack of energy, shortness of breath, dry mouth, and nausea. In addition to physical symptoms, patients reported psychological symptoms, such as anxiety, depression, and difficulty sleeping. Half or more of the patients in this study described their symptoms as frequent, severe and distressing. The authors suggested that the prevalence of these symptoms is similar to those seen in a terminally ill cancer population (Karus et al., 2005). A recent systematic review looked at palliative care-related problems at HIV diagnosis and found physical and psychological symptoms were also highly prevalent at diagnosis (Simms et al., 2011).

Pain and non-pain symptom management in HIV-infected patients

Managing HIV-infected patients with frequent and severe symptoms is complex and special consideration needs to be given to frequent potential drug-drug interactions between antiretrovirals and common palliative care-related medications (Table 15.1.3). Notwithstanding these concerns, it is important to note that,

Table 15.1.2 Selected HIV-related symptoms, aetiologies, and management strategies in the pre-HAART and HAART eras

Symptom	Pre-HAART-era aetiologies	Management	HAART-era aetiologies	Management
Pulmonary				
Dyspnoea/cough	PJP	Antibiotics	COPD	Inhalers, steroids, oxygen
	Bacterial pneumonia	Antibiotics	Pulmonary hypertension	Pulmonary vasodilators, afterload reducers, HAART
	TB	Anti-mycobacterials	Congestive heart failure	Diuretics, afterload reducers, HAART
			Cardiomyopathy	Diuretics, afterload reducers, HAART
Gastrointestinal				
Nausea/vomiting	Oesophageal candidiasis	Antifungals	HAART	Change HAART regimen, antiemetics
	CMV	Antivirals	Anxiety	Selective serotonin reuptake inhibitors, cognitive behavioural therapy
	Disseminated MAC	Anti-mycobacterials	Gastroparesis	Prokinetic agents
			Oesophageal reflux/gastritis	H_2 blocker, proton pump inhibitors
Diarrhoea	Disseminated MAC	Anti-mycobacterials	HAART	Change HAART regimen, anti-diarrhoeals
	Cryptosporidiosis	Antifungals	Irritable bowel syndrome	Behavioural modification, dietary changes, fibre
	CMV	Antivirals		
Abdominal pain	Disseminated MAC	Anti-mycobacterials	Hepatic steatosis/hepatoma	Pain management
	CMV	Antivirals	Cirrhosis/ascites	Diuretics, pain management
			Chronic pancreatitis	Pancreatic enzyme replacement, pain management
			Hepatitis C	HCV specific therapy
Constitutional				
Fatigue, weight loss, anorexia, wasting	AIDS	Methylphenidate, dronabinol, testosterone, oxandrolone, megestrol acetate	Malignancy	Targeted chemotherapy, psychostimulants,
	Opportunistic infections	Treat opportunistic infections	Depression	Antidepressants, cognitive behavioural therapy
			Frailty, multimorbidity, ageing	Address comorbidities, exercise
Neuropsychiatric				
Dementia	AIDS-related dementia	Supportive care	AIDS-related dementia	HAART
Delirium	AIDS	Antipsychotics	Hepatic encephalopathy	Lactulose, rifaximin, HAART
Depression/anxiety		Antidepressants		Antidepressants
Pain				
Peripheral Neuropathy	HIV-related neuropathy	Anti-depressants, anti-convulsants, opioids	HAART-associated neuropathy	change HAART therapy
Musculoskeletal pain	Opportunistic infections	Treat opportunistic infections	Osteonecrosis (e.g. hip or other large joints)	NSAIDS, opioids, surgery
			Non-specific musculoskeletal pain syndromes (low back pain, other regional musculoskeletal pain)	Adjuvants, cognitive-behavioural therapy, opioids

Please note that this table is not meant to be an exhaustive list, but rather a list of examples of how symptoms may manifest in the current treatment era of highly active antiretroviral therapy (HAART), as compared to how they may have presented in the 'pre-HAART' era.

CMV—cytomegalovirus; MAC, *Mycobacterium avium* complex; PJP, *Pneumocystis jirovecii* pneumonia/formerly *Pneumocystis carinii* pneumonia (PCP).

Table 15.1.3 Potential cytochrome P450-related drug interactions between antiretrovirals, anti-infectives, and common palliative care medications

Cytochrome P450 inhibitors	
Antiretrovirals	Protease inhibitors (ritonavir, atazanavir, darunavir, fosamprenavir)
Antibiotics	Quinolones (ciprofloxacin), metronidazole, co-trimoxazole
Antifungals	Azoles (ketoconazole, fluconazole, itraconazole)
Antidepressants	Selective serotonin reuptake inhibitors (fluoxetine, paroxetine, sertraline)
Antipsychotics	Haloperidol, thioridazine[a]

Cytochrome P450 inducers	
Antiretrovirals	Non-nucleoside reverse transcriptase inhibitors (efavirenz, nevirapine)
Antimycobacterials	Rifampin, rifabutin
Anticonvulsants	Carbamazepine, phenytoin, phenobarbital

Cytochrome 3A4 substrates (levels decrease in the setting of an inducer, and increase in the setting of an inhibitor)	
Antiretrovirals	Protease inhibitors (ritonavir, atazanavir, darunavir, fosamprenavir), non-nucleoside reverse transcriptase inhibitors (efavirenz); CCR5 antagonists (maraviroc)
Antibiotics	Co-trimoxazole
Opioids	Methadone, oxycodone, codeine, fentanyl
Non-opioid analgesics	Naproxen, ibuprofen
Appetite stimulants	Dronabinol
Antidepressants	Tricyclic antidepressants (amitriptyline, nortriptyline), selective serotonin reuptake inhibitors (citalopram, paroxetine)
Benzodiazepines:	Clonazepam, diazepam, midazolam
Hypnotics	Zolpidem

[a] Withdrawn in some countries but used in the United States.

When initiating a new medication in a patient taking antiretroviral therapy, it is always best to use a drug–drug interaction programme to check for the presence of interactions. This list is not meant to be comprehensive, but rather introduce the reader to the high potential for drug–drug interactions between medications commonly prescribed to HIV-infected patients and to patients in palliative care settings.

Use drug interaction resources sites:

in general, the approach to managing many symptoms such as pain does not substantially differ from that in non-HIV-infected patients with similar symptoms.

However, pain management in the HIV population may pose some unique challenges related to the fact that both HIV and chronic pain are at the nexus of psychiatric illness and substance abuse. A complete discussion of this is beyond the scope of this chapter; interactive cases on HIV and pain that focus on these complex issues may be found on the International AIDS Society's website (https://www.iasusa.org/content/hiv-and-pain). The key concepts follow:

First, chronic pain is subjective, suggesting that a patient's self-report of pain must be taken seriously and worthy of investigation; moreover, the absence of an objective finding of physical pathology does not preclude trials of pain management interventions.

Second, patients with active psychiatric illness or substance abuse, many of whom may have comorbid personality disorders, may express pain or its consequences, and requests for pain management, in a manner that causes frustration and anger among staff. It is important to recognize one's own countertransference in such situations, and try not to let it interfere with the care of the patient. A history of substance use must not in itself become a disqualification for having pain assessed and treated in a patient reporting pain.

Third, aberrant opioid-related behaviours, such as frequent calls to the clinic requesting opioids, a focus on opioids during visits, a pattern of lost/stolen prescriptions, have a differential diagnosis. This differential diagnosis includes addiction, pseudoaddiction (problematic behaviours driven by uncontrolled pain), psychiatric disorders other than substance use disorders (including personality disorders, anxiety disorders and others), and even criminal intent (135). These potential diagnoses can coexist, further increasing the importance of a detailed assessment of problematic behaviours, should they occur.

Fourth, the complexity of chronic pain in the HIV population supports consideration of a multimodality (sometimes multidisciplinary) approach in every case. Pharmacologic therapies may include drugs in numerous classes, such as opioids, non-opioids, and analgesic antidepressants and anticonvulsants, as well as non-pharmacological therapies, such as rehabilitative approaches like physical therapy and exercise, and psychological approaches such as cognitive behavioural therapy. All of these modalities, and in some cases, others offered by pain specialists, should be investigated for patients with chronic pain (Chou et al., 2009). Although there is limited evidence to support the effectiveness of long-term opioid therapy in any population, clinical experience is very large and most clinicians agree that these drugs may be useful on a long-term basis for some carefully selected and monitored patients.

In every individual patient, the risk versus benefit of chronic opioid therapy must be weighed. For some patients, including those engaged in active alcohol or drug abuse, the risk may be too high to select this therapy, or to continue it (Chou et al., 2009).

Finally, the need to apply opioid risk mitigation strategies has become more accepted, but some, such as opioid treatment agreements ('contracts') are controversial, and even those that are widely accepted in the United States (e.g. urine drug screens), must be considered case by case. Other approaches that might be considered include limit-setting for the use of extra doses, general policies regarding non-replacement of reported lost or stolen prescriptions, avoidance of staff 'splitting', maintaining consistency of only one clinician providing ongoing prescriptions to the same patient, and others. Although there is a limited evidence base for all of these strategies, one or more are frequently used to try to monitor for aberrant opioid use and other illicit substance abuse (Starrels et al., 2010).

Symptoms and adherence

The increased symptom burden in patients with HIV/AIDS may have an effect on adherence with ART and other ongoing care, a key aspect of effective HIV disease management over time. High levels of long-term adherence with ART are critical for treatment success and even modest lapses in ART adherence below the 90% level for any period of time significantly increase the risk of the emergence of drug-resistant HIV. A study of symptom prevalence in an outpatient HIV setting which found that both physical and psychological symptoms were highly prevalent (including pain, lack of energy, worry, diarrhoea, and sexual dysfunction), also found on multivariate analysis that poorer ART treatment adherence was significantly and independently associated with psychological symptom burden (Harding et al., 2010a); lower educational achievement was also significantly associated with increased global symptom burden. Further studies are needed to evaluate the impact of appropriate and aggressive symptom management on adherence, but the evidence to date suggests another strategic role for palliative care intervention in the comprehensive management of patients with HIV/AIDS, where it may be of key importance in facilitating successful disease-modifying therapy.

End-of-life care

It is important to remember that many HIV-infected persons who die in developed countries at this time may not be dying of AIDS, but rather, of one of the comorbidities described earlier. A study of 230 patients with HIV in a palliative care programme in the United States found that, of the 120 deaths, 36% died of end-stage AIDS, 19% of non-AIDS defining cancers, 18% of bacterial pneumonia or sepsis, 13% of liver failure and/or cirrhosis, 8% of cardiac of pulmonary disease, 3% of end-stage renal disease, 2% of amyotrophic lateral sclerosis, and 2% of unknown causes (Shen et al., 2005). Mortality rates from some of these causes, for example, liver failure and other end-organ failure, may be increasing even further over time.

However, despite advances in treatment for HIV, people continue to die of AIDS-related causes in the United States and abroad. Although ART is widely available in the United States, only 25% of patients with HIV have an undetectable viral load. The reasons for this are multifactorial and include issues of adherence, retention and access to care for vulnerable populations (Giordano et al., 2005). From 1996 to 2007, HIV outpatient study (HOPS) investigators found that 331 of 3 754 patients who were on treatment for at least six months died. They further found that mortality was increased for patients with a CD4+ cell count less than 200, older age, and higher serum levels of HIV RNA. They also found that mortality was increased in patients who had public insurance compared to those that had private insurance when CD4+ cell counts were greater than 200 cells/mm³. Since the publicly-insured patients had more frequent comorbidities, including cardiac disease, renal disease and chronic hepatitis, the investigators hypothesized that these treatable comorbidities contributed to the survival disparities seen between the publicly and privately-insured group (Palella et al., 2011).

In the current era, patients who actually die from AIDS per se typically fall into one of three categories: (1) those who were diagnosed late and have never been on ART or have only been on ART for a short time but are continuing to decline due to the severity of their illness at presentation (i.e. those for whom HAART is 'too little, too late'); (2) those who may have been diagnosed when their illness was at an early stage but due to a range of medical and/or psychosocial factors have never taken ART consistently and have progressed to irreversible and then to end-stage disease; and (3) those who have lived with HIV for many years, with multiple failed treatment regimens, who now have virus resistant to all current regimens.

Occasionally, an HIV-infected patient presenting with a late stage manifestation of AIDS, such as an opportunistic infection or malignancy, will be referred to hospice without a prior documented trial of ART. This can occur if the patient is newly diagnosed with HIV and first presents with end-stage AIDS. This may also occur in patients who have had persistent difficulties with retention in HIV primary care, poor adherence to ART, and/or struggles with psychiatric illness or substance abuse. While hospice referral may be appropriate based on the patient's illness severity, it is imperative that such patients be evaluated by an HIV specialist. Even in the sickest patients, a trial of ART and therapy directed at any other co-occurring life-threatening illnesses, is warranted. Many clinicians, even in hospice and palliative settings, have witnessed what has been described as the 'Lazarus syndrome', in which 'dying' patients with AIDS were placed, sometimes for the first time, on adequate ART, and soon experienced a dramatic return to their fully functional former lives (Brashers et al., 1999).

Advance care planning is an important consideration in caring for patients living with HIV. As with other chronic illnesses, goals of care should be addressed during the course of the disease and not only during times of exacerbation or crisis. A cross-sectional survey in the United States found that patients with AIDS are less likely to have discussed advance directives with their physicians compared with other chronically ill populations (Wenger et al., 2001). The investigators also found that practitioners discussed end-of-life care with black people and Latinos less often than with white people. In addition to racial disparities, they also found that patients infected with HIV via injection drug use and those with less education communicated the least about end-of-life issues. These end-of-life conversations may need to be addressed frequently and goals may change over the course of the disease given the non-linear progression of late-stage AIDS. There is some evidence to support the notion that physicians in HIV treatment settings may be uncomfortable addressing these issues with late-stage HIV infected patients and may themselves create unnecessary barriers to effective conversations about goals of care (Curtis and Patrick, 1997).

Prognostication has also been dramatically affected by ART in the current era, raising new challenges for both HIV specialists and palliative care clinicians. Prior to HAART, mortality rates for patients diagnosed with PJP admitted to an intensive care unit ranged from 53% to 62% (Morris et al., 2003). PJP mortality in the ICU has dropped to 29% and overall PJP mortality in the HAART era has declined to 11% (Radhi et al., 2008). Mortality secondary to opportunistic infections such as disseminated *Mycobacterium avium* complex (MAC), cytomegalovirus (CMV), *Mycobacterium tuberculosis* (TB), cryptococcus infection, progressive multifocal leucoencephalopathy (PML), and toxoplasmosis encephalitis have all decreased; however, all can still increase the risk of premature death or disability.

Since the advent of HAART, prognosis for those living with HIV is no longer simply a matter of viral load, CD4+ cell count, and history of specific opportunistic infections. A study looking at mortality of patients in an HIV palliative care programme at a large urban US medical centre found that for patients with late-stage AIDS, age and markers of functional status were more predictive of mortality than CD4+ count and viral load. This study also found that half of the deaths were attributed to non-AIDS specific causes such as cancer and end-organ failure (Shen et al., 2005). There is a vital need for more prognosis-related research in the current AIDS era, to further inform practitioners about when to refer for hospice and how to predict and anticipate the end of life in patients living with AIDS.

Hospice admission appropriateness

In the United States, hospice for most patients is a government-supported programme of comprehensive home-based services for end-of-life care. Eligibility for the programme requires that two physicians attest that the patient's life expectancy is 6 months or less if the disease runs its expected course. Prognostication is imprecise, of course, and physicians rely on predictive patient characteristics that have been endorsed based on limited data and experience. The most recent hospice admission criteria for patients with HIV/AIDS in the United States, along with those for other non-cancer diagnoses, were written by the National Hospice and Palliative Care Organization (NHPCO, formerly NHO) in 1996. These included: a CD4+ count of less than 25cells/mm^3 or viral load greater than 100 000 copies/mL, CNS lymphoma, untreated or refractory wasting, disseminated MAC, PML, systemic lymphoma, visceral Kaposi sarcoma, renal failure without dialysis, cryptosporidium infection, or refractory cerebral toxoplasmosis. In addition to meeting one more of the above criteria, patients must score less than 50% on the Palliative Performance Scale. With the advent of ART, some of these criteria are out of date, and most if not all of them could potentially be eliminated as predictors of early mortality in an individual patient by an adequate trial of appropriate ART. For this reason, patients with predictors of a short life expectancy typically are not considered eligible for hospice services unless there has been progressive disease despite ART, or the patient refuses a treatment trial.

Stopping ART and opportunistic infection prophylaxis

Despite the many guidelines in existence that address when to start ART in HIV-infected patients, there are no guidelines to inform clinicians and patients about when to stop ART or routine prophylaxis for opportunistic infections in patients with HIV at the end of life. As noted above, it is important to remember that most patients with HIV who die may not be dying of AIDS per se, but rather dying from a serious comorbid condition. This can make the decision about whether to stop ART and prophylaxis for opportunistic infections even more complex.

In general, the same decision-making process used for other medications—namely, a patient-by-patient burden versus benefit analysis—should apply to decisions about ART and prophylaxis. There are potential benefits of continuing HAART in late-stage disease, based on the assumption that continued viraemia could be associated with an increasing symptom burden. In one cohort study, more than one-third of patients who stopped ART experienced symptoms related to stopping the medication (Ahdieh

Grant et al., 2001). In late-stage disease, available regimens might only be partially active, but there is suggestion that treatment could possibly select for less fit virus even in the presence of elevated viral loads (Selwyn and Forstein, 2003). Maintaining CD4+ cell counts at higher levels also can be warranted, as it can provide protection against burdensome opportunistic infections. It is also known that peripheral viral load does not always correlate with CNS viral load (McArthur et al., 1997), and it is possible that continuing HAART may help sustain cognitive functioning and protect against HIV-associated encephalopathy or dementia (Frenkel and Mullins, 2001). Preserving mental status could have profound effects by allowing the patient with end-stage disease to remain clear about his/her goals and be a part of clinical decision-making. One could also argue in favour of the continuation of ART if there is a psychological benefit to the patient or family (e.g. the patient associates ART with a sense of well-being).

There are also reasons to consider discontinuing ART. If patient adherence was an issue prior to late-stage disease, then continuing ART might not have any therapeutic benefit and might actually contribute to patient anxiety over medication. Increased pill-burden has also been shown to be associated with decreased quality of life (Fincke et al., 1998). Continuing ART at the end of life could also contribute to drug-drug interactions between antiretroviral medication and common palliative care medications. Many ART medications need laboratory monitoring and dose adjustment which might not be consistent with end-of-life goals. Continuing ART while realizing its futility also could contribute to a type of therapeutic confusion, and therefore distract clinicians and/or patients from critical advanced care planning and end-of-life care. For patients entering into hospice or any other capitated system of care, the cost of ART may be an issue as well and might constitute a barrier to enrolling in hospice in some settings.

Terminal care

Much like any other end-stage chronic disease, the shift towards end-of-life palliation is a decision that requires much thought and collaboration between patients, families and caregivers. With HIV, there are disease-specific therapies and symptom-specific therapies that, when used together, can help manage patients' symptoms and significantly contribute to patient comfort (see Table 15.1.2). The disease-specific therapies are historically seen as justified by the effort to control the underlying disease and prolong life; however, they can contribute to patient comfort at the end of life. For instance, continuing treatment for PJP pneumonia might help treat dyspnoea, in addition to symptom–specific measures such as oxygen, opioids, and benzodiazepines. In some cases, the disease-modifying interventions may have no direct life-prolonging benefit but might help preserve quality of life in a dying patient (e.g. valganciclovir to suppress CMV and thus preserve sight in a patient with CMV retinitis); in others, they may both relieve immediate suffering, as well as prolong life (e.g. fluconazole or amphotericin B, in addition to adequate analgesics, for treatment of the odynophagia of oesophageal candidiasis, or the headache associated with cryptococcal meningitis).

Opportunities for integration

Given the complexity involved in the care of patients with HIV, whether treating symptoms when the virus is controlled or

helping with advanced care planning at the end-of-life, palliative care teams can play an important role in supporting both patients and physicians throughout the disease process. For this reason, palliative care has been suggested as a useful adjunct for the treatment of patients with HIV (Greenberg et al., 2000; Selwyn, 2005). Recognizing the potential impact of integration of palliative care into routine care, the World Health Organization (WHO) has stated that 'palliative care should be incorporated as appropriate at every stage of HIV disease' (WHO, 2006). Similarly, UNAIDS guidelines state that all people living with HIV should be provided with effective palliative care throughout their treatment course (UNAIDS, 2009).

Existing programmes that incorporate palliative care into HIV care are heterogeneous, offering a variety of services, including hospital-based palliative care, outpatient palliative care clinics, home hospice services and inpatient hospice. Several have been described in the literature, including a multidisciplinary consultation team for HIV-infected patients at a large urban hospital in New York City, which helped to resolve patient symptoms (Selwyn et al., 2003), and hospital-based palliative care programmes in sub-Saharan Africa, which also improved patient-reported symptoms (Tapsfield and Jane Bates, 2011).

It is recognized that palliative care is not a substitute for provision of ART. It should be viewed as an adjunct, which when incorporated throughout the HIV disease process, can improve outcomes, as stated above. Early palliative care involvement not only improves quality of life (Davis, 2004), but also can favourably impact adherence to treatment (Ammassari et al., 2001). It is thus critical both for quality of life and potential disease outcomes and survival to prioritize palliative care integration into routine HIV care.

There are several approaches to changing the usual HIV clinical care paradigm that warrant further exploration. First, sound, rigorously designed clinical trials comparing integrated HIV palliative care to usual HIV clinical care must be tested to establish the impact of the integrated services on treatment outcomes, patient satisfaction, and cost. Second, approaches to ensuring early access to palliative care expertise in HIV care settings need to be examined. Finally, further research will be needed into the value of early palliative care involvement in discussion about advance directives and goals of care in HIV-infected populations.

Developing countries

As of 2009, 33 million people were living with HIV worldwide (UNAIDS, 2009). Availability of ART in resource-limited settings is increasing—over 4 million people are on ART in low- and middle-income countries—and as a result, the number of persons living with HIV in these areas is expected to grow (UNAIDS and WHO, 2009). Although ART is available, the choice of different regimens is limited by cost. The regimens available frequently have increased toxicity and side effect profiles, and are drugs that have already been phased out in developed country settings (e.g. stavudine and zidovudine). The ageing of the AIDS epidemic that has been seen in the developed world has begun to be reflected in developing countries as well. A recent modelling study found that, in South Africa, HIV infections in the elderly will increase by 50% in the next 15 years. With increasing access to HAART in developing countries, there are 20% fewer people dying of HIV-related

causes in 2009 than in 2004, suggesting that the same phenomena of a growing population of ageing long-term HIV survivors, with increasingly complex care needs over time, may emerge there as well (Hontelez et al., 2011).

It was estimated that 9.5 million people were still in need of HIV treatment in 2008 worldwide, and though this number is an improvement, it still highlights the overwhelming disparities in access to treatment between resource-poor and resource-rich countries. This delay in treatment leads to increased early mortality, increased rates of opportunistic illnesses, and increasing rates of tuberculosis (WHO et al., 2009). In efforts to promote starting treatment earlier, the 2009 WHO guidelines changed the threshold for starting HAART from 200 cells/mm^3 as stipulated in the 2006 guidelines, to 350 cells/mm^3 regardless of symptoms. Recognizing the significant toxicity of stavudine, especially with regards to lipodystrophy and peripheral neuropathy, the 2009 WHO guidelines also recommended phasing out stavudine and using alternatives such as zidovudine or tenofovir as the first-line NRTI of choice (WHO, 2009).

It also has been documented that patients have high symptom burdens in resource-limited settings. A study of HIV-infected patients in South Africa in both rural ($N = 125$) and urban ($N = 396$) areas found that 56–72% had pain and that this pain was moderate to severe in about 60% of patients in both areas. Increasing age was associated with increasing pain. In addition to these unacceptable rates of pain, much of this pain was untreated or severely undertreated. The authors note that no patients were receiving strong opioids and only 3% were receiving so-called weak opioids (Mphahlele et al., 2012). Other studies also have shown that a substantial proportion of patients' symptoms are either entirely untreated or substantially undertreated (Karus et al., 2005). In addition to practitioner hesitancy to prescribe opioids, lack of access to these drugs in countries or specific facilities contributes to this inadequacy of treatment (Harding et al., 2010b). Despite WHO guidelines, many patients in resource-limited settings also remain on stavudine. Peripheral neuropathy (distal sensory polyneuropathy) is a frequent symptom seen in resource-limited settings secondary to untreated HIV infection or the use of antiretrovirals, such as stavudine. A retrospective review in South Africa found that, in patients on at least 6 months of stavudine, the incidence of peripheral neuropathy was 90.4/100 person-years in patients taking the standard dose of 40 mg of stavudine twice daily, and although this decreased with a lower dose of 30 mg, the complication of neuropathy remained unacceptably high (Pahuja et al., 2012). As options for HAART are limited in many developing countries beyond first-line and second-line regimens, it is crucial that as governments improve access that they also provide adequate resources to support adherence and retention in care.

Summary

As patients survive longer in the current HAART era, HIV infection is now a chronic disease. Ironically, this new longevity has increased the risks of other co-occurring diseases and related complications. As co-morbid conditions such as cardiovascular, pulmonary, renal, and liver disease; malignancy; frailty; and neurocognitive disorders all increase in this population, they contribute significantly to patients' pain and symptom burden. Unlike

in the 1980s and early 1990s when HIV infection was primarily a rapidly fatal, narrowly stereotypic illness, the current treatment era has changed and expanded the scope of palliative care needs for this population. Advance care planning also has become more complicated with longer and non-linear trajectories at the end of life. In addition to an ageing population, there are significant disparities still present in timely HIV diagnosis, treatment access, and outcomes. There is an overwhelming need to develop and study new models of care for chronic HIV disease that take into account these disparities and complicated co-morbidities. Integrating palliative care into routine HIV care not only improves patients' quality of life, but also has the potential to significantly impact mortality. In the early years of the AIDS epidemic, HIV care and palliative care were inseparable. Over a period of less than two decades, these two fields have both evolved rapidly, and in many ways diverged following the rapid advances in HIV treatment and the changing clinical manifestations of HIV disease. Once again, the rationale for integrating of HIV care and palliative care is strong and compelling. For effective disease management, improved symptom burden and quality of life, better care coordination, and facilitation of end-of-life care, palliative medicine has much to offer to the care of patients with HIV/AIDS in the HAART era. It is incumbent upon both HIV and palliative care providers to identify and help create opportunities for this re-integration.

Caring for the patient with advanced chronic obstructive pulmonary disease

Graeme M. Rocker, Joanne Michaud-Young, and Robert Horton

Introduction to caring for the patient with advanced chronic obstructive pulmonary disease

Chronic obstructive pulmonary disease (COPD) is an increasingly significant source of morbidity and mortality worldwide (Mannino and Buist, 2007). Despite under-diagnosis in early stages (the British Lung Foundation has referred to these patients as 'the hidden millions'), COPD is already the third leading cause of death in the United States and will be at this rank globally by 2020.

Historically, there has been an unjustified sense of nihilism towards treating the advanced stages of COPD. Although a phrase heard so often from physicians—'there is nothing more we can do for you'—may be seen as abandonment, it can imply a lack of knowledge and expertise in treating the myriad of distressing symptoms as the disease advances. Clinicians also experience frustration with the lack of accessible health system resources to ensure the provision of adequate care, and even helplessness when their prescribed biomedical treatments fail to alleviate symptoms in any appreciable way (Young et al., 2012a).

Given the considerable physical and psychosocial consequences of advanced COPD (Rocker et al., 2009), patients and families can be devastated by the message that there is nothing more to be done. To reduce the likelihood of this outcome, health professionals need a continual 're-thinking' of models of care and clinical interventions, and strong encouragement to provide the ongoing support needed by patients and families. This process can overcome the pervasive sense of professional nihilism that currently undermines efforts and worsens outcomes.

COPD is not 'just' a lung disease, but rather a complex systemic illness complicated by considerable psychosocial effects. As the illness advances, patients experience increasing symptom burden that also results in increasing stress for their family caregivers. Effective overall management requires complex, personalized interventions and proactive, collaborative models of care that address not only dyspnoea as the predominant symptom but also issues of hope, social isolation, strained relationships, and lack of responsive advance care planning. Our current health-care systems place a disproportionate focus on the provision of acute and facility-based services, which does little to address the complex needs of these patients and families who are for the most part housebound.

Primary care clinicians with whom patients and families have long-standing therapeutic relationships play a pivotal role throughout the trajectory of COPD (Young et al., 2012a). When patients' increasing symptom burden limits their ability to get out of their homes for non-emergent assessment, these crucial primary care services become less accessible and the care of patients with advanced and end-stage COPD becomes increasingly 'fragmented, episodic and reactive' (Crawford et al., 2013). Within this fragmented care framework, it is difficult to establish the extent of care provided by primary care physicians, specialist physicians, and hospice services (Horton et al., 2013). Patients are often caught in a cycle: without a better alternative, they may present repeatedly to the emergency room, to be admitted for aggressive care, and discharged back to a system that initially failed to meet their needs (Bailey, 2004). While the usual recorded admission diagnosis is acute exacerbation of COPD (AECOPD), the true precipitants of such presentations are often much more complex.

In this chapter, after briefly discussing conventional treatments, we highlight some newer understandings and approaches to care for advanced COPD. This includes a description of new information regarding the perception of dyspnoea that informs a rational approach to some innovative treatments, particularly for advanced disease. Subsequent sections focus on the use of individualized COPD 'action plans' (for AECOPD and for 'dyspnoea crises'), the value of engaging patients and their families in meaningful advance care planning dialogue, and the efficacy of newer models of care that employ the above interventions and aim to bridge the gap between chronic disease management and palliative care. In the final section, we review the use of opioids as a treatment for dyspnoea that is refractory to conventional COPD treatment.

Conventional COPD treatments

The goals of conventional management of COPD have changed little in recent years and professional society practice guidelines and consensus statements adequately outline standard approaches

(Marciniuk et al., 2011; Qaseem et al., 2011). Newer drug delivery devices and longer-acting agents have improved both patients' compliance and outcomes. While improvements in symptomatology may appear modest when assessed in clinical setting (especially in advanced disease), it is important that patients be encouraged to remain compliant with these treatments because they have been shown to significantly improve important clinical outcomes (Aaron et al., 2007; Calverley et al., 2007).

Inhaled therapy

Inhaled bronchodilator therapy should be optimized as per clinical practice guidelines (Marciniuk et al., 2011; Qaseem et al., 2011). Various formulations and delivery devices are available (metered-dose inhalers and spacers, dry powder inhalers, or wet nebulizers). Inhaler technique should be assessed to ensure that a patient is able to use a device effectively. In general, for patients with advanced disease, the combination of a long-acting anticholinergic, such as daily tiotropium, with an 'as needed' short-acting beta-agonist is a standard initial approach For the occasional patient who is unable to tolerate a long-acting anticholinergic, or when these agents are unavailable, a short-acting anticholinergic (ipratropium bromide) can be taken by metered dose inhaler and a spacer at a dose of up to 4–6 puffs four times daily. For many patients with advanced COPD, the addition of a combination inhaler containing a long-acting beta-agonist (LABA) and an inhaled corticosteroid (ICS) to a long-acting anticholinergic agent provides benefit in terms of symptom management and quality of life (Aaron et al., 2007; Calverley et al., 2007). As patients' symptoms become increasingly complex and beyond the range of inhaled therapy, other interventions will be required to optimize and preserve quality of life for as long as possible.

Systemic therapy

Theophyllines

Although theophylline-like medications have long been prescribed and are known for their effects on bronchodilation, the advent of newer and more selective inhaled LABA medications have provided clinicians with more effective alternatives. The effects of methylxanthines on bronchodilation are relatively weak and they are now considered a third-line treatment, notwithstanding some recent evidence that suggests new uses for this old drug. For example, theophylline has been shown to have beneficial anti-inflammatory effects and can reduce oxidative stresses that are increasingly recognized as a feature of COPD (Barnes, 2008). Nonetheless, side effects continue to be an issue and the adverse effects often outweigh benefits for many patients. Risks of toxicity through interactions with some antibiotics (e.g. clarithromycin) also pose potential limitations to their use and the need to monitor blood levels can be especially difficult for the many patients who are housebound as a result of their advanced disease.

Phosphodiesterase 4 (PDE_4) inhibitors

The emergence of PDE_4 inhibitors marks the first new COPD therapy in nearly 20 years. These drugs have been shown to reduce key inflammatory cells and mediators, but they do not have bronchodilator properties and their effect on patients' perception of dyspnoea is modest at best. Although they may be a viable option for those patients with moderate to severe COPD who have a chronic bronchitis phenotype, and who experience frequent exacerbations despite optimized therapies, their side effect profile continues to present challenges for many patients. The potential for side effects has tempered some clinicians' initial enthusiasm for their use. The most commonly reported adverse effects include diarrhoea, nausea, headache, and weight loss. The potential for gastrointestinal toxicity suggests that the PDE_4 inhibitors should be used with caution in cachectic patients.

Corticosteroids

Systemic steroids are not recommended for long-term use due to negative side effects and lack of compelling data demonstrating significant benefit (Pauwels et al., 2001). Nevertheless, despite this lack of data showing efficacy, some patients perceive symptomatic benefit and a trial of a long-acting steroid may be considered for the individual patient. Provided that continued assessment reveals benefits that outweigh risks, it is reasonable to ensure that patients, especially those with end-stage disease, are not denied a reasonable treatment approach that may provide them with an improvement in symptom control.

Oxygen therapy

During acute exacerbations of COPD

The use of oxygen in an AECOPD, especially for patients with known baseline hypercarbia, should be carefully controlled. A recent randomized trial demonstrated excess mortality in patients treated with uncontrolled oxygen en route to hospital (Austin et al., 2010) and the dangers of excess use of oxygen have been recognized since the 1960s (Campbell, 1960). It is critically important to choose the appropriate delivery device. The safest approach is to use a Venturi mask to supply an inspired oxygen concentration (FiO_2) of 24% or 28% to maintain a SpO_2 close to 89%. Inappropriately high FiO_2 (a risk with using nasal prongs in patients retaining CO_2) can cause a further increase in $PaCO_2$ by several mechanisms. The most significant effect is through worsening of V/Q mismatch via reversal of established pulmonary hypoxic vasoconstriction. Lesser effects are attributed to a lower minute ventilation through reduced hypoxic drive (for some patients), and reverse of the Haldane effect that causes displacement of CO_2 from more oxygenated haemoglobin into plasma.

Long-term oxygen therapy (LTOT)

For patients who are hypoxaemic, LTOT is prescribed for its benefits in reducing morbidity and mortality. Eligibility criteria vary between and within countries. While beneficial for many, LTOT can interfere with self-image and limit patients to their homes, and thus restrict activities that might otherwise contribute to a better quality of life (Eaton et al., 2002). While some patients will dislike the technical focus on machines, oxygen readings, or on unacceptable limitations, others adapt and endure, benefiting in some cases from improved health-related quality of life (Eaton et al., 2002).

Supplemental oxygen for the mildly hypoxaemic patient

Based on current evidence (Abernethy et al., 2010; Uronis et al., 2011), oxygen therapy for mild hypoxemia (i.e. PaO_2 > 55 mmHg without evidence of end-organ damage or PaO_2 > 60 mmHg with evidence of end-organ damage) cannot be recommended for routine use. Patients and caregivers often request oxygen in this setting and need to be helped to understand that their level of dyspnoea does not necessarily equate with 'oxygen starvation'. Nonetheless a therapeutic trial of oxygen may be indicated in the hospice setting for treatment of patients with persistent dyspnoea

despite maximal therapy (see other treatments for refractory dyspnoea below).

Managing acute exacerbations

Exacerbations of COPD are defined as a sustained worsening of the patient's respiratory symptoms from his or her usual stable state, which is beyond normal day-to-day variations and is acute in onset (Anthonisen et al., 1987). Exacerbations of COPD are associated an accelerated decline in lung function, impaired quality of life, and increased mortality. The most commonly reported symptoms are worsening shortness of breath, increased cough (with or without increased sputum production), and a change in sputum colour. Other signs and symptoms include wheeze, chest tightness, fatigue, decreased appetite, and for some, change in mood. As COPD progresses to advanced stages, the frequency of acute exacerbations increases. The damage to lung tissue and subsequent effects on symptom burden make it important to act quickly when an AECOPD occurs. Those patients at high risk of frequent episodes should be provided with a written 'action plan' as per professional society guidelines to ensure that they can activate treatments at home when they observe or experience signs and symptoms consistent with an AECOPD. It is vitally important to provide focused education in terms of when to activate the plan. Access to a help line has also been beneficial in this regard (Rice et al., 2010). In addition to adjustment of medications, this action plan may involve the use of bi-level positive airway pressure (BiPAP). BiPAP has become a standard of care for patients presenting with hypercarbic respiratory failure and should be considered as an intervention that can also provide symptomatic relief, where this fits with overall goals of care.

COPD: symptom burden related to dyspnoea

Dyspnoea is nearly universal in patients with COPD and in those with advanced illness. The symptom often is refractory to conventional treatments (Elkington et al., 2005; Horton and Rocker, 2010). The significant physical, emotional, social, and/or spiritual/existential suffering associated with the context of 'total dyspnoea' has been acknowledged only recently (Abernethy and Wheeler, 2008; Parshall et al., 2012). Dyspnoea is defined as the subjective and usually unpleasant experience of discomfort with breathing (American Thoracic Society, 1999). For many patients, dyspnoea pervades all aspects of their lives and is a significant source of disability that can profoundly affect quality of life. As dyspnoea progresses, increasing disability can render patients housebound and at risk for profound social isolation (Elkington et al., 2005). The relative social isolation that comes with advanced disease may help explain COPD as an independent risk factor for development of depression (Schane et al., 2008). Effective treatment initiatives need to address not just the physical, but also the psychosocial and existential suffering that is so pervasive and damaging for both patients and their family caregivers (Gysels and Higginson, 2009; Simpson et al., 2010).

The recent appreciation of a neurobiological component to dyspnoea (von Leupoldt et al., 2008) also offers support for interventions that extend conventional therapies. Functional magnetic resonance imaging scanning has provided new insights into the central perception of dyspnoea. The amygdala and anterior insular cortex are activated (von Leupoldt et al., 2008; Parshall et al., 2012), particularly when dyspnoea and fear coexist. Fear, anxiety,

and panic are common in advanced COPD (Gore et al., 2000; Gudmundsson et al., 2005). Anxiolytics seem relatively unhelpful in the management of dyspnoea (Rose et al., 2002; Simon et al., 2010), but may be useful for treating a coexisting anxiety disorder that can worsen dyspnoea symptoms.

Fear, anxiety, and panic, when unrecognized, underestimated, and untreated, can cause overwhelming 'dyspnoea crises' the occurrence of which may augment fear of death when dyspnoea worsens (Bailey, 2001, 2004; Booth et al., 2003). These crises are defined in a recent American Thoracic Society (ATS) consensus statement (Mularski et al., 2013) as a 'sustained and severe resting breathing discomfort that occurs in patients with advanced, often life-limiting illness and overwhelms the patient and caregivers' ability to achieve symptom relief'. Understanding the components of these crises in individual patients is key to effective management. An example of a patient-specific 'action plan' that includes tips for managing 'dyspnoea crisis' is provided later in this chapter. Several professional societies have now recognized the need to provide adequate palliation for patients struggling with refractory dyspnoea (Mahler et al., 2010; Marciniuk et al., 2011; Mularski et al., 2013). The Canadian Thoracic Society (CTS) (Marciniuk et al., 2011) has provided suggestions for a 'start low go slow' titration schedule for opioids, an approach supported by recent clinical trial data (Rocker et al., 2013).

Current approaches to the management of dyspnoea in advanced COPD

The CTS has recently released a clinical practice guideline (Marciniuk et al., 2011) (available via <http://www.copdguidelines.ca>) that encapsulates an evidence-based approach to the management of dyspnoea (see Fig. 15.2.1). This guideline (Marciniuk et al., 2011) builds on the concept of the dyspnoea ladder described some years ago (Rocker et al., 2007) and emphasizes a stepwise approach to palliation of refractory dyspnoea using conventional therapies, non-pharmacological approaches, and carefully initiated and titrated opioids. In advanced COPD, conventional therapies should be maintained and optimized, however the symptomatic benefit realized by these biomedical approaches may wane and additional supportive initiatives may be required.

Neuromuscular electrical stimulation and chest wall vibration

Neuromuscular electrical stimulation and chest wall vibration techniques can be effective and data from some recent RCTs suggest that they may be promising adjuncts to conventional treatment. They are discussed in more detail in a recent clinical practice guideline (Marciniuk et al., 2011) but use in the context of specialist palliative care is likely to be limited.

Patient self-management education

Self-management programmes tend to include disease-specific education, promotion of healthy lifestyles, along with tips on how to conserve energy and to manage emotional symptoms. They may include the use of an 'action plan' that helps patients to decide when to initiate antibiotics and/or oral corticosteroids early in the course of an impending AECOPD (Trappenburg et al., 2009; Bischoff et al., 2010; Walters et al., 2010). The aims

of such programmes are to hasten recovery (Wilkinson et al., 2004), reduce morbidity, and health-care utilization (Bourbeau et al., 2004). Professional societies have espoused the use of 'action plans', but emphasize the need for *effective* education and reinforcement (Nici and ZuWallack, 2012). Recent randomized trials in Canada (Bourbeau et al., 2003), the United States (Rice et al., 2010), and Europe (Casas et al., 2006) have confirmed the efficacy of action plans within a broader model of self-management. Reductions (by approximately 40%) in emergency room visits and hospital readmission rates were similar in the three studies. A meta-analysis of self-management education (1066 patients, eight trials) has confirmed improvements in health status and reduction in hospital admissions (Effing et al., 2007). A recent trial of patient self-management was terminated early due to increased mortality in the intervention cohort (Fan et al., 2012). The reasons for increased mortality in this study are not clear and any potential for harm will need further study.

Pulmonary rehabilitation

The use of pulmonary rehabilitation to address dyspnoea and related symptoms in advanced COPD is supported by a substantial body of evidence including a Cochrane review (Lacasse et al., 2002). These programmes can ameliorate dyspnoea and enhance exercise tolerance, functional capacity and health-related quality of life. They also reduce health-care utilization (Bourbeau et al., 2003, 2004). Pulmonary rehabilitation 'is designed to reduce symptoms, optimize functional status, increase participation and reduce health-care costs through stabilizing or reversing systemic manifestations of the disease' (Nici et al., 2006). Exercise is central to pulmonary rehabilitation and may interrupt the 'spiral of disability' (Polkey and Moxham, 2006). Effects can wane over time (Soicher et al., 2011), however, for housebound patients, opportunities to improve symptoms and function inevitably fade. Patients should be referred for pulmonary rehabilitation well before this point.

The traditional approach to pulmonary rehabilitation has included 6–12 weeks of facility-based, individualized exercise training, self-management education, nutritional counselling, and psychosocial support when patients are stable and at their baseline. Some now advocate for initiating these programmes during an acute admission (Eaton et al., 2009). Social aspects of these programmes should not be underestimated and some improvements are associated with relief from ongoing anxiety and depression that occurs in the absence of changes in lung function (Nici et al., 2010; Harrison et al., 2011).

As an alternative to a facility-based approach to pulmonary rehabilitation, Maltais et al. (2008) have demonstrated equivalent benefit of home-based pulmonary rehabilitation. This concept will likely be explored further as a component of more community-based and integrated care.

The American Thoracic Society has defined integrated care as 'a continuum of patient-centred services organized as a care delivery value chain for patients with chronic conditions with the goal of achieving the optimal daily functioning and health status for the individual patient and to achieve and maintain the individual's independence and functioning in the community' (Nici and ZuWallack, 2012). Discussions of goals of care and advance care planning and provision of palliative care should be logical and complimentary components of this continuum (Reticker et al., 2012).

Addressing gaps in care through integrated care systems

Much has been written about the need for alternative models of care to address the needs of patients and caregivers who are living with advanced COPD (Simpson and Rocker, 2008; Booth et al., 2011a; Fromer, 2011; Ortiz and Fromer, 2011). Given that patients and family caregivers have repeatedly given voice to their unmet needs (Rocker et al., 2008; White et al., 2011; Crawford et al.,

2013), it is incumbent upon health professionals to build comprehensive, integrated programmes of care that can respond more appropriately to these needs. Implementation of disease specific self-management strategies has shown some efficacy at reducing emergency room utilization and hospital admissions (Bourbeau et al., 2003, Rice et al., 2010). However, augmentation of usual care by 'à la carte' addition of these programmes in the absence of a well thought out, comprehensive, integrated approach is likely to fall short of optimal effectiveness and efficiency. Important elements to consider include robust physician support, a detailed plan that is based on patient-driven goals of care and includes an individualized 'action plan' to deal with crisis symptoms in the home (Horton, 2013).

Fromer has stated that 'chronic care for COPD must reach beyond the primary care practice into patients' lives in the community on one hand, and into practices' linkages with specialty, ER and inpatient care on the other' (Fromer, 2011). One example of an innovative programme that embodies this philosophy is the INSPIRED programme in Halifax, NS, Canada. An acronym for '*I*mplementing a *N*ovel and *S*upportive *P*rogram of *I*ndividualized Care for *P*atients and Families Living with *R*espiratory *D*isease', INSPIRED brings together a multidisciplinary team to address the needs of patients and families living with advanced COPD. Eligible patients are identified during hospital admission and upon discharge are enrolled in a structured programme that provides dedicated case management orchestrated by a skilled respiratory therapist (RT) educator who also acts as a care coordinator across care transitions. The care coordinator has robust support from fellow RTs, a pulmonary specialist with interest and expertise in community-based care in advanced COPD, and a spiritual care practitioner to address advance care planning issues. Patients are followed in their homes with bi-weekly visits spanning over a period of approximately 4 months. Emphasis is placed on providing proactive care through home-based education and support. Important elements of the programme include disease self-management education and advance care planning, help with navigating the local health-care system and gaining access to allied support services, improved communication with other health-care providers, and the provision of individualized action plans for both AECOPD and dyspnoea crisis.

INSPIRED has forged strong links with local primary care teams and palliative care programmes to improve the integration of care for patients living with advanced COPD in the community. Preliminary analysis of an initial cohort (Young et al., 2012b) continues and of 74 patients who completed the full programme revealed that participation in INSPIRED was associated with a 70% reduction in emergency room visits and length of hospital stay for those admitted (Graeme M. Rocker, personal communication, 31 January 2013).

Even with the best available home supports and detailed action plans, avoiding the emergency room may be impossible for some patients and families who are overwhelmed by panic and conditioned by years of reliance on the hospital when in crisis. A recent evaluation of home-based palliative care for patients with advanced COPD, found that despite access to comprehensive medical support that included after hours physician response, some patients continued to turn repeatedly to the emergency room when symptoms escalated rapidly (Horton et al., 2013).

Referrals to hospice/palliative care services may be seen by some as the most efficient way of addressing unmet needs in end-stage COPD. These services can be helpful in some cases. As they refine and adapt their programmes to address the needs of those with chronic non-cancer illness, however, it is important to recognize that the needs of the population with advanced COPD cannot be addressed by hospice/palliative care services in isolation from other elements of care that reflect best practices in COPD management (von Gunten, 2011).

The ideal care framework for advanced COPD combines the strongest elements of primary care and specialist expertise with implementation of an individualized and flexible multidisciplinary care approach. This approach should encompass education about disease progression and prognosis, emotional and practical support for caregivers, and treatments that integrate chronic disease management strategies with palliation of progressive symptoms. In addition, it is important to provide counselling about advance care planning and end-of-life decision-making, and assistance with practical interventions aimed meeting patient and family goals as illness progresses and death nears.

National support for such strategies are in their infancy in the United States and Canada, but are further advanced in the United Kingdom where there are clearly delineated standards and appointment of physician-leaders with responsibilities in both hospital and community settings.

Examples of an expanded approach used in the United Kingdom were recently described by Booth et al. (2011a). The 'Breathlessness Intervention Service' (BIS) has been established in Cambridge, United Kingdom, as a programme that focuses on patient-identified needs, regardless of diagnosis. BIS attends to symptoms and uses a flexible approach responsive to patient and carer(s), supplemented by education, and support. (Rocker et al., 2007; Booth et al., 2011a). The essence of the philosophy is to offer individualized evidence-based non-pharmacological interventions, along with conventional therapies (Bausewein et al., 2008). These include anxiety management (relaxation, visualization, and meditation techniques), positive psychological support, and attention to national guidelines standards, and COPD research objectives and best practices (Booth et al., 2006). In early assessments, participants indicated the importance they attached to having their concerns addressed (Booth et al., 2006), plus benefit to both patients and health-care systems as assessed through stages of the United Kingdom's Medical Research Council framework for complex interventions. Evaluation of the programme continues (Farquhar et al., 2009; Booth et al., 2011b; Farquhar et al., 2011) (Fig. 15.2.2).

Communication and advance care planning

Conventional systems of care often are characterized by a lack of timely and comprehensive care planning and communication that involves both patient and family, and key health professionals. As COPD becomes more advanced and numerous clinicians contribute to care, the responsibility to communicate with the patient and family about goals of care, including goals for end-of-life care, may become so diffused that no one ultimately takes on this role (Gott et al., 2009). Important discussions about advance care planning and end-of-life care may not occur because clinicians are unsure about who should initiate these conversations, as

Action Plan for Shorness of Breath (dyspnea)
Created for: [Patient Name +/− ID number]
Date: [Insert date plan was created]

A good morning routine to minimize shortness of breath first thing in the morning:

• Take 5 breaths from your incentive spirometer (slowly open airways). Use 4 time daily as needed
• Huffing/cough to clear your airway. Do your pursed-lip breathing if this helps
• Use your blue puffer, gray handihaler, and purple puffers as directed (don't forget to use your aerochamber and rinse after your purple puffer). Your blue puffer may be used as often as every four hours as needed
• Take your long-acting opioid medication [insert name, dose] as directed

When more short of breath than usual:

• With a slight increase in your shortness of breath at rest (not a result of infection or "crisis"), you can use an extra [insert dose] of your opioid syrup every 1–2 hours as needed for 'breakthrough' dyspnea between your regular doses
• For predictable shortness of breath with activity (i.e. getting up, dressed, bathed), time these activities ½ hour after your puffers and opioid dosing

For "crisis" shortness of breath (not due to infection) comes on suddenly, catches you by surprise:

• Use your hand-held fan and do pursed-lip breathing. Try recovery positions
• Use 2 puffs of your blue puffer (with aerochamber) or try your nebule instead
• Adjust oxygen flow from __ to __ litres/min for 10–15 mins only then re-adjust back to ___
• Take your anti-anxiety medication [insert name, dose], 1 tablet under the tongue
• If not setting, use Fentanyl, 12.5 ug from pre-prepared syringe. Let liquid dissolve under the tongue. Repeat in 10 mins if still not settling and call 911

For flare ups of COPD with increased sputum volume and mucky colour, use antibiotics and prednisone as per your COPD action plan.

Fig. 15.2.2 Sample of a personalized action plan for shortness of breath.

well as where and when. Among the barriers to effective advanced care planning (Patel et al., 2012) identified by physicians are prognostic unpredictability/uncertainty, difficulty in identifying an 'end stage' in COPD, the potential to erode patients' hope, time constraints, inadequate communication skills (Knauft et al., 2005; Goodridge, 2006; Gott et al., 2009; Spence et al., 2009), and the possibility that the goals of such communication may conflict with those of chronic disease management (Gott et al., 2009). Two other factors include patients'/families' 'natural ageing' view of declining quality of life in advancing COPD (Pinnock et al., 2011) and clinicians' awareness of the lack of adequate palliative support for these patients no matter what is communicated. If these barriers are not recognized, the result may be that conversations either do not happen or are less than adequate. To help prevent this outcome the INSPIRED programme has incorporated an in-home 'advance care planning' component.

To realise the potential benefits of effective care planning, its intent must be understood. The *Respecting Choices* model (Gundersen Lutheran Medical Foundation, Inc., LaCrosse, WI), defines *advance care planning* as an organized ongoing process of communication to help an individual understand, reflect upon, and discuss goals, values, and beliefs for future his/her future care (Patel et al., 2012) (including health-care decisions). In contrast to

the 'ongoing process' orientation of this definition, more often than not, advanced care planning is reduced to a clinician-centred, one time 'code status' discussion that tends to occur during an illness crisis (Barnard, 2002) and in a suboptimal setting (e.g. emergency room or intensive care unit) (Patel et al., 2012). When patients have not previously considered or discussed their values and care preferences in terms of quality of life, dignity, respect, concerns about dying, perceptions of care, and who they might choose as a substitute decision-maker, being asked to do so in an already emotionally charged crisis atmosphere can add unnecessary suffering. It is hardly conducive to making an 'informed choice' and thus can heighten the potential for inadequate or erroneous representation of patients' care related values/preferences.

The ethical principles of informed choice and respect for individual autonomy in the context of COPD require clinicians to talk with patients, and those they choose to include, about their goals of care before major illness crises occur. The discussion should be revisited as the illness advances to ensure the care plan remains current. A skilled, self-reflective facilitator, relational communication, a focus on uncertainty/hope, attention to readiness and current care concerns, targeted information/education, inclusion of the substitute decision-maker, and contextual sensitivity are important elements for effective advanced

care planning discussions. When patients are invited to reflect on their COPD experiences, hopes, and fears, clinicians are more likely to understand the personal values and perspectives that can help shape care plan relevant across the illness trajectory. In addition to their illness experiences, hopes, and fears, it is important to explore what provides patients' 'quality of life' and what they understand by terms such as personal dignity and respect. Patients may use phrases like 'no heroics', 'I don't want to be a vegetable', or 'I don't want to be kept alive on machines'. Clarifying exactly what prompts these comments and what the patient envisions in relation to them is also an important part of advanced care planning. Information about what is involved with various life-sustaining interventions as well as their potential burdens/benefits can help patients focus their preferences to better guide substitute decision-makers and clinicians. Taking time to ensure understanding and provide adequate emotional/existential support during and after these conversations is also an important aspect of effective advanced care planning.

Incapacitating dyspnoea, increasing dependency, isolation-induced social death, and profound uncertainty-related anxiety punctuate the experience of many of these patients and their informal caregivers/families. The burden of such symptoms demand advanced care planning that includes information (explanation plus burdens and benefits) on the range of potential life-sustaining treatment options as well as comfort measures including palliation of dyspnoea and anxiety through to the end of life. Topics to be covered should include cardiopulmonary resuscitation (including common complications and poor survival statistics), non-invasive ventilation (such as BiPAP), intubation and conventional mechanical ventilation, life-sustaining medications, intravenous hydration and/or nutrition, the role of feeding tubes and dialysis, and the meaning of comfort measures. Recent publications have addressed the role of non-invasive ventilation and how it may (or may not) fit with patients' overall goals of care (Curtis et al., 2007; Sinuff, 2011). Perhaps the most important element of every advanced care planning discussion is emphasizing the team's commitment to ongoing *care/non-abandonment* of the patient and family no matter what goals of care they set.

Ultimately the timing, setting, and manner in which advanced care planning occurs should be based on the needs of the patient and family or substitute decision-maker rather than those of health-care providers or institutions. Deciding 'when' to initiate such discussions is a matter of clinical judgement but should be informed by recognition of disease specific triggers that suggest the seriousness of the disease and might signal a time to engage the patient and family in advanced care planning:

- forced expiratory volume in 1 second less than 30%, oxygen dependence
- one or more AECOPD hospital admissions in the last year
- weight loss/cachexia
- decreased functional status
- increasing dependence on others
- age greater than 70
- lack of additional therapeutic options (Patel et al., 2012).

Health professionals also express confusion about the identity of the most appropriate person to initiate advance care planning discussions with a patient and family. Competence and experience are key—professional discipline less so. Tasking other interested, skilled members of the health-care team to take on advance care planning responsibilities is a logical option, given the lack of time available to most physicians. Regardless of who facilitates the discussion, the final step in effective patient-centred advanced care planning includes collaborating with physicians and other members of the patient's health-care team so that care preferences ascertained through competent advanced care planning guide decision-making and impact outcomes. Patient preferences may change after hospitalization (Janssen et al., 2012), and advance care planning policies and strategies need to reflect and accommodate such possibilities.

The value of timely, effective advance care planning cannot be overstated. These discussions can help patients and loved ones begin to prepare themselves emotionally for illness progression. In terms of potential impact, sensitive, timely advance care planning may increase the likelihood that a patient's end-of-life care wishes will be known and followed. This can decrease the stress for family members and potential for complicated grief following the death: it also may decrease ethical distress and dilemmas for staff, and increase satisfaction with care for all concerned (Wright et al., 2008).

When patients with COPD more fully understand the range and implications of life-sustaining treatments available, they tend to choose fewer life-sustaining procedures or at most a time-limited trial of specific life-sustaining interventions. This lowers the rates of intensive care admissions and the costs associated with the final weeks of a patient's life (Au et al., 2006). For all these reasons, ethical care for these patients calls for ACP.

In summary, advance care planning as a patient-centred, ongoing process of adjusting goals of care is much more than a means to an end (Sudore and Fried, 2010). It is about improving care throughout the illness trajectory, not just at end of life.

Opioid therapy for dyspnoea in COPD

An increasing body of evidence supports the use (and safety) of opioids for refractory dyspnoea in patients with advanced COPD (see also Chapter 8.2). Nevertheless, long-held biases about the risk of opioid-induced respiratory depression continue to limit more widespread acceptance by physicians (Rocker et al., 2012) despite recommendations for their use in several recent professional society statements and/or clinical practice guidelines (Lanken et al., 2008; Mahler et al., 2010; Marciniuk et al., 2011) and despite qualitative studies indicate efficacy and acceptability from patient and caregiver perspectives (Rocker et al., 2012). Physicians in general practice, internal medicine, palliative care and chest medicine have suggested that lack of education and knowledge concerning opioids are among the greatest barriers to opioid use in advanced COPD (Rocker et al., 2012). They also worried about possible censure for prescribing opioids in this context. These physicians distinguished opioid prescribing for cancer for which clear guidelines endorse use and prescribing for dyspnoea in advanced COPD, for which many believed that opioids are not seen as 'standard of care' (Rocker et al., 2012).

Data from recently completed or ongoing clinical trials of opioid therapy for dyspnoea are encouraging with benefit outweighing side effects and patients finding them beneficial over the longer term

(Currow et al., 2011; Rocker et al., 2013). In a Canadian trial, the side effects were minimal for most patients, and outweighed by benefit. Patients made choices to continue with opioids based on improvements to quality of life, or to dyspnoea or both (Rocker et al., 2013).

In essence, both existing data and extensive clinical experience suggest these opioid drugs should be part of the treatment armamentarium for dyspnoea that is refractory to standard therapy. Our own clinical trial experience suggests that an initial 'start low, go slow' approach works well (Marciniuk et al., 2011; Rocker et al., 2013), and helps patients gain confidence with this medication. Often patients are reticent to try opioids, associating them with impending death or being fearful of side effects. Sensitive and careful explanations can usually diffuse concerns (Rocker et al., 2012, 2013). Once the daily requirements of an immediate-release preparation (e.g. morphine syrup 1 mg/mL) are established through a gentle titration schedule, patients can move on to a sustained-release preparation taken daily or twice daily with additional immediate-release opioid for 'breakthrough' dyspnoea.

Dyspnoea seems to respond to comparatively lower doses of opioids than pain. If one opioid preparation is not well tolerated, alternatives are available and can be tried. As newer formulations and modes of delivery of fast-acting lipophilic opioids become available, there will be new opportunities to incorporate these preparations into patient care plans (Horton and Rocker, 2010) that seek to provide patients and caregivers with the means to control episodic and frightening dyspnoea crises (Rocker, 2012). Clinicians should be aware that current product monographs continue to counsel explicitly against use in setting of lung disease, this despite the absence of any supporting evidence.

Conclusions

Health-care systems are faced with the need to care for an ageing population significantly burdened with chronic illnesses and frailty (Lynn, 2008; Murray and Sheikh, 2008). As the prevalence of COPD rises, more patients and families will live with the burdens of advanced or 'end-stage' COPD than ever before. Specific interventions can ease the illness burden associated with advanced COPD and models of care that employ interventions and holistic approaches to care can further improve patient and family outcomes. The move towards an integrated care approach to COPD will help patients and their families reach informed decisions about their care throughout the trajectory of COPD. Intensive medical treatment focused on increasing survival and holistic, supportive, and palliative approaches focused on quality of life are no longer mutually exclusive within the spectrum of care; the emphasis often simply changes over time. If we seek to provide care that is truly patient-centred, transitions within this spectrum should occur seamlessly and provide safe and effective care 'from beginning to end' (Partridge, 2003).

Advanced heart disease

Steven Z. Pantilat, Anthony E. Steimle, and
Patricia M. Davidson

Introduction to advanced heart disease

Heart disease is the leading cause of death in the developed world (Lindenfeld et al., 2010; Go et al., 2013). Heart failure (HF) is the final common pathway of many cardiac conditions, a major source of morbidity, and the most common reason that patients with advanced heart disease present to specialists in palliative care. More than 5 million Americans, 15 million Europeans (out of a population of 900 million), and 1.5–2% of Australians have HF (Dickstein et al., 2008b; Jessup et al., 2009; National Heart Foundation of Australia and the Cardiac Society of Australia and New Zealand, 2011).

HF has been defined as:

a complex clinical syndrome with typical symptoms [such as breathlessness, oedema, and fatigue] that can occur at rest or on effort, and is characterized by objective evidence of an underlying structural abnormality or cardiac dysfunction that impairs the ability of the ventricle to fill with or eject blood (particularly during physical activity). A diagnosis of HF may be further strengthened by improvement in symptoms in response to treatment. (National Heart Foundation of Australia and the Cardiac Society of Australia and New Zealand, 2011)

Reproduced with permission from the *Guidelines for the prevention, detection and management of chronic heart failure in Australia*. Updated July 2011, Copyright © 2011 National Heart Foundation of Australia. Extract accurate at time of press, for update to information visit <HTTP://www.heartfoundation.org.au/>.

HF is divided into two types: *systolic*, which is also called HF with reduced ejection fraction (HFREF), and *diastolic*, or HF with preserved ejection fraction (HFPEF). The term HFPEF for the latter condition is preferred by some to emphasize the importance of contributing factors other than diastolic dysfunction. Systolic HF is characterized by the occurrence of the symptoms typical of this condition in association with a low ejection fraction; although somewhat arbitrary, this usually is taken as below 40%. In diastolic HF, the typical symptoms occur in association with a relatively normal ejection fraction, typically considered to be above 50%. Within the total population with HF, the prevalence of the systolic and diastolic types is roughly equal.

It is important for clinicians to know the underlying type of HF, as treatments differ based on type (Hunt et al., 2009). Additional categorization by class and stage also is relevant (Table 15.3.1) (Criteria Committee of the New York Heart Association, 1994; Hunt et al., 2009). The New York Heart Association (NYHA) class is a particularly helpful classification, as it provides some information about symptoms, functional status, and prognosis.

HF is a chronic illness characterized by periods of relative stability punctuated by exacerbations that may require hospitalization. It is the leading cause of hospitalization among Medicare beneficiaries in the United States and an increasing cause of hospital admission in Europe and Australia (Unroe et al., 2011). While most exacerbations can be managed effectively in hospital, each exacerbation is associated with a risk of death. Half of the patients diagnosed with HF die within 5 years of first hospital admission, a prognosis worse than many cancers (Stewart et al., 2001). Between one-third and one-half of patients die suddenly, irrespective of HF stage. This potential for sudden death creates an imperative for the discussion of preferences for care from the time of initial diagnosis.

Despite the high mortality, pharmacologic treatments for HF prolong survival and improve quality of life (Hunt, 2005; Heart Failure Society of America, 2006; Dickstein et al., 2008b; Jessup et al., 2009; McDonagh et al., 2011). Most patients respond to drug therapies, and some patients with advanced illness are eligible for specialized implanted therapies, such as cardiac resynchronization therapy (CRT) using a biventricular pacemaker, mechanical circulatory support with ventricular assist devices (VADs), and implantable cardioverter defibrillators (ICDs). A very small proportion of patients meet criteria for heart transplantation and have access to this surgery.

The availability of effective treatments, however, does not prevent illness-related suffering and burden. Even with optimal medical therapy, many patients with HF experience distressing symptoms, such as pain (41–78%), breathlessness (60–88%), fatigue (69–82%), and depression (9–56%) (McCarthy et al., 1996; Levenson et al., 2000; Bekelman et al., 2009; Pantilat et al., 2012). Some interventions, such as ICDs, may decrease the incidence of sudden death, and as a result, increase the proportion of patients who live with these debilitating symptoms (Stevenson and Stevenson, 2001; Heidenreich et al., 2002).

Many patients who receive an implanted technology experience the treatment itself as highly burdensome (Dickstein et al., 2008b; Tang et al., 2010). Approaches to care concerning these interventions are rapidly evolving and underscore the importance of consultation with HF specialists in treatment planning. This input is especially valuable for patients and their families as they make decisions about whether implanted therapies align with their values and goals. As in many areas of medical practice, the legal and ethical debates surrounding these decisions are still catching up with technological innovation (Sheehan et al., 2011).

Table 15.3.1 Definition of New York Heart Association (NYHA) heart failure class and American College of Cardiology/American Heart Association (ACC/AHA) stage (Criteria Committee of the New York Heart Association, 1964; Hunt et al., 2009)

NYHA class	Definition	ACC/AHA stage	Definition
None		Stage A	Presence of heart failure risk factors but no heart disease and no symptoms
Class I	No limitation of physical activity. Ordinary physical activity does not cause undue fatigue, palpitation, or breathlessness	Stage B	Heart disease is present but there are no symptoms (structural changes in heart before symptoms occur)
Class II	Slight limitation of physical activity. Comfortable at rest, but ordinary physical activity results in fatigue, palpitation, or breathlessness	Stage C	Structural heart disease is present AND symptoms have occurred
Class III	Marked limitation of physical activity. Comfortable at rest, but less than ordinary activity causes fatigue, palpitation, or breathlessness		
Class IV	Unable to carry out any physical activity without discomfort. Symptoms of cardiac insufficiency at rest. If any physical activity is undertaken, discomfort is increased	Stage D	Presence of advanced heart disease with continued heart failure symptoms requiring aggressive medical therapy

Source: data from Hunt, S.A. et al., Focused update incorporated into the ACC/AHA 2005 Guidelines for the Diagnosis and Management of Heart Failure in Adults A Report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines Developed in Collaboration With the International Society for Heart and Lung Transplantation, *Journal of the American College of Cardiology*, Volume 53, Issue 15, pp. e1–e90, Copyright © 2009 American College of Cardiology Foundation; and Criteria Committee of the American Heart Association NYCA 1964, *Diseases of the heart and blood vessels: Nomenclature and criteria for diagnosis*, Little, Brown and Co., Boston, USA, Copyright © 1964.

The high morbidity and mortality, the risk of sudden death at all stages of illness, the availability of interventions with significant burdens, and the chronic nature of the condition create an imperative for integrating palliative care into HF disease management (Goodlin et al., 2004; Pantilat and Steimle, 2004; Adler et al., 2009; Goodlin, 2009; Davidson et al., 2010; Janssen et al., 2011). Patients with HF, and their families, agree with guidelines developed by cardiology societies around the world and endorse an approach that provides palliative care alongside optimal medical management (Selman et al., 2007a, 2007b; Dickstein et al., 2008b; Hunt et al., 2009; Jaarsma et al., 2009; Bekelman et al., 2011; McDonagh et al., 2011; McKelvie et al., 2011; National Heart Foundation of Australia and the Cardiac Society of Australia and New Zealand, 2011). Broad agreement between cardiology and palliative care specialists support this integrated approach and should encourage palliative care clinicians to reach out to cardiologists and others who care for patients with HF (Low et al., 2011). While the involvement of palliative care specialists may be very limited for patients with class I HF, perhaps focusing on advance care planning, specialists may be required on a more regular basis for patients with class III and IV disease—to help manage persistent symptoms, discuss treatment preferences and goals of care, and provide support to the patient and family.

Despite agreement about the importance of palliative care in HF management, several barriers complicate the goal of simultaneous care (Selman et al., 2007b). First, prognosis in HF can be challenging and the severity of exacerbations can be difficult to gauge. Second, many cardiologists continue to misperceive palliative care as solely focused on the end of life. Combined with a reluctance to recognize the terminal nature of HF and a lack of training in symptom management and communication about advance care planning, this view can undermine optimal care and result in referral to specialized palliative care too late to realize the full benefits. Third, palliative care specialists may lack knowledge about medical management and interventions for HF, which may

have adverse consequences for patients and further reduce the willingness of cardiologists to refer. Fourth, patients with HF are medically complex and have comorbid conditions that may require the input of other specialists, complicating efforts to integrate best practices in cardiology and palliative care. This medical complexity also may impact on key decisions, such as the deactivation and withdrawal of devices, and thereby create added challenges for inter-professional cooperation. Finally, health-care systems typically lack palliative care services for people with HF and fail to adequately coordinate services to provide simultaneous care.

Palliative care specialists should work to overcome these barriers. Important strategies include continuing education about the trajectory and management of HF, ongoing efforts to develop good collaborations with cardiology colleagues, and participation in efforts to adapt the health-care system to serve the needs of patients with HF and their families.

Managing the disease of heart failure: optimal medical therapy and interventions

It is critical for palliative care specialists to understand the medications and interventions used to manage HF, as these treatments help patients live longer, avoid hospitalization, and achieve a better quality of life. In contrast to patients with advanced cancer, those with HF typically continue disease-modifying therapies until close to death. Although the benefits and burdens of individual drugs should be appraised regularly, the withdrawal of HF treatments places patients at increased risk of acute exacerbation, worsening symptoms and earlier death. Some treatments, however, may be less appropriate at the end of life because they do not directly affect cardiac function or relieve symptoms, and may require monitoring; for example, warfarin might be appropriately discontinued in the setting of advanced illness, particularly as

the risk of over-anticoagulation increases with changes in drug metabolism associated with organ failure.

Palliative care clinicians also must recognize the many reversible cardiac lesions that can cause HF and be able to discuss these with patients and their families. For example, revascularization and valvular repairs using either percutaneous or surgical techniques may improve heart function and provide significant symptom benefits. Given the complexity of these treatments, it would be ideal if all patients with advanced heart failure were referred to a cardiologist who specializes in heart failure management; through consultation, this specialist may be able to maximize and fine tune medical therapy and determine whether procedural interventions would be beneficial.

The risks, benefits, and burdens must be considered in recommending invasive treatments for HF, and patients and their families must have accurate information in order to make informed decisions. Regardless of the setting in which patients receive palliative care, understanding the role of HF medications and interventions, and their potential side effects and risks, and knowing which medications to avoid, will make the palliative care specialist best able to help patients and collaborate effectively with other clinicians.

Drug therapies for systolic heart failure (HFREF)

For patients with systolic HF, one of the cornerstones of treatment is neurohormonal blockade with an angiotensin-converting enzyme inhibitor (ACEI), an angiotensin receptor blocker (ARB), a beta blocker, and a mineralocorticoid antagonist (MRA) (Table 15.3.2). These drugs slow the progression of cardiac dysfunction, reduce mortality, and prevent hospitalization (Lindenfeld et al., 2010; McMurray et al., 2012). Diuretics also are indispensable because of their ability to reduce fluid retention; these drugs are so accepted that a trial of their impact on mortality would be impracticable and has never been done (McMurray et al., 2012). Other medications, including digoxin and the vasodilator combination

hydralazine-isosorbide dinitrate, play a role in subgroups of HF patients.

Although neurohormonal blockers and diuretics are initiated for their life-prolonging effect, they also alleviate symptoms and improve functional status. They are, therefore, appropriate late in the course of illness, including when the focus shifts exclusively to palliative care. For this reason, HF medications are often continued until the end of life, as long as the burdens of therapy are acceptable.

As noted, the potential complexity of optimal medical management of advanced HF would be best addressed if all patients had access to cardiologists, particularly those who specialize in this condition. This type of care is not available throughout most of the world, and even in developed countries, most patients with HF are cared for by primary care providers, not cardiologists or HF specialists. Nonetheless, palliative care specialists should recognize the potential value of a referral to a HF specialist, if this is possible, particularly when patients have refractory symptoms.

Diuretics

HF may manifest with fluid retention or symptoms of low cardiac output, such as fatigue, breathlessness, and altered mentation, or both. Fluid retention is associated with oedema and breathlessness due to pulmonary congestion associated with volume overload. While there are other causes of breathlessness in patients with HF, diuretic treatment to remove excess fluid is essential in most cases for symptom relief (Hunt et al., 2009). These drugs usually are given orally, but when fluid retention is severe or acute, they may be given intravenously to ensure bioavailability and improve immediacy of effect; especially if gut oedema (suggested by abdominal bloating and nausea) has set in (Hunt et al., 2009). Occasionally, use of outpatient intravenous diuretics may help avoid hospitalization. Although diuretics have not been proven to increase survival, their ability to alleviate symptoms justifies continuation and active adjustment right up until the time of death.

Table 15.3.2 Appropriateness of drugs for systolic heart failure (LVEF < 40%) based on New York Heart Association (NYHA) class and impact on key outcomes

Drug	NYHA class I	NYHA class II	NYHA class III	NYHA class IV	Survival	Hospital admissions	Functional status
Diuretic	X	+	+	+	?	↓	↑
Angiotensin-converting enzyme inhibitor	+	+	+	+	↑	↓	↑
Beta blocker	+	+	+	+	↑	↓	↑
Mineralocorticoid antagonist	X	+	+	+	↑	↓	↑
Digoxin	X	X	+	+	↔	↓	↑

X: no evidence

+: evidence for benefit

↑: improves/increases

↓: worsens/decreases

↔: no impact.

Thiazide diuretics may be sufficient in mild cases of HF, but loop diuretics such as furosemide are more potent and typically are required as HF progresses, especially if renal insufficiency is present (Faris et al., 2002; McMurray et al., 2012). Fluid retention varies and diuretic dosing should be flexible to accommodate changing disease severity, weight, symptoms, and renal function; the dose required initially to remove excess fluid may be higher than that needed chronically to maintain 'dry weight'. At all times, the correct dose is the lowest dose sufficient to maintain euvolaemia. Often, patients can be taught to make dose changes based on daily self-monitoring. For example, patients can weigh themselves daily and when their weight increases by a certain amount over their baseline weight (typically by 2 lbs or 1 kg) they can take an extra dose of furosemide daily until they return to their baseline weight.

When diuresis is inadequate with furosemide, adherence to medications and sodium restriction should be reinforced. If this fails, the dose may be raised or, if the patient is already responding well to individual doses, the frequency of dosing can be increased. Alternatively, the loop diuretic can be changed to an alternative with better oral absorption, specifically bumetanide or torsemide, on the assumption that gut oedema is present and may be interfering with absorption.

Patients who are not responding adequately to appropriately dosed loop diuretics may respond to the addition of a thiazide diuretic, such as hydrochlorothiazide or metolazone, or a potassium-sparing diuretic, such as spironolactone or eplerenone. By blocking the nephron sequentially, the combination of loop and these distally acting diuretics work synergistically to remove fluid. However, potassium loss may be either potentiated or reduced by these combinations and must be monitored closely.

ACEIs, ARBs, and hydralazine-isosorbide dinitrate

ACEIs block the conversion of angiotensin I to angiotensin II in the pulmonary vasculature and thereby inhibit the renin–angiotensin–aldosterone system. This activity results in lower arteriolar resistance and increased venous capacity, increased cardiac output, lower renovascular resistance, and increased urinary sodium excretion. Multiple studies have confirmed that these drugs are essential in the management of systolic HF because they improve symptoms by enhancing forward blood flow and slowing ventricular remodelling, and reduce adverse outcomes, including hospitalization and mortality (Dickstein et al., 2008; Hunt et al., 2009; National Heart Foundation of Australia and the Cardiac Society of Australia and New Zealand, 2011) All patients with reduced ejection fraction should receive them in the absence of contraindications. They are typically begun along with diuretics as soon as HF or a HF exacerbation is diagnosed. They are continued until close to the end of life, as long as they are tolerated and there are no significant adverse effects on blood pressure or renal function. A common side effect of ACEIs is cough, and less common but more serious reactions include hyperkalaemia, renal insufficiency, allergy, and angio-oedema. Although they are not nephrotoxic, they can cause a rise in creatinine that usually is mild and should not discourage continued use.

Patients intolerant to ACEIs should be treated with ARBs, that have been shown to have similar effects on symptoms and mortality. Patients intolerant to both ACEIs and ARBs because of hyperkalaemia or progressive renal insufficiency should receive the combination of hydralazine and isosorbide dinitrate. The downside of this combination is that it requires two medications taken multiple times a day, whereas ACEIs and ARBs are typically given once daily. In African Americans with systolic HF, the combination of hydralazine and isosorbide dinitrate, and a beta blocker, significantly reduced death and hospitalization. Treatment with these drugs should be considered for this population; there is no evidence of effectiveness in other groups. Nonetheless, palliative care clinicians may encounter patients who are receiving hydralazine and isosorbide dinitrate in addition to standard HF therapy, especially those who require treatment for persistent hypertension or refractory symptoms.

Beta blockers

Beta blockers, which block the sympathetic nervous system, were once thought to be contraindicated in HF. Now it is known that sympathetic activation, like activation of the renin–angiotensin–aldosterone system, leads to progression of systolic dysfunction and worsening of HF. Clinical trials have found that three beta blockers, bisoprolol, carvedilol, and sustained-release metoprolol succinate, markedly reduce mortality and hospitalization in patients with systolic heart failure (Packer et al., 2001; Hunt et al., 2005, 2009; Dickstein et al., 2008; Jessup et al., 2009). However, beta blockers cause improvement gradually and when started acutely may worsen HF. Hence, they are begun only after patients are stabilized and euvolaemic. Therapy is initiated at a low dose, which is increased slowly.

Beta blockers should be continued during most HF exacerbations and have been shown to benefit even patients with severe HF and NYHA class IV symptoms (Packer et al., 2001). However, they may need to be reduced or stopped for severe exacerbations, symptomatic hypotension, bradycardia, or hypoperfusion leading to end-organ dysfunction. Some patients with low cardiac output may become intolerant of beta blockers at the end of life (Hunt, 2005).

Mineralocorticoid receptor antagonists

The MRAs, spironolactone and eplerenone, block aldosterone and have been found to reduce mortality, prevent hospitalization, and improve functional class for patients with an ejection fraction of 35–40% or lower, and persistent symptoms despite beta blockers and ACEIs (Hunt et al., 2005; Dickstein et al., 2008; Hunt et al., 2009; Jessup et al., 2009). Along with beta blockers and ACEIs/ARBs, they complete 'triple therapy', the trio of agents that improve survival in HF. It is important to monitor vigilantly for hyperkalaemia, which is a common side effect and can limit use in late stage HF when renal insufficiency is more common. Baseline hyperkalaemia and creatinine clearance less than 30 mL/min are contraindications to starting these medications. If gynecomastia from spironolactone is problematic, eplerenone may be used instead.

Digoxin

Digoxin may be added to standard therapy of ACEIs, diuretics, and beta blockers for systolic HF, to improve symptoms and reduce hospitalization. It does not prolong survival and hence should not be given when symptoms are mild or absent. However, digoxin can play a role when the goals of care are palliative, particularly since it does not lower blood pressure and can be given to patients with hypotension. Beta blockers, which also lower heart

rate and have a much greater benefit, should be used preferentially when slow heart rate is limiting. Because higher serum levels have been associated with worse outcomes, digoxin should be used at a low dose and usually avoided with renal insufficiency.

Drug therapies for diastolic heart failure (HFPEF)

Nearly half of all patients with HF have preserved ejection fractions. Unfortunately, to date, no medication has been found to reduce mortality and morbidity in HFPEF. Hence, treatment is empiric and focused on treating concomitant conditions according to accepted guidelines: hypertension, rhythm abnormalities, ischaemia, and oedema. This approach often leads to the use of loop diuretics, beta blockers, and ACEIs in a fashion similar to systolic HF, though potentially with differences in rate and sequence of titration, dosing, or choices of agent.

Role of intravenous inotropes

Intravenous inotropes, such as milrinone or dobutamine, can improve cardiac function and relieve symptoms associated with HF. These drugs typically are used in hospitalized patients who develop hypotension during an exacerbation of HF, as an effort is being made to optimize medical management. Ideally, one of these drugs is given for a short period of time in a monitored environment, then tapered and discontinued as cardiac functioning improves with other treatments. Long-term use increases the risk of complications and sudden death, and should be avoided if possible. When weaning is accompanied by the reappearance of hypotension, however, and there are no options for advanced therapies such as mechanical circulatory support with a VAD or heart transplant, long-term therapy may be an option (Sherrod et al., 2009; Chua et al., 2011; Taitel et al., 2012). It should be recognized that inotrope dependence is a sign of very poor prognosis and the decision to proceed with this approach means acceptance of an increased risk of complications and death in order to palliate symptoms and potentially allow discharge from the hospital (Hauptman et al., 2006). Palliative care specialists may be called upon to assist with arranging outpatient inotrope infusions; in the United States, many home health, home infusion, and hospice agencies can provide these treatments.

Medications to avoid in people with HF

Medications of all types should be introduced cautiously in patients with advanced HF due to the potential metabolic disturbances associated with the disease. Some drugs used commonly in palliative care should be avoided all together, or used with extreme caution, due to their potential for worsening fluid retention or cardiac arrhythmia. For example, non-steroidal anti-inflammatory drugs (NSAIDs), including cyclooxygenase 2 selective inhibitors, can lead to fluid retention, volume overload, and HF exacerbation. Patients with advanced HF should be told to avoid NSAIDs in over-the-counter formulations. Thiazolidinediones used for management of diabetes also can cause fluid retention and should be avoided. Many drugs may affect the QTc interval and potentially predispose to arrhythmia, among which are methadone, tricyclic antidepressants, and venlafaxine; venlafaxine also can cause hypertension. All these drugs should be used with caution in patients with HF (Krantz et al., 2009). If goals of care are solely palliative, a patient could make an informed choice to use these medications and accept a small risk in exchange for better symptom control.

Non-pharmacologic disease management

Moderate restriction of sodium intake (< 2–3 g daily) is recommended for patients with more severe symptoms in the hope of relieving volume overload and potentially allowing lower diuretic doses (Dickstein et al., 2008b). Patients prone to hyponatraemia should also limit fluid intake to less than 1.5–2 L/day.

Exercise training probably improves survival in the population with HF (Piepoli et al., 2004) and has been found to lessen symptoms, increase stamina, reduce hospitalization, and improve depression (Belardinelli et al., 2012). Some exercise interventions may be too strenuous for patients with advanced HF, but all patients should be encouraged to be as active as possible to maintain maximal functional status.

Devices and interventions

The use of devices and interventions is a rapidly evolving area of HF disease management in developed countries. These therapies have risks and benefits, and the palliative care specialist should understand each intervention in order to help patients make informed decisions and manage these devices as the end of life approaches. The following information provides a background for the palliative care specialist, but does not offer definitive indications and protocols. The palliative care specialist should collaborate closely with HF specialists and those who insert these devices.

Implantable cardioverter defibrillators

ICDs are pacemaker-like devices implanted near the clavicle to sense ventricular arrhythmias or bradycardia and treat them with pacing or internal shock. More than 10 000 are being implanted each month in the United States alone (Hammill et al., 2010). They can reduce the risk of sudden death in patients with prior resuscitated arrest and selected patients with low ejection fractions (< 30–35%) despite optimal medical therapy.

While ICDs are highly effective when life-threatening dysrhythmias occur, it is difficult to identify patients at risk prior to a first episode. When used for primary prevention, follow-up data indicate that seven lives are saved over 5 years for every 100 devices implanted (Bardy et al., 2005). After considering the relative magnitude of this benefit, the potential exchange of a sudden death for a more prolonged death, and the fact that ICDs do not improve quality of life, some eligible patients choose not to undergo implantation. For some whose quality of life is poor, or who have comorbidities that shorten survival, the opportunity to avoid sudden cardiac death may not be a priority; for others, sudden death is preferable to one that occurs as the result of progressive HF with worsening symptoms.

When patients choose to have an ICD, they should be informed that the device can be turned off if their condition deteriorates and their goals of care change. Palliative care clinicians should have a clear plan for turning off an ICD if the patient prefers. To avoid painful shocks during the phase of active dying, events that may be very distressing to patients and families, there also should be a plan to discuss, and perhaps recommend, discontinuation of the device when the end of life is perceived to be soon (Goldstein et al., 2004; Russo, 2011). Although ICD firing is uncommon at the end of life, counselling about discontinuation is a marker of quality care (Clark et al., 2011; Bonow et al., 2012).

Specialists in palliative care should be able to discuss the technical aspects and the repercussions of ICD discontinuation. Turning

off individual functions of ICDs and CRT pacemakers (see below) is simple and non-invasive and can be done in a few minutes with a programmer specific to the device by a technician or clinician trained in its use. Palliative care specialists should have clear procedures for how to manage ICD deactivation, including a collaboration with the treating cardiologist and device representative who can assist in deactivating the ICD (Lampert et al., 2010; Padeletti et al., 2010). The technician places the programmer's magnet over the device in order to deactivate therapies. In medical facilities lacking electrophysiological expertise, or when a patient is at home and too ill to come to clinic, a device company representative may be available to bring a programmer to the patient and provide technical assistance to on-site personnel (e.g. home-hospice nurse) under the direction of the treating physician (Lampert et al., 2010; Padeletti et al., 2010). If these options are unavailable, hospice nurses or other clinicians may carry a magnet which when left over the device will deactivate the shock therapy function.

While deactivating the shock function of an ICD is unlikely to have any immediate impact and thus does not typically require immediate management of symptoms, it can evoke anxiety in patients who viewed this function as potentially life-saving. Addressing such concerns in advance can alleviate this anxiety. Some patients may choose to withdraw some functions of an ICD and not others. Pacing for chronic bradycardia and anti-tachycardia pacing, which can prolong life but causes no symptoms, may continue, for instance, while therapies for tachyarrhythmias or shock therapy can be stopped. The choice of these options depends on a patient's goals for prolongation and quality of life. For pacemaker-dependent patients, death may occur immediately after the pacemaker is turned off or take longer if dependence is partial. Patients and their families should be prepared for these possibilities and appropriate symptom control readied if needed. Deactivation, especially when it could lead to immediate death, may make some practitioners uncomfortable and they should be reassured this intervention is ethically appropriate (Lampert et al., 2010; Grubb and Karabin, 2011). At the same time, no provider should be compelled to deactivate a device if this is against their personal beliefs, In such situations, another provider should be found.

Cardiac resynchronization therapy

In selected patients, CRT using a biventricular pacemaker can improve symptoms and extend life. CRT acts to synchronize the contraction of opposite sides of the left ventricle when impaired native electrical conduction results in less coordinated contraction and diminished cardiac output. CRT has been shown to improve ventricular function and slow HF progression. Because it offers both symptom relief and a greater mortality reduction than ICD, CRT is a very appealing option that should be considered in eligible patients. Initially, patients shown to benefit were those with low ejection fraction, NYHA class III/IV symptoms and electrocardiographic evidence of left ventricular dyssynchrony (i.e. left bundle branch block). More recently, patients with less severe symptoms have also been found to benefit (Heidenreich et al., 2002). CRT devices are usually but not always combined with an ICD, depending on a patient's interest in preventing sudden death versus relieving symptoms. As above, patients may choose to deactivate the ICD if their goals change, or less commonly, choose to deactivate both the ICD and CRT functions.

Mechanical circulatory support/ventricular assist devices

VADs are pumps that are implanted in the chest and connected to the heart to pump blood (Fig. 15.3.1). A cable (driveline) that connects the VAD to a control device and battery exits the body through the skin. The vast majority of VADs are connected to the left ventricle (left ventricular assist device or LVAD) and only a small number are connected to the right ventricle or to both ventricles. In the United States, since 2006, approximately 4500 VADs have been placed and currently about 1500 per year are implanted (Kirklin et al., 2012). Initially, LVADs were used exclusively in patients awaiting heart transplant. This approach to LVAD use was termed 'bridge to transplant' (BTT). During the past several years, however, there has been increasing evidence to support using LVADs in patients with advanced heart disease who are not candidates for transplant. This approach is called 'destination therapy' (DT), as the LVAD is not leading to another procedure. In 2006, in the United States, 44% of LVADs were for BTT and only 15% were for DT. By 2011, the percentages had flipped and only 24% were for BTT while 34% were for DT.

In some countries, palliative care specialists are increasingly likely to help care for patients with LVADs in both the DT and BTT scenarios. They must coordinate with cardiologists and support effective self-management and hope. Patients and their families should be amply prepared for potential adverse events, including bleeding, driveline infections, thrombosis and thromboembolism, device failure, and death. They should be reassured that the LVAD can be stopped if quality of life becomes too poor (Allen et al., 2012). They should also be informed about the survival with LVADs, which currently is 80% at 1 year and 70% at 2 years and considerably worse, however, in patients who are in acute cardiogenic shock at the time of implantation. Some patients, particularly those with advanced multisystem organ failure, may be too ill to benefit from mechanical circulatory support (Peura et al., 2012).

Palliative care specialists who are asked to help care for patients with LVADs may be called upon to assist in the treatment of symptoms should patients decide to turn off the machine, or help the primary team manage complications. It is valuable to have protocols in place to address specific complications and the need to consider device withdrawal (Wiegand and Kalowes, 2007). In a study of 20 patients with LVADs as DT who were able to participate in decision-making, 17 chose to turn off the device (Brush et al., 2010). The most common reason for the decision to turn off the LVAD was a new or worsened medical condition, such as sepsis, infection, cancer, and renal failure. For all 20 patients, the time from turning off the LVAD to death was less than 20 minutes and the majority of patients died at home. Understanding the process for stopping the LVAD and having plans to manage symptoms, such as breathlessness, alleviates anxiety and provides support to patients and caregivers. Developing a clear plan to manage symptoms in the event of device failure also is critical to ensure patient comfort and dignity (MacIver and Ross, 2005; Wiegand and Kalowes, 2007; MacIver and Ross, 2012). Although not specifically studied, it is appropriate to use opioids for breathlessness and benzodiazepines for anxiety, as would be used for these symptoms in other end-of-life situations.

Surgical approaches

Surgical approaches in HF include valve replacement, myocardial revascularization, and cardiac transplantation. Although cardiac
Fig. 15.3.1 Patient with a left ventricular assist device. The pump is implanted in the chest and the cable connecting it to the control unit exits the body.

transplantation is an effective option for HF, donor shortage and patient selection limit access (Mancini and Lietz, 2010; Glower, 2012). Patients who are candidates for surgery are best served by an approach that integrates palliative care, including symptom management.

Managing the symptoms of heart failure

Symptoms such as pain, dyspnoea, and fatigue are highly prevalent in patients with HF, as common as in patients with cancer, and diminish quality of life (McCarthy et al., 1996; Levenson et al., 2000; Bekelman et al., 2009; Pantilat et al., 2012). Symptoms are caused by HF itself, especially breathlessness and fatigue, but also relate to comorbid conditions common in patients with HF, such as osteoarthritis, low back pain, chronic pulmonary disease, and diabetes. A guideline jointly developed and published by the American College of Cardiology, American Heart Association, and American Medical Association includes symptom management as a key performance measure for patients with HF (Bonow et al., 2012). Because many cardiology specialists are not trained in symptom management, palliative care specialists play a key role in managing distressing symptoms for these patients.

Pain

Pain is present in up to 78% of patients with HF (Goebel et al., 2009; Pantilat et al., 2012). Pain can result from heart disease (e.g. angina), from comorbidities (e.g. peripheral neuropathy or back pain), or from interventions (e.g. implants and cardiac surgery). There are no randomized trials of treatments for pain in patients with HF. Given the prevalent aetiologies of pain and the commonalities between HF and other serious illnesses, an appropriate

general approach to pain would be modelled on other serious illnesses such as cancer. There are a few caveats to this perspective, however. As explained earlier, NSAIDs other than low-dose aspirin should be avoided in people with HF, as they cause fluid retention and can lead to HF exacerbations, and some drugs that can affect the QTc interval, such as methadone, venlafaxine and tricyclic antidepressants, should also be used with caution due to the risk of arrhythmia. Otherwise, the general approach to pain in those with advanced HF would emphasize pharmacotherapy as the mainstay therapies, and usually employ acetaminophen (paracetamol) for mild pain and opioids for moderate to severe pain. The use of these drug classes, and the so-called adjuvant analgesics, is guided by the widely published experience in the management of cancer pain.

Breathlessness

Breathlessness is a feared and distressing symptom for people with HF (see also Chapter 8.2). While breathlessness can be chronic for people with class III and IV, exacerbations of HF are typically associated with acute episodes of breathlessness that lead to emergency department visits and hospital admission. Establishing a plan with specific directions for patients and caregivers about how to respond to episodes of breathlessness is a critical role for the palliative care specialist. A practical plan and a well-educated patient and family can eliminate the use of the emergency department as the default for every episode. The complex interplay of breathlessness and anxiety mean that non-pharmacological strategies such as relaxation and breathing exercises may be of use.

Breathlessness associated with HF can result from a range of causes, including fluid congestion, leading to acute and chronic pulmonary oedema and pleural effusions, and skeletal muscle

dysfunction. Optimal medical management, including titration of diuretics, is a key step in preventing and responding to both aetiologies of breathlessness. Non-pharmacological strategies such as exercise are also of importance. Large pleural effusions that persist despite best medical management can be drained with thoracentesis, if consistent with patient wishes and goals of care.

The acute onset of breathlessness from pulmonary oedema is typically managed in hospital with intravenous diuretics, supplemental oxygen, and oral nitrates. Opioids are also a useful strategy, and as with other indications, should be started at a low dose and increased slowly if needed. A similar approach can be applied to outpatient settings, including at home, although there are no data to confirm its effectiveness. Nonetheless, acute breathlessness in the home may be addressed with oral opioids, nitrates such as sublingual nitroglycerine, and oral diuretics such as furosemide. Providing the patient and caregiver with an algorithm of which medications to take, doses, and frequency, as well as clear instructions on when to call for help, may allow patients to avoid the emergency department.

Patients and caregivers should be alerted to signs of increasing pulmonary oedema, including weight gain, orthopnoea and worsening dyspnoea on exertion. If these signs gradually worsen and the patient is able to recognize them and has a plan for taking additional doses of diuretics in response, a more severe episode of breathlessness may be prevented. For chronic breathlessness, low dose opioids are effective and safe (Chua et al., 1997; Jennings et al., 2001). Supplemental oxygen plays a role in relieving breathlessness for patients who are hypoxic, but is not more effective than air for patients who are not hypoxaemic (Abernethy et al., 2010). Patients with refractory breathlessness despite optimal medical management of HF and treatment with opioids may be candidates for home intravenous inotropes, as described earlier, but the burden and risks of this approach should be carefully considered.

Oedema

Many patients with HF have chronic lower extremity oedema that can be painful and sometimes spontaneously weep. Explanation and reassurance to patients and their families is important. Limiting fluid and salt intake, and adjusting diuretics, to manage lower extremity oedema are key steps. Elevation of the legs, preferably above the level of the heart, may be helpful. Bandages and wraps for weeping lesions and blisters when oedema is severe can also provide symptomatic relief. In some instances, testicular oedema may be severe and appropriate support devices for patient comfort should be obtained.

Fatigue

Fatigue is a common symptom in patients with HF and is present in up to 82% of patients. Optimal medical management of the HF may ameliorate fatigue and other approaches can be used to target the symptom directly. The latter strategies have not been tested in the HF population, but are used in other illnesses. They include cognitive techniques to conserve energy (e.g. by pacing) and rehabilitative approaches such as special equipment (e.g. a shower chair) and therapeutic exercise. There are no studies of stimulant medications and the potential risks of these drugs in patients with severe HF limit their use. In one trial, however, caffeine at a dose equivalent to two cups of coffee improved exercise duration in patients with HF; this approach may have a role for HF patients with limited exercise tolerance (Notarius et al., 2006).

Fatigue also may be reduced if contributing factors can be safely and effectively managed. Fatigue may be related to anaemia, but routine correction of anaemia of chronic disease with blood transfusion or erythropoietin carries too much risk and is not recommended (Dickstein et al., 2008a). Similarly, obstructive sleep apnoea (OSA) can cause fatigue and may provide a target for therapy. While patients with HF are no more likely to have OSA than the age-matched general population (both have a prevalence of OSA of 2–10%), fatigue associated with obesity or refractory hypertension, should raise suspicion and prompt a work up for OSA (Sin et al., 1999, 2003). Treatment of OSA with continuous positive airway pressure (CPAP) in patients with HF can improve quality of life (McKelvie et al., 2011). Patients with advanced HF are more likely to have central sleep apnoea than the general population, but unfortunately, a trial of CPAP in these patients found no benefit of treatment (Bradley et al., 2005).

Depression

As many as half of patients with HF are depressed, and depression is associated with fatigue and poorer quality of life, as well as negative outcomes such as hospital readmission and mortality (Dracup et al., 1992; Albert et al., 2009; Bekelman et al., 2009; Johnson et al., 2012b; Pantilat et al., 2012; Rollman et al., 2012). Although a randomized trial showed that sertraline was not more effective than placebo for improving depression or cardiovascular outcomes in HF patients, depressed patients with HF would be expected to respond to treatment like other patients and should be treated with standard approaches (O'Connor et al., 2010). Based on clinical experience, selective serotonin reuptake inhibitors (SSRIs) are preferred for patients with HF; tricyclic antidepressants are associated with tachycardia and arrhythmia and should be avoided. Psychostimulants work quickly to treat depression in patients with cancer but studies are lacking in people with HF, and as noted, psychostimulants should be used with caution, if at all, due to the potential risk of arrhythmia and tachycardia. Exercise training and t'ai chi have been shown to reduce depressive symptoms in people with HF (Blumenthal et al., 2012; Redwine et al., 2012). Exercise training is especially recommended given its additional benefits of reducing fatigue.

Prognosis

Prognostication is challenging in HF. Although many cardiology specialists and patients may not consider HF a terminal illness, the prognosis is worse than for some cancers, with median survival from first admission of 5 years for both systolic HF and HFPEF (Stewart et al., 2001; Tribouilloy et al., 2008). At the same time, HF prognosis varies greatly depending on the presence of characteristics associated with worse prognosis. These markers of poor prognosis include higher NYHA class, weight loss/cachexia, advanced age, repeated hospital admissions, hyponatraemia, history of sudden death, hypotension, declining functional status, frailty, and comorbid conditions such as chronic obstructive pulmonary disease and end-stage renal disease (Harkness et al., 2012). Hence, younger patients responding well to medications who have NYHA class I/II symptoms, ICDs, and few comorbidities may have an annual mortality of 3% (Moss et al., 2009), while patients who are NYHA class IV despite optimal therapy may have an annual mortality greater than 70% (Rose et al., 2001).

There are many indices to aid in prognosis for people with HF but most are too complex to use easily at the bedside. The most commonly used and cited prognostic index in HF is the Seattle Heart Failure Model (SHF) (Levy et al., 2006; Mozaffarian et al., 2007; Kalogeropoulos et al., 2009). The SHF has five components, including demographic characteristics, medications, diuretics, devices, and laboratory values; an online calculator that is available on many portable device platforms simplifies its use, assuming the clinician has access to all the necessary data elements (<http://depts.washington.edu/shfm>). The Gold Standards Framework Prognostic Indicator Guide developed in the United Kingdom is simpler to use at the bedside and contains well established prognostic criteria, including NYHA class III or IV, a positive response to the so-called surprise question ('Would you be surprised if this patient died in the next 12 months?'), repeated hospital admissions with symptoms of HF, and difficult physical or psychological symptoms despite optimized tolerated therapy.

While either of these indices can help guide clinicians to identify patients with HF in need of specialist palliative care, neither index performed well in predicting 1-year mortality in a prospective trial (Haga et al., 2012). Nonetheless, the criteria in the Gold Standards Framework, some of which are familiar to palliative care specialists, combined with other factors associated with poor prognosis can provide guidance to patients, caregivers, and clinicians in planning for the future. The lack of sensitivity and specificity of these and other indices should not dissuade palliative care specialists from sharing with patients the best information they have about prognosis, including the fact that death can happen suddenly.

Advance care planning

A critical element of palliative care is effective communication and development of a clear plan for care (Pantilat and Steimle, 2004; Davidson, 2007). As a patient ages, the likelihood of dying from their cardiac condition or another terminal illness increases (Wiegand and Kalowes, 2007). Sadly, there are countless examples of the adverse consequences associated with inadequate communication, including needless distress and futile treatments (Quill and Holloway, 2012). To avoid these consequences, communication must be ongoing and address both present and future plans.

Advance care planning (ACP) is a patient-centred communication process allowing patients and their families to participate in discussions concerning their future care (Kirchhoff et al., 2012). The process allows patients to have their preferences known even if, at the time of crisis, they are too unwell to make decisions about their care. The term ACP is now commonly used, rather than 'advance directives'. The ACP process should involve a discussion of the patients' values and preferences regarding care, and a sharing of information that allows informed decision-making about life-sustaining and life-prolonging therapies.

Conversations about ACP can be challenging for health professionals and patients alike, and ideally, they should not take place during times of crisis (Davidson, 2007; Ahluwalia et al., 2012). It may be helpful to use models of shared decision-making, through which the individual is presented with options and collaborative decision-making is undertaken to elicit preferences (Allen et al., 2012). Religious and cultural factors should be part of the ACP process.

Because up to half of patients with HF die suddenly at any stage of illness, it is incumbent upon clinicians to discuss ACP early (Stevenson and Stevenson, 2001). Because exacerbations of HF are likely and sudden death is a real possibility, the discussion should cover patient preferences for hospitalization during exacerbations and for resuscitation in the event of cardiac arrest. When the issue is addressed openly, many patients will say that they prefer a sudden, quick and painless death from cardiac arrest and do not want to undergo resuscitation.

As discussed earlier, there are increasing numbers of individuals with implantable devices. These devices have important implications for future care and how a patient may die, and ACP is important for every patient considering an implant. ICDs are meant to prevent sudden death, and therefore, an implant may mean that a patient is more likely to die from progressive HF, with its associated symptoms of dyspnoea, fatigue, oedema, and functional decline. Among patients who have ACP conversations prior to implantation, two-thirds decide to have the device placed and one-third do not.

In those with implanted devices, ACP discussions also require consideration of device deactivation or LVAD withdrawal. The ethical and legal issues raised by deactivation of ICDs at the end of life are similar to those raised by withholding or withdrawing other life-sustaining medical interventions in other clinical settings. As discussed above, avoiding an arrhythmic death, with associated ICD activation, is often an important consideration, as device firings can cause distress to the patient and their family (Goldstein et al., 2004). To avoid this outcome, it may be appropriate for an ICD to be deactivated near the end of life, following discussion with the patient and family. There is a wide variation among individuals regarding their preferences, and this fact underscores the need to tailor and target approaches (Dev et al., 2012). The ACP process should employ open and sensitive communication with the patient and their family about prognosis and goals of care, and use reliable mechanisms for documenting patient preferences to ensure that the wishes of the patient are respected (Pantilat and Steimle, 2004).

ACP is an ongoing, iterative process and should not be considered as a single conversation or document (Davidson et al., 2007). Implicit in the process is providing psychosocial support to the family and caregivers, and ensuring communication across care settings to ensure that the patient's wishes are respected (Jaarsma et al., 2009). The conversations should focus on goals of care and not merely on specific interventions or devices. By first eliciting a patient's goals, the clinician can then help guide patients about the interventions and devices that may help achieve those goals and those that would be problematic. For example, optimizing medical management promotes better quality of life, being at home, and reduces symptoms. A patient that expresses these outcomes as goals may then be more willing and able to adhere to their medical regimen.

Psychosocial support

Patients with HF and their caregivers have the same needs for support—social, psychological, emotional, and spiritual—as those with other serious illnesses. Comprehensive palliative care should address all these issues. Many patients with HF worry about sudden death, and those with ICDs and LVADs may have concerns

about the ICD firing or the LVAD failing. Patients may also worry about acute episodes of breathlessness and of suffocating. Anticipating these concerns, discussing them honestly and compassionately, eliciting and responding to questions and concerns, developing a clear plan for responding to urgent situations, and being available to the patient and caregiver may relieve anxiety and allay concerns.

Setting and approaches

The setting and approach to care will largely depend on available resources and funding models. In developed countries, the principles to be considered may include access to specialist expertise in both cardiology and palliative care; a multidimensional approach to care that considers physical, social, psychological, cultural, and existential issues, as well as concrete services for homebound patients; involvement of the family and support for caregivers; case management for complex patients; and coordination across care settings. Clear communication among providers and across settings, especially at times of transition, is critical to ensuring a consistent and coordinated approach to patient care. Ideally, the referral to specialist palliative care services should be on the basis of need, rather than clinical diagnosis or prognosis. All members of the health-care team, including the primary medical and nursing providers and cardiology specialists, are empowered and trained to address the complexity of HF care at the end of life. As a core principle, it is important to meet patients and their families where they are in terms of acceptance and acknowledgement of their situation. Open-ended questions such as, 'When you think about the future what do you hope for?' and 'When you look ahead what worries you the most?' can help establish what patients understand about their current situation and what values and goals are most important (Pantilat and Steimle, 2004; Pantilat, 2009).

Ideally, palliative care services for people with HF are available in all treatment settings, including hospital, home, outpatient/ clinic, and nursing home. Because of the need for optimal medical management, most commonly the palliative care specialist serves in a consultative role. In all settings, collaboration among teams—primary, palliative care, cardiology, and others—and between disciplines—nurses, physicians, social workers, chaplains, pharmacists, and others—is most likely to promote the best care for the patient (Johnson et al., 2012a). Nurses often play a key role in managing patients in HF disease management programmes. These nurses that specialize in the care of people with HF should learn the core principles of palliative care and become adept at talking with patients about prognosis and ACP.

In HF, self-monitoring programmes can help patients manage their HF at home. Although there are conflicting data regarding the efficacy of these programmes (Chaudhry et al., 2010; Inglis et al., 2011) clinical experience is generally favourable. They typically include having patients weigh themselves daily and adjust diuretics in response to weight gain or symptoms of oedema. They may use telemonitoring of weight and symptoms by programme staff. Palliative care specialists can become engaged with self-monitoring programmes to assist in managing distressing symptoms and promoting ACP. Similarly, palliative care specialists can work with HF programmes in hospital and clinic settings to provide direct care to patients and to help teach their cardiology colleagues about palliative care. Such close collaboration also serves to teach the palliative care specialist about managing HF.

In the United States, although heart disease is the leading cause of death, HF is the admitting diagnosis to hospice services in only 12% of cases (Teno et al., 2004). Similarly, palliative care and hospice are underutilized for patients with HF in other countries (Selman et al., 2007a, 2007b). Palliative care specialists can use data showing that hospice is associated with prolonged life in patients with HF to encourage their colleagues to refer more patients with HF to palliative care and hospice (Connor et al., 2007).

Conclusion

Heart disease is the leading cause of death in the developed world and causes significant morbidity and repeated hospitalization. With increasing use of optimal medical management and devices, including ICDs, CRT, and LVADs, survival and quality of life may improve. At the same time, greater access to such interventions introduces challenges, concerns, and expectations that must be managed. Palliative care specialists need to understand the important role of medical therapy and invasive interventions in maintaining quality of life and longevity for patients with HF. Ensuring that HF is managed optimally will address many symptoms and referral to HF specialists may be necessary in advanced illness. At the same time, palliative care treatments should be integrated at every stage of illness to promote the best possible quality of life. Palliative care should enhance the capacity for effective communication among clinicians, and the patient and family, and should provide more options in the management of symptoms. The key principles of palliative care should guide comprehensive care planning regardless of the setting or model of care. Integrating a palliative approach in HF care has the potential to increase quality of life, decrease suffering and health-care costs, and improve the quality of care.

Dementia

Eric Widera and Rachelle Bernacki

Introduction to dementia

Dementia is not a single disease, but rather a clinical syndrome characterized by the insidious onset and gradual progression of impairments in at least two of the following cognitive domains: (1) memory, (2) executive function (reasoning, planning, and judgement), (3) visuospatial ability, (4) language, (5) and personality or behaviour (McKhann et al., 2011). Importantly, the decline in cognitive abilities must be severe enough to interfere with social and/or occupational functioning, and cannot be accounted for by other psychiatric conditions such as depression or delirium.

An estimated 24 million individuals worldwide have dementia (Ballard et al., 2011). This number is expected to increase as more countries have ageing populations. The incidence increases with age, rising from 5% in those aged 71–79 years to over 30% in those aged 90 and older (Plassman et al., 2007). Alzheimer's disease represents the majority of these cases and is characterized by a progressive and irreversible cognitive and functional decline that ultimately leads to death. The advanced stages of dementia are associated with significant palliative care needs, including high symptom burden, frequent transitions in care, and the use of burdensome treatments at the end of life.

Screening for dementia

The clinical diagnosis of dementia often occurs well after the onset of cognitive impairment, making it important for palliative care providers to screen for dementia in older adults. Brief and effective screening tools are available that can aid in identifying dementia, including the Mini-Mental Sate Examination (MMSE), Montreal Cognitive Assessment (MoCA), and the Mini-Cog. Although long considered a standard, the MMSE lacks sensitivity to detect the early stages of cognitive impairment. The MoCA (<http://www.mocatest.org>) is a brief and validated screening tool that is available at no cost and has high sensitivity and specificity for detecting mild cognitive impairment (MCI) and dementia. The Mini-Cog, which can generally be done within 3 minutes, is an effective screening instrument that combines a three-item recall test with a clock-drawing test. The Mini-Cog is considered positive if a patient cannot recall all three items, or if the patient can recall one or two items and also has an abnormal clock draw.

Types of dementia

Alzheimer's disease

Alzheimer's disease is the most common type of dementia, accounting for 60–80% of all dementia cases. The clinical hallmark of Alzheimer's disease is a slowly progressive impairment in memory. Characteristic findings seen at autopsy include the accumulation of extracellular amyloid plaques, intracellular neurofibrillary tangles, and loss of neurons. These pathological findings are not specific, however, and can be found at autopsy in older adults who never had clinical evidence of dementia. Amyloid plaques are thought to be the result of abnormal metabolism of amyloid-β 40 and amyloid-β 42, which results in its accumulation in areas of the brain that are responsible for learning and memory, most notably the hippocampus and entorhinal cortex. Neurofibrillary tangles consist mainly of hyperphosphorylated tau protein, a microtubule assembly protein. It is still a matter of debate whether plaques and tangles are the mediators or the by-products of the pathogenesis of Alzheimer's disease and neuronal death (Querfurth and LaFerla, 2010).

Vascular dementia

Vascular dementia, the second most common type of dementia in the elderly, is the result of ischaemic or haemorrhagic cerebrovascular disease or ischaemic-hypoxic brain lesions. There are several subtypes of vascular dementia. Multiple lacunar infarcts or deep white matter changes related to chronic ischaemia may cause a subcortical dementia, which often has an insidious onset and a slowly progressive course. Multiple cortical infarcts usually occur in patients with multiple vascular risk factors and may progress in a 'stepwise' fashion characterized by the sudden onset of cognitive deficits followed by periods where deficits stabilize.

Dementia with Lewy bodies

Dementia with Lewy bodies (DLB) is another slowly progressive neurodegenerative disease that is associated with abnormal alpha-synuclein clumps (Lewy bodies). Patients with DLB experience a progressive cognitive decline, accompanied by vivid hallucinations, motor features of parkinsonism, and fluctuating cognition with pronounced variations in attention and alertness. Patients with DLB may be very sensitive to neuroleptic medications. If exposed to these medications, they may have a sudden exacerbation of parkinsonism, impaired consciousness, or a neuroleptic malignant syndrome. Parkinson's disease with dementia is a more appropriate diagnosis than DLB when the motor features of parkinsonism are present for longer than 12 months prior to onset of dementia.

Frontotemporal dementia

Frontotemporal dementia (FTD) is characterized by focal degeneration of the frontal and/or temporal lobes. Age of onset is typically younger than Alzheimer's disease, with most patients being

diagnosed in their 50s and 60s. The most common presentation of FTD is that of progressive personality changes, including marked behavioural disinhibition or apathy, and loss of social awareness occurring early on in the disease. Patients with FTD have executive function deficits but their memory and visuospatial functions are mostly spared. However, over time FTD progresses to a more global dementia.

Natural history

There are significant differences in how different types of dementia present early in the course of the disease. In the advanced stages, however, patients with different disorders usually appear more similar in appearance.

Patients with the most common types of dementia may present with MCI, which refers to cognitive impairment that does not meet the criteria for dementia. In the amnestic subtype of MCI, which may represent a transitional stage from normal ageing to early Alzheimer's disease, individuals develop clinically observable memory impairment but no significant change in daily functioning. These patients often experience progression of memory impairment over time, and ultimately experience cognitive impairment that interferes with everyday function, which may fulfil the diagnostic criteria for dementia.

Over time, individuals with dementia require increased need for assistance and eventual complete dependence with more basic activities of daily living (ADLs), such as bathing, dressing, and feeding (Widera et al., 2011). In the most advanced forms of dementia, individuals lose the ability to ambulate independently, to communicate with others, to eat without assistance, and to maintain bowel and bladder continence. Persistently severe disability with complete dependence in basic ADLs is the predominant functional trajectory in the last year of life (Gill et al., 2010). Of note, rapid progression of cognitive and functional decline should be concerning for delirium and not be solely attributed to dementia (see Chapter 17.5).

The progression of dementia may be categorized into stages based on disease severity. Standardized cognitive assessment tools, such as the MoCA or the MMSE can be used to stage severity but they lack important functional measures. Global severity scales better rate severity as they include functional assessment. Three of the most commonly used global measures for staging include the Clinical Dementia Rating (CDR) scale, the Functional Assessment Stage (FAST) scale, and the Global Deterioration Scale (GDS). The CDR rates impairments in memory, orientation, judgement and problem-solving, community affairs, home and hobbies, and personal care. The CDR ranges from 0 to 3, with a score of 3 indicating advanced disease. The FAST scale consists of seven major stages split into 16 different substages (see Table 15.4.1), with stage 7 generally indicating advanced dementia. The GDS also divides the disease process into seven stages, assigning patients to a 1–7 scale, with the latter indicating very severe impairment.

Prognosis

The prolonged period of severe functional and cognitive impairment that occurs prior to death makes it difficult to determine short-term prognosis in advanced dementia (Brauner et al., 2000). However, longer-term prognosis is clear. The median survival after the diagnosis of Alzheimer's disease ranges from 4 to

Table 15.4.1 Summary of Functional Assessment Staging (FAST) (Anonymous, 1996)

Stage	Skill
1	No subjective or objective difficulties
2	Complaints of misplacing objects. Subjective word finding difficulties
3	Difficulties with job performance evident to co-workers. Difficulty with organization
4	Impairments in instrumental activities of daily living
5	Needs assistance with dressing to match weather or occasion
6 (a–e)	Difficulty dressing, bathing, toileting without assistance (stage 6a–c). Occasional or more frequent urinary incontinence (6d) and faecal incontinence (6e)
7 (a–f)	Speech limited to less than six intelligible words per day (7a) to one or less (7b). Inability to ambulate independently (7c), sit up without assistance (7d), smile (7e), and hold head up (7f)

Source: data from Reisberg B., Functional assessment staging (FAST), *Psychopharmacology Bulletin*, Volume 24, Issue 4, pp.653–9, Copyright © 1988.

6 years (Larson et al., 2004). For those with advanced disease, markers of poor short-term survival include aspiration, urinary tract infections, sepsis, pressure ulcers, fever, and weight loss (Luchins et al., 1997). One study observed that nursing home residents with advanced dementia and pneumonia had 6-month mortality rates of 47%; residents who had a febrile episode and those with an eating problem had mortality rates of 45% and 39%, respectively (Mitchell et al., 2009). Another study reported that advanced dementia patients hospitalized with either pneumonia or a hip fracture had a 6-month mortality rate exceeding 50% (Morrison and Siu, 2000b). These data suggest that, while patients with advanced dementia can survive for long periods of time with severe functional and cognitive decline, they are also at risk of sudden, life-threatening events such as respiratory and urinary tract infections.

Despite the poor prognosis, many patients and families, as well as some physicians, do not consider dementia a 'terminal illness' with a recognizable end-stage course. For instance, health-care providers have overly optimistic prognoses for individuals with advanced dementia. In one study of nursing home admissions, only 1% of residents were perceived to have life expectancy of less than 6 months, but 71% died within that period (Mitchell et al., 2004). Not perceiving dementia as a terminal illness can lead to poor quality outcomes at end of life. One study found that a family's perception of dementia as 'a disease you can die from' predicted higher patient comfort during the dying process (van der Steen et al., 2013). However, only 43% of family members in this study perceive dementia as a terminal illness (van der Steen et al., 2013).

In the United States, Medicare hospice eligibility criteria for dementia are based largely on whether a patient meets Stage 7 on the FAST and whether they have at least one complication from their dementia (aspiration, upper urinary tract infection, sepsis, multiple Stage 3–4 ulcers, persistent fever, or weight loss > 10% within 6 months) (Luchins et al., 1997). The FAST criteria are widely used, despite their limited reliability for prognostication

and the observation that many patients do not follow FAST stages sequentially. While other validated models have been developed to predict survival in advanced dementia, their accuracy remains only moderate in predicting the risk of death within 6 months (Yaffe, 2010). The Advanced Dementia Prognostic Tool (ADEPT) (Mitchell et al., 2010) is one such tool, which is intended to identify nursing home residents with advanced dementia at high risk of death within 6 months and can be found online at <http://eprognosis.ucsf.edu/mitchell.php>.

Better tools for prognostication in dementia are needed. In their absence, at a minimum, clinicians can educate family members about the expected outcomes of advanced dementia and prepare families for the types of scenarios they might encounter. Such education, while time-consuming, is key to ensuring that high-quality care is provided to advanced dementia patients.

Place of death and multiple transitions

Most patients with advanced dementia require nursing home level of care at some point during their illness. Many of these patients die 'in place' at the nursing home. For example, a recent study reported that nearly half (49%) of Medicare patients with dementia died in a nursing home (Teno et al., 2013).

Simply knowing where someone dies may not say much about the care they received at the end of life. While patients with advanced dementia who received hospice at end of life in the United States increased dramatically from 19.5% in 2000 to 48% in 2009, the proportion of patients with very short hospice stays (< 3 days) doubled, from 5% to 10% (Teno et al., 2013). In addition, 65% of advanced dementia patients were hospitalized in the last 90 days of life (with 10% hospitalized more than three times) and 22% were hospitalized in the intensive care unit in the last 30 days of life (Teno et al., 2013). The median number of transitions per decedent increased from two in 2000 to three in 2009 (Teno et al., 2013). These transitions are costly and difficult for caregivers and reflect the chaos and 'churning' effect dementia patients may experience at end of life.

Costs of care

Dementia creates a substantial financial burden for patients, family members, and society. The total monetary cost of dementia in 2010 was estimated to be between $157 billion and $215 billion in the United States alone (Hurd et al., 2013). These costs are mainly attributable to the cost for providing institutional and home-based long-term care. This highlights an important point in dementia care across the globe. Despite the fact that many programmes, like Medicare in the United States, provide nearly universal health care coverage to the population aged 65 years or older, they do not cover the full financial cost associated with dementia. Data from the Health and Retirement Study, which measured out-of-pocket health-related expenditures, showed that the average total out-of-pocket costs in the 5 years prior to the death of a household head or spouse was $66 155 (Kelley et al., 2013). The average out-of-pocket spending for those with dementia was double that of the average spending of those dying from gastrointestinal disease or cancer.

Symptoms in dementia

There is a growing body of literature showing that individuals with dementia are at risk for the undertreatment of symptoms (Bernabei et al., 1998). Symptoms such as pain, dyspnoea, and agitation are common and increase in prevalence as patients approach the end of life (Mitchell et al., 2009). In one study of nursing home residents with advanced dementia, 46% had dyspnoea, 39% had pain more than 5 days per month, 39% had stage II–IV pressure ulcers, and 54% had agitation within the 18-month follow-up period (Mitchell et al., 2009).

Pain

Assessing and managing pain pose significant challenges in dementia, as evidenced by undertreatment of pain in this population independent of treatment setting. In a study of community-dwelling adults, individuals with dementia had a 20% decreased probability of receiving analgesics for daily pain relative to patients with normal cognition (Landi et al., 2001). In another study of residents living in long-term care, documentation of pain and analgesic use decreased as cognitive impairment increased (Reynolds et al., 2008). A hospital-based studied observed that patients with advanced dementia recovering from a hip fracture surgery received only one-third of the amount of opioid analgesia compared with comparable, but cognitively intact, adults (Morrison and Siu, 2000a).

One reason why individuals with dementia may be at risk for the undertreatment of pain is that they tend to report less pain to both their health-care providers and caregivers than cognitively intact adults. It is not a reduction in the actual experience of pain that leads to this underreporting, as numerous studies have shown that pain sensitivity and perceptual processing of pain remain largely intact even with advanced dementia (Widera and Smith, 2009). Rather, under-reporting is most likely due to poor patient recall and difficulty with the communication of painful symptoms.

Providers should include a combination of patient reports, caregiver reports, and direct observation of the patient when assessing pain in dementia. Patient report remains an important component of pain assessment, as even individuals with moderate to severe dementia may be able to communicate the presence and severity of pain. Verbal rating scales may be more difficult for individuals with dementia, and verbal descriptor scales, visual analogue scales, pain thermometers, and Faces Pain Scales should be considered as alternatives. Direct observations by health-care providers or caregivers should play a larger role in those with cognitive impairment than in cognitively intact older adults. Observational signs of distress may include changes in facial expressions, vocalizations, body movements, interpersonal interactions, activity patterns, and mental status. Agitation, irritability, and physical aggression may also occur, especially if there is exacerbation of pain during caregiver tasks.

Several pain scales based on non-verbal signs and symptoms have been developed and validated in older patients with cognitive impairment. The best validated tools include the Pain Assessment in Advanced Dementia (PAINAD), the Pain Assessment Checklist for Seniors with Limited Ability to Communicate (PACSLAC), and the Doloplus-2 scale (Pargeon and Hailey, 1999). After a tool is selected, it is best to continue to use the same tool for follow-up assessments.

The choice of analgesic for a patient with dementia should be based on several factors: the severity of pain, the previous responses to analgesic medications, the interaction of the analgesic with co-morbid conditions, and the care setting and support

services. Acetaminophen (paracetamol) should be considered the first line of therapy for mild pain when caring for those with dementia. It can also be considered as a potential empiric treatment when the presence of pain is uncertain, as there is evidence that acetaminophen may lead to improved activity levels, social engagement, and behaviour symptoms in nursing home residents with moderate to severe dementia (Chibnall et al., 2005; Husebo et al., 2011). The use of non-steroidal anti-inflammatory drugs, including cyclooxygenase 2 selective inhibitors, should generally be used with great caution due to risks of gastroduodenopathy, renal failure, cardiovascular complications, and fluid retention.

An opioid may be appropriate for any patient with moderate or severe pain, or pain that does not respond to non-opioid therapy. Around-the-clock dosing and the use of a long-acting formulation should be considered, as individuals with dementia may not be able to readily request pain medications. Although the potential for precipitated delirium is an often-cited fear of using opioids in dementia, current evidence suggests that the undertreatment of pain is a greater risk factor for the development of delirium than the use of opioids in hospitalized adults with cognitive impairment (Morrison et al., 2003).

Neuropsychiatric symptoms

Nearly all patients with Alzheimer's disease develop neuropsychiatric symptoms, such as depression, psychosis, or agitation, at some stage in their illness (Ballard et al., 2009). The behavioural manifestations of these symptoms may take the form of repetitive mannerisms and vocalizations or physical aggressiveness. They may occur at any stage of illness, including in the severe and even terminal stages. In one study, 85% of hospice-eligible nursing home residents with advanced dementia exhibited one or more neuropsychiatric symptom (Kverno et al., 2008). These symptoms have been associated with decreased quality of life of both patients and their families, and an increased caregiver burden; they are associated with the caregiver's decisions for nursing home admission.

The management of neuropsychiatric symptoms should focus first on identifying a primary cause and creating a treatment plan to eliminate or mitigate this cause. Underlying physical or medical problems should be investigated, including that the development of a new illness, such as a urinary tract infection or delirium. New symptoms, such as pain and constipation, should be assessed for and treated. For instance, in one cluster randomized control study of nursing home patients with behavioural problems, an empiric stepwise protocol starting with a trial of scheduled acetaminophen resulted in a decrease in the number of symptoms, including agitation (Husebo et al., 2011). An evaluation of unmet needs, such as thirst, hunger, sleep difficulties, and sensory deprivation, also should be performed to identify possible causes of new behaviours. Documenting the antecedents of the behaviour, the behavioural disturbance, and the consequences of the behaviour (the ABCs) can help reveal unmet needs and triggers for a particular problem.

The treatment plan for neuropsychiatric symptoms includes management of the potential causes, various non-pharmacological interventions, and drug therapy. Among the non-pharmacological therapies with some evidence of efficacy are music therapy, massage, and physical activity (Hulme et al., 2010). Drug therapy is usually intended to reduce agitation. Antipsychotic medications are widely used, despite warnings to avoid them if possible, given their association with significant increases in stroke and death (Schneider et al., 2005; Sacchetti et al., 2010). There is limited evidence that these drugs help improve problematic behaviours in patients with advanced dementia with the exception of some modest efficacy for the treatment of aggression and psychosis over a short 6–12-week course (Ballard and Waite, 2006). There also is limited evidence of long-term benefit. For these reasons, antipsychotics should only be considered as additional therapies when non-pharmacologic approaches have failed or the behaviours are severe enough to become a safety issue.

There is little difference in effectiveness or side effects between first-generation antipsychotics (such as haloperidol) and second-generation drugs when used for short durations. Extreme caution is warranted when using these agents in patients who have DLB, as this illness is associated with severe and even life-threatening deterioration following exposure to this drug class.

Mood stabilizers, including valproic acid and divalproex, are also frequently prescribed to treat dementia-related behaviours. However, a Cochrane review revealed that these agents are ineffective to treat agitation and have an unacceptable rate of adverse effects, including somnolence, thrombocytopenia, infection (Lonergan and Luxenberg, 2009).

Depression

Depression occurs in up to 50% of individuals with Alzheimer's disease and is often chronic in nature (Steinberg et al., 2004). The diagnosis of depression is often difficult to make in a patient with dementia because cognitive impairment leads to poor recall and reporting of depressive symptoms. In addition, depression can present atypically in dementia, often manifesting as behavioural symptoms, such as physical aggression, vocalizations, or refusal to eat.

The evidence supporting the use of antidepressant drugs to treat depression in those with Alzheimer's disease is limited, with published controlled trials reporting equivocal results. The Depression in Alzheimer's disease study, phase 2 (DIADS-2) trial and the HTA-SADD study are the largest randomized controlled trials of an antidepressant to date in this population (Rosenberg et al., 2010; Banerjee et al., 2011). In DIADS-2, individuals with depression and mild-to-moderate Alzheimer's disease were randomly assigned to receive sertraline or placebo. No significant benefits were reported in mood, non-mood neuropsychiatric symptoms, function, quality of life, or global cognition at either 12 or 24 weeks. Adverse events were more frequent in patients randomized to receive sertraline than those who received placebo. Patients who received the drug experienced diarrhoea, dizziness, dry mouth, and pulmonary serious adverse events. The HCT-SADD trial compared both sertraline and mirtazapine against placebo and found no benefits at 13 and 39 weeks for both.

If the clinical decision is made to offer drug therapy to a patient with dementia and comorbid depression, the usual first-line treatment in patients with Alzheimer's disease should be a selective serotonin reuptake inhibitor (SSRI), serotonin and norepinephrine (noradrenaline) reuptake inhibitor (SNRI), or a norepinephrine reuptake inhibitor (NRI), as they have less risk for adverse effects than the tricyclic antidepressants and monoamine oxidase inhibitors. Choice of a specific agent should be based on past

effectiveness, medical comorbidities, potential side effects, and pharmacologic interactions.

Cognitive decline

Individuals with Alzheimer's disease have decreased production of choline acetyl transferase, resulting in reduced acetylcholine synthesis and impaired cortical cholinergic function. Cholinesterase inhibitors, such as donepezil, galantamine, and rivastigmine, affect the clinical manifestations of Alzheimer's disease by increasing cholinergic transmission. Memantine, an *N*-methyl-D-aspartate (NMDA) antagonist, has a mechanism of action distinct from that of the acetylcholinesterase inhibitors.

Use of cholinesterase inhibitors or memantine in patients with moderate-to-severe Alzheimer's disease results in statistically significant improvements in cognitive, functional, and behavioural outcomes (Birks, 2006). However, the clinical significance of these outcomes is modest at best. The addition of memantine to acetylcholinesterase inhibitors also seems to be of little value (Howard et al., 2012). No significant benefits were observed from the combination of donepezil and memantine over donepezil alone in a trial of 295 patients with moderate to severe disease who were already taking donepezil (Howard et al., 2012).

Cholinesterase inhibitors also may improve outcomes in non-Alzheimer's dementia, including vascular dementia and DLB. In particular, patients with DLB may have significant improvements in behavioural symptoms and hallucinations, in addition to small improvements in cognition (McKeith et al., 2000).

Despite the lack of evidence that cholinesterase inhibitors and memantine are efficacious in individuals with very advanced dementia or those who are near the end of life, they are commonly used. For example, a study of hospice enrolees with dementia observed that 21.3% were prescribed at least one of these medications (Weschules et al., 2008). Nearly one-third of patients who receive cholinesterase inhibitors experience an adverse effect, with nausea, vomiting, and diarrhoea the most common (Birks, 2006), and in community-dwelling older adults, use of these drugs is associated with increased risks of syncope, bradycardia, permanent pacemaker insertion, and hip fracture (Gill et al., 2009). Given the lack of established benefit and risk of adverse events, both cholinesterase inhibitors and memantine generally should be discontinued or avoided in populations with far advanced dementia or short life expectancy.

Eating and swallowing problems

Eating and swallowing difficulties become nearly universal as dementia progresses to the advanced stages. In one prospective study, over 85% of 323 nursing home residents with advanced dementia developed eating problems during an 18-month study period. In those who died, over 90% developed eating problems in the last 3 months of life. When these difficulties arise, family members and health-care providers are likely to be confronted with the decision to administer food and fluids via a nasogastric tube or via a percutaneous endoscopic gastrostomy (PEG) tube. In the United States, placement of these tubes is common. Nearly one-third of nursing home residents with advanced dementia have feeding tubes placed, although there is great variation based on geography and nursing home characteristics (Ahronheim et al., 2001; Mitchell et al., 2003).

The frequency of feeding tube insertion is notable given the lack of evidence of benefit. Numerous observational studies have demonstrated that feeding tubes do not improve survival, prevent aspiration pneumonia, decrease the risk for pressure ulcers, or improve patient comfort (Finucane et al., 1999; Teno et al., 2012). Harms of feeding tube placement are well documented in the literature, although not often discussed by physicians prior to tube insertion (Teno et al., 2011). In one study, one in five tube-fed residents experienced a tube-related complication necessitating a hospital transfer in the year following insertion. Furthermore, over one-third of individuals required physical or pharmacologic restraints to prevent tube dislodgement (Teno et al., 2011).

It is important to consider potential modifiable factors when eating problems arise in individuals with dementia. Comorbid illnesses like depression, medication side effects, and oral health problems, such as xerostomia, are among the many conditions that may result in reduced oral intake, followed by weight loss. When no modifiable factors are identifiable, careful hand feeding and proper oral care should be recommended as better alternatives than PEG placement for individuals with advanced dementia (Yoneyama et al., 2002).

Palliative care interventions in dementia

In addition to symptom management, care for individuals with advanced dementia should involve a number of key palliative interventions, including advance care planning, avoidance of potentially inappropriate interventions, hospice referral, and caregiver support. There is now ample evidence showing improved outcomes for patients and caregivers when such interventions are performed (Engel et al., 2006).

Advanced care planning

Advance care planning is important for all patients with serious illness, but the types of decisions that have to be made are especially difficult when the patient suffers from advanced dementia and may not be able to communicate. Patient preferences are often not documented early despite the anticipated loss of capacity that occurs with dementia. A common reason for this is that family members often do not realize the importance of discussing advanced care plans with their love one until it is too late to have the discussion (Hirschman et al., 2008). Clinicians should routinely lead end-of-life planning conversations with dementia patients and families before moments of crisis, such as hospitalization for aspiration or fever. This is particularly important given the finding that nursing home residents whose health-care agents had an understanding of the poor prognosis and the clinical complications expected in advanced dementia were much less likely to have burdensome interventions in the last 3 months of life than were residents whose agents did not have this understanding (Mitchell et al., 2009).

Before clinicians discuss specifics, the planning conversations should explore overall patient values and goals, including whether comfort and quality of life are viewed as overriding priorities. Later, these views may be more helpful for surrogate decision-makers when asked to weigh the risks and benefits of the many interventions frequently performed on those with advanced dementia. Specific aspects of care, such as artificial nutrition and hydration, intubation, cardiopulmonary resuscitation, and other common medical interventions, should be discussed and this discussion should be documented in an advance directive.

A key element of this advance care planning is the selection by the patient of an agent, who would make decisions on behalf of the patient should he or she lack the capacity to do so. This agent is given written durable power of attorney to make health decisions when the patient loses capacity.

The discussion of prognosis is inextricably linked to the discussion of goals of care and advance care planning. Conveying information about prognosis is clinically challenging, and patients or families often misperceive or discount the information. This may result from a misunderstanding of medical terms, such as 'controlled' or 'terminal', or from a lack of consistency in the messages provided by different clinicians. Patients and families often ask several clinicians the same questions about prognosis, and all members of the clinical team should communicate the same information in a consistent fashion. Many physicians are concerned about destroying hope when discussing goals of care in the context of poor prognosis (Davison and Simpson, 2006). Clinicians should be able to provide direct information about the disease while supporting a wide spectrum of realistic hopes that patients and families may have depending on the situation. 'Hope for the best, prepare for the worst' acknowledges that hope can be sustained while also planning for the occurrence of clinical situations that may change quickly.

New tools are being used for helping patients and families understand the realities of their prognosis. Older adults who viewed a video depiction of a patient with advanced dementia after hearing a verbal description of the condition were more likely to opt for comfort as their goal of care compared with those who solely listen to a verbal description (Volandes et al., 2009). They also had more stable preferences over time (Volandes et al., 2007). In another study, the use of videos led to decision-making that was more patient focused, dealing with issues such as quality of life and effects on the family, and less conventionally treatment centric, with an intent to preserve life as long as possible (Deep et al., 2010).

Avoidance of potentially burdensome treatments

Hospitalization is often considered when individuals with advanced dementia develop infections such as pneumonia (Volicer et al., 2003). Hospitalization for an infection should be thought of as a significant event in the course of advanced dementia, as it heralds an increased short-term morbidity and mortality. Some data suggest that the hospital may not be the optimal setting for the treatment of pneumonia, at least for nursing home residents; mortality rates appear similar whether treatment is provided in a nursing home or hospital, with some evidence suggesting greater functional decline in hospitalized residents (Fried et al., 1995, 1997; Mylotte et al., 1998).

Pneumonia is the most commonly identified cause of death among individuals with advanced Alzheimer's disease and the treatment of pneumonia in this context may be challenging. In one recent prospective study of 323 nursing home residents with advanced dementia, antibiotic therapy for episodes of pneumonia improved survival compared with no antibiotic treatment, but also was associated with lower scores on the Symptom Management at End-of-Life in Dementia scale, indicating more discomfort compared to untreated residents (Givens et al., 2010). If antibiotics are not given, comfort can adequately maintained with aggressive use of antipyretics, analgesics, and oxygen if hypoxic.

Hospice

In the United States, hospice is a health-care system supported by the government and intended to provide specialist palliative care for patients approaching death and their families. Most patients are treated in the home, although care also can be provided in other settings, such as nursing homes. Other countries maintain other models of hospice, most focused on end-of-life care. Whatever the model, a specialized programme for end-of-life care, such as hospice, should be considered when patients with dementia progress into an advanced stage of the illness. In the United States, use of hospice in this population has been associated with improved patient and caregiver outcomes compared to usual care (Mitchell et al., 2007), including improved pain management, less aggressive care at the end of life (Miller et al., 2001), fewer unmet needs during the last 7 days of life (Kiely et al., 2010), and greater satisfaction among family members with end-of-life care (Shega et al., 2008). Individuals with advanced dementia who are enrolled in hospice are also more likely to die in their location of choice and less likely to die in the hospital (Shega et al., 2008).

Use of hospice services in the United States has been increasing over the last decade. For instance, Miller and colleagues found that hospice use for nursing home decedents with advanced dementia increased from 15% in 1999 to 43% in 2006 (Miller et al., 2010). The use of hospice benefits may be underutilized in part because prognostication is uncertain and restrictive hospice eligibility guidelines impact early referrals. In the same study by Miller and colleagues, a quarter of individuals were enrolled in hospice for 1 week or less prior to their death (Brickner et al., 2004; Miller et al., 2010).

Caregiver support

The majority of care provided to individuals with dementia is done at home and by family caregivers. This care is a physically, emotionally, and financially stressful experience that has been associated with a range of adverse health outcomes including high rates of anxiety and depression. There is now good evidence to suggest that interventions that combine caregiver education, counselling, and support can improve caregiver health. Callahan and colleagues developed a collaborative care model that involved advanced practice nurses integrated within a primary care clinic. In a randomized controlled trial of this intervention, the authors found significant improvements in caregiver distress and depression (Callahan et al., 2006). Another model, REACH II (Resources for Enhancing Alzheimer's Caregiver Health), focused on enhancing caregivers' coping skills and management of dementia-related behaviours by using a multicomponent home- and telephone-based intervention (Belle et al., 2006). REACH II significantly improved caregiver quality of life in terms of burden, depression, self-care and healthy behaviours, social support, and management of patient problem behaviours. Unfortunately, these proven multicomponent interventions are not available to most caregivers.

Conclusion

Although dementia is caused by a heterogeneous group of disorders, its relentless progression ultimately creates a common set of problems for the patients who are affected and their families. Meticulous assessment of unmet needs for palliative care will

identify opportunities for interventions that can reduce suffering and illness burden, and ensure that clinical decisions in the setting of far advanced illness are medically appropriate and consistent with the values of the patient.

Neurological disorders other than dementia

Raymond Voltz, Stefan Lorenzl, and Georg S. Nübling

Introduction to neurological disorders other than dementia

Whereas a palliative care approach is commonly accepted in the care of patients with glioblastoma or brain metastases, this is not yet so for many other neurological disorders. Having said that, it must be remembered that Dame Cicely Saunders, in her visionary concept, had included the care of patients with amyotrophic lateral sclerosis (ALS) or motor neuron disease. It has become clear in recent years that her 'total pain' concept, multiprofessional approach, early palliative care integration, and academic models all are very relevant to many patients suffering from neurological disorders.

Causes of death

What do patients with neurological disorders die of? How do they die? Very often this is not known to the specialist neurology services that typically stop caring for patients when they cannot attend clinics any more. These patients are then cared for at home or in nursing homes, often with little or no connection to palliative care or neurology.

Evidence is emerging that a palliative care approach would be very helpful for patients with many types of neurological diseases. One example is multiple sclerosis (MS). Although there is a common belief that patients do not die from MS (Voltz, 2010), the reality is that MS patients are threefold more likely to die prematurely in comparison to the general population (Hirst et al., 2008). Another common diagnosis classically not considered for palliative care services is ischaemic or haemorrhagic stroke. Although about 30% of patients die within the 'acute stroke' phase, defined as the first 30 days after the event (Roberts and Goldacre, 2003), and the event leaves another 30% permanently disabled with chronic deficits, this population is not recognized to have unmet palliative care needs. Experience with stroke patients is now emerging from palliative care services and it is apparent that specialist care can help with symptom control, psychosocial issues, and end-of-life decisions; the latter decisions often involve challenging scenarios such as withdrawal of mechanical ventilation, artificial nutrition, tracheostomy, and neurosurgical procedures (Burton et al., 2010; Holloway et al., 2010).

Palliative care may be very important even in more rare diagnoses, such as sporadic inclusion body myositis. Two recent, long-term observational studies demonstrated a high symptom burden of patients in end-stage disease; furthermore, 13% of patients died by euthanasia or terminal sedation, demonstrating the severe suffering of these patients near the end of their lives (Hohlfeld, 2011).

Although the proximate cause of death in neurological disorders often is an expected complication of a chronic illness, such as pneumonia (Hirst et al., 2008; Pennington et al., 2010), the downward trajectory of many of these illnesses means that decisions concerning withdrawal of life-sustaining therapy may be encountered before the acute terminal event occurs. In some settings that have legalized forms of physician-hastened death, the decisions are layered with even more complexity. In the Netherlands, for example, euthanasia seems to be even more an issue in neurological patients than in the cancer population. Whereas about 1% of the cancer population dies through euthanasia, it is about 20% in ALS, with the number being stable over recent years (Maessen et al., 2009). This potential for euthanasia increases the obligation to understand the nature of suffering associated with neurological conditions, and the varied means to address the contributing sources. In the example of ALS, both lay observers and professionals may believe that suffocation occurs at the end of life; this is not the case, however, and patients with ALS die a peaceful natural death, not only under hospice care but also in a neurology service (Neudert et al., 2001).

Neurological patients outside of the Netherland also seem to be at a high risk for developing a wish for hastening death or suicide. In MS, suicide is a frequent cause of death, and a long protracted course with severe neurological deficit in many leads to a wish for hastening death. In all these situations, the palliative care approach may identify the reasons behind this wish, assist and support, and may try to bring up the parallel existing will for life again (Voltz et al., 2011).

One of the obstacles in expanding access to palliative care for neurological patients is the relatively poor knowledge of palliative care approaches among the diverse professionals who care for these patients. Although palliative care is far broader than end-of-life care, the pivotal point that death is inevitable and likely to be soon may be a lever to improve palliative care skills in existing services, or to encourage referral to specialist palliative care. Teaching professionals about prognosis and the usual clinical course in advanced illness, such as by introducing 'death rounds' for physicians-in-training, is one way to underscore the life-limiting nature of neurological illnesses, teach about the role of palliative care throughout the course of the disease, and

learn from a group while sharing the emotions around a death (Khot et al., 2011).

Amyotrophic lateral sclerosis

Motor neuron diseases are a group of syndromes affecting the primary and/or secondary motor neurons, with ALS being the most common and most severe manifestation. ALS is the most frequent neurological disease on palliative care wards. Thus, knowledge of the symptoms, course of disease, and treatment options is essential for palliative care specialists.

Amyotrophic lateral sclerosis: a brief summary

The incidence of ALS is estimated at approximately 2/100 000 per year, with a mildly elevated risk for male gender (Logroscino et al., 2010). The life expectancy of ALS patients averages at 2–4 years from symptom onset (Forsgren et al., 1983). Two manifestations of the disease are mainly recognized. The spinal variant is characterized by early, often asymmetric tetraparesis, and late onset of deficits in cranial nerve function. The bulbar variant occurs in approximately 20% of all cases and presents with a predominant affection of speech and swallowing, followed by progressive muscle weakness. Neurobehavioural dysfunction such as apathy, disinhibition, or dysexecutive behaviour occurs in a significant proportion of patients (Chio et al., 2012). In the course of the disease, patients suffer from decreased mobility, loss of speech and swallowing, and progressive dyspnoea. Additional symptoms frequently occur, including dysphagia, dysarthrophonia, dyspnoea, mucous congestion of airways, muscle cramps, and sleep disturbance.

Approaches to treatment

Since ALS is a fatal disorder invariably leading to progressive disability and death, treatment has to be adapted to the patient's preferences. While some patients may be willing to take any action to prolong survival, others refrain from invasive treatment options, given the severe disability and family burden accompanying late stages of the disease. Detailed discussions about the course of disease, benefits, and disadvantages of treatment options, as well as the patient's personal preferences are essential and should be addressed at an early stage of the disease, to help all personnel involved to best understand each patient's values and expectations. Advanced directives ensure the patient's autonomy and provide an important assurance for caregivers and clinicians. Importantly, the patient has to be aware that life-prolonging treatments do not have to be carried out indefinitely, and that symptom control is always an alternative.

Symptoms and treatment options

In ALS, symptoms occur at various time points and with various severities, rendering a stepwise treatment plan impossible. Early recognition and treatment are essential to preserve quality of life for patients and their caregivers. The diversity and rapid progression of symptoms often require a multidisciplinary approach. Treatment options are summarized in the section 'Medication at the end of life'.

Respiratory insufficiency

Respiratory insufficiency invariably occurs in the course of disease. The treatment strategy largely depends on the patient's preferences, and for this reason, prolonged artificial ventilation and tracheostomy should be discussed early. Pre-emptive measurements to prevent secondary causes of respiratory insufficiency, such as yearly influenza vaccinations or polyvalent pneumococcal vaccines, are recommended. Supplemental oxygen can lead to carbon dioxide retention and should not be used routinely.

Respiratory insufficiency is commonly treated with non-invasive positive pressure ventilation (NIPPV), which has been shown to prolong survival and improve quality of life (Bourke et al., 2006; Andersen et al., 2012). NIPPV is often started as a nocturnal measure in patients showing signs of nocturnal hypoventilation, such as morning headaches and increased daytime sleepiness. Objective measures that can be used to justify the start of NIPPV include percutaneous nocturnal oximetry and forced vital capacity (FVC). Although definite criteria for the initiation of NIPPV have not been established, there is some evidence suggesting a pronounced effect on survival if NIPPV is started at FVC values greater than 65% (Lechtzin et al., 2007). Furthermore, the indication for NIPPV treatment has to be appraised critically in patients with neurobehavioural impairment, where decreased efficiency was observed (Chio et al., 2012).

As the disease progresses, the use of NIPPV is often extended to daytime. The patient must be aware that NIPPV use cannot be extended indefinitely, and that termination of NIPPV in advanced respiratory failure without prior tracheostomy will result in rapid hypoventilation and death. Weaning off NIPPV in patients declining invasive ventilation must be carried out under morphine and benzodiazepine treatment to prevent dyspnoea and anxiety. Thus, advanced directives for the treatment strategy at this point are strongly recommended. It is an ongoing debate whether pre-emptive use of palliative sedation could be an option in this situation (Berger, 2012).

While tracheostomy extends life in ALS, its impact on patient and caregiver quality of life has to be considered carefully. Furthermore, patients with invasive ventilation are often denied access to palliative care wards. Dyspnoea, whether occurring during NIPPV treatment or spontaneously, is best controlled by opioids. Depending on concomitant symptoms, these can be administered orally, nasally, transdermally, or via continuous subcutaneous infusion using a syringe driver. Dyspnoea-related anxiety is best managed by addition of benzodiazepines, such as oral or sublingual lorazepam or midazolam.

Mucous congestion of the airways

Mucous congestion is difficult to manage in patients with impaired coughing. Treatment with mucolytics such as ambroxol or *N*-acetylcysteine may be attempted, but are of limited benefit. A combination of beta receptor antagonists, nebulized saline, and furosemide is recommended (Andersen et al., 2012). Guided respiratory exercise is mostly considered helpful by patients. The use of mechanical aids such as the CoughAssist®, high-frequency chest wall oscillation, or a home suction device can be applied.

Malnutrition

Malnutrition in ALS mainly results from dysphagia and hypermetabolism. Since malnutrition entails a poor prognosis, treatment of dysphagia plays an important role in ALS (Marin et al., 2011). Early swallowing deficits can be improved by speech and language therapy. At this time, referral to a dietician should also be discussed. Feeding tube placement should be discussed early, since

many patients are reluctant to undergo this measure. Gastrostomy can be performed under endoscopic control, while radiologic guidance should be preferred in patients with respiratory insufficiency or severe mouth opening dystonia (Thornton et al., 2002; Desport et al., 2005). In patients with neurobehavioural dysfunction, gastrostomy showed poor outcome (Chio et al., 2012).

Sialorrhoea

Sialorrhoea and drooling are commonly associated with swallowing deficits. Non-pharmacological treatment options include sage tea and consultation with a speech and language therapist to improve swallowing. Pharmacological treatment should begin with low-dose amitriptyline or a hyoscine hydrobromide transdermal patch. Atropine sulphate can be used orally as a permanent medication. For the inpatient setting, subcutaneous atropine sulphate and glycopyrrolate are available. If pharmacological treatment fails, injections of botulinum toxin A or B in the salivary glands (Jackson et al., 2009; Guidubaldi et al., 2011) or salivary gland radiotherapy might be considered.

Spasticity and muscle cramps

Spasticity often occurs in patients with predominant affection of the primary motor neuron. Spasticity may lead to discomfort, pain, and decreased mobility. Physiotherapy should be applied to maintain a full range of motion and avoid contractures (Andersen et al., 2012). While pharmacological treatment with baclofen or tizanidine efficiently reliefs spasticity, patients often discontinue treatment due to side effects such as asthenia and general muscle weakness. Furthermore, treatment of lower limb spasticity can further decrease mobility in patients with preserved ambulatory function and should thus be considered carefully in these cases. Nabiximols, a synthetic cannabinoid, is approved for treatment of therapy-refractory spasticity in multiple sclerosis in several European countries and Canada, and may be considered as an off-label use to treat spasticity in ALS. Focal spasticity can be treated with repeated injections of botulinum toxin A, although literature concerning its use in ALS is sparse.

Muscle cramps often occur early, and can cause significant discomfort and sleep disturbance. The current guidelines from the European Federation of Neurological Societies (EFNS) recommend levetiracetam as first-line treatment (Andersen et al., 2012), but quinidine sulphate also offers effective relief and is the treatment of choice in our outpatient department. Alternatively, phenytoin or carbamazepine can be tried.

Insomnia and fatigue

Insomnia may occur due to various reasons such as muscle cramps, pain, respiratory distress, or depression. If treatment of these symptoms does not restore sufficient sleeping quality, antidepressants (amitriptyline, mirtazapine) or hypnotics (zolpidem) can be applied. For debilitating fatigue, modafinil or another psychostimulant such as methylphenidate may be tried (Andersen et al., 2012).

Pseudobulbar affect

Pseudobulbar affect results from corticobulbar degeneration and manifests in inappropriate laughter or crying incongruent to the patient's mood. It can largely affect social interactions and strain both patients and caregivers. It is of great importance to point out to relatives and caregivers that the patient is completely unable to control their emotional outbursts and that they do not reflect their actual mood, since these outbursts are often perceived to be offensive.

A combination of dextromethorphan and quinidine has been approved by the US Food and Drug Administration for use in pseudobulbar affect, but there also is evidence to suggest a positive treatment effect of antidepressants, mainly citalopram and amitriptyline (Pioro, 2011). Antidepressants might be attempted especially if concomitant depression is suspected.

Depression, suicidality, and death

The inevitable prognosis and continuous, rapid decline often lead to despair and depression in ALS patients. The widespread belief that death in ALS usually occurs through suffocation further increases many patient's wish for an early termination of their suffering through physician-hastened death. ALS patients must be monitored carefully and repeatedly for signs of depression. In particular, if continuous psychosocial support is insufficient or unavailable, antidepressants should be used (Andersen et al., 2012), with the choice of medication being partially directed by concomitant symptoms. For example, if drooling is present, a tricyclic antidepressant such as amitriptyline should be used.

Suicidality and the wish for physician-hastened death is an important issue in ALS. Up to 20% of ALS patients opt for physician-hastened death in countries where this is a legal option (Maessen et al., 2009). We repeatedly experience patients asking for physician-hastened death, both in our outpatient department and on our palliative care unit. The reasons for such requests are mainly the fear of an excruciating death, loss of personal autonomy, or fatigue (Maessen et al., 2009). However, in almost all cases patients can be convinced that appropriate symptom control and pre-emptive measurements to maintain a maximum of autonomy are sufficient to refrain from such measures. Most patients die a sudden, non-violent death, often while sleeping. This might be due to nocturnal hypoxia or autonomic failure may be due to constant hypoxia.

Patient management

ALS is a rapidly progressive disease requiring anticipatory planning and regular re-evaluation of the patient's condition. It is of great importance to inform patients and caregivers of the progressive nature of the disease, as well as of common symptoms such as tetraparesis, dyspnoea, and respiratory insufficiency. Advance directives should be issued early and updated regularly. Swift management of issues related to supportive care and assistive equipment is essential to avoid additional burden for both patients and relatives. Since caregivers are often over-challenged by the multitude of organizational tasks, bringing social workers or other organizational resources into care management can greatly alleviate caregiver burden. The symptoms occurring in the course of disease require a multiprofessional approach, which should best be organized by a single person or institution, for example, a nurse practitioner, a general practitioner, or a specialized ambulant palliative care team. The ALS Peer Workgroup recently suggested triggers for hospice referral for ALS patients (McCluskey and Houseman, 2004).

Given the often devastating course of disease in ALS, the psychosocial, spiritual, physical, and financial burden for the primary caregivers must always be considered. Caregivers are usually inexperienced in patient care. Furthermore, information on practical issues such as requesting therapeutic appliances is usually sparse.

Inpatient treatment of ALS patients offers the unique opportunity to address psychological, spiritual, as well as practical issues, with both patients and the caregivers.

Parkinsonian syndromes

Parkinson's disease and related conditions

Parkinson's disease (PD) and Parkinson-related conditions such as progressive supranuclear palsy (PSP), multiple system atrophy (MSA), and corticobasal degeneration (CBD), are more common than ALS and have a longer course of the disease. No disease-modifying or effective neuroprotective agents are currently available for PD. Disease trajectory is frequently divided into the supportive phase, the phase of transition, and the terminal phase (Bunting-Perry, 2006).

Distressing motor symptoms include bradykinesia, muscle rigidity, dystonia, instability of gait, and tremor. Physiotherapy is the mainstay of non-pharmacologic therapy to improve balance and self-confidence. Painful dyskinesias and dystonias are distressing for patients and carers and require aggressive management. More frequent and lower doses of carbidopa/levodopa might improve motor fluctuations. Controlled release preparations, adding a dopamine agonist, or amantadine are other considerations.

Autonomic dysfunction such as orthostatic hypotension is common in MSA but may occur in PD as well. Increased sweating, delayed gastric emptying, constipation, sialorrhoea, urinary urge incontinence, and erectile dysfunction are also part of the dysautonomic spectrum of Parkinson-related disorders.

Progressive dysphagia is due to rigidity and hypokinesis as well as the gradual involvement of the dorsal motor nucleus of the vagus nerve in the disease process. There is no evidence to suggest a survival or quality of life benefit by feeding tube placement in advanced parkinsonism (Yamazaki et al., 2011). This remains an individual decision following discussion with patient and caregivers.

Depression, panic attacks, and anxiety are frequent psychological features of parkinsonism. There are conflicting data on the effectiveness of selective serotonin reuptake inhibitors (SSRIs) versus tricyclic antidepressants in the management of depression associated with PD. SSRIs are frequently preferred because of their more favourable side effect profile. While a concern of many specialists, large studies have not demonstrated that SSRIs worsen motor symptoms in PD.

Psychosis, hallucinations, and delusions are common in Parkinson-related disorders. Dose reduction of antiparkinsonian medication often helps. If hallucinations are a source of distress, it is recommended that anticholinergic drugs should be withdrawn first, followed by amantadine, catechol-O-methyl transferase inhibitors, and dopamine agonists if necessary. Stopping levodopa treatment is not usually an option, but a dose reduction might be attempted. Low doses of atypical neuroleptics (e.g. quetiapine, 25 mg/day) can be beneficial without significantly worsening motor symptoms.

Day time sleepiness and complex sleep disorders are often associated with advanced PD. Restless legs syndrome responds well to low-dose dopamine agonists before bedtime. Valproic acid, gabapentin, and benzodiazepines are also useful in this situation. Rapid eye movement (REM) sleep behaviour disorder (RBD) is often an early symptom of PD, manifesting in complex active behaviour during REM sleep. Most dopaminergic drugs as well as anticholinergics worsen RBD.

Cognitive dysfunction is very common in this patient group and different from the neuropsychological features of Alzheimer's disease. Executive dysfunction and visuospatial impairment are usually present, while the initial memory impairment is less prominent. Cholinesterase inhibitors (CI) are used with moderate success (Rolinski et al., 2012). The potential benefit of CIs has to be weighed against worsening tremor and nausea.

Atypical parkinsonian disorders

The term 'atypical parkinsonian disorders' (APD) encompasses a group of conditions displaying Parkinson-like symptoms that do not or poorly respond to antiparkinsonian drugs. These syndromes frequently present with distinguishing symptoms that are seldom seen in PD. They are also referred to as Parkinson-plus disorders and have distinct neuropathological characteristics. The most common diseases of this group include PSP, CBD, dementia with Lewy bodies (DLB), and MSA. Despite these conditions being rapidly progressive, there is now evidence that quality of life can be preserved with high-quality palliative care. This is especially true in PSP and MSA.

In contrast to the normal life expectancy of patients suffering from PD, the median survival of APD is estimated at 6 years for PSP, 9.5 years for MSA, 7 years for CBD, and 9 years for DLB. Although these conditions do share similar features, their presentation and therapeutic challenges are very different. For example, increased sensitivity to neuroleptics is highly specific to DLB and presents with impaired consciousness and severe acute parkinsonism regardless of the dose administered. Anticholinergic agents and tricyclic antidepressant should be avoided if orthostatic hypotension is present, and benzodiazepines frequently cause paradoxical agitation in DLB.

Atypical Parkinsonian disorders are not traditionally managed by palliative care teams. However, since there are no disease-modifying agents available and the wide spectrum of symptoms have a significant impact on the quality of life of the patients and families, palliative care intervention has a lot to offer in the management of these conditions.

Symptomatic management of atypical parkinsonian disorders

Motor function

Motor symptoms are often the presenting symptoms in parkinsonian disorders, and dopaminergic agents may offer temporary relief. The most commonly used drugs are carbidopa/levodopa, amantadine, imipramine, and selegiline. Zolpidem has been reported to improve eye movements in PSP, but benefit is transient and sedation is likely (Cotter et al., 2010). As the antiparkinsonian medications become ineffective over time, they can be gradually reduced and even discontinued. As the patient becomes more and more disabled and persistent neuropsychiatric problems develop, the priority of care shifts to preservation of quality of life through effective symptom control.

Neck and back pain is very common in advanced atypical parkinsonian disorders. Similarly to PD, it arises from stiffness, rigidity, or dystonic spasms. Treatment with botulinum toxin can reduce dystonia and consequently dystonia-associated pain,

but often fails to improve coordination and motor function. Alternatively, analgesics can be prescribed according to the World Health Organization analgesic ladder approach.

Falls occur frequently in PSP and MSA and can cause serious injuries. In PSP, amitriptyline might reduce the frequency of falls in the early stages of the disease. Occupational therapists often suggest helmets and other safety devices, such as transfer belts or grab bars to prevent or cushion falls. Despite these measures, insight and safety awareness becomes a problem as cognitive deficits develop.

Myoclonus might be present in PSP, CBD, and MSA, and treatment usually requires benzodiazepines (e.g. clonazepam) or levetiracetam. Blepharospasm or eyelid apraxia may be treated with botulinum toxin A injections, even in advanced stages of the diseases.

Dysautonomia

Dysautonomic symptoms are hallmark of MSA but occur across the whole spectrum of parkinsonian syndromes. Treatment options of orthostatic dysfunction include reduction of L-dopa, use of compression stockings, increased sodium intake, and improved hydration. If these measures prove to be ineffective, fludrocortisone (0.1–0.2 mg/day) and midodrine (2.5–10 mg three times a day) can be considered. Urgency and urinary incontinence are straining symptoms for patients with decreased mobility and occur frequently. If substances like oxybutinin or tolterodine show little effect, regular injections of botulinum toxin can be considered before suprapubic catheterization. Urinary tract infections should be identified early. Occasionally intermittent catheterization might be necessary. Erectile dysfunction might precede the onset of these conditions by years.

Dysarthria and dysphagia

Dysphagia and dysarthria are caused by extensive medullar neuronal loss and involvement of the corticobulbar pathways in the disease process. Oropharyngeal dystonia and impaired reflexes put patients at risk of choking and aspiration. However, feeding tube placement should be considered on a case-by-case basis, depending on the stage of the disease and respecting the patient's preferences. In dementia and parkinsonian syndromes, the decision between radiologically inserted gastrostomy versus percutaneous endoscopic gastrostomy depends on tolerance of sedation and local policies.

Psychiatric symptoms

Personality and mood changes are common in each of these disorders and a characteristic clinical feature of DLB. The cognitive domains affected initially in DLB are executive function, attention, and visuospatial function as opposed to the amnestic deficits of Alzheimer's disease. Cognitive changes in MSA are less likely and occur later in the course of the disease. In PSP and CBD, patients gradually develop subcortical dementia, characterized by mental slowing, language deficits, impaired memory, apathy, and irritability. A pronounced frontotemporal pattern was noted in a subset of patients with PSP. Cholinergic deficits are thought to underlie the cognitive impairment of PSP, but trials of cholinergic agonists and cholinesterase inhibitors have failed to show improvement. Impulsive behaviour might be treated with SSRIs, but amitriptyline can also be effective if the anticholinergic side effects are acceptable.

Sleep disorders

Sleep disorders such as insomnia, daytime somnolence, sleep apnoea, and restless leg syndrome are not uncommon in atypical parkinsonism and can be managed effectively. RBD is a prominent feature of DLB that describes complex motor manifestations of vivid dreams. Patients with RBD might harm themselves or their partners. Treatment options include bedtime clonazepam, and melatonin.

The last phase

In their last days of life, patients with parkinsonian syndromes often suffer from pneumonia. Bradykinesia increases dramatically, and often even spasticity is seen. Communication might not been possible due to severe generalized dystonia (including larynx and pharynx muscles as well as mouth opening dystonia). Eyes are often wide open, but apparently there is an inability to control eye movements. Seizures as well as myoclonic jerks occur frequently. Since extensive stiffness often is distressing for both patients and caregivers at this stage, transdermal dopamine agonists or subcutaneous apomorphine can be considered. Nausea and vomiting, a common complaint of apomorphine treatment, is usually not observed in late-stage patients. It is not rare for patients to exhibit profound cachexia, even if tube feeding has been placed earlier on. However, patients are often able to understand and make decisions. Therefore, decisions regarding life-limiting procedures should be discussed not only with the relatives but also with the patient. In our experience, most patients with parkinsonian syndromes refuse life-prolonging therapies.

Multiple sclerosis

MS is an inflammatory autoimmune disorder affecting about 2.5 million people worldwide and representing the most common cause of neurological disability among young adults in some countries. In recent years, novel immunomodulatory therapies have emerged and have been able to modify disease activity significantly (Miller and Rhoades, 2012). However, what this means in the long-term course of the disease remains to be seen, as MS remains incurable, and many patients who are severely affected today never had the chance to receive these modern treatments. Because of the complex clinical situation with a large range of physical symptoms and psychosocial issues, and a large proportion of patients with a wish for hastened death, care models are arising including palliative care services for severely affected patients.

What does it mean to be severely affected? The physical status is generally measured using the 'Expanded Disability Status Score' (EDSS). However, measuring only physical impairment, this alone is not sufficient to measure the full impact of the disease (Gruenewald et al., 2004). A purely subjective feeling of being 'severely affected' will identify MS patients with a longer disease duration, more likely to be of a progressive form, and having an EDSS of 6.5 (range 1–9.5) (Strupp et al., 2012).

In this patient group, there are many unmet needs. Starting with a mean of nine symptoms, mainly neurological symptoms, such as difficulty using legs or arms, fatigue, or spasticity, MS compares with other diagnoses that have conventionally been the targets for specialist palliative care, such as cancer, heart disease, or lung disease (Higginson et al., 2006). Patients, relatives, and

Table 15.5.1 Drug treatment options in symptoms in neurodegenerative disorders. Choice of therapy should be made considering optimal route of application and concomitant symptoms

Symptom control in neurodegenerative diseases	
Constipation	Ensure sufficient hydration Many options: (1) osmotic laxatives such as lactulose or polyethylene glycol, (2) stimulant laxatives such as senna, (3) 5-HT agonists such as prucaloprid, or (4) opioid antagonists such as methylnaltrexone
Dyspnoea	Opioids (e.g. in the opioid-naïve, oral morphine at a starting dose of 2 mg every 4 hours or transdermal fentanyl at 12 micrograms/hour)
Dyspnoea-related anxiety	Fast-acting anxiolytics (e.g. sublingual lorazepam 0.5–1.0 mg every 4 hours as needed) and/or continuous benzodiazepine therapy (e.g. lorazepam 1–2 mg every 6 hours or midazolam 10–30 mg/day)
Fatigue	SSRI (e.g. citalopram 20 mg/day) or a psychostimulant (e.g. modafinil starting at 100 mg daily or methylphenidate starting at 5 mg twice daily)
Muscle cramps	Quinidine sulphate 200 mg daily
Pain	Depending on severity and chronicity, trials of drugs such as tilidine, metamizole, tramadol, or tapentadol may be considered, or treatment with oral morphine or alternative pure mu agonist may be used; non-traditional analgesics, such as an analgesic antidepressant (e.g. a tricyclic or a serotonin-norepinephrine reuptake inhibitor), also are tried
Pseudobulbar affect	First choice: dextromethorphan/quinidine 20 mg/10 mg daily, increasing to twice daily after 1 week; an alternative choice would be a SSRI
Pseudohypersalivation	Sage tea Amitriptyline, 25 mg once a day Hyoscine hydrobromide transdermal patch, initially ¼ patch daily Botulinum toxin A, e.g. 50 IE injected in the salivary glands Salivary gland radiotherapy
Psychosis, agitation, irritability, dysphoria	Create a calm and stable environment Quetiapine (25–50 mg/day), clozapine
REM sleep behaviour disorder (RBD)	Clonazepam (0.25–1.5 mg), melatonin (3–12 mg)
Respiratory failure	NIPPV Tracheostomy Symptomatic treatment with opioids, e.g. morphine (see 'Dyspnoea')
Rigidity, brady-/akinesia Note: severe akinesia is rare	Amantadine IV, PO (600 mg/day) Rotigotine patch (2–8 mg/day) Apomorphine SC (6 mg/hour) Midazolam IV, SC (60 mg/day)
Sleeplessness	Zopiclone, zolpidem Amitriptyline (25 mg PO, especially if hypersalivation is present) Mirtazapine Quetiapine (25 mg PO)
Spasticity	Physiotherapy Baclofen (e.g. starting dose of 5 mg twice daily, titrated upwards as needed), Tizanidine (e.g. starting dose of 2 mg at night, titrated upwards as a twice-daily dose as necessary) Botulinum toxin A
Thick secretions	Ensure sufficient hydration Mucolytics, e.g. ambroxol, N-acetylcysteine Beta antagonists Supportive measures, such as nebulized saline, manually assisted coughing techniques, modified postural drainage, humidification, mechanical insufflation–insufflation devices, high-frequency chest wall oscillation

professionals all identify unmet needs in this population, and a full picture will only be achieved if all stakeholders' views are included (Golla et al., 2012).

One major aspect of care is the need for open communication about the disease status and fears arising from that. Patients constantly have to adapt to a new disease phase, sometimes a continuing process over years. The need for communication does not necessarily correlate with any 'objective' aspect of the disease, such as EDSS, duration of disease, age or the subjective feeling of being severely affected. Physicians just have to ask and find out

how much patients want to know. Patients expect us to talk about serious issues in MS with themselves as well as their loved ones (Buecken et al., 2012).

So what does this mean for the management of these patients? First, all health professionals involved in the care of severely affected MS patients should implement the core aspects of palliative care as a best practice. Second, coordination of helping services in a given region must also focus on this patient group, and include palliative and hospice services. For example, encouraging results have been observed using a regional coordination palliative care MS hotline in Cologne, Germany, for severely affected patients. Beyond coordination, it is valuable for specialists in palliative care to provide advice and help to existing MS services, a model which has been tested very successfully in London. There, significant changes were seen in symptom control (e.g. identification and treatment of nausea, use of opioids for neuropathic pain), the burden of relatives was reduced, and there was a diminished need for inpatient admission (Edmonds et al., 2010).

Of course, the provision of palliative care services to patients with MS still seems counter-intuitive to some patients, relatives, and professionals. The future will show, however, that integration of this service will be of great benefit to MS patients. As the European Code of Good Practice states: 'Clinical experience and the results of recent studies lead us to conclude that patients severely affected by MS in Europe should have access to palliative care assessment and services.'

Medication at the end of life

To date, there is no cure for patients suffering from neurodegenerative diseases. Nonetheless, effective drug treatment can alter the individual's functional status, offer improved symptom control, and may even prolong life in many of these disorders, such as PD or MS. However, most of these drugs have their greatest effects when the disease is at a very early stage. They often fail to prove useful in advanced stages, when symptom burden is higher.

In these late stages, pharmaceutical options may be further limited, for example, by swallowing deficits, malabsorption, polypharmacy, or comorbidity. Especially in neurodegenerative diseases with deficits of swallowing, late-stage medication thus has to be applied via alternative routes, such as subcutaneous, transdermal, or rectal. Table 15.5.1 summarizes pharmaceutical options for symptom control in neurodegenerative diseases, with respect to alternative routes of administration. No distinction is made between different disorders, since comparable symptoms often occur in late-stage neurodegeneration irrespective of the underlying disease.

End-stage kidney disease

Fliss E. M. Murtagh

Introduction to end-stage kidney disease

End-stage kidney disease (ESKD), like end-stage cardiac or respiratory disease, leads eventually to death. However, unlike cardiac or respiratory disease, life-sustaining treatment in the form of dialysis is available. Initially, dialysis was a short-term treatment for patients with acute renal failure, with no provision of longer-term maintenance dialysis for patients with chronic renal failure. But the first dialysis programmes started in the 1960s and have steadily expanded in subsequent decades. At first, older patients or those with multiple co-morbidities were excluded, but more recently, the criteria for dialysis have been relaxed, and many more patients have been accepted onto dialysis programmes. For example, the number of patients receiving dialysis in the United Kingdom rose fivefold, from 5000 in 1984 to 25 000 in 2006 (Ansell et al., 2007). This rise reflects several factors beyond increasing acceptance onto dialysis programmes, including an increase in the prevalence of renal disease, ethnic variations in renal disease, and an older population.

Despite technical advances and changes in the way dialysis is delivered, it still remains a challenging treatment for many patients. Dialysis usually requires invasive procedures and then protracted treatment sessions three times each week. While some uraemic symptoms are relieved by dialysis, the overall symptom burden of those receiving dialysis remains high (Murtagh et al., 2007c). For some patients with severe co-morbidity and short life expectancy, dialysis is either not feasible or is unlikely to improve quality or quantity of life. Other patients decide not to have dialysis, instead choosing conservative (non-dialytic) management of their renal disease. Their renal management then focuses on delaying progression of renal disease and controlling complications, alongside control of symptoms and psychosocial support as the disease progresses towards death.

There are, therefore, several groups of patients among those with ESKD who benefit from palliative care, whether that care is delivered by palliative care or nephrology clinicians, or by an integrated team which shares care across speciality boundaries. These patient groups are:

- those who choose or are advised not to embark on dialysis (conservative or non-dialytic management)

- those who are failing to thrive on dialysis, and who experience worsening quality of life and increasing symptom burden despite dialysis

- those who discontinue dialysis.

Epidemiology

It is estimated that the age-adjusted prevalence of stage 3–5 chronic kidney disease (CKD) in the United Kingdom is approximately 11% of women and 6% of men (Stevens et al., 2007). This is equivalent to 4 million people in the United Kingdom. A similar prevalence of CKD has been reported by studies from other countries (Chadban et al., 2003; Coresh et al., 2003). Only a small proportion of these will progress to ESKD, and to the time when a decision between conservative or dialysis treatment is required. Nevertheless, because the overall prevalence of CKD is relatively high, a large number of patients will reach ESKD.

Epidemiological studies also show that the prevalence of ESKD increases rapidly with advancing age. Stage 3–5 CKD is present in less than 1% of people under 35 years but is present in 40% of people over 75 years (Stevens et al., 2007). Initiation of dialysis is therefore much more frequent in the elderly, and the proportion increases sharply among those over 65 years, peaks between 75 and 85 years, and only drops off after 85 years. This strongly age-related nature of ESKD means that the numbers with ESKD will increase further as the overall population in developed countries ages. Certainly the number of patients on renal replacement therapy is increasing steadily and it is likely that this trend will continue for some years to come (Roderick et al., 2004). The United States Renal Data System (USRDS) reports 354 000 people on dialysis in 2006, with the prediction that this will increase to 533 000 by 2020 (USRDS, 2008). As the number of patients reaching ESKD increases, so will the number of patients choosing conservative treatment.

The exact number of patients who die of renal failure after conservative management (i.e. without receiving dialysis) is very difficult to ascertain, partly because of the lack of routinely collected data, but also because few population-based, rather than service-based, studies are conducted. Some patients with severe co-morbidity may never be referred to renal services. In reported series of patients known to renal services and managed in specialist low-clearance clinics, approximately 15–20% of those with declining renal function will follow a conservative pathway (Smith et al., 2003; Murtagh et al., 2007d). In reality, this figure is likely to vary considerably between units depending on the demographics of the catchment population, and on how services are structured. A national observational study in Australia indicates that about 14% (one in seven) of patients with ESKD referred to nephrologists plan not to dialyse (Morton et al., 2012b). Comprehensive service provision with integrated palliative care needs to be improved to meet the demands of the ageing population. There have always been some patients managed conservatively, without dialysis, but practice has varied over time and between countries (Lambie et al., 2006), and between individual nephrologists (Kee et al., 2000), and it is only recently that there has been greater recognition of the conservatively managed group of patients, with

systematic study beginning to be undertaken in order to address some of these very relevant questions.

Survival

There is limited evidence about the duration of survival of conservatively managed patients. First, although there have always been patients managed without dialysis, only recently has this group been recognized as a distinct population needing study. Second, it has been difficult to identify when survival should be measured *from*—patients may not require dialysis until well into stage 5 CKD, as they begin to experience worsening uraemic symptoms. And even if dialysis is planned, some will die of co-morbid disease before dialysis can commence, and others experience only a very slow decline in renal function, such that dialysis is not actually needed for some time. Third, documented survival may well reflect the demographics, co-morbidity, and local practice at any one renal unit, rather than mortality data that is readily generalizable.

There have been no prospective randomized trials which assess the benefit of dialysis versus conservative management in this population. The ethical challenges that this would raise are such that a randomized trial is unlikely to occur, and only a small number of observational studies are currently available to inform practice. Smith et al. report survival of 38 patients who, after multidisciplinary assessment, were recommended palliative (conservative) treatment rather than dialysis (Smith et al., 2003). In this cohort, ten patients did not follow the recommendation and instead chose to have dialysis, while the remainder followed the conservative pathway as recommended. Statistically, survival was not significantly different between the two groups, although numbers were small. A second study considered all patients over 75 years with stage 5 CKD managed in specialist nephrology care (Murtagh et al., 2007d). Notably, this study excluded those referred into nephrology care late, after estimated glomerular filtration rate (eGFR) reached less than 15 mL/minute (late referrals are more likely to be managed conservatively (Joly et al., 2003), and are known to have worse survival). Seventy-seven patients (60%) were established on a conservative (non-dialytic) treatment pathway (Murtagh et al., 2007d). Patients managed without dialysis had a 1- and 2-year survival (measured from first reaching stage 5 CKD) of 68% and 47% respectively. Those managed conservatively had a significantly worse survival than those on a dialysis pathway, suggesting some benefit from dialysis for older patients, at least in terms of survival. However, it was impossible to exclude a selection bias, with fitter patients choosing dialysis, and factors other than dialysis were almost certainly contributing to the better survival in the dialysis group. If the patients with higher co-morbidity were considered in isolation, then the difference in survival between the two groups was much reduced. More recent evidence from a recent larger study shows that median survival from entry into stage 5 CKD was less in conservatively managed patients (21.2 months) than those on dialysis (67.1 months, p < 0.001), but similarly for patients over 75 years with high co-morbidity and diabetes, this survival advantage was lost (Chandna et al., 2011).

When there is no residual renal function, patients withdrawing from dialysis have a very short survival, with the evidence reporting a mean survival between 8 to 10 days (Murtagh et al., 2007a).

Most patients will have a shorter survival than this, living just a few days after dialysis is discontinued, but the range is 1–46 days. If there is residual renal function, for instance, after a brief trial of dialysis, then survival can be very much longer (sometimes months), according to the level of residual renal function and the underlying disease processes.

Symptoms

There has been little study into the symptoms of those managed conservatively, without dialysis, although this may change as this population grows and there is greater recognition of their specific needs. Most of the work to date has been undertaken in the United Kingdom (Murtagh et al., 2007b, 2011; Noble et al., 2007, 2008; Murtagh, 2009), but needs to be duplicated in other settings and countries. There is some work on the patient experience of conservative management (Noble et al., 2008), and the impact of it on families and carers (Ashby et al., 2005; Low et al., 2008).

The symptom work that has been done shows that patients with conservatively managed stage 5 CKD have a high prevalence of symptoms (Murtagh et al., 2007b), similar in terms of overall burden to patients with advanced cancer, although with differences in the patterns of symptoms and the level of distress caused. Patients with ESKD are among the most symptomatic of any chronic disease group (Solano et al., 2006). Identifying and controlling symptoms is a high priority for patients and families (Steinhauser et al., 2000), and notably improves their quality of life (Weisbord et al., 2003). For those with ESKD, excellent symptom management becomes an increasingly high priority as the duration of time they remain dependent on chronic renal replacement therapy increases (Singer et al., 1999; Steinhauser et al., 2000). It is also important to recognize that, while renal replacement therapy in the form of dialysis provides major benefit, including symptom relief, it will not always ameliorate or abolish symptoms and may sometimes contribute to them.

Prevalence of specific symptoms

Anxiety and depression

Anxiety is reported as occurring in 12–52% and depression in 5–71% of dialysis patients (Murtagh et al., 2007e). Much of this variation reflects variation in the populations assessed, the definitions of anxiety and depression used, and the instruments used to detect them. Screening tools, such as the Beck Depression Inventory, tend to identify a somewhat higher proportion (45–50%) of potential depression than diagnostic tools, depending on the level of cut-off used (Kimmel, 2001, Wuerth et al., 2005). Patients managed without dialysis probably have similar levels of anxiety and depression, although evidence remains limited, and the prevalence of anxiety and depression likely increases over time (Murtagh et al., 2007c). They have a high prevalence of the symptoms of feeling anxious or sad (63% and 50%, respectively), and 45% have depressive scores above the standard cut-off on the Geriatric Depression Scale (Murtagh et al., 2007c).

Pain

Pain is a common problem for patients with advanced renal disease. In a recent Canadian study, 50% of all haemodialysis patients reported chronic pain, and over half of these described their pain

as severe (Davison, 2007). An Italian study reported a similar proportion (48%) of dialysis patients affected by pain (Mercadante et al., 2005), as did a US study which identified 50% of haemodialysis patients as reporting bone or joint pain (Weisbord et al., 2005). These studies demonstrate that pain is more common in dialysis patients than previously recognized. Pain prevalence in conservatively managed stage 5 CKD is similar, with baseline pain prevalence of 53% (Murtagh et al., 2007b), increasing markedly over time to affect 73% of patients by the month before death, with over half of these reporting severe pain (Murtagh et al., 2007c). For those withdrawing from dialysis, pain affects about 50% of patients (Cohen et al., 2000; Chater et al., 2006).

Pruritus

Numerous studies provide evidence on the prevalence of itch, suggesting that pruritus affects between 28% and 60% of patients on haemodialysis, and between 50% and 68% of those on peritoneal dialysis (Murtagh et al., 2007e). Four studies report higher prevalence still (between 70% and 74%) among haemodialysis patients (Merkus et al., 1999; Curtin et al., 2002; Subach and Marx, 2002; Dyachenko et al., 2006). Pruritus prevalence in those with stage 5 CKD managed without dialysis is also high (74%), suggesting it is similarly prevalent in those with ESKD not on dialysis (Murtagh et al., 2007b).

Restless legs

The reported prevalence of the symptom of restless legs among dialysis patients varies considerably, from 12% to 58% (Murtagh et al., 2007e). This compares with prevalence of at least 10–15% in the general population (Medcalf and Bhatia, 2006). For this symptom, perhaps more than any other, reported prevalence depends heavily on the definition used. Earlier studies have tended to use less well defined criteria, while more recent studies have used the specific criteria developed by the International Restless Legs Syndrome Study Group (IRLSSG) to define restless legs syndrome (RLS) (Allen et al., 2003). These latter studies indicate a somewhat lower prevalence of the syndrome of restless legs among patients receiving dialysis, between 12% and 22% (Manenti et al., 2009). Of those with stage 5 disease not receiving dialysis, 48% report the symptom of restless legs (Murtagh et al., 2007b), although this study did not formal IRLSSG criteria. As with pruritus, there is some indication that RLS is associated with poorer prognosis which may again be mediated partly through impaired quality of sleep (Hui et al., 2000).

Sleep disturbance

Sleep disturbance is a common problem in patients with ESKD but it is hard to determine the exact prevalence of this problem because of the challenges of definition. Insomnia affects at least 10–15% of the general population (Drake et al., 2003), but the prevalence of sleep disturbance in renal patients is notably higher. Several studies have described prevalence and findings range from 20% to 83% (Murtagh et al., 2007e). This wide range reflects varying definitions, but whatever definition is used, it is clear that this is a symptom which troubles many dialysis patients. Those stage 5 CKD patients who opt not to have dialysis and are managed conservatively also have a high prevalence of sleep disturbance, with 41% experiencing some difficulty with sleep, and 21% (of all conservatively managed patients) reporting severely distressing sleep disturbance (Murtagh et al., 2007b).

Fatigue

Tiredness or fatigue is also a symptom which is difficult to define, and therefore to quantify. Despite this, there is evidence that it is one of the most common symptoms experienced by renal patients; in most studies, between 70% and 97% of dialysis patients are affected by fatigue (Kutner et al., 1985; Chang et al., 2001; Kundhal and Lok, 2005; Jhamb et al., 2008). A very high proportion of conservatively managed stage 5 CKD patients are also affected by fatigue, with 90% of patients affected by fatigue, and 35% of all patients severely distressed by this (Murtagh et al., 2007c). Qualitative studies also suggest it is one of the most difficult symptoms for patients to cope with (Chang et al., 2001; Murtagh et al., 2007c).

Other symptoms

Other key symptoms have been shown to be important for patients with ESKD. These symptoms include nausea and vomiting, drowsiness, breathlessness, leg oedema, dry mouth, lack of appetite and altered taste, poor concentration, dry skin, and constipation. Some symptoms, for example, breathlessness, are frequently linked to co-morbidity, such as coexisting cardiac or respiratory disease, and their prevalence very much reflects the demographics of the population, with older populations and those conservatively managed (without dialysis)—who are almost always older patients—displaying a notably higher prevalence of these symptoms (Murtagh et al., 2007c).

Symptoms due to co-morbid conditions

In those with ESKD, it is not always clear whether uraemia, dialysis, or co-morbid conditions are the most dominant cause of each symptom, and for many patients a combination of causes and triggers contributes to their overall symptom burden. Co-morbid conditions do play a major part in causing symptoms, particularly for the older patient, who may have vascular disease, cardiac problems, diabetes mellitus, or other co-morbidities. Some of the commoner co-morbid conditions which contribute to symptom burden include diabetic gastroparesis, other diabetic neuropathies, other diabetic complications, cardiovascular disease, and peripheral vascular disease.

Diabetic patients with end-stage renal disease have often had their diabetes for many years, and may have other complications in addition to their renal impairment. Diabetic gastroparesis due to autonomic nerve damage is common in long-standing diabetes, and is characterized by anorexia, early satiety (feeling full), nausea, and sometimes vomiting. Advanced uraemia itself also leads to delayed gastric emptying, which can contribute to this problem. Delayed gastric emptying may itself cause gastric reflux and dyspepsia. Diabetic patients also suffer from other neuropathies, such as autonomic neuropathies affecting the mid and lower gut, and characterized by alternating diarrhoea and constipation. Non-autonomic diabetic neuropathies that affect the peripheral nerves may occur. The neuropathic pain associated with diabetic neuropathies can be severe, persistent, and difficult to control. Skin and soft tissue problems are also common in the diabetic patient; decubitus ulcers or diabetic foot may occur and amputation may sometimes be required. The severity of these skin and soft tissue problems may be such that these pains are sometimes difficult to control.

Assessment of symptoms

Global symptom measures

Several global symptom measures have been used to evaluate the whole range of symptoms in renal disease. These include instruments used in other advanced diseases, such as the Edmonton Symptom Assessment System (Parfrey et al., 1989; Davison et al., 2006a, 2006b), and the Memorial Symptom Assessment Scale short form (Weisbord et al., 2003; Murtagh et al., 2007b). Other measures have been validated specifically for use in those with renal disease. These include the Dialysis Symptom Index, developed from the Memorial Symptom Assessment Scale by Weisbord et al. (2004), and the renal version of the Patient Outcome Scale (symptom module) (Murphy et al., 2009), derived from the generic version of the Patient (or Palliative) Outcome Scale which is used across a wide number of conditions and countries.

Symptom-specific measures

Although the whole range of symptoms which patients experience needs to be assessed, there is a wider range of instruments which have been used to assess individual symptoms, such as pain, pruritus, or depression. These may provide a more detailed and accurate picture of each symptom, especially for research purposes. A range of measures are available for measurement of pain (Melzack, 1975; Daut et al., 1983), depression (Beck and Steer, 1984; Kutner et al., 1985; Martin and Thompson, 2000), pruritus (Majeski et al., 2007), or RLS (Allen et al., 2009). The Cambridge–Hopkins restless legs questionnaire is based on the IRLSSG criteria, but also distinguishes RLS from other conditions, with good sensitivity and specificity (Allen et al., 2009). A range of other measures for individual symptoms exist, and are useful for research purposes, but fairly brief validated measures which capture the whole range of symptoms may be most useful in the clinical setting.

Management of symptoms

Once symptoms have been identified and assessed, they need to be actively managed. Evidence shows that management of symptoms is often suboptimal for renal patients (Davison, 2003; Bailie et al., 2004). Renal impairment places a major constraint on use of medication, since many medicines are renally excreted, and may therefore accumulate substantially in renal impairment. For those on dialysis, careful consideration also needs to be given to the effect of dialysis on drug clearance.

Management of pain

As with any other disease group, the suspected causes of pain need to be carefully delineated, and management tailored to these causes. Removal or specific treatment of the underlying cause when feasible is always the best approach, and only when this cannot be achieved should palliation be the main focus. Non-opioid, opioid, and adjuvant analgesics can be used in the ESKD population, but careful consideration needs to be given to:

◆ potential risk of adverse effects, which may be exacerbated by uraemia

◆ whether there is risk of nephrotoxicity (it is critically important not to risk remaining renal function)

◆ elimination of the drugs used, and how this will be influenced by the renal impairment.

World Health Organization step 2 and step 3 opioids will be briefly considered here, but the reader is referred to extensive reviews of analgesic use for more details (Davies et al., 1996; Dean, 2004; Mercadante and Arcuri, 2004; Murtagh et al., 2007f).

Codeine and dihydrocodeine

There are reports of serious side effects following codeine use in patients with advanced renal failure, in particular profound hypotension (Parke et al., 1992), respiratory arrest (Talbott et al., 1997), and profound narcolepsy (Matzke et al., 1986). Dihydrocodeine is thought to have similar metabolism and elimination to codeine, and there are similar reports of prolonged narcosis (Barnes and Goodwin, 1983; Redfern, 1983). For these reasons, use of codeine and dihydrocodeine is not recommended in ESKD.

Tramadol

Ninety per cent of tramadol is excreted via the kidneys (Lee et al., 1993), and in renal impairment, there is about a twofold increase in the elimination half-life (Lee et al., 1993). Because of this increased elimination half-life, it is recommended that the dose interval be increased to 12-hourly, and the dose reduced. Uraemia also lowers the seizure threshold, and tramadol may be more epileptogenic in ESKD patients (Gardner et al., 2000). For these reasons, an alternative drug is preferred for ESKD patients, and if the use of tramadol is absolutely unavoidable, a dose of 50 mg 12-hourly should not be exceeded.

Morphine and diamorphine

Morphine and diamorphine are not recommended for use in ESKD, because of the problems with metabolite accumulation, and because at least some of these metabolites are clinically active.

Fentanyl

Less than 10% of fentanyl is excreted unchanged in the urine. In renal failure, no dose modification appears necessary when fentanyl is given as a bolus injection (Coral et al., 1980), but there is limited evidence on the pharmacokinetics when it is administered either in repeated doses or by continuous infusion. One study suggests that the parent compound may accumulate with sustained administration (Koehntop and Rodman, 1997), and a further study demonstrates reduced clearance of fentanyl in patients with renal failure (Scholz et al., 1996). Despite these concerns about accumulation, fentanyl is, on present limited evidence, one of the preferred opioids in ESKD, because the metabolites are inactive. Some authorities suggest dose reduction with declining renal function: 75% of normal dose if creatinine clearance is 10–50 mL/minute, and 50% normal dose if creatinine clearance is less than 10mL/min (Broadbent et al., 2003). Careful monitoring for any gradual development of accumulation and toxicity would certainly be wise in any case of sustained administration (beyond 1 or 2 days), and there may be some basis for gradual dose reduction if fentanyl is used over days or weeks. Transdermal patches can be used, but careful review, with vigilance for accumulation, is important. The very wide individual variations in its pharmacokinetics (Bentley et al., 1982; Labroo et al., 1997) would also support a cautious approach.

Alfentanil

Alfentanil is shorter acting than fentanyl, and is both less potent and less lipid soluble. Like fentanyl, it is highly protein bound and its protein binding is reduced by a high urea, but despite this the volume of

distribution and elimination half-life appears unchanged in patients with renal failure (Chauvin et al., 1987). Alfentanil is therefore also one of the preferred opioids for use in ESKD, but is limited to end-of-life use, given that it is only available for parenteral use.

Buprenorphine

Buprenorphine is metabolized in the liver to norbuprenorphine, and buprenorphine-3-glucuronide, and these metabolites are principally excreted via the biliary system (Mercadante and Arcuri, 2004). Because of its high systemic clearance and largely hepatic metabolism, buprenorphine has the potential to be reasonably safe in patients with renal failure. Some evidence shows no change in the pharmacokinetics of buprenorphine in renal impairment (Summerfield et al., 1985), but other work shows some accumulation of metabolites (Hand et al., 1990). No adverse effects were reported, and specifically no sedation or respiratory depression. Buprenorphine also has the advantage of being available in sublingual, transdermal, and injectable preparations. Note that buprenorphine is omitted from some of the reviews of analgesia in renal impairment because it is not available in all countries.

Hydromorphone

A single-dose study indicates hydromorphone accumulation in renal impairment (Durnin et al., 2001) (with proportionately greater accumulation in severe renal impairment), and a further detailed pharmacokinetic case study over 14 days (Babul et al., 1995) demonstrated clear accumulation of H-3-G. Since H-3-G is known to be a more potent neuro-excitant, there has been considerable concern about the use of hydromorphone in severe renal impairment. However, a retrospective review by Lee and colleagues (Lee et al., 2001) suggests that hydromorphone may be reasonably better tolerated than morphine in patients with renal impairment, although levels of renal impairment were small. Overall, the evidence to support the safety of hydromorphone in renal impairment is extremely limited. It may be reasonable, given the available evidence, to use hydromorphone carefully in mild or even moderate renal impairment, provided doses are reduced and the dose interval increased, and with careful monitoring and titration. In severe renal impairment, its use cannot be recommended however, until there is more evidence available.

Methadone

Methadone is metabolized mostly in the liver, and excreted both renally and faecally (Davies et al., 1996). There is large inter-individual variation, but also considerable difference between acute and chronic phase dosing (Rostami-Hodjegan et al., 1999). Some evidence suggests that plasma concentrations are no higher than in those with normal renal function (Kreek et al., 1980), suggesting that faecal excretion might compensate in those with renal impairment. Because of this, and the limited possibilities for use of other opioids, methadone has been used reasonably often for patients with renal failure and no adverse effects have been reported. Caution should be exercised on two counts, however: firstly, because of a well-described risk of accumulation and toxicity, experienced specialist supervision of methadone use should be available, and secondly, because of the wide individual variation, doses and effects should be closely monitored. The titration and use of methadone is fully described elsewhere (Morley, 1998; Blackburn et al., 2002), but in severe renal impairment a dose reduction of 50–75% is recommended (Broadbent et al., 2003).

Oxycodone

A study by Kirvela et al. showed that the elimination of oxycodone in renal failure is significantly prolonged, and excretion of its metabolites is severely impaired (Kirvela et al., 1996), with wide inter-individual variation. Work by Kalso and colleagues also suggests that some of the effects of oxycodone may be mediated through its metabolites (Kalso et al., 1990). There are also reports of central nervous system toxicity and sedation with oxycodone in renal failure (Fitzgerald, 1991). This raises queries about the use of oxycodone in renal impairment, and there is insufficient evidence to determine whether or not it is safe to use in ESKD patients. Some clinicians use it with caution, reducing the dose and increasing the dose interval, while others avoid using it. Broadbent suggests the use of 75% of normal dose when creatinine clearance is 10–50 mL/minute, and 50% when creatinine clearance is less than 10 mL/minute (with unchanged dose intervals) (Broadbent et al., 2003).

Management of fatigue

Fatigue is multidimensional (Lee et al., 2007), with physical, cognitive, and emotional elements (O'Sullivan and McCarthy, 2007). There is a complex but poorly understood relationship between fatigue, sleep disturbance, physical functioning, and depression in those with renal disease (Brunier and Graydon, 1992; McCann and Boore, 2000). It is not clear, for instance, whether the reduced physical functioning which occurs with renal disease itself causes fatigue, or whether in fact the symptom of fatigue is a consequence of poor function. Fatigue is an important symptom because it is very common, highly distressing to patients, and there are a number of causes which are potentially treatable. These causes can be classified as related to the renal disease, to dialysis itself, or related to co-morbid conditions. The renal disease may cause anaemia, hyperparathyroidism, and uraemia, all of which may directly contribute to fatigue. Secondary to these direct effects are dietary and fluid restrictions, impaired nutrition, and the side effects of medications, all of which may contribute to fatigue, even if they are not the predominant causes of it. For those on dialysis, dialysis inadequacy, post dialysis fatigue, and the burden of dialysis itself may also play a part in instigating or perpetuating fatigue. Conditions unrelated to renal disease, such as hypothyroidism, should be considered and excluded. Non pharmacological managements of fatigue, such as exercise, cognitive and psychological approaches, and complementary treatments, are important, especially as pharmacological interventions become increasingly limited.

A systematic review of the use of erythropoietin-stimulating agents demonstrates that in renal patients there is a consistent relationship between haematocrit and energy/fatigue domains in quality of life (Ross et al., 2003); as haematocrit increases, so energy levels increase and fatigue reduces. When anaemia is due to kidney disease, which is likely if GFR is less than 30mL/min/1.73m^2 (less than 45 in diabetics) and no other cause (such as blood loss, folic acid or vitamin B_{12} deficiency) is identified, then active treatment with erythropoietin-stimulating agents is likely to improve fatigue. It is not clear, however, how long treatment should be maintained in those who are nearing the end of life; most clinicians continue treatment while the patient still continues to gain symptomatic benefit.

Management of nausea and vomiting

Nausea and vomiting are extremely unpleasant symptoms, and are often multifactorial. Assessment requires a thorough history

including establishing the history and pattern of both nausea and vomiting separately. Profound nausea and/or repeated vomiting will prevent absorption of any medications taken orally, and alternative routes (such as sublingual, rectal, or subcutaneous routes) need to be considered, at least until nausea and vomiting is controlled.

The first step is to identify the specific cause of nausea and vomiting where possible, since cause-directed treatment is most likely to succeed. Uraemia and a variety of drugs (including opioids, anticonvulsants, antibiotics, and antidepressants) can cause this kind of persistent nausea. Gastroparesis or delayed gastric emptying, (which may be caused by drugs, such as opioids, or by primary diseases, such as diabetes mellitus), usually presents with a history of post-prandial nausea or vomiting of undigested food which relieves nausea. Bloating, epigastric fullness, flatulence, hiccough, or heartburn may accompany this. Nausea related to gastritis is often associated with heartburn, dyspepsia, or epigastric pain. Constipation may exacerbate nausea and vomiting.

For delayed gastric emptying or gastroparesis, metoclopramide can be use, although doses should be reduced by 50%, and there is an increased risk of dystonia. Haloperidol or levomepromazine is often used for nausea related to uraemia or drug-related nausea, although there is increased cerebral sensitivity, and both drugs need dose reduction. 5-hydroxytryptamine (serotonin) type 3 (5-HT$_3$) antagonists can also be used, although the side effect of constipation will need active management. Because gastritis is common among uraemic patients, there should also be a low threshold for treatment with a proton pump inhibitor if gastritis could be a contributory factor.

Management of pruritus

The aetiology and pathogenesis of pruritus in ESKD remain unclear, and treatment options are limited in their effectiveness. Pruritus is thought to arise in C fibres located in the skin, distinct from those which mediate pain (Schmelz et al., 1997). These C fibres transmit via the contralateral spinothalamic tract to the brain (thalamus and hypothalamus) via the reticular formation (Lugon, 2005). Connections to distinct cortical areas (the anterior cingulate process, supplementary motor area, and inferior parietal lobe) then mediate, via motor areas, the powerful, almost involuntary, desire to scratch. The difficulty is that pruritus could originate at any level in this pathway (in the skin at the level of the receptors, neuropathically in the afferent nerve pathway, neuropathically in central neural pathways, or centrally from psychogenic causes). In ESKD-related itch, complex interacting factors operate at more than one place in the pathway (Lugon, 2005), so that it is extremely difficult to elucidate any one discrete cause for itch. Current hypotheses postulate abnormal inflammatory/immune processes, dysfunction in the opioid receptor system, and/or neuropathic processes within the nervous system itself.

Immune modulators (such as ultraviolet (UV) B light, tacrolimus, and thalidomide) have been proposed to treat itch. These all act in various ways to decrease pro-inflammatory cytokines. Others have proposed disturbance in the endogenous opioids system as a cause of itch (Yosipovitch et al., 2003; Patel et al., 2007). Kappa (κ)-opioid receptor agonists have been shown to have anti-pruritic effects in animals, and κ-opioid receptor antagonists enhance itch in animal studies (Ikoma et al., 2006). It is for this reason that opioids such as butorphanol (which has mu

(μ)-opioid antagonist and κ-opioid agonist action) (Dawn and Yosipovitch, 2006), and opioids antagonists such as naloxone and naltrexone, have been proposed to treat itch. There is also some evidence that a relatively new κ-opioid agonist (nalfurafine) may be useful (Wikstrom et al., 2005). Evidence has emerged to support the link between itch and neuropathic processes. There are a number of features of itch which suggest a neuropathic process, and Akhyani and colleagues report association between clinical neuropathy and itch in haemodialysis patients (Akhyani et al., 2005). Neuropathic agents (lidocaine, gabapentin, and capsaicin) have been used to treat itch, with some success. However, the neuropathic component could be a secondary, rather than primary cause of ESKD-related pruritus. The role of histamine in acute itch is long established. Acute histamine-induced itch is well described, and histamine receptors appear to sensitize at least some of the C fibres which mediate itch. What is less clear is how this acute itch response relates to the chronic itch experienced by ESKD-related pruritus. Nevertheless, antihistamines are widely used in the management of ESKD-related pruritus, with varying results. A final important factor in ESKD-related itch is xerosis, or dry skin. Xerosis may be an important factor in older people with ESKD (Keithi-Reddy et al., 2007). And although uraemia is the most likely cause of pruritus, other common causes of pruritus need to be considered if the symptom is not resolving, such as skin disorders, skin infections such as scabies, and liver impairment.

The first step in management is to optimize renal management; high phosphate may contribute to pruritus (Lugon, 2005), and dietary advice and the use of phosphate binders should be considered to reduce phosphate levels. Hyperparathyroidism may also be a contributory factor and should be considered. Dry skin may both cause and contribute to pruritus, and so should be treated actively; liberal emollients should be used if dry skin is present. Older people living alone may find it hard to apply emollients easily; spray applications are often helpful in this instance. Preventive measures, such as nail care (keeping nails short) and keeping cool (light clothing, and tepid baths or showers), are useful concurrent measures.

The evidence as to which medications are effective is limited, often conflicting, and no one single preparation can be recommended above others. Choice of treatment should be influenced by the stage of disease—for instance, UV light may be practical for those who remain relatively well, while antihistamines may be more appropriate nearer end of life. Time should be taken to discuss with the patient the need to persist with any one medication, and to explain and minimize side effects where possible. A clear plan of management, and persistence in following treatment through, goes a long way to helping patients cope with the distress that this symptom can sometimes cause. The psychological and social dimensions of severe itch are considerable (Murtagh et al., 2007c), and psychological, family, and social support is an important component of management.

Management of restless legs

RLS is characterized by an urge to move the legs, uncomfortable sensations in the legs, and worsening of symptoms at rest, especially during the night. The formal IRLSSG criteria are (a) urge to move the legs, usually with unpleasant sensations in the legs, (b) worse during periods of rest or inactivity like resting or sitting, (c) partial or total relief by physical activity, and (d) worse

symptoms in the evening or night rather than the day (Medcalf and Bhatia, 2006). The exact cause for restless legs is not well understood but the dopaminergic system in the central nervous system is somehow disrupted (Manenti et al., 2009). There is limited evidence in uraemic RLS that iron deficiency (O'Keeffe et al., 1993), low parathyroid hormone (Rijsman et al., 2004), hyperphosphataemia, and psychological factors (Takaki et al., 2003) may play a role. Treatment should involve correction of these factors, and reduction of potential exacerbating agents, such as caffeine, alcohol, nicotine, and certain drugs (sedative antihistamines, metoclopramide, tricyclic antidepressants, selective serotonin uptake inhibitors, lithium, and dopamine antagonists) (Manenti et al., 2009). Calcium antagonists may also exacerbate RLS (Telarovic et al., 2007).

There is very limited evidence about treatment of restless legs in CKD patients, and much of the evidence is extrapolated from patients with idiopathic restless legs (Silber et al., 2004). Gabapentin, dopamine agonists, co-careldopa, and clonazepam are the treatments most commonly used, with varying results. All need dose reduction, and gabapentin in particular accumulates rapidly if there is no dialysis; it can be given in low dose post dialysis sessions, and should be used with extreme caution in ESKD patients who are not receiving dialysis.

Management of sleep disturbance

A detailed history of any sleep disturbance is important, in order to identify sleep apnoea, RLS, and pruritus, which may be the underlying reason for the sleep disturbance; these each need treating in their own right initially to resolve any sleep problems. General sleep hygiene measures are important in addressing sleep disturbance; avoiding caffeine after lunch, reducing overall caffeine intake, avoiding alcohol (which is both depressant and stimulant), and avoiding daytime sleeping. If sleep apnoea is excluded, other exacerbating symptoms are treated optimally, and general measures are unsuccessful, then hypnotics may be necessary, ideally short term to attempt to re-establish sleep patterns. For those with a longer prognosis, hypnotics carry a risk of dependence, and this needs consideration in management. The shorter-acting hypnotics, such as zolpidem 5–10 mg or temazepam 7.5–10 mg, are preferable. These are generally safe in dialysis patients, although ESKD patients may be more sensitive to benzodiazepines in general, and lower doses are often required than in the general population.

Management of breathlessness towards end of life

The most common causes of breathlessness or dyspnoea in the renal patient are anaemia, pulmonary oedema (related to fluid overload or to coexisting cardiovascular disease), or co-morbidity (cardiac or respiratory disease). Anaemia produces significant symptoms including dyspnoea, and although anaemia is likely to be due to renal failure in the CKD patient, other causes should be considered and excluded. It is important to identify the underlying cause of breathlessness, since treating the underlying cause is almost always the most appropriate and effective first line of management. If volume overload is identified as a cause or contributor, more frequent or longer dialysis, with ultrafiltration, can be helpful. If treatment of the underlying cause has been exhausted, then symptomatic measures to relieve breathlessness will be required. These include general and non-pharmacological measures, psychological support, and pharmacological measures.

General measures in advanced disease include sitting upright rather than lying (which maximizes vital capacity), using a fan or stream of cool air which can provide effective symptom relief (Booth et al., 2004a), inhaled oxygen if hypoxia is confirmed or suspected (Booth et al., 2004b) and a calm, settled environment. For the patient whose mobility is limited by breathlessness, physiotherapy and occupational therapy can help to maximize mobility and provide appropriate aids to improve function constrained by breathlessness. Since breathlessness is a profoundly unpleasant symptom, assessment and management of the underlying psychological state is important. Breathlessness is very commonly associated with anxiety, often in an escalating cycle (anxiety causing worsening dyspnoea, which triggers worsening anxiety, and so on). Information, education, and support of patient and family are therefore critical.

As prognosis worsens, general and non-pharmacological measures will have less to offer, and pharmacological measures directed at the symptom of breathlessness itself may be more appropriate. Untreated moderate or severe dyspnoea at the end of life is very distressing, and should be treated as actively as pain or any other distressing symptom. Breathlessness is an increasingly important and dominant symptom in renal patients towards the end of life (Murtagh et al., 2007c), so it is important to try and anticipate and plan for future episodes. Not all patients will, for instance, choose to be admitted for maximal treatment with intravenous diuretics in the last days or weeks of life.

Pharmacological treatments directed specifically at breathlessness include opioids and benzodiazepines (especially if there is moderate or severe associated anxiety). Low-dose opioids are helpful in relieving breathlessness near the end of life in end-stage cardiac and respiratory disease (Jennings et al., 2001, 2002), and clinical experience suggests that this is true for renal patients too. However, there are considerable constraints on the use of opioids in renal patients; the guidance as for pain management should be followed, although dose of opioids for breathlessness is likely to be notably smaller (usually half or quarter the starting dose for pain) and titration upwards is undertaken to a lesser degree. If small doses are not at least partly effective, combining an opioid such as fentanyl with low dose midazolam towards the end of life (last few days or hours) may bring relief where either alone is only partially effective. This is often a better strategy than increasing the dose, since adverse effects quickly increase as doses rise.

Benzodiazepines are useful when there is coexisting anxiety (as there often is), but again need to be used with care and in reduced doses. Shorter-acting benzodiazepines are recommended, such as lorazepam 0.5–1 mg orally or sublingually four times a day (if used sublingually, it has a quicker onset of action and may more readily restore a sense of control to the frightened and anxious patient). If the patient is in the last days of life, midazolam (at 25% of normal dose if eGFR is less than 10) can be given subcutaneously and titrated according to effect. Midazolam can be given every 2–4 hours, although ESKD patients are sensitive to its effects and do not usually need frequent or large doses. A starting dose of 1.25 or 2.5 mg is common, and often sufficient. If more than one or two doses are required, a subcutaneous infusion over 24 hours is most practical.

Communication and advance care planning

There is growing evidence on the information provided to, and the communication needs of, patients with ESKD, as well as the kind

of trade-offs that patients are willing to accept. In a recent study, patients were willing to forgo 23 months of life expectancy with home-based dialysis in order to decrease their travel restrictions, although there is inconsistency between patient and family preferences (Morton et al., 2012a). Communicating early and clearly about the options and possibilities is an important part of good quality care.

The evidence also provides wider pointers for clinicians. First, detailed discussions about the future and about preferences and priorities do not remove hope, as some professionals believe; rather, they sustain realistic hope and empower patients to work towards possibilities consistent with their own values (Davison and Simpson, 2006). They help patients and families to make the most of life, in the face of an advancing, life-threatening condition. Second, there are a variety of reasons why patients opt for conservative management (Noble et al., 2009). These will influence how patients and families view the future, after the decision is made; a patient who views conservative management as a 'logical and affirming choice' will respond differently to one who is 'angry and believed they were somehow giving up on life' (Noble et al., 2009). Subsequent advance care planning therefore needs to be responsive to the perspective patient and family bring to the process; it is about helping them towards greater empowerment, whatever the starting place, but some will have a very different psychological journey ahead, as compared with others. Third, advance care planning is not only about key medical decisions, such as decisions about dialysis, or agreement to 'not for resuscitation' order when in hospital. When done well, it also involves enhancement of the final days, weeks and months with positive decisions about family relationships, resolution of conflict, and living well until the end of life (Hines et al., 2001a); all priorities which patients themselves rate highly (Singer et al., 1998). This approach helps move away from isolated decisions about the utilization of medical supportive measures, which are sometimes influenced more by transient factors than by stable 'core' values (Fried et al., 2007), and builds on a more integrated person- and family-centred care.

There is some overlap between making dialysis decisions and planning ahead for subsequent care, because the former will inevitably involve some exploration of the patient's preferences and priorities. However, advance care planning becomes more far-reaching as the illness progresses. Patients and families often want advice and information, such as what to expect at different stages, when and why hospitalization might be appropriate, what other active management is right for them, who is available to care for them at home, and where do they prefer to be cared for and to die, if practicable. This is a dynamic and evolving process, not one or even a few fixed episodes, and there needs to be good liaison to ensure it is effective. Timing is critical; not all issues will be right to discuss at any one time, and there will need to be evolution in discussions as the disease itself advances. There is a fine balance between introducing issues for discussion too early, and leaving them too late, so that opportunities are missed, and 'default' care becomes inevitable (Holley, 2003). Family and other carers need to be actively involved in discussions whenever possible (Hines et al., 2001b) and according to patient preference, to enable consistent responses at times of crisis or decline. Communication among professionals is critical; there may be a number of professionals who also need to be aware of decisions, preferences, and priorities, including primary care professionals, who may have major responsibility if the patient is at home.

There has been some study of the experience of illness among conservatively managed stage 5 CKD patients (Murtagh, 2009), and this work suggests that loss of control and related uncertainty are a particular feature for these patients. Advance care planning can help reduce this sense of loss of control (Davison and Torgunrud, 2007). This is important, since for a number of these patients, the prospect of death was not their main concern; uncertainty about the path of their illness before death troubled them more. Above all, participants expressed a wish not to be a burden to their family and others (Murtagh, 2009); advance care planning helps to make explicit preferences and priorities about care, and identifies what can be provided to support families and reduce that burden (provided, of course, that appropriate services are available).

Conclusions

People with ESKD have extensive palliative care needs. They therefore need significant medical, nursing, psychological, and social care as their illness advances towards the end of life. This chapter has focused on the challenges of symptom recognition, assessment, and management, and the need for advance care planning, but has not addressed the considerable psychological, spiritual, and practical care that these patients need, or the high level of coordination between providers that is important for ensuring effective and accessible care.

Symptoms can arise directly from the renal disease itself, as a consequence of dialysis, or from co-morbid conditions (particularly in older patients). This diversity makes them harder to assess and address, and detailed assessments and interventions are needed. Pharmacological management of symptoms is one of the most challenging aspects of the care of those with ESKD. Although the emphasis in this chapter has been on pharmacological management, it should be stressed that psychological, social, and spiritual aspects of management are also important, especially towards the end of life. It is for this reason that care of renal patients is best managed with multiprofessional teams, including counsellors and psychologists, occupational therapists and physiotherapists, dieticians, and chaplains, and most importantly, professionals with both nephrology and palliative care skills.

Palliative medicine in the intensive care unit

Nathan I. Cherny, Sharon Einav, and David Dahan

Introduction to palliative medicine in the intensive care unit

Approximately half of the patients admitted to an intensive care unit (ICU) are likely to die during ICU admission (Pronovost et al., 2002) and in some countries almost a fifth of the overall number of adult deaths occur in an ICU (Angus et al., 2004). Furthermore, the proportion of emergency ICU admissions has almost doubled within the last decade (Herring et al., 2013).

On admission to intensive care, both the severity and extent of pre-existing chronic diseases and the prognosis of the acute disease are often unknown, consequently it is difficult to predict the response to ICU treatment for an individual patient. In the ICU, the disease trajectory starts with a trial of major life-saving efforts. Often, however, these efforts fail to stabilize the patient and over time, it becomes increasingly apparent that the patient will either die or remain alive only with ongoing life support systems such as permanent ventilation (Truog et al., 2008).

Intensive care is not a homogenous concept or reality; ICU populations are varied in both case mix and age composition (Mosenthal et al., 2012). Thus, for example, surgical ICU decisions are often influenced by a 'covenantial'-like relationship between the surgeon and their patient characterized by a sense of obligation to protect the patient during the surgery and its aftermath and an exaggerated sense of accountability for the patient's outcome (Schwarze et al., 2010). Trauma ICUs are characterized by a disproportionately large number of relatively young patients, often without confounding pre-existing medical problems but with sudden onset of acute life-threatening catastrophic injuries (Deitch and Dayal, 2006). Neurological/neurosurgical ICUs are characterized by patients at risk of physiological survival despite vastly compromised neurological function (Patel et al., 2002; Bershad et al., 2008).

Irrespective, several factors characterize all of these settings: patients are fragile, their risk of mortality is high, and their immediate prognosis is often uncertain. Patients are often required to undergo unpleasant invasive procedures, they often suffer pain and discomfort, and are highly dependent. In addition, family members, who themselves are under duress are often required to be involved in decision-making processes. Under these circumstances, palliative care principles are critical in the relief of patient distress, communication with family members, and in the management of patients who are not responding to life-saving approaches (Curtis, 2008; Truog et al., 2008)

Why is delivery of palliative care different in the ICU?

Palliative and end-of-life care in ICU is characterized by a number of distinct factors that challenge the delivery of end-of-life care:

- *Professional culture:* the ICU physician and nurse training is primarily directed at life support and staff often have a professional culture regarding the primacy of saving lives, vital sign monitoring and stabilization, a low threshold for medical interventions, and, sometimes, a risk of 'depersonalizing' the individual.

- *Uncertainty:* almost every decision involved in ICU care is confounded by uncertainty and limited abilities to accurately predict outcomes for individuals. In particular, this relates to decisions to admit patients to ICU or not, and to decisions to continue or forego treatments. These decisions are influenced by both medical criteria (e.g. need for ventilatory and/or haemodynamic support, the likelihood of survival and morbidity) and non-medical criteria (e.g. patient wishes, values and goals, and cultural and religious beliefs), and how each should best factor into any decision-making.

- *Time course:* the typical course of an admission to ICU is acute, mostly within hours or days. This gives both patients and relatives little time to adjust to changes in expected life expectancy and often limits their ability to inform the ICU staff of their preferences.

- *Environment:* the patients are often in a room shared by other ICU patients, they are attached to multiple devices which create a noisy environment, and the room is often illuminated 24 hours a day. Families are often struck by the markedly changed appearance of the patient due to his/her medical condition, and often, fluid overload. Access to the bedside may be limited by stringent visiting hours and isolation measures and the patient is often attached to life-support devices such as ventilatory support, continuous dialysis, or infusions of vasoactive drugs, the discontinuation of which may result in rapid deterioration and death.

- *Patient communication:* most patients are not able to participate in discussions because of either their illness or sedation (Heyland et al., 2003).

- *Scarce and expensive resource:* due to its high demand on work force (often one nurse for two patients for all duty shifts) and

its demand on high levels of medical technology, ICU is very costly. For the same reasons, ICU beds are a scarce resource (Zilberberg and Shorr, 2012) and both staff and family may be aware that the patient is consuming an expensive resource and there may be pressure to transfer the patient to a less intense environment for a more 'deserving' patient. The term 'inappropriate treatment' is often used by intensive care clinicians to describe care that involves the use of considerable resources without a reasonable hope that the patient will recover to a state of relative independence or ability to interact with their environment (Sibbald et al., 2007).

The scope of the issue

Palliative care in the ICU incorporates symptom control, goal setting, and communication which is essential for all patients, as well as the special issues related to the care of patients whose condition is not improving and who are approaching death. There is wide consensus regarding the need for palliative care competencies in the ICU; multiple authorities have published policy and guideline documents and standards on this subject. These standards were reviewed by Nelsen et al. (2010a) and are summarized into seven key points:

1. Patient care maintaining comfort, dignity, and personhood. Such care incorporates regular assessment and optimal management of pain and other distressing symptoms.

2. Timely, clear, and compassionate communication by clinicians with patients and families. Honest, complete, and repeated communication should be as dictated by the condition of the patient, with input from all pertinent members of the multiprofessional team.

3. Clinical decision-making processes which are led by patients' preferences, goals, and values.

4. Identification of, and respect for, patients' advanced medical directives and surrogate decision-makers.

5. Development of contingency plans for withdrawal of supportive interventions.

6. Interdisciplinary support of families during the critical illness and for families of patients who died in the ICU, in the bereavement period.

7. Emotional and organizational support for ICU clinicians. Support systems and resources for caregivers that address moral distress, burnout, and post-traumatic stress disorder. This should include a mechanism for staff members to request a debriefing or to voice concerns with the treatment plan, decompress, vent feelings, or grieve.

Practical issues

Among the key practice points for palliative care in the ICU are issues related to communication, assessment and management of symptoms, and end-of-life care transitioning and management

Communication with families

Family-centred care requires that patients be seen as embedded within a social structure and web of relationships (Truog et al., 2008; Jacobowski et al., 2010; Levin et al., 2010). Despite this,

communication issues with clinicians are the most common source of complaints among families of deceased patients, with as many as 30% of family members feeling dissatisfied with communication in the ICU (Baker et al., 2000; Abbott et al., 2001) the major problems being inadequate dedicated time, inconsistent information, and provision of information by multiple health-care providers (Azoulay et al., 2000; Azoulay and Pochard, 2003). Suboptimal communication can also affect not only the psychological well-being of family members and satisfaction with care but also clinical decision-making (Jacobowski et al., 2010; Huang et al., 2012).

Family members need early and frequent interaction with the key clinical personal providing care and support to inform the family of the patient's condition and treatment, answer questions, and include the patient's surrogates in the decision-making process. Such meetings provide an important opportunity to clarify misunderstandings, talk about goals of care, prognosis, and contingency planning for worst case scenarios. Initial meetings should focus on a description of the patient's status, the measures undertaken to attempt to stabilize their condition, the level of risk and the likelihood of recovery, death, or permanent dependence on life support.

Good communication and regular family meetings not only improve the psychological well-being of family members (Lautrette et al., 2007; Wall et al., 2007; Gries et al., 2008) but may also be associated with a reduce length of ICU stay (Lilly et al., 2003; Norton et al., 2007).

Subsequent family meetings should be held when a change occurs in the medical status of the patient. This is particularly true if the treating clinicians believe that the goals of care should be reassessed and perhaps transitioned to palliation care and/or conflicts exist among family members, or between the family and treating clinicians regarding care issues.

Family members and relevant health-care providers, generally including physician, nurse, and social worker, should participate in the family meeting which should be led by a facilitator nominated from the clinical team. Since in most circumstances the family have no pre-existing relationship with the ICU staff, the participation of the patient's primary clinician is highly desirable. Additionally the nurse caring for the patient and a social worker should be included. To avoid presentation of conflicting information, it is prudent for the staff to corroborate their evaluations and understanding in preparation for the meeting. In situations where differences of opinion exist regarding management or prognosis, these should be explained to the family in a balanced manner that shows respect for all of the involved clinicians.

Additional factors that have been shown to improve satisfaction from family–clinician meetings include the ability of the clinician to listen, encourage questions, show empathy, provide emotional support, and be attentive to the patient's values and allowing family members sufficient opportunity to express themselves (Billings, 2011a, 2011b; Billings and Block, 2011).

Formal communication between providers and the family should be a continual process, and informal meetings with individual family members can occur in parallel even more frequently to provide updates and discuss pertinent issues and concerns.

Discussing prognosis

Meaningful participation in decision-making processes requires an understanding of prognosis (Bacchetta et al., 2006; Ford et al.,

2009; Aldawood, 2010; Billings, 2011a). Additionally, regular discussion of prognosis helps families prepare for the possibility of the patient's death. Discussion of prognosis should be framed in a context of probabilities. To this end, ICU physicians may use a range of prognostic tools including the SAPS (Metnitz et al., 2005; Moreno et al., 2005), Apache III (Knaus and Wagner, 1989; Knaus et al., 1991), and sepsis-related organ failure (SOFA) (Vincent et al., 1996). It is important to appreciate though that these scoring systems were developed to predict outcomes for *populations* and that they have limited accuracy in predicting survival for an individual patient (Rocker et al., 2004).

Additional methods to evaluate the extent and severity of the acute insult vary depending on the nature of the prevailing problem: for instance, in hypoxic brain damage clinical signs are supplemented by neurophysiological examinations (Wijdicks et al., 2006).

Uncertainty should always be openly acknowledged. However, this should be accompanied with an explanation of the factors that will help decrease the uncertainty and an estimate of when more accurate information will be available. The phrase 'hoping for the best and preparing for the worst' (Back et al., 2003) aligns with the family's hope that the patient will survive the hospitalization, while at the same time emphasizing the need to prepare for the contingency that the patient may not survive. Importantly, discussion of prognosis must be accompanied by an assessment of likely future functional outcome and mental state if the patient does survive.

End-of-life conversations

End-of-life conversations should be part of the natural progression of dialogue about the course of an illness. Such discussion should occur when considering the changing of goals of care, whether due to deterioration or due to failure to progress (Badger, 2005; Crighton et al., 2008). Transitioning to palliative care should be introduced as one of the potential contingencies if treatment does not go well (Glavan et al., 2008).

In the ICU, most patients are unable to express their preferences either because of their illness or because they are sedated. Unless the patient has a written advanced directive, decisions are made on their behalf by surrogates (usually family members) or a nominated healthcare proxy in coordination with the health-care team (Fried et al., 2002). If the patient's values and preferences are known they should be respected. This is called 'substituted judgement' or 'surrogate decision-making' (Fried et al., 2002).

Important questions in this process include (Ward et al., 2011):

- What are the essential clinical issues we are addressing?
- What are the clinically reasonable choices?
- What are the pros and cons of the treatment choices?
- What is the likelihood of success of treatment, and how confident are we in this estimate?
- Is the family now an 'informed participant,' with a working understanding of the decision?
- What role should the family play in making the decision?
- How will the decision impact the patient's life?
- What does the family think is the most appropriate decision for the patient?

The role of a surrogate is very challenging and should be addressed with extreme sensitivity and respect for the difficulty of the task at hand. While dealing with the complex emotions engendered by seeing their loved one in a state of profound illness they are also being asked to understand the illness, the life-sustaining interventions used, and the treatment options, and to be able to participate in decision-making with the health-care team not according to what they would want; rather, what the patient would want if still able to speak for him- or herself. This should be stressed and developed in part with substituted judgement. This approach is confounded by findings that patients rarely discuss specific treatment options with their family members, and surrogate decisions often do not correlate with what the patient would actually want done (Sulmasy et al., 1998; Shalowitz et al., 2006).

Situations in which the patient's preferences are unknown challenge both clinicians and family to find a mutual understanding of the patient's 'best interests'. Whenever possible, it is desirable to have a situation in which there is agreement between the involved clinicians and family members in a manner that is consistent with the patient's known wishes or values. In this shared process the family usually contributes their knowledge regarding the patient's values and treatment preferences while the physician contributes their knowledge regarding the patient's present medical condition and expected prognosis (Berger et al., 2008). The relative contribution towards the decision-making process from family members and physicians varies between countries due to differences in culture and legalities. Regardless, it should be clear that considerations regarding the forgoing of life support are a medical issue and the question to the family is to what extent such (in)action is consistent with the values of the patient. In this process the physician may offer a range of therapeutic strategies but also makes specific recommendations for their consideration and assent. It is never appropriate to make the patient and family feel solely responsible for the decision to forgo life-sustaining treatment and. indeed, some patients and families prefer to have physicians make these decisions without consultation (Searight and Gafford, 2005a, 2005a).

Legal guidelines regarding end-of-life decision-making are less clear when patients without capacity lack an appropriate surrogate and in practice, decisions are often made by the intensive care clinicians without judicial, peer, or institutional review (White et al., 2006).

Rarely, there may be times when sedatives and analgesics could be discontinued in the hope of engaging the patient in these decisions (Truog et al., 2008). More often than not, attempts may not result in a return to lucidity because the patient's illness is too severe. Furthermore, such attempts may be inappropriate when the patient's wishes are known, death is imminent, or discontinuing drugs would cause significant pain and suffering. In these situations, surrogates should be entrusted to make decisions for the patient as outlined above.

Organ and tissue donation is an integral part of end-of-life decisions and is grounded in respect for individuals and families, respectful communication and decision-making, and compassionate care (Williams et al., 2003). Patients and their families should be offered this opportunity as standard end-of-life care based on the presumption that organ donation may be consistent with the patient's values or recorded wishes. The request process for donation should focus on the benefit to the potential recipients

and on the possibility of something good coming out of the tragedy of their loved one's death.

End-of-life decisions are stressful and monumental in the lives of those involved (Kesselring et al., 2007; Huang et al., 2012)., consequently the both patients and families must be given as much time as possible to reach their own decisions, and information should be delivered in ways that are sensitive to the patient's cultural, religious, and language needs.

Dealing with conflicts in intensive care

Conflicts regarding end-of-life decisions between families and health-care providers (Breen et al., 2001) or between members of the care team (Goold et al., 2000) are very common. The most common types of conflicts arise around decisions regarding whether to withdraw or withhold treatment (Studdert et al., 2003; Danjoux et al., 2009).

Such conflicts are often very damaging to trust and effective cooperation. From the clinician's perspective, polarization of views with efforts to persuade the family that they are wrong, may degenerate to questioning of the family's competence or intentions (Azoulay et al., 2009; Danjoux et al., 2009). From the family's perspective, this situation is associated with feelings of isolation, misunderstanding, abandonment, and doubt towards the integrity of the clinician's commitment to the patient's best interests (Azoulay et al., 2009; Danjoux et al., 2009).

Meetings to try to resolve conflicts should start by focusing on the common goals of caring for the patient and the family. Since the underlying issue is often distress over the patient's imminent demise, it is also important to acknowledge the emotions that underlie the conflict. Families may need time to come to grips with end-of-life decisions and sometimes simply allowing the family a day or two observe the ongoing deterioration in the patient's condition and to process the information that they received may be enough for them to acknowledge a patient's terminal condition. Often repeated discussions are needed since about half of the family members may not adequately understand the patient's diagnosis, prognosis, or treatment even after meeting with the physician (Azoulay et al., 2000). Many intensive care services work closely with bioethicists and social workers who may be invaluable in helping resolve conflicts (Schneiderman, 2006). It is often useful to have a 'trial of therapy' with agreed goals and timeframes that everyone can agree on (Lecuyer et al., 2007).

Conflicts between staff regarding issues of over treatment or premature forgoing of treatment are very common and are a major cause of moral distress and burnout among intensive care staff (Hamric and Blackhall, 2006; McAndrew et al., 2011; St Ledger et al., 2013). This underscores the importance of collegiality and interdisciplinary involvement in critical decision-making in which the opinions of all relevant staff members are respectfully considered (see Chapter 14.6).

Symptom management in intensive care

When patients are conscious, common symptoms can be evaluated using routinely available symptom assessment scales. However, among those patients who are delirious, sedated, or paralysed evaluations are notoriously difficult (Hawryluck et al., 2002).

There is very limited direct data on the prevalence and severity of symptoms in intensive care. What data are available highlight the prevalence of pain, dyspnoea, thirst, nausea, hunger, tiredness, anxiety, generalized discomfort, and depression (Nelson et al., 2001; Li and Puntillo, 2006; Puntillo et al., 2008, 2010). The high prevalence of post-traumatic stress disorder among survivors is indirect evidence of the severity of trauma involved for many patients (Davydow et al., 2013).

Evidence-based guidelines for the evaluation and management of pain, dyspnoea and delirium in the ICU have recently been updated by the American College of Critical Care Medicine in conjunction with Society of Critical Care Medicine and American Society of Health-System Pharmacists (Barr et al., 2013).

Pain

Pain in the ICU is often related to iatrogenic causes, procedures, and interventions. Moderately or severely uncomfortable procedures that are commonly performed in the ICU include suctioning, turning, catheter insertion, wound care, and the presence of endotracheal and nasogastric tubes (Puntillo et al., 2004). Despite this only a minority of patients receive adequate pain therapy for these procedures (Payen et al., 2007). Minimizing pain with pre-emptive analgesia or avoiding iatrogenic sources of pain should be part of the pain relief plan. Management of patient pain and discomfort with analgesia first, before resorting to sedative therapy, results in improved patient outcomes compared to standard sedative-hypnotic regimens (Devabhakthuni et al., 2012). ICU patients undergoing painful procedures often exhibit facial tension and expressions such as grimacing, frowning, and wincing. Additionally physical movement, immobility, and increased muscle tone may indicate the presence of pain. Tearing and diaphoresis in the sedated paralysed and ventilated patient represents autonomic responses to discomfort (Herr et al., 2006). Based on these observations, standardized pain scoring systems based on physiologic variables and behavioural observations have been developed. The Behavioural Pain Scale was developed and validated for use in the ICU with mechanically ventilated patients (Payen et al., 2001).

Agitation

Patients in intensive care commonly experience agitation and anxiety and the presence of these symptoms are associated with worse clinical outcomes (Atkins et al., 1997; Fraser et al., 2000). Agitation is an undifferentiated clinical symptom and it may be provoked by multiple mechanisms including pain, delirium, hypoxemia, hypoglycaemia, hypotension, or withdrawal from alcohol and other drugs.

Before resorting to sedative medications, steps to reduce anxiety and agitation should be undertaken including optimization of patient comfort, administration of adequate analgesia, frequent reorientation, and adjustment of the environment to maintain normal sleep patterns.

When necessary, sedation should be titrated to maintain a light rather than a deep level of sedation, unless clinically contraindicated. The Richmond Agitation-Sedation Scale (RASS) (Sessler et al., 2002) and Sedation-Agitation Scale (SAS) (Riker et al., 1999; Ryder-Lewis and Nelson, 2008) are the most valid and reliable sedation assessment tools for measuring quality and depth of sedation in adult ICU patients. Non-benzodiazepine medications, such propofol or dexmedetomidine, are associated with improved ICU patient outcomes, including a shortened duration of mechanical ventilation and intensive admission as well as a

lower incidence of delirium and long-term cognitive dysfunction (Barr et al., 2013).

Dyspnoea

Dyspnoea and respiratory distress are common symptoms among patients admitted to an ICU (Nelson et al., 2001; Li and Puntillo, 2006; Puntillo et al., 2008, 2010). Evaluation of respiratory distress among non-verbal ventilated patients is challenging and is dependent on recognition of behavioural indicators of respiratory distress which include (in descending frequency) tachypnoea and tachycardia, a fearful facial expression, accessory muscle use, paradoxical breathing (diaphragmatic), and nasal flaring (Campbell, 2007). Patients undergoing mechanical ventilation generally need some degree of sedation in order to maintain a modicum of comfort. This is usually achieved with propofol or dexmedetomidine (Anger, 2013; Barr et al., 2013). Benzodiazepine medications such as midazolam, while commonly used, are not preferred since they are associated with, more prolonged duration of mechanical ventilation, and higher incidences of delirium and cognitive dysfunction (Barr et al., 2013).

Intravenous opioids and sedatives allow the assumption of greater control of respiratory function with mechanical ventilation, and to decrease the discomforts inherent in being on life support. Intermittent bolus doses of medications are used to supplement the infusions in anticipation of and in response to interventions that would be expected to increase pain and suffering. The use of continuous infusions results in better pain control and lower total doses of medication overall, yet many patients do require moderate to high doses of opioids and sedatives.

Patients who do not require ventilation will often require symptomatic therapy for dyspnoea including oxygen and systemic opioids (see Chapter 8.2).

Delirium

Delirium and agitated delirium are common among ICU patients as a consequence of their medical condition, substance intoxication or withdrawal, use of medication, lack of a day–night cycle, or a combination of these factors and others. Delirium is associated with increased ventilator dependency, an increased length of ICU admission, and higher short- and long-term mortality (Zhang et al., 2013). As with other symptoms, it is often overlooked or misdiagnosed because of the difficulty of assessing mental states in intubated patients.

The Confusion Assessment Method-Intensive Care Unit (CAM-ICU) Assessment Tool was specifically designed for use in non-verbal but rousable intensive care patients (Ely et al., 2001) and is the is the best documented method of diagnosing delirium in the ICU (Jacobi et al., 2002). With the CAM-ICU, delirium is diagnosed when patients demonstrate (a) an acute change in mental status or fluctuating changes in mental status, (b) inattention measured using either an auditory or visual test, and either (c) disorganized thinking, or (d) an altered level of consciousness. This very brief evaluation technique has a 93% sensitivity and 89% specificity for detecting delirium as compared to full DSM-IV assessment by a geriatric psychiatrist (Ely et al., 2001).

As an initial step, patients should be evaluated for distressing symptoms, such as pain or dyspnoea, which may contribute to delirium, and if identified these ought to be addressed. Non-pharmacological approaches include removing physical restraints, promoting sleep, reducing noise and lights, and providing a calming family or staff presence (Harvey, 1996). The use of haloperidol, while common, is contentious and is not well founded in evidence. There are limited data that atypical antipsychotics, such as quetiapine may reduce the duration of delirium in adult ICU patients. Neither of these should be used in patients at high risk for torsades de pointes (patients with baseline prolongation of QT interval, patients receiving concomitant medications known to prolong the QT interval, or patients with a history of this arrhythmia). Data suggests that dexmedetomidine may be the preferred option for delirium unrelated to drug or alcohol withdrawal (Anger, 2013; Barr et al., 2013).

Transitioning to palliative care and foregoing intensive care life-support

When intensive supportive measures are unlikely to achieve the patient's goals of care, or the duration or invasiveness of treatment required to achieve the patient's medical goals would be unacceptable to the patient, treatment goals change and the goals change from curing to a focus on palliative and end-of-life care. This almost always involves decisions regarding the withdrawal (discontinuation) of life support or not starting life support measures (see Chapter 5.8). Indeed, most patients who die in ICUs do so when life-supporting measures are withheld or withdrawn (Prendergast et al., 1998; Prendergast and Puntillo, 2002; Cook et al., 2003; Sprung et al., 2003). In most situations, the recognition that the patient will not survive occurs relatively quickly, most often in less than 4 days (Sprung et al., 2003). Both changing goals and making decisions to withhold/withdraw life-support are difficult for all involved, and implementing them requires planning skill and a high level of clinical vigilance and compassion.

Preparing the family members

Family preparation begins with discussions such as those described above (Truog et al., 2008). Clinicians must assist families through both the transition in goals and the dying process of the patient. Families need detailed explanations about the steps that will be taken to ensure patient comfort, and should also be prepared for the physical changes their loved one will likely undergo. The anticipated changes in respiratory pattern should be described as a normal part of the dying process. Clinicians should offer families the opportunity to spend more time with their loved one prior to withdrawal of life support and, if need be, to meet with a spiritual carer (e.g. chaplain) or a social worker.

Place of care

To the extent possible in the difficult environment of the ICU, the goal is to provide both patient and family a quiet, private space devoid of technology and alarms. This may be difficult in units where patient beds are separated by curtains. When the dying process is prolonged or when demands for an ICU bed cannot be met in other ways, transfer to another area in the hospital may be unavoidable. It is important to start communicating this possibility a day or two before it is necessary. This transfer should occur smoothly with deference to the needs of the patient and family. Some actively dying patients with difficult-to-treat symptoms may actually benefit from ongoing care in the ICU to ensure a comfortable death. Every effort should be taken to reassure family members that continuity of clinical and especially comfort care will be maintained.

Comfort measures

Ensure availability of analgesics and sedatives to rapidly treat distress. This should include infusions of opioids and sedatives, as well as bolus doses of rapidly acting agents to manage distress.

Discontinue interventions that are not consistent with the goals of care

All routine interventions that provide no comfort to the patient (e.g. routine vital signs, blood tests, and radiographs) should be discontinued. All therapies should be re-evaluated and those that do not contribute to patient comfort should be discontinued. An 'allow natural death' (AND) or 'do-not-resuscitate' (DNR) order should be documented (Truog et al., 2008). Unless there are specific objections by family members, electronic monitoring should generally be discontinued as it does not provide comfort and it may distract the family from care of the patient and of one another (Rubenfeld, 2004; Truog et al., 2008). Discontinuation of vasopressors, inotropes, and antibiotics results in no discomfort and they do not need to be weaned (Truog et al., 2008).

When a patient has specifically refused one form of life-sustaining treatment on the basis of personal values (e.g. when a patient refuses intubation while requesting other therapies) continuing limited sets of life-sustaining treatments is reasonable and appropriate. In general, these wishes should be followed as long as they are consistent with good quality care and they do not compromise the care of other patients.

Discontinuing medical ventilation

This is the most dramatic aspect of end-of-life care in the ICU. Discontinuing mechanical ventilation is often very difficult, and sometimes traumatic for clinicians and families alike. The goal is to discontinue ventilation in a manner compatible with staff and family sensitivities and at the same time to assure patient comfort during all phases of the procedure. Well-tested protocols have been developed and published to facilitate safe and effective approaches to withdrawing mechanical ventilation (Treece et al., 2004). Among the principal considerations are the following key elements:

Discontinue neuromuscular blockade

Neuromuscular blockade may mask patient distress and confound the physical assessment of stress (Brody et al., 1997). Neuromuscular blockade should be discontinued before withdrawal of life support either by allowing the paralytic agent to wear off or by pharmacologically reversing its effects. In the rare cases in which it is felt that waiting for the return of neuromuscular function would be excessively burdensome, deep sedation should be established before withdrawal of therapies (Truog et al., 2008).

Pre-emptive sedation

Many patients may need pre-emptive dosing of opioids and sedatives to prevent any sudden increase in dyspnoea which may occur even if the patient has been gradually weaned from ventilator support (Billings, 2012). The amount of opioids and sedatives required is variable and is influenced by the baseline dosing requirements prior to withdrawal and the patient's level of distress. There is wide interindividual variability for dosing requirements and, for some patients required doses may be high (Brody et al., 1997). Sedation should be administered continually with provision for bolus rescue doses as needed (Brody et al., 1997).

Whether discontinuation of ventilatory support should be accompanied by pre-emptive anaesthesia and deep sedation is controversial. While this is accepted practice in some places (Billings, 2012), it is not universal and some argue that this is a modified version of physician-assisted death (Rady and Verheijde, 2010; Carvalho et al., 2011).

Discontinuing ventilation support

Ventilator support is gradually withdrawn by decreasing the fraction of inspired oxygen and the amount of positive pressure ventilation over a period of 10–30 minutes in a way that allows the patient to comfortably transition to spontaneous breathing on room air through the endotracheal tube. The patient is assessed for signs of distress after each reduction in support and additional boluses of intravenous analgesics or sedatives should be administered as needed.

Extubation or not

Practices vary widely with regard to extubation (Brody et al., 1997). Extubation at the end of life is a complex decision that defies dogmatic approaches and agreement should be achieved between staff and the patients surrogate decision-makers regarding this issue. While some clinicians suggest extubating the patient to free the patient from unnecessary lines and tubes prior to death, and to facilitate a more natural appearance during the dying process this may not always be prudent. Patients who are extubated after receiving high levels of ventilator support, and those with difficulty clearing secretions or protecting their airway, often become distressed with struggling and gasping (Prendergast and Puntillo, 2002). Indeed, in many situations, especially when upper airway collapse is anticipated, it is acceptable to leave the endotracheal tube in place.

Continuing care

Patients should be cared for in a clinical setting that allows for monitoring of symptoms and the ability to treat them effectively. Some actively dying patients with difficult-to-treat symptoms may benefit from ongoing care in the ICU to ensure a comfortable death.

At the bedside of the imminently dying patient

Whenever possible, a member of the health-care provider team should offer to be available to be with the family as the patient is dying. Such a presence reinforces that the dying patient's welfare remains important, and provides support and guidance to the family at a time of extreme stress. In so doing, the health-care professional can defuse some of the strangeness of the situation for the family, and make it somehow more of a normal and natural process (as indeed it is).

When possible, encourage family participation in patient care (Prendergast and Puntillo, 2002). This promotes a sense of comfort, intimacy, and involvement when families are in an otherwise strange and tragic and, sometimes, impersonal situation. Family members can be encouraged to communicate with their loved one through speech, touch, song, prayer, or music. Caregiving activities can include assisting with face washing or hair combing, or gentle massage. For some family members, however, being present as the patient is dying is overwhelming and respect for emotional limits is itself a caring practice.

The role of the clinician at the bedside of the dying patient is to ensure adequate relief of patient distress and to provide support

and guidance to the grieving family. The physician should evaluate the patient to ensure that the patient is comfortable. If present, pain, dyspnoea, agitation, or any other distressing symptoms that are remediable should be rapidly and effectively treated. Once adequate comfort is achieved, the physician should reassure the family that the patient is not in distress.

Families vary in the degree of professional support necessary at the bedside of the dying. Attentive and continual presence is often needed when family supports are limited or coping is frail. In other situations it may be more appropriate for the clinician to acknowledge the primacy of family and friends in this setting and to take a background position of availability if necessary.

If it is clear that breaths are agonal and the patient is about to die, it is often appropriate to indicate this to the family with the reassurance that the patient appears comfortable. The clinician should indicate that death has occurred when there are no signs of life and offer support and condolences. Families often talk and cry over the dead person, kiss them, and hug them. Adequate provision for time and privacy in this situation is strongly recommended.

After a patient death

The death of a patient stresses the physical and emotional resources of the professional health-care providers as well as the grieving family and friends. Members of the care team often require some degree of emotional recuperation. This process can be facilitated by expressions of mutual support and appreciation, and debriefing sessions in which the care of the patient is reviewed. The patient's family should be contacted personally to enquire about their well-being and to offer a meeting to address any outstanding issues regarding the patient's illness, treatment, and death.

Organizational issues for palliative care in the ICU

Models of care

A variety of models have been proposed to enhance palliative care involvement in the care of ICU patients. The Improving Palliative Care in the ICU (IPAL-ICU) project has identified two main models of palliative care involvement in ICUs (Strand and Billings, 2012).

A 'consultative model' seeks to increase the involvement of dedicated teams of palliative care clinicians in the care of ICU patients, especially for those patients at high risk for suffering and death. In this model, palliative care experts/teams are called in by the ICU team once the latter have recognized relevant problems with care. These tend to occur when the patient, family, and staff experience conflicts around goals and methods of care. Studies on the use of proactive palliative care consultations for patients at a high risk for dying, led to significant reductions in ICU length of stay, increased DNR ('do not resuscitate') orders, reduced non-beneficial resource utilization after a DNR order, and increased transition to goals focused on comfort, without affecting mortality rates (Campbell and Guzman, 2004; Norton et al., 2007). Proactive ethics consultations for patients at high risk of dying, have also demonstrated similar benefits, including reduced conflict among the staff members and between staff and family members (Schneiderman et al., 2000).

An 'integrative model' promotes integration of palliative care principles and education into the daily care of all ICU patients by ICU teams. This approach is less reliant on palliative care services or on the willingness of ICU staff to refer to palliative clinicians. This model focuses on interventions to increase staff awareness of patient/family palliative care needs, improve communication skills, and incorporate palliative care skills training in staff education. This model of care requires collaboration between ICU and palliative care leadership in the development of palliative care guidelines for use in ICU, and the training of ICU 'nurse experts' to promote palliative care principles in the ICU. Some departments combine the consultative and integrative approaches.

Education

Although there is a wide consensus that end-of-life care is a critical skill for intensive care clinicians, there are no uniform widely endorsed guidelines for the training of intensive care clinicians in palliative and end-of-life care and evidence suggests that the scope of actual training is variable (Kane et al., 1998; Nelson et al., 2006; Lofmark et al., 2008; Forte et al., 2012). The European COBATRICE core curriculum for ICU professionals includes palliative care competencies such as discussions of end-of-life care with patients and families, and the management of withholding and/or withdrawal of death deferring therapies but provides little detail on the scope or nature of the training and competencies to be achieved (Bion and Barrett, 2006).

Detailed curriculum guidance was developed by a multidisciplinary taskforce including intensive care specialists, palliative care specialists, ethicists, and consumer advocates (Danis et al., 1999). This very comprehensive document highlighted nine attitudes and skills critical for good palliative care performance by intensive care clinicians: appreciating the patient as a person; communicating effectively by listening well to patients and their families; being able to deal with prognostic uncertainty; being comfortable broaching the topic of death with patients and their families, and supporting them in facing this reality; negotiating the overall goals of care; switching from the simultaneous provision of life-supporting therapy and comfort care to comfort care only; providing excellent palliative care; giving explanations, ranging from small details to the large picture, in clear, understandable language; and working effectively in collaboration with a multidisciplinary health-care team. The American Association of Colleges of Nursing have developed a comprehensive modular training programme for end-of-life care specifically designed for nurses working in intensive care (Ferrell et al., 2007).

Improving palliative care practices in an established ICU

An international multidisciplinary working group has developed a practical guide for organizing initiatives to improve palliative care in an ICU (Nelson et al., 2010b). They advocate a phased mutistep process as outlined in the following sections:

Convene an interdisciplinary planning/implementation workgroup

Identify a core group of 'key stakeholders' who will collaborate to plan and lead implementation of the effort. These should include leaders from the ICU, the palliative care consultation service, and hospital administration. Representation of both physicians and nurses is essential, and involvement of staff educators and other disciplines such as social work, psychology, and chaplaincy is preferred.

Conduct a needs assessment

The needs assessment identifies opportunities and priorities for improvement, highlights the importance of the initiative, justifies the investment of resources including staff effort, helps to build support and collaboration within the ICU, and provides a baseline for evaluating results. This step should be completed before the development of strategies to improve care.

Define the problem

An ICU palliative care initiative is often prompted by concerns about one or more of the following: (1) high rates of death or other unfavourable outcomes in the ICU; (2) high utilization of ICU resources for patients who are unlikely to benefit, constricting availability for other patients in need; (3) distress or dissatisfaction reported by patients and/or families; (4) delayed and/or inconsistent performance of evidence-based palliative care processes such as identification of the patient's surrogate decision-maker, investigation of advance directive status, and proactive communication about prognosis and care goals between the interdisciplinary ICU team and the patient's family; (5) distress or burnout experienced by ICU staff; and (6) underutilization of palliative care specialists in care of ICU patients.

Evaluate resources for end-of-life care for ICU patients

This process should incorporate an inventory of available resources such as the availability of an adequately-staffed palliative care consultation service, social worker, mental health professional, chaplain, and ethics consultant. Educational resources are critical since clinicians may need to strengthen knowledge and skills in relevant areas of palliative care, such as management of multiple symptoms in the context of organ failure and adverse effects from first-line analgesic therapy; legal, regulatory, ethical, and empirical frameworks for surrogate decision-making and limitation of intensive care therapies; and approaches to prognostic uncertainty, strong emotions, and conflict in ICU family meetings.

This process should also seek alternative places of care for patients who no longer need or cannot benefit from continued ICU therapy. An increasing number of hospitals have created in-patient palliative care units that can accept ICU patients for whom comfort has become the paramount goal of care; some of these units will care for patients receiving mechanical ventilation. In other hospitals, ventilated patients whose care is focused on comfort can be transferred to a regular ward. Step-down units may also be available.

Develop an action plan

The report highlights five key steps in developing an action plan for a successful and sustainable ICU palliative care initiative: (1) establish overall goals that address unmet needs using available resources, and that are consistent with institutional priorities; (2) set initial targets that are clear and feasible within a specified time frame; (3) identify the changes in clinical practice and systems that are needed to achieve the targets; (4) address the need for new documentation processes to reflect clinical changes; and (5) plan for evaluation of progress toward specific targets and overall goals. For example, an ICU aiming to improve communication between the clinical team and families of critically ill patients may set a target that within 6 months at least half of families of patients in ICU for 5 or more days will have opportunity to meet with interdisciplinary ICU team for goal setting.

Conclusions

Intensive care patients have high degrees of morbidity and a relatively high risk of mortality. Under these circumstances, quality care demands a high level of skill in the core palliative care competencies, including communication, symptom control, goal setting, and end-of-life care. The particularities of the intensive care setting alter the context of discussions and decision-making and the particular issues relating to the foregoing of life-sustaining interventions as part of end-of-life care. The right of patients to adequate relief of unpleasant symptoms at the end of life and the right of family members to compassionate care imply duties incumbent upon individual clinicians working in this setting as well as on the organizational structures to ensure adequate levels of skill, compassion, and organization to meet the challenging needs of intensive care patients and their families.

Further research is required to optimize strategies for staff education, to reduce the incidence of conflict and moral distress surrounding these issues, which is common in this setting, and to optimize the delivery of palliative care in intensive care setting.

SECTION 16

Issues of the very young and the very old

16.1

Talking with families and children about the death of a parent

Anna C. Muriel and Paula K. Rauch

Introduction to talking with families and children about the death of a parent

Anticipating the death of an adult who is the parent of young children is particularly distressing for families and medical providers. Concerns about the children's welfare, and impulses to protect children from the pain of parental loss, create challenges to honest communication. Nonetheless, attention to children's developmental stage and specific needs can guide clinicians in helping surviving family members to support children during the end-of-life period and into bereavement.

Clinicians and families alike may fear that parental loss during childhood will necessarily create mental health problems in the future, but studies show that the majority of bereaved children do not develop psychiatric disorders. While the loss of a parent during childhood will certainly affect a person's life, individuals usually go on to have meaningful lives and loving relationships. Studies of bereaved children from the time of a parent's death reveal that even though many children may develop non-specific, subclinical, and transient behavioural disturbances (Vida and Grizenko, 1989; Black, 1998) in the year following a parent's death, only one in five children develop a psychiatric disorder (Dowdney, 2000). Epidemiological studies highlight the importance of pre-existing psychosocial risk factors in families with an ill parent, and higher rates of subclinical psychiatric issues and decreased global function in children following the death of a parent (Kaplow et al., 2010). Rather than the simple fact of parental loss predicting future difficulties, studies also show that the quality of the surviving parent's care (Harris et al., 1986; Bifulco et al., 1987), or general home life (Breier et al., 1988) are better predictors of subsequent adult depression. Other factors that may mediate depression in adulthood are reports of warmth and empathy in surviving parents, and the opportunity to participate in the mourning process (Saler and Skolnick, 1992).

Research on normative childhood bereavement has found that children make active efforts to maintain a connection to their deceased parents, and construct a relationship that may shift with developmental stages in an effort to cope effectively with the loss (Silverman et al., 1992). The role of the surviving parent can be particularly important in providing the child with opportunities to remember and memorialize the dead parent, facilitating integration of the loss throughout different phases of growth and development (Nickman et al., 1998).

The terminal phase of parental illness may be a vulnerable time for children as they experience more anxiety and depression, lower self-esteem, fears, misconceptions, and behaviour changes (Christ et al., 1993, 1994; Siegel et al., 1996). The literature on children's coping with parental illness shows that children living with parental cancer have more anxiety associated with an inability to discuss the illness, decreased time spent in age-appropriate activities, and ongoing worries about the cancer (Nelson et al., 1994). These anxieties may be mediated by increased communication, as children given specific information about the illness have been shown to have lower rates of anxiety (Rosenheim and Reicher, 1985). However, these conversations between parents and children may not happen readily; even parents who are generally rated highly as communicators by their children are no more likely to disclose the probability of death than parents with low general communication ratings (Siegel et al., 1996).

Parental depression and family dysfunction in the context of parental illness are also important predictors of child emotional and behavioural problems (Thastum et al., 2009). Families coping with anticipated deaths may be additionally vulnerable to parent–child differences in coping due to the well parent's physical and emotional preoccupation with the dying spouse, as well as differences in cognitive understanding and therefore anticipation of the death (Saldinger et al., 2004). These differences may have implications for child coping and outcomes (Saldinger et al., 1999). There may also be a range of children's responses to the graphic experience of a parent's terminal illness with attendant changes in appearance, function, and dependence on medical equipment, which can sometimes, but not always, be mediated by overwhelmed adult caregivers (Saldinger et al., 2003).

Specific attention is needed for patients as parents, and targeted interventions may help mediate parental, family, and child distress. Some subsets of parents may have higher levels of concern about their children, including mothers, single parents, or those with metastatic or recurrent cancer, a subjective understanding of incurable disease, and current mental health treatment (Muriel et al., 2012). Parents of children under 18 years have higher rates of panic and anxiety than patients with advanced cancer who do not have dependent children. This population of parents has also been shown to prefer more aggressive treatment, and to be less likely to engage in advanced care planning. They were also judged by their caregivers to have worse quality of life in the last week of life (Nilsson et al., 2009). Palliative care clinicians are poised

to address parenting issues directly and ease family suffering through open communication, planning, and support.

How children understand death at different ages

In thinking about how to talk with families and children anticipating parental death, it is essential to have a sense of how children at different ages understand death itself. This will be influenced by children's general level of cognitive and emotional development as well as by their exposure to death in their community. There will be individual variations in children's temperaments and development, and parents need to be respected in knowing their own children best. For clinicians, however, an understanding of basic needs at different ages provides a useful guide for recommendations for supporting children during the terminal phase of a parent's illness and death.

Infants and toddlers (0–2 years)

Infants and toddlers are working on the complex tasks of attachment, basic self-regulation, and trust in their environment and caregivers. These youngsters have no understanding of time, or of the finality of death. However, they are sensitive to separations, and will feel the absence of a familiar caregiver even with no comprehension of the permanence of death. They may be distressed by changes in regular routines, and will also probably be affected by the emotional distress of grieving adults around them.

While familiarity and structure are helpful for people of all ages during difficult times, it is even more essential for the youngest children. During the stressful months or weeks leading up to a parent's death, it is best if infants and toddlers can be cared for by a limited number of familiar caregivers who can get to know a child's routine and provide care in as consistent and predictable a way as possible. Feeding, nappy changing, bathing, and sleeping should have associated routines and things that help a child to feel secure: bottles and cups, stuffed animals and toys, blankets, and portable crib are examples of important items. The closest caregivers can provide schedules and instructions for other childcare helpers to ensure that important parts of the child's day proceed in a predictable manner even when they are not available.

Pre-schoolers (3–6 years)

Pre-school children have a wider range of social interactions, and particular ways of understanding the world around them. Egocentrism, associative logic, and magical thinking have strong bearings on how they understand parental illness and death. These self-referential ideas need to be mediated in order to prevent misunderstandings and guilt about what is happening in their family. For example, a 4-year-old may believe that something they did, like jump on a parent or misbehave, caused their parent's illness. A child who yells 'Bad Mummy' during a tantrum may think that saying this, or wishing her to 'go away', can actually make someone die and go away. Children of this age do not yet have an understanding of the irreversibility of death, and so they may also offer solutions to death, and expect the person to be 'all better'. They may also attribute the grief and distress of other adults to their own behaviour and need frequent reminders that they are not the cause of everyone's upset feelings.

Pre-schoolers, therefore, need regular conversations about how nothing a child says or does can make a parent ill or die. Adults need to enquire about how the child thinks their parent became ill or died, and dispel misconceptions repeatedly. In addition, caregivers may need to be patient with a natural disconnection of feelings and content, such that a child might talk about the death very matter-of-factly or make up a song about it, and yet might become cranky or have trouble with routine activities or changes in schedule. Parents of pre-schoolers can also expect some regression under stress, so that a fully toilet-trained child may have trouble using the potty, or a child may get upset being dropped off at a previously beloved nursery.

In discussing death with young children it is important to be concrete and use observable examples. Descriptions of death as 'going to sleep' can create worries about bedtime or not waking up. Heaven may be conceptualized as a place that one can visit or come back from. It is therefore helpful to talk about death as meaning that 'the body doesn't work anymore', that the person can't move or breathe, or think or feel, etc. Adult survivors are sometimes surprised and disturbed by how often young children need this explanation.

School-age children (7–12 years)

School-age children are immersed in mastering academic, physical, and social skills, and are working to understand cause and effect logic. They are often quite invested in fairness and are sensitive to things that set them apart from their peers. By 6 or 7 years of age children understand consistently the permanence of death. Their conceptions may still be very concrete, though, and they may have difficulty understanding more abstract or spiritual issues. In fact, they can be preoccupied with factual, medical, or physical aspects of death and dying that feel difficult for adults to discuss. The uncertainty about time that is inherent in terminal illness may be particularly hard for younger children to grasp, and so anticipating the death itself may become distorted. For example, a 10-year-old child hearing that a parent is very, very ill and 'coming home to die', may think that the parent will die that very night. School-age children are also vulnerable to worries about their own health or the health of their surviving family members, and need reassurances about this over time.

Because so much of these children's day is spent at school, it is important that the appropriate school personnel be informed about what is happening with an ill and dying parent. Children may not want to have teachers approach them to discuss the illness at school. However, they should know to whom they can go if they are having a difficult day. Teachers might adjust some expectations for schoolwork, but it is helpful for children to still have a certain level of responsibility and routines so that they understand that life will go on even in the context of a parent's illness and death. Children may also need additional help with school tasks and activities, and families may come to rely on other families in their community in order to support their children's participation in age-appropriate activities.

Adolescents (13 years and older)

Teenagers are in the process of identity formation and separation from parents. They have more adult capacities for abstract thinking, but their brains are not fully mature until into their twenties. Adolescents understand that death is final, irreversible, and

Box 16.1.1 How children understand death at different ages

Infants and toddlers (0–2 years)

Developmental context: establishing attachment and trust.

◆ Have no understanding of finality of separation, but feel absence of a familiar caregiver

◆ May be distressed by disruptions in routines

◆ Will be affected by the emotional distress/grief of surviving adult caregivers.

Pre-schoolers (3–6 years)

Developmental context: driven by egocentrism, magical thinking, associative logic.

◆ Are not able to understand that death is irreversible and permanent

◆ May attribute death or survivors' emotional distress to own actions or attributes

◆ Distress and behavioural changes may be fuelled by disruption in routine.

School-age children (7–12 years)

Developmental context: mastering skills, fairness, cause and effect logic, peer relationships.

◆ Understand that death is final and irreversible

◆ May have difficulty with abstract/spiritual issues

◆ May ask factual questions that can be painful or offensive to adults

◆ May struggle with unfairness of loss.

Adolescents (13 and above)

Developmental context: working on separation-individuation, identity formation.

◆ Understand that death is final, irreversible, and universal

◆ May struggle with existential issues

◆ May focus on personal effects of loss.

universal, and may think actively about existential and spiritual issues. They may also vacillate between abstract ideas about their parent's death, and being preoccupied with very specific and self-centred ways in which it affects their life. These young people are also likely to project forward into the future and worry about their life progressing without their parent, anticipating sadness about milestones that their parent will not be there to witness.

Surviving caregivers may need help to understand adolescent self-involvement as developmentally normal, and not attribute it to negative character flaws. In addition, adolescents will continue to need support and guidance, and be at risk of more independence than they are ready for in the context of a parental death. Families should be careful of teenagers who are taking on too many adult responsibilities, or are engaging in risky behaviours such as substance abuse or illegal activity. Older adolescents also need specific information about a parent's illness and probability of death as they make decisions about moving away from home for

employment or education. While parents may want to give them as much freedom as possible, these young adults need accurate information in order to make decisions that will be most comfortable for them, and minimize the possibility of regrets about being too close or too far away during the end of a parent's life (Box 16.1.1).

An approach to talking with families

With a basic understanding of where children are developmentally, clinicians can address parental concerns about helping their children through this difficult time. This task will also be influenced by the family culture around communication in general, the adults' capacities to integrate end-of-life care, and the expected progression of disease.

Clinicians can begin by assessing the adults' understanding and expectations of the illness and death. What do they understand about the expected time course? What do they know about the expected symptomatology? What do they hope for in terms of location and likely medical circumstances of the death?

The stage is then set to explore with the parents the children's understanding of the illness to date. What language has been used? What do they expect about the outcome of the illness? What prior experiences have the children had of major life changes, or death in their community or family? How have they managed these as a family? Do the parents have particular concerns about their children's coping with the illness so far? What are they worried about in terms of their coping with death? The answers to these questions will provide scaffolding for the discussion, and help parents to have honest conversations with their children while addressing worries and misconceptions along the way. Parents should be encouraged to use honest, straightforward, and age-appropriate language, checking frequently for the children's understanding, and welcoming questions as they arise. If the children have not yet been told the specific name of the illness, for example, 'leukaemia', 'glioblastoma', or 'cardiomyopathy', it is important to do so now, to minimize confusion and anxiety about illness in general.

With careful discussion with parents and adult caregivers, it may not be necessary for clinicians to meet directly with the children. In some clinical settings, it is not possible, and for most children information mediated by their parents is most easily integrated and discussed in varying iterations over time. However, when children are present during medical encounters by chance or by design, they should be welcomed into the discussion so that their questions can be addressed. Some older children may ask to participate in meetings with medical providers in order to feel included more fully in the family experience. Children may stump clinicians or parents with questions that are anxiety-provoking or out of the blue. Asking a child what got them thinking about that issue may help clarify exactly what the child is curious or worried about, and allow adults to provide specific answers without going into more detail than the child is interested in.

Timing of discussions with children

Families often wonder when to talk about the terminal nature of a parent's illness with the children. Sometimes it is hard for parents to talk openly, even when the children have already observed the parent's deteriorating status, or have overheard others talking about the likelihood of death. At other times, parents have

trouble holding back the fact that there is a transition in care from curative to palliative treatment, even if there is no observable change in the parent's appearance or function, and death is probably many months away.

Generally, the worst way for a child to hear news is by overhearing it, and many children will experience well-intentioned protection as exclusion. A child left to their own conclusions about a parent's terminal illness may also be vulnerable to misconceptions about why the illness is progressing, or how their life will change after a parent dies. On the other hand, it is difficult for younger children to understand that a parent may live for some time even in the terminal phase, and it is confusing to be anticipating the death at every turn.

It is important to discuss the changes in a parent's appearance and functional status as they occur, and potentially use these markers to discuss the probability of death within weeks or days with children school-age or above. Many children will ask about death directly in the context of seeing a parent getting 'worse, or very, very sick'. For adults who feel worried about introducing the idea of death, asking, 'Do you know what could happen if Mum gets even more unwell? Or different parts of her body stop working?' will allow children to articulate that they are worried about death too. For the youngest children, acknowledging the functional changes as they pertain to their interactions with the parent may be enough: 'Dad used to be able to take walks with us and play with you, but now he can't because he is more unwell, so he stays in bed a lot.' Conversations with pre-school children about death may be most meaningful after the death has occurred.

Decisions about the setting for end-of-life care in a family context

One of the most important decisions for families facing an anticipated parental death is where they would like the death to occur. There is no one answer that will suit every family, and the ill adult may have prior experience or personal wishes that will dictate whether they die at home, in the hospital, or in an inpatient hospice setting. If families have choices, they should consider the needs of the children in addition to the medical or personal needs of the dying person.

Sometimes an inpatient hospice or hospital setting makes the most sense for families. In this case, the challenge may be that the well parent will have to divide their time between the inpatient setting with their spouse, and being at home with the children. Having thoughtful, familiar adults at home can ease this strain and allow the children to continue with their usual home and school activities. Visits with children should be facilitated whenever possible (see 'Visits between ill parents and children').

If families are interested in home hospice services, and expect a parent to die at home, attention to certain logistical details can make things more comfortable for children. Whenever possible, having the dying parent in a room with a door, as opposed to an open or family area, allows the children to titrate their own exposure to the ill parent and medical equipment. The advantage of having everyone at home is that the children can maintain their usual routines and probably have more access to their well parent. If there will be other adults staying in the home to help, they should also be aware of the children's needs for privacy and daily routines. A home death also makes it even more important to talk

about changes in medical status and check for questions or misconceptions about what is happening. Children may have particular fears about the death itself, and clinicians can help both adults and children who are curious by anticipating symptoms and treatments for pain, secretions, shortness of breath, etc., and explaining what the physical process of dying might look and sound like. This also allows older children to consider how much they want to be around during the final days and hours. When a parent dies at home, thought should be given to where the children will be when the undertaker arrives to remove the body.

Visits between ill parents and children

If a parent is expected to die in an inpatient or hospice setting, visits from children should be facilitated whenever possible. Children who express reluctance may have specific worries, for example, seeing blood, or having their parent die during the visit, and can usually be reassured with explanations and contingency plans. It is best to avoid an agitated or delirious parent who may be frightening, but a child can still visit a sedated parent. Older children and adolescents who are reluctant to visit need opportunities to discuss their concerns, and be able to make a decision for themselves that they can feel comfortable with over time.

Most importantly, children need to be prepared for the visit, with descriptions of the setting, medical equipment, roommates, as well as the physical and functional status of the parent. For younger children, these descriptions may need to be concrete comparisons to the last time they saw their parent. An additional supportive adult should accompany the child so that they can leave when the child is ready, even if the well parent would like to stay. Younger children may only be able to tolerate brief visits, or might need structured quiet play or drawing activities to do in the room. Touching a sick parent should never be forced, but can be modelled and supported if the child is willing. After the visit, adult caregivers should take some time to debrief and ask the child what was most interesting, fun, scary, or uncomfortable, in order to reassure the child and prepare better for the next visit. When personal visits are not possible, other kinds of contact between the ill parent and child should be encouraged. Children often enjoy making cards and notes that can be used to decorate a hospital room, and if able, parents can make recordings of themselves reading books or singing songs that can go home to young children (Box 16.1.2).

When death is imminent, last visits can be meaningful for children once they have an understanding of the finality of death. Older children may have the same wishes that adults do to have a few minutes alone with a dying parent, even if comatose, to say a last 'I love you', or share an important private moment. If possible, older school-age and teenage children should be asked about whether or not they want to be called to the bedside near the end of life or immediately after the death. For example, does a child want to be brought home from school, or woken in the middle of the night at the time of death, or not? Some children very much want to be included, while others may prefer to have healthier memories of their parent, or feel afraid and uncomfortable about seeing their parent very ill and dying. The guiding principle is to provide children with information so that they can make decisions that will help them feel that their needs and wishes are considered during this important time. It is important to remind families,

Box 16.1.2 Facilitating visits to an ill or dying parent

◆ Explore and alleviate worries or reluctance about visiting

◆ Prepare children for what they will see:
  • hospital or hospice setting
  • medical equipment
  • other patients
  • physical condition of parent
  • functional status of parent

◆ Bring an extra supportive adult who can leave when the child is ready

◆ Provide structure or activity for younger children

◆ Avoid an agitated or delirious parent

◆ Debrief after the visit

◆ Provide alternatives to a personal visit

◆ Remember that there are many opportunities to say goodbye.

however, that there are many opportunities to say goodbye before the death, immediately afterwards, during memorial services and funerals, as well as during private moments of reflection or prayer.

Legacy leaving

Parents who have come to terms with a diagnosis of a terminal illness often think about specific legacies or communications that they would like to leave for their children. Even the usual family photos and memorabilia become good foundations for telling stories about a parent after they have died. Parents may choose a variety of other more intentional communications, such as letters or audio recordings specifically for each child, or at particular milestones. There is little data on how these communications are received by children over time, but surviving children often look for indications from both the dead parent and surviving adults, about who the parent was as a person, their values and ideals, and what the parent saw in them, their child. Sometimes parents leave specific meaningful objects, or annotate books, music, or movies that have been important to them. Children may want to choose special objects to keep themselves either before or after the death. The wider community can also be engaged in legacy-leaving, as friends and relatives attending the memorial service can be asked to write down a memory or thought about the parent that can be compiled for the children and shared when they are curious later. Children spend a lifetime revisiting the loss of the parent, and may become interested in their parent as they themselves reach different phases in their own life.

Children's participation in funerals and memorial services

Children of any age may participate in different aspects of funerals and memorial services. Family tradition will dictate whether there is a wake, religious service, interment, or family gathering afterwards, and children may be included for all or part of these events. As with hospital visits, it is important to prepare children for what the event will be like including the setting, who will be there, what the service will be like, what they will and will not be able to do, and that there may be a range of feelings expressed by people, from sadness to warmth and humour. Younger children will need a familiar adult to care for them throughout, and be responsive or leave when they are unable to sit still or remain quiet.

Older school-age and teenage children can be included in the planning or asked if they want to participate by reading, or playing music during the service. Many funeral homes will provide a private time for the family to have a special children's service or quiet visiting time. Children sometimes like to place a picture, note, or special object in or on top of the coffin. School-age children may have specific questions about the preparation of the body or cremation. Adult caregivers may want to learn about the process in advance, so that they can answer children's questions better. Alternatively, they should know whom to ask (funeral directors sometimes have age-appropriate information) about these issues during the difficult and chaotic days around the parent's death. Younger children, who do not yet fully understand death, may find the interment disturbing as they do not want to see their parent lowered into the cold, dark ground. Families may consider not having young children attend the burial itself, and be able to visit the gravesite at another time. For families who spread ashes or have non-traditional services that do not involve a burial site, it may still be important for the family to designate a special place to go to reflect or remember the parent.

Conclusion

The untimely death of a parent is one of the most challenging events for families and the clinicians who care for them. Attention to children's needs during this time is an important aspect of clinical care, and is much appreciated by adults in the family. A basic knowledge of child development and the ways that children understand illness and death can provide a template from which to engage families about how to help their children during this time and into bereavement. When clinicians support honest, child-centred communication, and help families anticipate common situations and questions, surviving adults are able to use their own best resources to provide thoughtful care for the children.

Care of children with advanced illness

John J. Collins, Kirsty Campbell, Wendy Edmonds, Judith Frost, Martha F. Mherekumombe, and Natasha Samy

Introduction to care of children with advanced illness

The World Health Organization (WHO) supports the global application of the principles of palliative care to every child with a life-limiting illness, irrespective of geographical location (WHO, 1998a) whilst acknowledging that treatment options are limited in some countries. The care of the child with advanced and progressive illness and their family requires a holistic approach to the often complex physical, social, psychological, and spiritual needs as well as support in bereavement. This inevitably requires a paediatric palliative care team with diverse skills and abilities to meet these needs.

This chapter will discuss the global perspective of paediatric palliative care and the role of the team, nursing, and volunteers in that care. The significant physical and psychosocial issues for the child with advanced illness will be discussed, as well as bereavement support of families. The necessity of quality improvement and strategies for setting up such a programme will be outlined. The reader is directed to Box 16.2.1 for additional resources and to Section 9 in this textbook regarding pain management for children needing palliative care.

Paediatric palliative care: a global perspective

Most of the world's children with advanced incurable illnesses die either in hospital or at home. Inpatient hospice units for children are an alternative for some children and are usually located in more affluent countries. While paediatric palliative care services are growing globally, approximately 70% of the world's children have no access to paediatric palliative care and only 6% have fully and multiple integrated services (Knapp et al., 2011). There is a greater disease burden in developing countries with more deaths, almost half of these occurring in Africa (Downing et al., 2012). Paediatric palliative care provision and delivery in developing countries can only happen through increased resources (Downing et al., 2012).

According to the World Bank, a developing country is one with a low- or middle-level economy per gross national product per capita and it also includes Hong Kong (China), Israel, Kuwait,

Singapore, and the United Arab Emirates (World Bank, 2004). The funding required for palliative care services is often beyond the financial means of many developing countries. Palliative care service implementation is sometimes hindered by lack of economic and political government support. Funding sources in such circumstances are often from external resources and by non-governmental organizations (Callaway et al., 2007). Despite all the problems encountered in developing countries, there continues to be a growing awareness of the need for paediatric palliative care and the International Children's Palliative Care Network (ICPCN) is at the forefront of the global development of paediatric palliative care.

Africa

Just over 40% of African children are under the age of 15, with a mortality rate of 14.5%, mostly in sub-Saharan Africa (Downing et al., 2010). The under-5 child mortality rate in Sub-Saharan Africa is one in eight, more than 17 times the average for developed regions which is one in 143 (United Nations Children's Fund, 2011). Although most of the deaths are from communicable diseases and malnutrition, a large number of deaths are attributable to HIV/AIDS and cancer. HIV/AIDS has impacted on paediatric palliative care in Africa, resulting in an increased demand for services in already resource poor countries. Care is also complicated by late presentations, essential drug affordability, shortages especially of morphine, and lack of qualified health professionals (Amery, 2009; Downing et al., 2012).

Many African countries have made tremendous progress in paediatric palliative care provision and education. For example, Malawi has now integrated palliative care for children into all referral hospitals in all regions of the country. South Africa has pioneered paediatric palliative care in Africa (Marston et al., 2012). Education outreach has been mostly through Tanzania, Uganda, and South Africa to other regions in Africa. Integration has mostly been possible through organizations such as the Elizabeth Glaser Pediatric AIDS Foundation especially in Tanzania and Zambia, and the Paediatric AIDS Treatment in Africa (PATA) which works in 15 African countries. In addition, the Southern African Children's Palliative Care Network was launched in Cape Town in September 2012 in collaboration with

and with support from the Hospice Palliative Care Association of South Africa, The Bigshoes Foundation, and the ICPCN (ehospice, 2012). The network arose to provide input and support for an integrated approach to improve palliative care for children across South Africa.

African services rely mostly on community volunteers and families for the identification of patients needing services. Palliative care models need to be adapted to the African setting and also take into consideration cultural variations and preferences. Home care is the most commonly used model of care in Africa because it is affordable. Unfortunately there are more patients than can be supported through such services, because of a shortage of skilled health workers (Harding et al., 2010).

Complex psychosocial issues impact on the care of children in Africa where there is a large number of children orphaned from AIDS. Stigmatization of children with HIV/AIDS, cultural beliefs, and rituals, mainly around death and dying also affect provision of effective palliative care services (Amery, 2009). These challenges require palliative care to be provided in a multidisciplinary team, which should include the family, nurses, doctors, social workers, community health workers, traditional healers, volunteers, and others as appropriate.

Asia

Of the 47 Asian countries, approximately 66% have no recognized paediatric hospice or palliative activity and only 2% of Asia has services integrated with mainstream services (Wright et al., 2008; Knapp et al., 2011). In Malaysia, through Hospis Malaysia, there are initiatives to set up a national paediatric care team to provide paediatric palliative care in hospitals and communities (Hamzah and Lan Kuan, 2012). Paediatric palliative care is provided mostly by adult physicians and various specialities. In Thailand, there are few paediatric palliative care programmes. Lack of palliative educational programmes, national palliative care guidelines, adequate finances, trained personnel, and a shortage of opioids are major challenges to effective delivery of services. Education is needed to change mind sets to focus on quality of life, improve symptom control, and address the misconceptions surrounding opioid use (Pairojkul, 2012).

India

India has palliative care services located mostly in the large cities and urban areas and 72% of the population living in rural areas have no access to these services (Mathews and Suresh Kumar, 2012). Services are provided by non-governmental organizations, public and private hospitals, and hospices. An estimated 200 000 children under the age of 15 live with HIV/AIDS, and only 4% of these have access to antiretroviral therapy. India has four established children's palliative care programmes with other programmes under development. Opioid use and availability in India has been affected greatly by current government legislature and fears surrounding its prescription. As a result, recent rulings should see opioid supply improve throughout the country (Pallium India, 2012).

Middle East

Paediatric palliative care in the Middle East is a new and developing concept driven mostly by non-governmental organizations. The Middle East has diverse cultures, political conflicts, various religions, and traditions which impact on the delivery of palliative services. There are also cultural taboos which impact on paediatric palliative care education. Palliative care providers need to be culturally sensitive to the different rituals and faiths but also sensitive and proactive to a family's needs to ensure a 'good death' and appropriate support in bereavement (Siblermann et al., 2012). Kuwait has taken a significant initiative with the development of Beyt Abdullah Children's Hospice.

Central America

Paediatric palliative care in Mexico has experienced similar challenges to other developing countries but has made substantial progress in the care of children with life-limiting diseases, with an increased awareness of paediatric palliative care (Okhuysen-Cawley et al., 2012). Mexico also has a shortage of trained paediatricians, medical specialists, and support services for terminally ill children. Difficult symptom management is, however, provided by the treating oncologists or anaesthesiologists with an interest in chronic pain management who are supported by paediatric palliative physicians in Costa Rica and Argentina and locally through the Associacion Mexicana de Cuidados Paliativos. In addition, the Instituto Nacional de Pediatria in Mexico City provides tertiary paediatric palliative care services (Okhuysen-Cawley et al., 2012). As with many developing countries, essential medications are available mostly in urban centres. Rural areas, where most indigenous people live, have limited access to contemporary medical care and rely on traditional remedies. Access to medical care is limited by poor accessibility, fear and distrust of health professionals, and strong traditional belief systems which emphasize life and death as a transcendental continuum (Okhuysen-Cawley et al., 2012).

Paediatric palliative care in Costa Rica is delivered mostly through the Paediatric Palliative Care and Pain Control Clinic (PPCPCC) which covers only an estimated third of the population of children with life-limiting illnesses (Quesada-Tristán and Masís-Quesada, 2012). This service is provided through the Children's National Hospital in collaboration with the Foundation for Palliative Care Unit a non-profit organization. There are number of barriers encountered by the PPCPCC which include identifying and mapping children who need to be referred to the programme. Comparable barriers include health professionals' misunderstanding of the concept of paediatric palliative care, limitation of resources, and finances. In Costa Rica, the paediatric palliative care programme is organized into four teams that operate in different areas of the country. The teams comprise a hospital-based team, day care centres, or home-based care and a team that is both day centre- and home-based, covering the entire country with a telephone support service for palliative patients (Quesada-Tristán and Masís-Quesada, 2012).

South America

Of the 23 South American countries about 67% have no demonstrable paediatric hospice-palliative care activity, whilst 8% of countries offer localized service (Knapp et al., 2011). In Brazil paediatric palliative care usually is offered when a child is dying and the Brazilian Pediatric Society is working towards improvement in collaboration with the Brazilian Intensive Care Association, local universities, and hospitals (Lago and Piva, 2012). Argentina has created Pediatric Palliative Care Units (PPCUs) distributed in the

six provinces to provide medical care to children with life-limiting illnesses, palliative education, and research (Germ et al., 2012). Home care programmes have also been developed through the units. Challenges faced by the PPCU are similar to other countries. In Chile, paediatric palliative care is coordinated through paediatric hospitals, specifically in oncology units (Torres et al., 2012). Oncology children have access to pain and symptom management through the Pain Relief and Palliative Care programme (PR and PC) operating in National Child Antineoplastic Drugs Program (PINDA) cancer centres throughout Chile. Health reforms in Chile have incorporated PR and PC for care of children with advanced cancer (Torres, 2012). Palliative care services likewise operate in outpatient, hospital, or home settings with telephone follow-up. Despite palliative care services being limited to oncology patients with advanced disease, the Ministry of Health is creating committees to work in conjunction with paediatric palliative care units in hospitals, to extend services to other children with life-limiting illnesses.

The team in paediatric palliative care

Paediatric palliative care is delivered best by a team with a diverse skill set working together to enhance and deliver quality patient care. Care and support is coordinated and individualized to the patient and family (Baker et al., 2008). The team can include nurses, doctors, social workers, volunteers, chaplains, allied health practitioners, and other therapists (Crawford and Price, 2003). Excellent communication is vital to ensure good teamwork in the delivery of palliative care. This can be either formal, in the form of case conferences, or informal, via electronic means. It is important that clear lines of communication are established, particularly as to who the family should call should a change occur in the child's condition or if there is an exacerbation in pain or other debilitating symptoms. Case conferences are integral to the care planning, delivery of services, and help in the collaboration of care by defining and negotiating the roles of care as the patient's condition and psychosocial needs changes (Crawford and Price, 2003; Mitchell et al., 2008).

The role of nursing in the paediatric palliative care team

Palliative care nursing includes care planning and/or the provision of care to a child identified as needing palliative care, regardless of

the projected duration of the child's illness and regardless of the location of care. The level and type of intervention provided will depend on the skill, expertise, or location of the nurse, as well as the needs of the child and their family. Paediatric palliative care nursing, whilst still relatively new as a specialty, has developed rapidly over the last 10–15 years.

Paediatric palliative care nursing is a mix of art and science that begins at diagnosis, or referral to palliative care, through to supporting the family in the bereavement process. These skills can support the family to adapt to the challenges of caring for a dying child and also empower the child to express needs, develop their goals of care, and work with his/her family to achieve them. Some children may require palliative care nursing for short periods while others require care over many months or years. 'Graduation' from palliative care needs can occur for a very few children as they either reach adulthood, obtain a treatment (e.g. liver transplant), or recover.

Aranda (2003) describes a framework for the role of nursing in palliative care. She describes three levels of nursing which are the palliative approach, specialist interventions, and specialist palliative care. The palliative approach is any care provided by any health professional with 'a core set of knowledge and skills' to a person with a life-threatening or terminal illness. This care is provided by a generalist nurse who may or may not have paediatric and/or palliative experience but is caring for a child receiving palliative care. Higher needs related to palliation are either carried out by the generalist nurse supported by a specialist palliative care nurse or, at times, provided by specialist palliative care nurse in collaboration with the generalist nurse. Aranda describes specialist interventions as those provided by specialists outside palliative care, such as wound care nurses and specialist palliative care by those with qualifications and advanced practice skills in palliative care whether these are in hospital, home, or hospice (Aranda, 2003).

Paediatric palliative care nursing at home is likely to fall under the auspices of community/domiciliary care of either generalist nurses or dedicated palliative care teams who are not necessarily familiar with paediatric needs. Direct care from a specialist tertiary paediatric palliative care service is less likely. More usually, care provided by domiciliary nurses will be overseen by a specialist paediatric palliative care service. Box 16.2.2 outlines the potential role of paediatric palliative care nursing in a child's home.

Family support volunteers in paediatric palliative care

A volunteer service within a paediatric palliative care team, if adequately supervised, is a flexible and cost-efficient way to alleviate a child's and family's distress. Volunteers can fill a support gap and not leave the family feeling indebted to friends and family. They can assist with practical help around the home, sibling support, craft and diversional activities for an unwell child, and social support for parents and family. They can undertake simple daily activities which are challenged by time and exhaustion in the family unit.

In Australia, there are two volunteer programmes supporting Paediatric Palliative Care families specifically at home. The Family Support Volunteer Program in Victoria is one of the services offered by Very Special Kids, a charity established for over 25 years, supporting families caring for children in palliative care

Box 16.2.2 The potential roles of paediatric palliative care nursing in the home

- Creating/implementing a care plan which includes assessment of symptoms and psychosocial needs in conjunction with the child's primary treating team and all other services involved
- Assessment of the home and relevant equipment needs
- Identifying the family unit and wider community support and ensuring relevant persons are present at family conferences
- Identifying and ensuring appropriate community clinicians are involved and planning of support such as contact details, details of home visiting, and so on.
- Providing appropriate information (at family's request) to community groups such as schools, cultural/religious support groups, volunteer services, interpreter services, and so on.
- Generating a plan for anticipated deterioration and/or emergency situations
- Generating a plan for end-of-life care which includes location of care and identifying family goals
- Accurate reporting systems for any interventions.

(Very Special Kids, n.d.). Part of a suite of services offered to families includes sibling support programmes, counselling, hospice respite, and end-of-life care. The volunteer programme provides practical and social support in the family home (Very Special Kids, n.d.).

The Family Support Volunteer Program at The Children's Hospital at Westmead (New South Wales) was established in 2009 and has been working as part of the palliative care team, providing both practical and social support for children, parents, and siblings. The service has a funded management position responsible for recruitment, training, and coordination of volunteers. The volunteers range in age from 21 to over 70 and come from a wide socioeconomic demographic and diverse cultural and ethnic backgrounds, widely reflecting the community they support.

Case study: volunteering and practical support

An 8-year-old girl with neurological disease was receiving palliative care. Both parents and a 13-year-old brother were living at home. The family were of Lebanese Australian background. Their oldest child died aged 2 of the same condition. Some extended family was available locally for support but the mother identified the length of her daughter's illness as a reason to not 'impose' on help offered. Due to the mother's caring responsibilities, the family were her main social contact. A 22-year-old female volunteer from an Australian/Asian background was placed with the family, initially to play with the unwell daughter and offer light practical help. As placement progressed, routines formed and as the home tasks were completed the mother, volunteer, and daughter started taking walks in their local area and visiting cafes. The mother commented, 'I really look forward to Fridays now, we get everything done and get out of the house. I wasn't able to do that previously.'

Case study: volunteering offering personal support and reducing impact on friendships

A single parent was caring for a 16-year-old boy profoundly disabled since birth, and a 15-year-old daughter. The family were supported by community organizations for respite care at home. A 55-year-old female volunteer was placed with family, initially to offer light practical support around the home and transport for the sibling to a local job after school. The placement lasted over 2 years with 6 months as a bereavement placement. The mother identified a valued difference in the support provided within the volunteer role which did not have the demands of reciprocity expected in friendship or the impersonality of paid service providers.

In current times of global migration, families may find themselves without family and community support, in a different country from their birth. These families face the added complexity of navigating health systems in second languages and in an alien culture, without wider family to provide support. Effective development of a volunteer programme could encompass education for palliative care volunteers, to provide tutoring in the local language and culture to support families in communicating with health and community services or to collaborate with other volunteer services which provide a home tutoring service.

Symptom management in children with advanced illness

Children with advanced illness are often highly symptomatic and their symptom burden may increase with time, especially when the terminal phase is reached (Drake et al., 2003). This symptom burden consists of physical, psychological, spiritual, and other factors and this entire matrix needs to be considered. Physical symptoms may be caused either by the underlying illness, side effects related to medical interventions and treatment, or causes unrelated to either the primary disease or its treatment. The assessment and diagnosis of symptoms is fundamental to the clinical care of the child with advanced illness. Palliative therapeutics generally should only be implemented once the underlying causative mechanisms have been established, since therapies directed at the primary cause may ultimately have a more effective outcome for symptom management. Clinical assessment of symptoms is complemented by symptom measurement. Measurement refers to the application of a metric to a specific dimension of symptom experience. The measurement of symptoms in children often utilizes formal scales that assess symptom intensity or frequency.

Symptoms, symptom burden, and quality of life in children

It is frequently assumed that a child's quality of life is directly related to their degree of symptom burden. This is not necessarily true as quality of life is a complex, multifactorial, and dynamic process. This complexity is compounded in paediatrics by quality of life (QOL) measurement. QOL measures frequently assess functional status rather than involve a comprehensive evaluation of the health-related quality of the child's physical, emotional, and social domains of life. Even with measures tailored appropriately to the child's capacity, a variety of barriers to the inclusion of QOL

end points in clinical trials have been identified (Bradlyn et al., 1995). Attitudinal bias against self-reported health questionnaire data, lack of validated measures, and the absence of a QOL 'gold standard' are some of the difficulties faced when incorporating these measures into clinical research and practice (Bradlyn et al., 1995).

Symptom measurement and symptom management studies in children with life-threatening illness

The progress in symptom control for adults receiving palliative care does not have a parallel experience in children. This is due, in part, to the paucity of symptom control research in children and explains the reliance of best practice in paediatric palliative care on the best evidence in adult palliative care. In addition, most of the validated symptom assessment tools in paediatrics have focused on three common symptoms, pain, nausea (Zeltzer et al., 1983, 1984a, 1984; LeBaron and Zeltzer, 1984), and fatigue (Hockenberry-Eaton et al., 1998; Hockenberry et al., 2003). In contrast to instruments measuring nausea and vomiting, instruments measuring pain in children largely have been validated predominantly in the non-cancer setting. Systematic symptom assessment may be useful in assessing symptom burden as part of decision-making towards palliative care and in future epidemiological studies of symptoms in dying children.

One major difficulty in performing symptom management studies in dying children pertains to the heterogeneous nature of symptoms in this population. Children with cancer, for example, tend to receive therapies directed at control of their tumours until very late in the course of their illnesses and are frequently very ill and highly symptomatic. These epidemiological and treatment variables make it less likely that a subpopulation of children receiving palliative care exists who have a stable, chronic pattern of symptoms amenable to evaluation in a trial.

Multidimensional symptom assessment tools for children

The Memorial Symptom Assessment Scale (MSAS) 10–18 is a 30-item patient-rated instrument adapted from a previously validated adult version to provide multidimensional information about the symptoms experienced by children with cancer aged 10–18 (Collins et al., 2000). The analyses supported the reliability and validity of the MSAS 10–18 subscale scores as measures of physical, psychological, and global symptom distress, respectively.

A revised MSAS was created as an instrument for the assessment of symptoms in children with cancer aged 7–12 years (Collins et al., 2002). Validity was evaluated by comparison with the medical record, parental report, and concurrent assessment on visual analogue scales for selected symptoms. The data provide evidence of the reliability and validity of MSAS (7–12) and demonstrated that children with cancer as young as 7 years can report clinically relevant and consistent information about their symptom experience. The instrument appeared to be age appropriate and may be helpful to older children unable to independently complete MSAS 10–18.

Symptom management in children with advanced illness

The adequate, proficient, and timely management of symptoms in the dying child is of critical importance. Not only is it important from a humanitarian viewpoint, but also it is apparent that the memory of unrelieved symptoms in dying children may be retained by parents many years after their child has died (Wolfe et al., 2000). It will be impossible for children and their families to negotiate the domains of psychological and spiritual care if physical symptomatology has not been treated adequately. As few controlled studies of symptom management have been performed in childhood, many of the therapies used in children have been devised utilizing best practice for adults. The reader is referred to the adult section of this volume for the principles of management of unusual symptoms. An emphasis has been given in this chapter to the palliative care emergencies of childhood. Less urgent symptoms are discussed in alphabetical order in 'The palliation of other symptoms in childhood advanced illness'. Pain management for children is discussed in Chapter 9.13.

The palliative care emergencies of childhood

Seizure control

Seizures in paediatric palliative care patients may be either recent in onset or part of a long-standing, underlying seizure disorder. In the former situation, the onset will usually be frightening to patients and families and may be due to many possible causes (e.g. cerebral metastases, infection, metabolic disorder, hypoxia, etc.) which must be excluded, as treatment directed at the primary causes may be appropriate whilst anticonvulsant therapy is implemented. Worsening seizure control in a patient with an underlying seizure disorder may indicate either disease progression or factors related to anticonvulsant dose, class, or administration which should be reviewed.

Buccal midazolam has been shown to be at least as effective as rectal diazepam in the acute treatment of seizures (Scott et al., 2002). Administration via the mouth is more socially acceptable and convenient and may become the preferred treatment for long seizures that occur outside hospital. The buccal dose is the same as the oral dose of midazolam used for sedation (0.3 mg/kg per dose, maximum dose 15 mg) and should be used as a single dose only. Traditionally, refractory status epilepticus is treated with barbiturate-induced coma or general anaesthetics, both of which require invasive cardiorespiratory and haemodynamic monitoring and are associated with significant complications. Midazolam has been effective in terminating seizures refractory to diazepam, lorazepam, phenytoin, and phenobarbitone in paediatric patients (Scott et al., 2002).

Spinal cord compression

Spinal cord compression is an unusual complication of childhood cancer and occurs most often late in a child's illness. Back pain, more often than abnormal neurologic signs or symptoms, is the usual initial presenting sign of spinal cord compression in children (Lewis et al., 1986). Spinal cord compression is an emergency, since adult data show that if treated whilst a patient is ambulatory, the probability of retaining ambulant status is 89–94% (Loblaw and Laperriere, 1998). The mainstays of management are

radiological diagnosis and treatment with radiotherapy for radio-sensitive tumour and corticosteroids (Abrahm, 1999).

Bleeding

Although the fear of external bleeding is paramount in the minds of families and caregivers of children dying of either haematological malignancy or liver failure, massive external bleeding as a mode of death in childhood is uncommon. While some children with malignancy receive blood products indefinitely, this is not always feasible or appropriate. Many families negotiate the use of blood products only if minor bleeding or anaemia becomes problematic. If the fear of external bleeding is overwhelming for families, this may influence their choice of location of the child's death and attitude towards blood product transfusion.

Terminal dyspnoea

Dyspnoea is an uncomfortable awareness of breathing (Bruera et al., 1993b). In the terminal phase it is often highly distressing to patients and for families to watch. Terminal dyspnoea may be due to a variety, and perhaps combination, of causes. These include pulmonary metastases, intrinsic lung disease or infection, cardiac failure, acidosis, muscle weakness, and so on. Diagnosis is important as this may influence choice of therapies. Non-invasive ventilation may be a viable choice for symptom management of dyspnoea related to muscle weakness, for example, and bronchospasm could be reversed easily with bronchodilators.

Most of the data on the management of terminal dyspnoea are from studies of adults with terminal malignancy. There are no data on the appropriate management of dyspnoea related to muscle weakness or complications of cystic fibrosis, for example. The goal of palliative therapies for terminal dyspnoea is to improve the patient's subjective sensation. The subjective sensation of dyspnoea is improved in patients receiving supplemental oxygen (Bruera et al., 1993a). In addition, systemic opioid therapy (Bruera et al., 1993b; Boyd and Kelly, 1997), cognitive behavioural strategies (Corner et al., 1996), and non-pharmacological strategies, such as using a handheld fan (Galbraith et al., 2010) benefit patients with dyspnoea related to terminal malignancy. As anxiety is often a component of terminal dyspnoea, judicious prescription of a benzodiazepine may be warranted.

Secretions

The management of noisy secretions in an unconscious patient is aimed at reducing the distress of the family, other patients, and staff. The sound of noisy secretions can be haunting to all concerned and should be given some priority by the attending clinician. Accepted management strategies include explanation to relatives, positioning, suction, and anticholinergics (e.g. hyoscine hydrobromide or glycopyrrolate) (Hughes et al., 1996).

Terminal delirium

Delirium during the final phase of dying is one of the most distressing symptoms for caregivers to watch, especially if the delirium is agitated. The interpretation of the latter may be that the delirium is a manifestation of an internal existential angst. This latter interpretation is unlikely, since the aetiology of delirium in the setting of an actively dying patient is usually multifactorial with a physical rather than psychological basis (e.g. hypoxia, metabolic derangement, central nervous system disease, infection, fever, etc.). Simple causes that can be corrected, hypoxia, for example, should be excluded. As terminal delirium cannot be predicted, a therapeutic plan for its management should be considered in every dying child. The usual therapies consist of haloperidol for delirium per se with consideration of adding a benzodiazepine if there is agitation as well.

The palliation of other symptoms in childhood advanced illness

Constipation

The aetiology of constipation is often multifactorial and may include reduced physical activity, mechanical obstruction, metabolic derangement, poor diet and low fluid intake, bowel atony due to opioids, and so on. Although unusual, bowel obstruction and faecal impaction must be excluded and treated urgently in any child presenting with constipation. Generally, dietary changes are recommended in the first instance (increased vegetables and fruity, bulk, prune juice, etc.). In addition, attention should be given to hydration, mobility, and other activities of daily living. Chronic opioid therapy necessitates the prescription of a regular laxative. There is little evidence to guide the prescription of laxatives in children. Whilst there are emerging adult data to suggest oral naloxone (Culpepper-Morgan et al., 1992) and subcutaneous methylnaltrexone (Portenoy et al., 2008; Thomas et al., 2008) may be appropriate for the management of opioid-induced constipation, a senna and lactulose combination is often prescribed in the adult population (Abu-Saad and Courtens, 2001). It is not clear if a senna/lactulose combination is appropriate for children. The osmotic laxative, Movicol-Half® is being used increasingly to treat constipation in children. There are, however, few data on its use in children.

Fatigue

Fatigue is a common symptom of children with cancer (Hockenberry-Eaton et al., 1998; Collins et al., 2000, 2002) and one that is often highly distressing. The aetiology of fatigue in children dying of cancer may be due to a combination of factors including anaemia, poor nutrition, insomnia, metabolic derangement, the increased effort of breathing in patients with dyspnoea, side effects of medication, and psychological factors. In the assessment of fatigue in a child, and the matrix of its potential causes, it is important to establish if this symptom is distressing to the child and/or their family. If so, the potential remediable causes should be considered. There are adult and limited paediatric data on the use of stimulant medication for the treatment of opioid-induced somnolence (Bruera et al., 1992a, 1992b; Yee and Berde, 1994). In children, it has become more common practice to switch opioids, for somnolence as a dose-limiting side effect of opioid therapy (Drake et al., 2004).

Insomnia

Sleep disturbance is common in children with advanced illness (Collins et al., 2000, 2002; Herbert et al., 2014). In the context of cancer, insomnia is both prevalent and distressing to children and, by inference, distressing to caregivers. The aetiology of insomnia is multifactorial and is often a combination of physical,

psychological, and perhaps environmental factors. When depression is a factor, consideration should be given to psychotherapy and pharmacologic treatment. Fatigue often coexists with sleep disturbance. Lifestyle changes, including improved sleep hygiene, exposure to sunlight, and exercise may be helpful to improved sleep. Low-dose amitriptyline, if not contra-indicted, is often a helpful pharmacologic agent for the management of insomnia in terminally ill children, particularly if pain is a symptom management issue. An alternative consideration could be melatonin.

Mouth care and hydration

Routine mouth care promotes patient comfort and ability to eat and drink, prevents halitosis, and helps identify problems such as dry mouth, candidiasis, and ulceration (WHO, 1998b). Lip emollients and mouthwashes are important therapies for mouth care. The sensation of a dry mouth may be due to local (e.g. mouth breathing, candidiasis, radiotherapy to salivary glands, etc.) and systemic causes (e.g. dehydration, anticholinergic drugs uraemia, etc.) and is often distressing. The issue of hydration in dying patients is a contentious issue. Small but frequent volumes of fluid to maintain insensible losses may be appropriate via the oral route. However, this may be impossible in some instances unless other routes of administration are considered. As with all therapies, the benefits and deficits of any intervention must be discussed with the patient and family before any therapeutic intervention is implemented.

Nausea and vomiting

Nausea and vomiting are not uncommon in children receiving palliative care. Nausea and vomiting occur when the vomiting centre in the brain is activated by any of the following: cerebral cortex (e.g. anxiety), vestibular apparatus, chemoreceptor trigger zone (CTZ), vagus nerve, or by direct action on the vomiting centre. A clear diagnosis must be sought as to aetiology as the list of potential causes is great and therapies different, depending on the putative mechanism (WHO, 1998b).

Psychosocial issues in caring for a child with advanced illness

The emotional, psychological, and physical stress of caring for a child with a life-limiting illness impacts on the whole family unit. Issues such as social isolation and the impact of emotional and physical absence on relationships within the family can lead to high conflict and low support situations for parents and siblings (Mastroyannopolou et al., 1997). *The Hardest Thing We Have Ever Done* (Palliative Care Australia, 2004) is a social impact study of caring for terminally ill people in Australia and identifies that families with poor social support are at risk of experiencing coping and psychological distress. McGrath (2001a, 2001b) identifies the need of practical support by parents in the initial stages of a child's treatment, followed by emotional support to be able to cope with the challenges of caring for a palliative child.

The death of a child is uncommon in many societies. As a consequence, members of the community may be apprehensive and unsure of the approach to the child and family. In addition, staff working with dying children may be unaccustomed to providing palliative care and may be in a setting where specialist paediatric palliative care is unavailable. The death of a child challenges beliefs and assumptions about the world. Rosov (1994) suggests these include that parents will die before their children, that parents can protect their children from harm, and the sense of confidence, safety, and security as a parent. Psychosocial care can be defined as holistic care provided to address physical, social, psychological, and spiritual needs of children and their families (Davies et al., 2002). The following case studies illustrate some of the common psychosocial issues faced by children receiving palliative care and their families.

Case study: the impact on the family unit

Richard is an 8-year-old boy with a life-limiting congenital cardiac condition. He was referred to palliative care 8 months ago. Richard is one of two children of Paula and Adam.

Throughout his life, Richard has experienced many painful procedures, tests, and treatments. He was considered for heart transplant, and spent over a year living interstate with his parents in order to trial treatments. Richard's parents have coped with his illness by focusing on it to the detriment of other family relationships.

Upon Richard's referral to palliative care, his parents were told that he had 'weeks to months' to live. Paula and Adam spent time ensuring that Richard and his brother John were told about Richard's prognosis and had several broad discussions about death.

The family were able to use their faith as a guide to explain death and what happens when people die. It was important to Richard, who was aged 7 at the time of referral, and his family, to be baptised as soon as he turned 8. Richard's family believed that anyone who died aged younger than 8 would automatically go to Heaven because they were pure. Anyone aged 8 or older would need to be baptised. Given that Richard's health was up and down, it was unknown whether he would make it to his 8th birthday party, or to his baptism, which was scheduled for the following day.

He did, in fact, live to experience both his birthday and baptism, and continues to live with his family, almost a year after he was given weeks to months to live. Whilst he is still unlikely to live to adulthood, and there is still a risk that he will die suddenly at any moment, his parents have made him the focus of their lives. His sibling receives sporadic attention from their parents, and very little one-on-one time with them.

His brother, John, has begun to disassociate from his parents, preferring to spend time on his own. He does not argue or talk back the way other children his age would when refused something, such as a small snack or time on the computer. At school his confidence has dropped dramatically, and he is now fearful of activities that he cannot master. He is often cared for by his grandparents.

Whilst his parents are aware of the stress placed on the sibling, they do not allow themselves to be taken away from Richard and his needs. The family successfully engaged several celebrities to fulfil wishes, such as trips, toys, and visits to their home, and this appeared to be a primary focus for them.

The family unit is an invaluable resource in palliative care, in particular when the dying person is a child. The family unit is looked to for its ability to provide care, thus involving them

intimately in the dying process (Kissane, 2000). Richard's parents have taken on much of his care at home; thereby isolating themselves from many respite services, and have also relied upon the extended family to fill in any gaps in care for the siblings.

In Richard's case, the assessment conducted indicated that religious rituals, such as his baptism, were important to him, as well as to his parents and grandparents. Richard also has taken an interest in his funeral, such as who will attend, who will give eulogies, and the kind of music that will be played. Whilst many adults may find this morbid and threatening, it is vital that dying children are given the emotional space to make their wishes known (Davies et al., 2002). A spiritual assessment conducted with the dying child is one method of beginning this discussion.

Kissane (2000) discusses the challenge in palliative care of balancing anticipatory grief and living life to the fullest. Richard and his entire family were caught in this very dilemma. His parents were trying to make the most of his life, given the unpredictability of his death, whilst his sibling coped with little time and attention from their parents. Additionally, his grandparents, who were reducing working hours and looking to retirement, took on the responsibility of caring for John and occasionally Richard. The involvement of grandparents as carers is growing, particularly as they often have more flexibility than working parents and are most often unpaid for the care they provide (Jenkins, 2012). Thus the changes to everyday life and the expectations placed on grandparents when a child is dying cannot be overestimated. Most of the palliative care—physical, emotional, spiritual, and psychological—was provided to Richard and his family in their home.

The parents' role as caregivers is usually redefined when their children become ill. Parents perceive themselves as 'decision-makers, nurturers, protectors, advocates, and caregivers' for their children (Bluebond-Langner et al., 2010). That said, adolescents involved in end-of-life decisions have been reported to understand the consequences of their decision and are also capable of participating in these complex decision processes (Hinds et al., 2005). In paediatric palliative care, psychosocial distress in a child or family is usually linked to illness-related factors. Appropriate interventions are often designed in response to these factors.

At times, good psychosocial care permits the child or family to not speak about issues with health professionals. The case of Chris, an 18-year-old boy with osteosarcoma, illustrates this. In keeping with family values and their cultural beliefs the family never discussed his impending death with him, despite giving him total control over his own symptom management including talking with palliative care services about his management. Discussions with his family were about updating them, addressing their own fears and questions, but never care planning. Three days before he died, Chris called a relative and gave them a detailed shopping list, including store names and specific gifts to buy for each of his family members. As the eldest child, he also called each of his two younger siblings to his bedside and gave them 'instructions about their future lives'. The value of the psychosocial support to this young teenager was to make time, to accept that he knew what was happening to him, and offer bereavement support in a request that we 'take care of his mum'.

Psychosocial issues are as diverse and individual as the families receiving care. The health professional who listens, who seeks to communicate openly with families by spending time just being 'present' with the family will increase awareness and understanding of the needs of the child and family. Integration of psychosocial care into paediatric palliative care includes establishing communication with the multidisciplinary team caring for the patient and a careful patient assessment. This includes assessing the family's ability to cope, their social and financial status, and linkage to appropriate social, community, and spiritual support (McSherry et al., 2007).

The clinician in bereavement support

The role of the clinician supporting a bereaved family can be multifaceted. As Bowlby (1961) indicated, the quality of the attachment to the deceased forms the basis of the grief reaction. The clinician will need to assess the quality of the relationship between the child, siblings, and parents. Additionally, it is beneficial to assess the attachment style of each member in the family to understand how they will grieve, and the most effective interventions for that particular attachment style (Bowlby, 1961).

Grieving rules describe the norms that are recognized in society as acceptable grief responses and they specify when, where, how long, and for whom people should grieve (Brabant, 2001). The clinician can ascertain some of the grieving rules that govern the bereaved person by inquiring what they think about grieving, and what they think others think about grieving (Brabant, 2001). This enables the clinician to address any grieving rules which may hamper the ability to manage grief.

Despite the acute pain associated with grief, the long-term impact of bereavement on siblings can be both positive and negative. As Oltjenbruns (2001) discusses, siblings who were not told about the serious nature of their brother's or sister's illness, may experience a number of difficulties. These can include an increased sense of isolation, a belief that others, such as parents, have minimized the significance of their loss, a diminished trust of those around them, and a misconception of what actually happened. With support from clinicians, bereaved siblings and parents should be able to work through these issues.

However, the impact of the death of a brother or sister is not always negative. Schaefer and Moos state that crises can be a catalyst for personal growth and that people can emerge from crises with enhanced social and personal resources, and new coping skills (Schaefer and Moos, 2001). The outcome of personal growth does not diminish the pain and devastation of the loss; however, once the individual has moved from the acute pain of grief, the search for meaning can lead to growth (Schaefer and Moos, 2001). In particular, children who experience bereavement are more likely to be less judgemental, more compassionate and tolerant, have a desire to help others who are grieving, and prioritize their family (Schaefer and Moos, 2001).

Considerations in bereavement work with families

The death of a child has been described as a 'loss like no other' (Rosov, 1994). Raphael (1983) describes that this is because the death of a child defies the natural order of life and societal expectations. A child represents the hopes and dreams for the future of his or her parents, grandparents, and extended family. The death of that child extinguishes those hopes and dreams and leaves the family with a devastating loss that can linger for years after death. Following the death of a child, the role of the counsellor is to support families to rebuild their lives whilst keeping the memory of their child alive.

Hope is a key element in bereavement work (Cutcliffe, 2004). The bereavement trajectory often reflects parents' lack of hope, the pursuit of hope, and the eventual regaining of hope. Hope represents a link to the future, and for many families, their children are representative of the hope they have for themselves and their family's future (Raphael, 1983). The following case history is illustrative:

Case history: the impact of past trauma

Rachel's family moved to Australia as refugees, after experiencing years of torture and persecution in their home country. They described moving to Australia as having a fresh start, and being an opportunity for their eight children to receive an education that would not have been possible in their home country. Their older children enrolled in practical courses which enabled them to work to contribute to the family's income. The family worked hard to establish themselves in Australia, facing the common struggles of refugee families—finding and maintaining work and accommodation, and adjusting to a new country, language, and culture. The children also faced the struggle of fitting in at school, making new friends, and integrating into a new education system.

Two years after moving to Australia, the second youngest child, Rachel, was diagnosed with a brain tumour. She received numerous trial treatments, before being referred to palliative care. Three months later, she died in hospital. Rachel's siblings were not told of her initial diagnosis, or of her poor prognosis. The parents explained that they did not want the children to worry, or to lose focus from their school work.

Rachel's sister, Mariam (17), was referred for bereavement counselling 6 months after Rachel's death. She explained that Rachel's death was a complete shock to her, and that she did not know that Rachel was so unwell. Mariam was in her final year at high school, and had her end of school exams approaching in 3 months. Prior to Rachel's death, Mariam was a bright student who was at the top of her class. Since Rachel's death, Mariam described being unable to concentrate on school work, that thoughts of Rachel intruded on her when she tried to study, and that she did not retain any information she read. Mariam was very worried that she would not receive the marks she needs to study at university.

Reflection on the case history

The move to Australia represented hope for Rachael's family. It was an opportunity to escape the persecution experienced in their home country and engendered hope for the parents that their children would receive a good education and be able to go on to develop worthwhile careers. However, Rachel's death has had an impact on all the members of her family. Not only were her parents mourning and less available to their children due to their own grief, but her sister Mariam's education was directly impacted upon. For Mariam, the impact of Rachel's death will linger for years, particularly as her final years of schooling were affected. This could have potential implications for further study or career path she had planned to pursue.

An important consideration in working with bereaved families is the impact of past trauma. It is not uncommon for children and adolescents who have experienced trauma to re-experience these symptoms following a secondary traumatic event (Cook et al., 2005). Given their past history of trauma, Rachel's parents and siblings were offered bereavement support in order to reduce the risk of complications during the grieving process.

The death of Rachel had a dual effect on her parents. Not only did they grieve the loss of their daughter but also one of the specific reasons that compelled them to leave their home country—securing a positive future for the children—was under threat as a result of their grief. Mariam's experience of grief not only left her unable to achieve her own goals but also the hopes and dreams of her parents for their children. Her parents were left questioning whether they made the right decision to leave their home country, now being bereaved in a country where they had limited social support.

Quality improvement and paediatric palliative care

Batalden and Davidoff (2007) define quality improvement as 'the combined and unceasing efforts of everyone—healthcare professionals, patients and their families, researchers, payers, planners and educators—to make the changes that will lead to better patient outcomes (health), better system performance (care) and better professional development (learning)'. These 'efforts' consist of processes to gather data about service provision, reviewing this information, identifying opportunities for improvement, trialling activities to improve the services, and re-evaluating the service.

All stakeholders receiving and delivering clinical care are interested in the quality and safety of care. Consumers wish to know that the services they are receiving care of a high standard. Clinicians wish to know that the services they provide are meeting defined standards. In addition, if clinicians aspire to attain standards of excellence in the services they deliver, a quality programme will be able to identify areas for improved performance in the quest for such a goal. Administrators and policymakers also have a vested interest in the quality and the outcomes of clinical services. At a governmental level, policymakers must ensure that health-care resources are being used well, that standards are being attained, and problematic clinical services identified quickly.

As paediatric palliative care has only become a specialty in its own right over the past 10–15 years and has been mainly focused on service development, it has had little opportunity to participate in quality improvement programmes. It is timely that quality improvement programmes are introduced into paediatric palliative care services as the status quo is never good enough and an honest appraisal of the quality of a clinical service will lead to improvement in the quest for excellence

The process of setting up a quality improvement programme in paediatric palliative care has been described previously (Collins et al., 2009) and is summarized in Box 16.2.3.

1. Identify a quality lead to create and implement a quality strategic plan

The appointment of a quality lead without a clinical load is important, given the specialized nature of the area, the lack of training in quality improvement included in clinical education, the lack of time on the part of the existing clinical personnel, and the need for a neutral person to be dealing with the sensitive areas of feedback and complaints should they arise.

Box 16.2.3 How to set up a quality improvement programme in paediatric palliative care

1. Identify a quality lead to create and implement a quality strategic plan

2. Identify defined standards and measure the clinical service against the standards

3. Develop measures of quality for palliative care

4. Collate and evaluate data from the quality programme and look for opportunities for improvement

5. Implement ongoing quality review as part of clinical care.

2. Identify defined standards and measure the clinical service against the standards

The document 'IMPaCCT: Standards for Paediatric Palliative Care in Europe' (Craig et al., 2008) outlines core standards for palliative care provision for children and their ethical and legal rights. In Australia, the *Standards for Providing Quality Palliative Care for All Australians* (Palliative Care Australia, 2005) guide care. This latter document influences the way care is delivered and planned. It moves away from the simplistic diagnostic basis for determining need, and focuses on establishing networks that allow patients to access the right care when needed. Palliative Care Australia developed a self-assessment review programme for services to use as a quality improvement tool—the National Self-Assessment Program (NSAP)—Paediatric (Palliative Care Australia, 2012). This enables paediatric services to review their clinical service against the standards to identify opportunities for improvement.

3. Develop measures of quality for palliative care

Consumer satisfaction as a measure of the quality of paediatric palliative care

There is controversy in the literature as to the meaning and value of consumer satisfaction surveys. The controversies relate to few alternatives to satisfaction being available, no widely held definition of satisfaction exists, methodological inconsistencies across studies (Aspinal et al., 2003), and a vulnerable population which may not feel free to express negative comments. It is essential that families are assured of the anonymity of survey responses, that the data are collated by a staff member who does not provide care to the survey population, and they are given contact details of a person outside of the department for support. Solely relying on consumer satisfaction surveys to determine clinical and policy change in paediatric palliative care may not be appropriate.

Measuring quality by identifying or creating outcome measures

Part of quality measurement involves the use of outcome measures. These may include clinical indicators (measures of clinical outcomes), process indicators (measures of clinical processes), and qualitative reflective review. Outcome measures are designed to identify the rate of occurrence (or non-occurrence) of an event

which in turn reflects the care that was provided, or not. Data aggregated from all patients receiving the service can highlight areas that need improving, and can be used to measure the service against particular standards.

Process indicators for paediatric palliative care have been developed and implemented as a measure of care delivery for services in Australia and New Zealand. These indicators are linked closely to, and have been mapped against, the Australian Standards and are used in service evaluation. The indicators developed for use in Australia and New Zealand includes the following as key indicators of best care and are used to evaluate services:

◆ Equity of service provision (access to services, including respite care)

◆ Facilitating the right location of care (ensuring families have options for treatment at home)

◆ Child- and family-focused service delivery (including the family in decision-making)

◆ Access to the right place at the right time for end-of-life care

◆ Care planning and symptom management

◆ Family education and social support

◆ Holistic care

◆ Bereavement services.

4. Collate and evaluate data from the quality programme and look for opportunities for improvement

Data collection and collation should be an easy process with clear templates to collect the data and simple electronic or paper databases to collate it. Data can be compared with similar clinical services collecting the same indicators thus allowing benchmarking and peer review. Once an opportunity for improvement has been identified, work must begin to identify how the service can be improved.

5. Implement ongoing quality review as part of clinical care

A quality improvement programme needs to be designed in such a way as to be sustainable in the long term. This means the programme needs:

◆ input from all staff during development to share ownership of the programme

◆ a data collection system that is easy and not time-consuming

◆ timely distribution of results to maximize usefulness of data and support from clinical staff for ongoing collection

◆ to be dynamic, and change with changes in the delivery of care

◆ education for all clinical staff.

Some planning, including realistic time-frames and achievable goals, is necessary for a sustainable programme. Over time, the process becomes imbedded and normalized as part of the department's work. The available information can also be used showcase the department, particularly for external review or accreditation processes.

Conclusion

The care of the child with advanced and progressive illness and their family requires a holistic approach to the often complex physical, social, psychological, and spiritual needs including bereavement. This inevitably requires a paediatric palliative care team with diverse skills and abilities to meet these needs. Whilst the WHO supports the global application of the principles of palliative care to every child with a life-limiting illness, irrespective of geographical location (WHO, 1998a), the development of services for children will be contingent on the application of more resources.

Palliative medicine and care of the elderly

Meera Agar and Jane L. Phillips

Introduction to palliative medicine and care of the elderly

Most deaths in the older patient occur in the context of chronic disease, often with multiple comorbidities and physiological change. Clinicians also need to be aware of particular geriatric syndromes that occur frequently, such as frailty, falls, and delirium. Managing symptoms and maintaining function are still important goals, however care may be delivered in residential care (nursing home) or community and hospital settings, with the older person particularly vulnerable during transitions in care. Advance care planning is also crucial to ensure care decisions are not made in crisis. Supporting caregivers is essential, with caregivers often either adult children who have their own family and work responsibilities to juggle or an older spouse who may have concurrent medical problems themselves. Although the fields of geriatric and palliative medicine have evolved separately, there is commonality of goals: maximizing quality of life by maintaining function and optimizing symptom control, continuity of care regardless of setting, and integrated care of the 'whole person'—in contrast to seeing the patient as a cluster of separate illness and organ systems (Geriatrics-Hospice and Palliative Medicine Work Group, 2012). This chapter will outline the principles of care for the older person, when one or several underlying illnesses continue to progress with death as the likely outcome.

Epidemiology of ageing

Epidemiological factors are crucial when considering the care of the older person and the role of palliative care. With the changing reasons for death as a result of modern medicine, most adults die when they are old, often from a non-malignant disease that they have had for some time and its associated multimorbidity (American Geriatrics Society Expert Panel on the Care of Older Adults with Multimorbidity, 2012), and after a significant period of disability (Lynn and Goldstein, 2003; Effiong and Effiong, 2012). In the United States, the life expectancy is 78.7 years (Minino et al., 2011; Minino and Murphy, 2012). The proportion of the world's population who are greater than 65 years will continue to rise (Mathers et al., 2009). By 2050 it is projected that 16% of the world's population will be over 65, totalling 1.5 billion people compared to 1950 where it was 5% (Mathers et al., 2009). At least half of people over 65 will have at least three coexisting chronic conditions, with one in five having five or more (Mangin et al.,

2012). This includes musculoskeletal, psychiatric, cognitive and chronic pain-related problems each often associated with substantive symptomatology and disability. The tendency for individuals to be treated in disease 'silos' and the risks associated with polypharmacy add to the burden of adverse outcomes (Mangin et al., 2012),

Death rates for 2010 in the United States showed decreased mortality in virtually all age groups, when compared to 2000 data; with the second largest decrease (13.3%) seen for those aged 65 and older (Minino et al., 2011; Minino and Murphy, 2012). Heart disease, cancer, chronic lower respiratory diseases, stroke, and accidents could account for 63% of deaths in 2010 in all age groups. In the group aged over 65 years, the leading five causes of death were heart disease, cancer, chronic lower respiratory diseases, stroke, and Alzheimer's disease (Minino et al., 2011; Minino and Murphy, 2012). Equally, ischaemic heart disease, cerebrovascular disease, cancer, and respiratory disease remain the predominant causes of death in Europe (Eurostat, 2011). In Australia, the top five causes of death are ischaemic heart disease, cerebrovascular disease, dementia, cancer, and chronic lower respiratory diseases (Australian Bureau of Statistics, 2010). Globally, utilizing World Health Organization statistics, ischaemic heart disease, cerebrovascular disease, and lower respiratory diseases similarly remain leading causes of death (Mathers et al., 2009).

Over 50% of the world's population over 65 live in low- and middle-income countries and this leads to the increasing trend of non-communicable diseases as leading causes of death (Mathers et al., 2009). In all regions, apart from Africa, in 50% or more of cases, non-communicable diseases were the cause of death (Mathers et al., 2009).

Assessing the needs of older people

Older people with progressive life-limiting illnesses are increasingly being managed in the community, often for longer periods and with significant levels of morbidity and associated disability. It is estimated that two-thirds of all older Americans who resided in the community require long-term care assistance with personal care and instrumental activities of daily living (Stone, 2000). A combination of age, co-morbidities, and psychosocial factors can complicate treatment for various chronic and complex conditions, and impact on an older person's capacity to adhere to treatment regimens. Community-dwelling older people are also at higher risk of developing a range of geriatric syndromes such as

delirium, dementia, and depression, and are more likely to experience abuse, neglect, and social isolation (Moore et al., 2009). Medication use also tends to increases with age and even though many older people may benefit from taking fewer medications, clinicians are often reluctant to withdraw medication in the absence of robust evidence (Holmes et al., 2006). The effective management of the multiple co-morbidities associated with ageing are often clinically and managerially complex, time-consuming, and frequently challenging.

Within an aged population, there is a subset of older people who will not die of one specific terminal illness, but, rather, will experience progressive frailty (Carey et al., 2008). For these people, their slow and dwindling decline is characterized by multiple co-morbidities and progressive functional and cognitive impairment, resulting in a gradual loss of functional reserve, increased susceptibility to illness, and a reduced capacity to recover from such events (Carey et al., 2008). Many will require long-term care assistance at home until their care needs exceed available community resources, prompting an admission to a nursing home or an inpatient setting in crisis. It is important to distinguish older people with progressive life-limiting illnesses who may live for an extended period (even years), and who will benefit from screening, specific medical interventions, and advance care planning from those who are rapidly approaching the end of their lives and who may consequentl benefit from appropriate palliative care services (Carey et al., 2008).

The ambiguity associated with determining the most appropriate time to initiate the transition from intensive medical treatment to palliative care for older people has promoted a range of international policy responses (Department of Health, 2008; Australian Government Department of Health and Ageing, 2011). The UK End of Life Care Strategy emphasizes the importance of improved recognition of an approaching death and advance care planning, with a view to increasing choice, particularly around the place of death (Department of Health, 2008). Clinicians are encouraged to consider whether the person they are caring for is at risk of dying with the next 12 months, before initiating the necessary end-of-life conversations and appropriate care and support required to meet the older person's palliative care needs (Department of Health, 2008). The rising burden of chronic conditions, population ageing, and increased demand on specialist palliative care services underpins policies advocating for a population-based approach to palliative care (Palliative Care Australia, 2005; Department of Health, 2008). This policy change has prompted specialist palliative care services to diversify to incorporate a wider range of populations, providers, and settings (Luckett et al., 2012). As part of the reorientation of health-care services, a 'palliative approach' has been identified as being essential to extending palliative care to underserved populations, such as older people. Such an approach is built around core competencies that every health professional should have for people who are dying, while specialist case is reserved for those who have more complex needs.

A palliative approach

A palliative approach is particularly relevant for older people with progressive life-limiting illnesses who need integrated and coordinated care well before they are dying (Wilhelmson et al., 2011). Integrating the elements of the World Health Organization's

(n.d.) vision of palliative care into the goals of care for older people living with progressive chronic conditions that cannot be cured is feasible with a palliative approach. A palliative approach allows for care to be targeted to the specific needs of the illness trajectory and the needs of the older person and their family. Whilst recognizing the inevitability of death, a palliative approach also focuses on optimizing older peoples' quality of life by maximizing comfort and function, and offering appropriate treatment and support for distressing symptoms (Australian Department of Health and Ageing and National Health and Medical Research Council, 2006). In addition to addressing the older person's psychological, spiritual, social, and cultural needs, a palliative approach acknowledges the needs of caregivers and actively encourages their input into care planning (Palliative Care Victoria, n.d.). Integrating a palliative approach into care for older people ensures that they are offered care in accordance with complexity and need, independent of their diagnosis or prognosis (Waller et al., 2008).

While models of cancer care are well defined and pathways to specialist palliative care evident, it is likely that the majority of the older people with chronic conditions, such as chronic heart failure and chronic respiratory disease, will continue to be cared for by their primary care team, with input from relevant medical specialists (Luckett et al., 2012). A palliative approach can be provided readily by the older person's usual care team; however, if the older person's needs or symptoms become more complex, specialist palliative care team input ought to be sought. As death nears, a palliative approach ensures that the care team is well prepared and able to support the older person to die in the preferred place of care (Palliative Care Victoria, n.d.).

Rethinking goal setting in the context of chronic illness in older adults: maximizing well-being and partnering with others

Initiating a palliative approach for an older person ought to be initiated long before the terminal phase of illness so that the impact of the co-morbidities are acknowledged, their comfort and dignity is optimized, and their caregivers' needs are adequately addressed. Older peoples' palliative care needs are frequently under-assessed and therefore under-treated, particularly in relationship to their pain, need for information to inform decision-making, access to support and care at home, specialist palliative care input, and palliative care in nursing homes assessment and care (Davies and Higginson, 2004). There are specific transitions when health professionals need to think about an older person's prognosis and need for a palliative approach to care, such as when:

◆ you answer 'yes' to the 'surprise question'

◆ the person has a newly diagnosed life-limiting condition

◆ there is a worsening prognostication markers for a specific disease

◆ there is a downward step in response to treatment

◆ the person has multiple hospital admissions

◆ there is admission to a nursing home

◆ if his/her spouse has recently died (Murray et al., 2005).

Palliative care needs assessment

Detecting the need for a palliative approach to care has been made simpler with the development of tailored assessment tools for both cancer and other chronic and complex illnesses (Waller et al., 2008). These palliative care specific needs assessment tools assist:

◆ to match the types and levels of need experienced by people with progressive illnesses and their caregivers with the most appropriate people or services to address those needs

◆ health professionals in general and in specialist practice, to determine which needs may be met in that setting and which needs are more complex and may be better managed by specialists

◆ to facilitate communication between primary and specialist care providers about patients and caregivers' needs and actions taken to address these (Waller et al., 2008).

Having identified the need for a palliative approach there are a number of innovations, particularly in the context of chronic illness, that ought to be considered in order to maximize function and well-being of older people with progressive life-limiting illnesses, including referrals where appropriate to:

◆ *Geriatric oncology:* despite cancer being essentially a disease of ageing, the routine assessment of performance status does not capture the full range of health and social problems that some older people experience, such as functional dependence, co-morbidity, polypharmacy, malnutrition, cognitive dysfunction, and depression (Hurria et al., 2007; Terret, 2008). To address this limitation, the National Comprehensive Cancer Network Guidelines (2009) recommends that a multidimensional comprehensive geriatric assessment be integrated into the treatment for all people aged over 70 years of age with cancer. Undertaking a comprehensive geriatric assessment helps to identify older people whose health and/or psychosocial problems may potentially interfere with proposed treatment (Hurria et al., 2007; Terret, 2008). Allowing additional support to be provided helps to identify remediable conditions influencing treatment decisions, establish treatment goals, and, if required, allows a modified treatment plan to be developed (National Comprehensive Cancer Network, 2009). Despite these benefits, the integration of a comprehensive geriatric assessment into routine oncology practice has been limited by cost and the lack of data to date of improved outcomes (Bellera et al., 2012). Regardless of local practices, assessing geriatric needs helps to ensure that the older person with cancer and their caregivers receive the most appropriate care and support to enable them to cope with the effects of cancer and its treatment.

◆ *Heart failure clinics:* referral to a heart failure clinic is highly relevant for many older people with this condition. Heart failure clinics aim to reduce mortality and rehospitalization rates and improve quality of life through individualized patient care (Hauptman et al., 2008). These positive outcomes are achieved through the consistent application of guidelines with a focus on:

- disease management
- functional assessment
- quality of life assessment
- optimizing medical therapy and drug evaluation

- device evaluation
- nutritional assessment
- follow-up
- advance care planning
- communication
- provider education
- quality assessment (Hauptman et al., 2008).

Attendance at these specialist clinics provides older patients and their caregivers with an opportunity to be involved in shared decision making and to have timely conversations about palliative and end-of-life care preferences (Waterworth and Gott, 2010).

◆ *Pulmonary rehabilitation:* chronic obstructive pulmonary disease (COPD) is a common disorder with a high prevalence among older people and an increasing mortality rate (Gelberg and McIvor, 2010). Older people affected by COPD are at an increased risk of cardiovascular events, osteoporosis, fractures, peripheral muscle wasting, depression, and anxiety. This array of problems makes a multidisciplinary approach optimal and such care should begin with stratification of disease severity and prognostic information for each patient (Gelberg and McIvor, 2010). However, if older people with COPD are well enough to participate in pulmonary rehabilitation, they are likely to derive a clinically significant benefit in terms of their dyspnoea, fatigue, and overall well-being (Lacasse et al., 2006). Advanced age on its own ought not be an exclusion criteria for referral to pulmonary rehabilitation given that no correlation between age and outcomes have been found (Gelberg and McIvor, 2010). Given this population's significant symptom burden, elevated risks of mortality and suboptimal access to pulmonary rehabilitation, a comprehensive assessment is an important element of a palliative approach for people with COPD (Reticker et al., 2012).

◆ *Breathlessness clinics:* for people with breathlessness any cause, there has been increased interest in the impact of nurse- or physiotherapist-led interventions, including breathlessness clinics. There is some evidence that a breathlessness clinic may improve management of dyspnoea in patients with advanced lung cancer (Scottish Intercollegiate Guidelines Network, 2005).

◆ *Rehabilitation:* the primary focus of rehabilitation is on restoring function, coping with disability, and decreasing the burden of chronic disease (Wu and Quill, 2011), making rehabilitation a highly appropriate consideration for older people with a range of chronic and complex illnesses, such as cancer, heart failure, renal failure, or stroke survivors with palliative care needs (Dy and Feldman, 2012). Integrating rehabilitation and palliative care helps maximize older people's function and autonomy, and minimize dependency, whilst balancing their quality of life and end-of-life preparation (Wu and Quill, 2011). The primary goal of palliative rehabilitation is to minimize dependence in domains such as mobility and self-care, while providing comfort and emotional support (Javier and Montagnini, 2011). This is achieved by focusing on:

- preventive strategies to minimize complications from the primary disease

- restorative strategies that help regain function and loss of strength due to treatment, disease or both

- supportive strategies to maintain function at the new baseline

- palliative strategies that reduce the burden of care and maximize quality of life (Dietz, 1980).

The input of multiple disciplines is required, with physiotherapists and occupation therapists playing a major role in helping to maintain older people's functional capacity. This is achieved through a range of targeted interventions, including use of various physical modalities to better manage pain, provision of adaptive and assistive equipment, environmental modification, exercise programmes and energy-conservation strategies (Javier and Montagnini, 2011). While benefits of palliative rehabilitation have been demonstrated in a series of smaller retrospective studies, there is a need for larger randomized controlled trials in this population (Javier and Montagnini, 2011)

Establishing care partnerships

The complexity of older people's care demands the formation of a collaborative partnership between primary care, geriatric and palliative care services, together with other health-care providers in accordance with need. While specialist palliative care services need to partner with primary care and geriatricians, there is also a need for geriatricians to access specialist palliative care teams for advice and support on management of older people's symptoms, communication, and psychological and spiritual support if necessary (British Geriatrics Society, 2010). Facilitating input from relevant disciplines to shape the treatment and care plan for older people in accordance with their priorities and needs may require the establishment of case management processes (Phillips et al., 2013). The sharing of information and honesty are integral aspects of all goals of care discussions, which need to be clearly documented.

Advance care planning

Advance care planning is an interactive process of ongoing communication between a competent patient, significant others, and their health-care team(s). The purpose of the advance care plan for older people is to record their wishes regarding treatment decisions and the values that underpin these decisions in order to extend their autonomy and to guide decision-making (Sudore et al., 2008). It plays an important role in clarifying treatment goals to inform care (Higginson and Sen-Gupta, 2000; Lorenz et al., 2006). Advance care planning is particularly relevant for frail older people who are at increased risk of loss of capacity as a result of dementia or a cerebrovascular accident (Dy and Feldman, 2012). However, the potential of advance care planning to improve care outcomes for older people is currently limited by the absence of systematic implementation and in many jurisdictions, no legislation that enshrines the wishes set out in such a plan. In non-cancer conditions and nursing homes where markers of prognosis can be less explicit, ensuring advance care plans are made in the context of patient and family wishes is important (Lynn and Goldstein, 2003). Promoting mechanisms of communicating these wishes across care settings has yet to be fully realized (Volandes et al., 2011). In the setting of dementia, caregivers are more likely than clinicians to want interventions to support (Sampson et al., 2005). Unless appropriate advance care plans are in place, health professionals in acute care may assume that aggressive treatments are in

order for older people with dementia rather than care focusing on quality of life (Andrews, 2009; Hines, 2009).

Unfortunately, if the older person has already lost capacity, the opportunity to plan their care in advance or hold discussions with their families about their care preferences will be more limited. In this circumstance, the question that should be asked of families is 'What would I want under these circumstances?' and never simply what the caregiver would want for them. In this situation, there is a greater reliance on jurisdictional laws as to the required approach for managing their care needs and substitute decision making (Public Guardianship Office, 2005; NSW Guardianship Tribunal, 2011).

Managing older peoples' care transitions

Older people with complex care needs require models of care that facilitate smooth transitions across health-care interventions and settings. Transitional care describes a set of actions that involves the movement of a person from hospital, subacute and post-acute nursing facilities, home, primary, and specialty care offices or nursing home to another care setting or different levels of care within the same location (National Transitions of Care Coalition, 2008). Transitional care is based on a comprehensive plan of care and the availability of health-care practitioners who are well-trained in chronic care and have current information about the patient's goals, preferences, and clinical status. It includes logistical arrangements, education of the patient and family, and coordination among the health professionals involved in the transition and effective communication (National Transitions of Care Coalition, 2008). An integrated 'shared care' model of palliative care implemented by a Canadian specialist palliative care service reported a 7% reduction in the number of patients with cancer presenting to emergency departments (EDs) in the first 12 months (Lawson et al., 2009). A key feature of this model was the specialist service's capacity to cross all care settings from hospital, community, and palliative care unit. However, managing older populations with a non-malignant diagnosis poses tougher challenges, such as preventing avoidable hospital admissions by enhancing primary care and caregiver support (Jiwa et al., 2002; Shipman et al., 2008).

Palliative care in the home setting

Despite many older people preferring to die at home, it is not always feasible due to social or practical reasons. As older people near the end of their life, they frequently require significant assistance with transportation, homemaking services, nursing, and personal care, much of which is provided by informal and formal caregivers (Rolls et al., 2011). Enabling older people to be cared for at home until death is strongly linked to intensity of available home care support, living with relatives, and family support (Froggatt, 2005).

Contemporary health-care policy advocates case management, collaboration, and integrated teams to better support older people with complex and multiple needs through interprofessional practice (Trivedi et al., 2013). Although the effectiveness and cost-effectiveness evidence for interprofessional practice improving care outcomes for older people is weak, there is evidence that well-integrated and shared care models improve processes of care and have the potential to reduce hospital or nursing/care home use for older people (Trivedi et al., 2013). In the United States, a study

exploring nurse practitioner models to better support the many older people with complex illnesses at home who would benefit from palliative care but who have elected not to accept hospice enrolment, found that additional funding is required to ensure the financial viability of such a role (Bookbinder et al., 2011).

Approximately half of all older people with advanced dementia will die at home (Mitchell et al., 2005). Achieving this outcome is dependent upon older people and their caregivers having access to a significant level of support over an extended period of time, as the average length of time from the onset of dementia symptoms to death is 4.5 years (Xie et al., 2008). Depending on the age at diagnosis and presence of co-morbidities, this illness trajectory can extent out to more than 10 years (Xie et al., 2008). This uncertainty reinforces the importance of implementing a palliative approach to care early in the older person's illness trajectory. There is widespread agreement that care for people in the advanced stages of dementia should be palliative (Alzheimers Australia, 2006). Bereaved family members of people with dementia in the United States who received hospice care reported higher ratings of the quality of care and quality of dying (Teno et al., 2011). Models are needed to support people with dementia over extended periods preceding the terminal phase of care and assist transitions when these are unavoidable (Luckett et al., 2012).

Living alone

Living alone influences both the place of care and place of death. Being older and living alone near the end of life is increasingly common as people, particularly women, live longer and families are smaller and frequently more dispersed (Grundy et al., 2004). The numbers of older people living in poverty is also increasing, whilst employment trends and other economic factors impact on the support older people living alone can expect to receive. These factors challenge the capacity for older people to age and die well in their preferred place of care (Rolls et al., 2011). Older people living alone near the end of life have practical, emotional, physical, and existential needs, underpinned by a desire to be independent and maintain a sense of dignity (Aoun et al., 2008). Those most vulnerable and least likely to be in a position to access palliative support include older people living in rural or inner city communities and people with fewer financial resources or smaller social networks (Rolls et al., 2011). Changes in living and social circumstances mean that, in times of crisis, older people no longer have such ready access to informal caregivers as in previous generations. The focus across the developed world on 'ageing in place' although well intended is largely dependent upon on the availability of a spouse, partner, or adult child who is prepared to take on the caregiver role, or a reliance on paid carers (Rolls et al., 2011). However, not all older people have continuous access to caregiver support making it difficult for them to be cared for at home as their care needs increase. This has implications for palliative care. Older people are more likely than younger people to request hospitalization as the end of life nears (Rigby et al., 2010), making confirming their place of care preferences important throughout their illness trajectory. When considering older people's preferences, two separate conversations are indicated to identify preference for current place of care as well as the preferred location for care immediately prior to death (Agar et al., 2008).

Palliative care in hospitals

Across the developed world, more than half of all deaths occur in hospitals, ranging from 56% in the United Kingdom (Department of Health, 2008), 65% in Australia, and 45% in the United States, with people aged 75–84 years having the highest death rate (Department of Health, 2008). In the United States, Canada, and recently in the United Kingdom, there is evidence that the number of people dying in hospitals is being averted with an increasing number of home deaths (Gomes et al., 2012). Despite this positive trend and the emphasis on remaining at home for end-of-life care, dying within the acute care setting will continue to be the reality for many older people.

The models of care largely adopted in the acute care sector are consultative models, inpatient palliative units/beds, and nurse practitioner models (Rabow et al., 2004; Sudore et al., 2008). Consultative acute care palliative care services tend to focus on (a) prognosis and goals of care conversations, (b) pursuing documentation of advance directives, (c) discussion about foregoing specific treatments and/or diagnostic interventions, (d) family and patient support, (e) discharge planning, and (f) symptom management (Manfredi et al., 2000). Hospital palliative care teams help to improve symptom control and quality of life, alleviate emotional burden, and improve caregiver and patient well-being (Hanks et al., 2002; Higginson et al., 2003), whilst also reducing hospital costs (Morrison et al., 2008). In the United States, palliative care provided to hospitalized patients with advanced disease has resulted in lower costs of care and less utilization of intensive care compared to similar patients receiving usual care (Penrod et al., 2010). The establishment of palliative care services within the acute care sector in the United States is more likely to occur in larger hospitals, academic medical centres, not-for-profit hospitals, and VA hospitals compared to other hospitals (Morrison et al., 2005). Meeting the end-of-life care needs of older people dying in the acute care sector demands greater attention and investment in a model of care that is responsive to the complex needs of this growing population.

Emergency departments

There is an increasing pressure on EDs, particularly by older people (Gruneir et al., 2011). A number of older people will die in the ED with few of these people being known to a specialist palliative care service (Beynon et al., 2011). ED presentations are frequently the end result of inadequate symptom control, absence of caregivers, or logistical (Agarwal et al., 2012). Many ED deaths may be prevented if a palliative approach is adopted and the older person's palliative care needs are identified earlier, appropriate referrals are made, and advance care planning is completed (Beynon et al., 2011). The capacity of coordinated models of care to decrease unnecessary ED usage has been demonstrated in heart failure (McAlister et al., 2004), and likely to be applicable to older people requiring palliative care. Previous ED attendance or admissions ought to be the trigger for initiating the necessary palliative supports to improve older people's quality of life, capacity to optimize their time at home or in their place of choice, whilst also reducing the pressure on busy EDs, which are not designed for delivering great palliative care (Beynon et al., 2011). Research exploring treatment uncertainty, quality of life, costs, ethical and social issues; optimizing timely and effective interactions between emergency

and other health services; and strengthening community-based care are all required to inform end-of-life care delivery and policy in the ED (Forero et al., 2012). The importance of the ED as a setting for palliative care is explored further in Chapter 3.3.

Palliative care in nursing homes

The emphasis placed on supporting older people to live at home for as long as possible has resulted in nursing home residents becoming older and frailer. Nursing homes are increasingly the place of where many older people will live out their life for a relatively short period of time. The burden of disability and death that occurs in this care setting is significant, and the palliative care needs of nursing home residents and their caregivers is extensively detailed in Chapter 3.4.

Supporting caregivers

Informal caregivers play a major role in helping older people remain at home. The burden on informal caregivers is often profound, especially as the 'palliative phase' of an illness for both malignant and non-malignant conditions is often prolonged (Luckett et al., 2012). This is often also care that has no start date (with people slipping into the role and no time defined for an end date). Many caregivers of older people are themselves older and/or ill, with this role impacting on their health (Mitchell et al., 2010a). Often older people are providing aspects of care for each other rather than one being sole caregiver for the other. While many caregivers may derive immense satisfaction from their role, for others there are often unintended adverse consequences, including (a) significant social, financial, and employment implications; (b) health implications; (c) increased risk of depression and anxiety which may increase as death approaches; (d) feelings of sadness, anger, resentment, isolation, and inadequacy; and (e) potential for increased risk of psychological morbidity and complicated grief, especially if the patient has unrelieved physical or psychological symptoms (Waller et al., 2008). Despite informal carers having high levels of need for support and psychological morbidity, a systematic review examining interventions to better support informal caregivers of people with palliative care needs found few well-designed studies generating high levels of evidence (Harding and Higginson, 2003). Caregivers of older people with dementia who are approaching the end of life have different but equally intense needs to carers of patients dying from other diseases (Schulz et al., 2003). Caregivers in this setting experience numerous losses associated with progressive dementia, as well as managing and coping with dementia-related behaviours (Goodman et al., 2010).

Elements of a palliative approach model of care for community dwelling older people

Despite the ambiguity in nomenclature describing palliative models of care and the scarcity of high-level evidence, a recent rapid review identified seven elements of care as being essential to addressing the needs of older people at the end of life and their caregivers:

1. Timely access to specialist palliative care knowledge and expertise, in accordance with needs

2. Case management, coordination, and promotion of communication across care settings

3. Support for home-based care including after-hours practitioner access

4. Tailoring and targeting services to the right population and setting, particularly when addressing cultural needs

5. Consideration of workforce issues across the care continuum

6. Collaboration across the health-care continuum including home, community, acute and residential aged care

7. Integrating health and social services to support palliative care in the community (Luckett et al., 2012).

Palliative care for specific diagnoses and geriatric syndromes

There are some specific diagnoses and syndromes that warrant special mention due to the prevalence in the older person and the specific clinical approaches needed to respond optimally. The term 'geriatric syndrome' is utilized in the context of a multimorbid process leading to specific phenomenology (Flacker, 2003). This concept focuses on common clinical conditions, which don't fall neatly into specific disease categories (Flacker, 2003; Inouye et al., 2007).

Dementia

Dementia is a progressive terminal illness for which there is no cure (Birch and Draper, 2008). Research advances in dementia treatments are unlikely to alter this picture significantly in the foreseeable future (Brodaty et al., 2011). From 1999 to 2008, 879 281 Alzheimer's disease-related deaths were identified in United States (Moschetti et al., 2012). The age-adjusted mortality rate for Alzheimer's disease increased from 45.3 per 100 000 population in 1999 to 50.0 per 100 000 in 2008. Dementia is now the third leading cause of death in Australia (Australian Bureau of Statistics, 2010). In the United States, between the years of 2000 and 2008, the proportion of deaths due to heart disease, stroke, and prostate cancer decreased by 13%, 20%, and 8%, respectively, whereas the proportion due to Alzheimer's disease increased by 66% (Alzheimer's Association, 2012). It is becoming the predominant reason for admission to residential aged care or nursing homes (Van Rensbergen and Nawrot, 2010). For example over half (53%) of all people living in residential aged care in Australia have a recorded diagnosis of dementia (Australian Institute of Health and Welfare, 2009).

There are several key challenges to delivering effective palliative care for the person with advanced dementia (Birch and Draper, 2008). Some areas which need special consideration include difficulties in identifying a well-defined terminal phase, a more protracted duration of end-stage illness over weeks to months (rather than hours to days), issues relating to communication and decision-making, assessment of pain in the cognitively impaired, and specific symptoms such as behavioural disturbance (Sachs et al., 2004).

Families of the person with dementia have many of the same needs as people caring for those with other life-limiting illnesses, including a need for information about:

◆ the patient's condition

◆ future changes

◆ the treatment plan.

There are also specific needs relating to dementia. Families often have limited knowledge about the dementia illness trajectory, resulting in expectations that differ from the health professionals providing their care (Hertogh, 2006). When these needs are unresolved, families are less prepared for end-of-life care and decision-making (Forbes et al., 2000). Having a relative with advanced dementia living in a residential aged care facility can be a significant burden and the role of a proxy decision-maker can be extremely stressful (Forbes et al., 2000; Caron et al., 2005). When the family members of residents with advanced dementia understand that prognosis is poor, there is a decreased likelihood of the resident having interventions in the last 90 days of their life that may be burdensome (Mitchell et al., 2009).

Communication issues with the patient, between services, between service and family, and the difficulties of advance care planning are major barriers to care provision. Decision-making and issues of consent surrounding treatment interventions are complex, particularly in relation to nutrition and hydration, treatment of pneumonia, and whether or not to send a resident to hospital, particularly when the wishes of the resident are unclear (Lamberg et al., 2005).

Predictors of mortality in residents with Alzheimer's disease living in aged care facilities include limitation of physical function, pressure sores, urinary incontinence, use of restraints, and indicators of delirium (Gambassi et al., 1999). Co-morbidities such as respiratory disease, cardiovascular disease, diabetes mellitus, and malnutrition are also strong predictors of mortality (Coventry et al., 2005). While they have limitations, there is mounting evidence to support criteria and tools that help with prognostication (Clelland, 2008).

The Functional Assessment Staging (FAST) tool is a seven-stage system to identify progressive functional decline and has been used to classify people with dementia (Coventry et al., 2005). There are concerns that FAST may not be valid for all types of dementia and that the Karnofsky Performance Status score may be more able to predict survival than FAST (Schonwetter et al., 2003). More recently Mitchell et al have assessed the validity of a mortality and risk score (Advanced Dementia Prognostic Tool (ADEPT) for residents with advanced dementia). The variables that best predicted survival were length of stay, age, gender, dyspnoea, pressure ulcers, total functional dependence, whether the person was bedfast, decreasing levels of oral intake, bowel incontinence, body mass index, weight loss, and congestive heart failure (Mitchell et al., 2010b). While it proved better than previous guidelines, the ADEPT tool was only moderately accurate at predicting survival (Mitchell et al., 2010b).

Nutrition and swallowing difficulties are common in the advanced stages of dementia (Palecek et al., 2010). Treatment decisions surrounding nutrition and hydration are often emotionally charged and raise ethical and moral issues for residents, families, the treating health professionals, as well as society (Wasson et al., 2001). This often results in staff as well as family members feeling compelled to 'do something' (Wasson et al., 2001). Studies have shown percutaneous endoscopic gastrostomy feeding for older people with end-stage dementia to result in adverse consequences including pain, gastrointestinal bleeding, use of restraints, faecal incontinence, and aspiration (Finucane et al., 1999). A higher incidence of pneumonia has been reported in tube fed patients (Bourdel-Marchasson et al., 1997). Further, a systematic review highlights that the use of feeding tubes has no survival benefit for this group of patients (Finucane et al., 1999).

Several studies highlight the poor recognition and treatment of pain in residential aged care facilities (McAuliffe et al., 2009; Corbett et al., 2012). Little is still known about the potential of dementia-related neuropathology contributing to the pain experience in dementia (Corbett et al., 2012). People with end-stage dementia appear to receive less medication for pain than patients without cognitive difficulties (The Australian Pain Society, 2005). Cognitive impairment and communication difficulties contribute to pain going unrecognized (Morrison and Siu, 2000). Not only are cognitively impaired residents prescribed less analgesia than other residents they also are administered less analgesia by the nurses caring for them (Chang et al., 2009).

Behavioural disturbances that impact on caregivers include a range of difficulties including wandering, agitation, aggression, sexual disinhibition, apathy, and shouting (O'Connor et al., 2008). Reducing behavioural disturbances and maintaining communication and personhood requires a range of approaches. A systematic review of psychosocial treatments for the management of behavioural and psychological symptoms of dementia (BPSD) (O'Connor et al., 2008) highlights the importance of clear communication, understanding triggers, social interaction, and environment (O'Connor et al., 2008). Moreover, non-pharmacological treatments worked best when they were adapted to the specific interests of the individual, and consistency and avoiding punishment are key (O'Connor et al., 2008). It is also important to rule out coexisting conditions such as constipation, depression and anxiety, and delirium. A comprehensive assessment undertaken by a professional with appropriate training in, for example, dementia care mapping can assist in devising individualized management plans for BPSD (O'Connor et al., 2008).

There are some aspects of end-of-life care that are particularly challenging or forgotten. For example, the spiritual care of persons with dementia is often overlooked. It is possible to nurture the spiritual well-being of people even when their dementia is advanced (Ryan et al., 2005). It is also important to consider the multiple losses experienced by caregivers prior to the death, such as loss of companionship and witnessing the loss of cognition of their loved one (Chan et al., 2012). Anticipatory grief may also be present at the time that decisions about the need for and transfer to institutional care are being made (Chan et al., 2012).

Delirium

Delirium is a medical illness characterized by change of level of consciousness and cognition, which develops rapidly and fluctuates, occurring in the context of an underlying medical condition (American Psychiatric Association, 2000.). Delirium is a common condition in the older person, and it is important to understand it is preventable and, if not prevented, then reversible in many cases. Increasingly, subsyndromal presentations are recognized, with less severe symptoms but all core domains of sleep–wake cycle, thought process, language, attention, orientation, and visuospatial ability present (Meagher et al., 2012; Trzepacz et al., 2012).

Delirium in older people is often under-recognized or misdiagnosed, yet is the most common complication of a hospital admission for older people (Young and Inouye, 2007). It develops in up to half of older adults postoperatively, and occurrence rates of delirium in medical inpatients vary between 11% and 42% (Siddiqi

et al., 2006). Delirium in palliative care is covered in more detail in Chapter 17.5, and here we will highlight the pertinent issues when it occurs in the older adult. Increasing age, dementia and cognitive impairment, visual impairment, admission to hospital for fracture, and severe medical illness are important risk factors for delirium (National Institute for Health and Clinical Excellence (NICE), 2010). There are also multiple medications, which can precipitate or increase risk of delirium (Clegg and Young, 2011). Preventative strategies include orientating approaches, managing dehydration and constipation, avoiding unnecessary catheterization, optimizing oxygen saturation, encouraging mobility, and resolving reversible causes of sensory impairments by providing visual and hearing aids where needed (NICE, 2010). Caution should be exercised in prescribing antipsychotic medications to older people with delirium (Delirium Clinical Guidelines Expert Working Group, 2006). Non-pharmacological strategies (environmental, behavioural, social) are first-line strategies to manage the symptoms of delirium (Delirium Clinical Guidelines Expert Working Group, 2006). Delirium is a highly distressing experience and hence information about delirium should be made available to people who have experienced delirium after its presentation and their family/carers (Delirium Clinical Guidelines Expert Working Group, 2006).

Pain

The majority of older people with advanced illness will experience pain in some form, either as a result of diagnosed pathological processes or treatments trialled to manage their condition (Scottish Intercollegiate Guidelines Network, 2008). Many older people have more than one source of pain. Their pain is frequently underassessed and, as a consequence poorly managed. Age-related changes in pharmacokinetics and pharmacodynamics add to the challenges of effectively managing older people's pain (Dalacorte et al., 2011).

Constipation

Constipation is a prevalent problem in the older person (Gallegos-Orozco et al., 2012). On self-report, 26% of women and 16% of men over 65 years consider themselves constipated (Gallegos-Orozco et al., 2012). This rises to 34% and 26% respectively in the group aged 84 and older, and over half of the people in long-term care facilities. The symptomatology may not necessarily be reduced frequency of bowel movements, but straining and passage of hard stools may be reported (Gallegos-Orozco et al., 2012).

Constipation is associated with several medical conditions of high prevalence in the elderly population (including Parkinson's disease, diverticular disease, hypothyroidism, dementia, and stroke) and also medications (including iron and calcium tablets, calcium channel blockers, non-steroidal anti-inflammatory drugs, tricyclic antidepressants, and opioids). Intrinsic changes in colonic physiology including reduced number of neurons in myenteric plexus, increased collagen deposition, reduction in inhibitory nerve input, increased binding of plasma endorphins, and changes in anorectal function also occur and can predispose this population to develop constipation (Gallegos-Orozco et al., 2012).

Prevention of constipation is important as underlying illnesses progress and immobility and reduced oral fluid and fibre intake occurs. An elderly person with constipation requires a detailed history and examination, including a rectal examination. Constipation management is discussed in more detail in Chapter 10.3.

Falls

Falls are often multifactorial in origin, and include motor problems (gait and balance, muscle weakness), sensory impairment (vestibular, vision, peripheral neuropathy), cognitive and mood impairments, postural hypotension, medication, and environmental hazards (Close and Lord, 2011). Fall risk is increased with medications for cardiovascular diseases (such as digoxin, type 1a antiarrhythmics and diuretics), benzodiazepines, antidepressants, antiepileptics, antipsychotics, anti-Parkinsonian drugs, opioids and urological spasmolytics and provide a modifiable risk factor (Huang et al., 2012). Once a person has fallen, it can lead to further immobility due to the fear of falling. Falls are associated with fractures, head injury, and further functional decline (Gates et al., 2008). It is important to regularly screen for falls risk, in particular when a change of environment, physical, or cognitive function has occurred (Close and Lord, 2011). A risk assessment also will allow individualized intervention, and to assess the patient's ability to understand and cooperate with falls risk reduction strategies, such as pushing the call bell to get assistance to go to toilet (Close and Lord, 2011).

Multifaceted interventions should be considered, addressing the factors specific to the individual include reducing environmental hazards, adjusting or ceasing psychoactive and hypotensive medications, gait retraining, use of assistive devices, and appropriate footwear (Gillespie et al., 2009; Close and Lord, 2011). The role of vitamin D supplementation is controversial (Verbrugge et al., 2012)

Frailty

Frailty has been variously defined as diminishing capacity to withstand stress or increased vulnerability to adverse outcomes (reduced ability to maintain or regain homeostasis), physical disability, impairment in activities of daily living, social withdrawal, slow motor processing, cognitive changes, weight loss, or negative energy balance (Boockvar and Meier, 2006; Sternberg et al., 2011). There is a point of contention as to whether disability and functional decline are components of frailty or its outcome (Sternberg et al., 2011). The definition developed by Fried and colleagues (Walston et al., 2006; Ko, 2011) is widely used for research purposes, and includes three or more of the following: unintentional weight loss, poor grip strength, self-reported exhaustion, low physical activity levels, and slow walking speed. It has been more difficult to develop an operationalized definition for use in clinical practice (Rodriguez-Manas et al., 2013). When caring for older adults, there is a spectrum of resilience ranging from the most frail and vulnerable to highly independent and robust (Walston et al., 2006). Though frailty is more common in older adults and those with multiple comorbidities, it can occur independent of age, disability, or illness (Ko, 2011).

Frailty is believed to be a complex interaction of several factors, including physiological alterations with ageing, comorbid disease, nutritional inadequacy, environmental impacts, and genetic and lifestyle factors (Heuberger, 2011). It is likely that the accumulation of factors has a synergistic effect (Heuberger, 2011). A key feature is weight loss and sarcopenia (Boockvar and Meier, 2006; Ko, 2011). Frailty can be present in the obese older adult, and the

'sarcopenic obese' is associated with significant health burden (Heuberger, 2011). Dysregulation of neuromuscular, endocrine, and immune systems seem key (Ko, 2011). Pro-inflammatory cytokines, activation of promoter genes relating to catabolism and catabolic cytokines, testosterone deficiency, hypovitaminosis D, low insulin-like growth factor, ghrelin, and growth hormone have been implicated in epidemiological studies (Heuberger, 2011; Ko, 2011; Shardell et al., 2012). Chronically high interleukin 6 is strongly associated with multiple disease states (diabetes, anaemia, atherosclerosis, heart failure, and dementia), and predicts increased disability, mortality, and sarcopenia in older adults (Ko, 2011).

Frailty has been associated with an increased risk of falling, hospitalization, reduced activities of daily living, disability, and death, after adjusting for health and socioeconomic status and disability (Ko, 2011). It has been estimated that 3–5% of deaths in older adults could be delayed if frailty was prevented (Shamliyan et al., 2012). Primary prevention of frailty includes addressing comorbid illness such as hypertension; chronic disease management, exercise, and nutrition are strategies for secondary prevention. The principles of good palliative care guide tertiary prevention, such as maintaining and improving function, control of symptoms, maintaining psychological well-being, and preventing hospital admissions where possible (Sternberg et al., 2011). Currently, the strategies, which have demonstrated benefits, are exercise and geriatric interdisciplinary assessment (Ko, 2011). Exercise strategies include progressive resistance exercise training, multicomponent training (resistance, endurance, balance, and flexibility), and t'ai chi, and have been demonstrated to improve performance of activities of daily living, reduce chronic elevation of inflammatory mediators, improve gait velocity, and decrease falls; whilst also improving quality of life and emotional health (Province et al., 1995; Chin et al., 2008; Ko, 2011). Exercise may have limited benefits in the severely frail.

To date there has been no definitive evidence demonstrating benefit of hormone replacement for improving muscle mass and strength in the treatment of frailty (Ko, 2011). Testosterone replacement can increase lean muscle strength but its effects on improved function have been mixed, and it has adverse effects that may be more problematic in the frail older person (Ko, 2011). Vitamin D replacement also can increase muscle strength, and decrease falls; however, its efficacy in frailty is yet to be determined (Ko, 2011). Medication may have a role in reducing incidence of frailty by inhibition of inflammatory pathways (statins, angiotensin-converting enzyme inhibitors), but the vast majority of medications are likely to have a net effect 'stressor' which could destabilize the frail person (Heuberger, 2011; Gnjidic and Hilmer, 2012).

Geriatric evaluation and management (GEM) and comprehensive geriatric assessment (CGA) are two models on interdisciplinary geriatric care, the first where the team directly delivers care, and the latter a consultative model (Ko, 2011). These assessments include a geriatrician, nurse, social worker, and occupational or physical therapist. The objectives of GEM and CGA are to improve physical and psychological function, reduce hospitalization and long-term care placement, and reduce early mortality (Ko, 2011). Similarly models in the outpatient or home setting such as the programme for all inclusive care of the elderly (PACE), and acute care setting (acute care for the elderly) have similar goals. More

recently, longer time of enrolment in PACE is independently associated with: change of resuscitation status towards less aggressive care, reduced hospitalization, and death in a non-hospital setting (Pak et al., 2012).

Depression

Older age has been demonstrated as a risk factor for depression (Ellison et al., 2012; Zhao et al., 2012). Depression in the elderly is also associated with an increase by 50% in health-care costs, compared to the non-depressed with similar chronic medical illnesses (Ellison et al., 2012). Risk factors for later life depression include unmarried status, living alone, lack of social supports, negative life events such as bereavement, and lower socioeconomic status (Ellison et al., 2012). Depression often occurs in the context of comorbid psychiatric or medical illnesses. Specific medical disorders associated with a higher risk of depression include cardiovascular disease, Parkinson's disease, cancer, stroke, lung disease, arthritis, loss of hearing, and dementia (Ellison et al., 2012). It should be noted that 25–50% of family caregivers also experience depression (Ellison et al., 2012). Depressive symptoms such as anorexia, insomnia, fatigue, and weight loss may be non-specific, and reflect symptoms of concurrent comorbid medical illnesses. Older people may also have difficulty reporting symptoms due to cognitive impairment or due to fears of stigma associated with psychiatric illness. There are several scales validated for use in the older adult population, including the Geriatric Depression Scale, Cornell Scale for Depression in Dementia, Beck Depression Inventory, and Hamilton Depression Scale (Ellison et al., 2012). It is important to distinguish sadness and difficult coping with depression, and a common misperception is that depression is a part of normal ageing leading to its under-recognition and under-treatment.

Due to the frequency of concurrent cognitive impairment and depression, causal relationships have been explored but there is yet to be definitive evidence (Ellison et al., 2012). It has been demonstrated that older patients with depression demonstrate cognitive deficits in several neuropsychological domains, including processing speed, verbal and non-verbal memory, and executive functioning (Ellison et al., 2012). These cognitive symptoms sometimes do not fully respond to effective antidepressant treatment. Evolving evidence does support the concept that depression and the number of depressive episodes are independent risk factors for the future development of dementia (Ellison et al., 2012). Proposed mechanisms include hypothalamic–pituitary–adrenal axis dysregulation, cerebrovascular ischaemic white matter lesions, and inflammation in the central nervous system (Ellison et al., 2012).

Treatment of depression in the older patient with chronic illness requires a multifactorial approach, including psychological, cognitive, and behavioural interventions as well as medication (Ellison et al., 2012). Referral to specialist psychiatric services may be needed for those who have failed an adequate trial of depression treatments, those at risk of self-harm and suicide, those who abuse alcohol or other substances, those with comorbid psychiatric conditions or dementia, and those who need electroconvulsive therapy (Ellison et al., 2012). Time to onset of efficacy and the adverse event profile are important factors to inform therapeutic options in the older adult, especially if disease is progressive.

Managing multimorbidity

More than 50% of older adults have three or more chronic diseases (American Geriatrics Society Expert Panel on the Care of Older Adults with Multimorbidity, 2012). The best way to approach decision-making and clinical management in the older adult with multimorbidity remains challenging. It is important that the person is able to be adequately informed about the expected treatments benefits and harms (American Geriatrics Society Expert Panel on the Care of Older Adults with Multimorbidity, 2012). In particular when considering 'preference sensitive' decisions, based on values and preferences, the person will need to weigh up the potential therapies for each condition, the increased risk of adverse events, and the possibility of more limited benefits (American Geriatrics Society Expert Panel on the Care of Older Adults with Multimorbidity, 2012). It is also important to consider whether participants with multi-morbidity were included in the clinical trials evaluating the treatment options at hand (American Geriatrics Society Expert Panel on the Care of Older Adults with Multimorbidity, 2012).

Physiological changes with ageing

Hearing and vision changes

Age-related changes in hearing and vision are prevalent, and can impact on a wide range of issues relating to care. The person may not report symptoms due to embarrassment, and it may lead to difficulty in obtaining history and following management. Age-related hearing loss is known as presbycusis. Presbycusis is associated with progressive deterioration of auditory sensitivity, loss of the auditory sensory cells, and central processing functions, and is associated with the ageing process (Li-Korotky, 2012). Another common cause is cerumen impaction, which is more common due to decreased number of cerumen glands and activity.

Common causes of vision impairment in the older person include age-related macular degeneration, glaucoma, cataracts, and diabetic retinopathy, with one in three people over the age of 65 having some form of vision-reducing disorder (Quillen, 1999).

Sensory impairment increases risk of falls and delirium, as well as decreasing function and the ability to be self-caring.

Dry mouth, dysphagia, and tooth loss

Some studies have shown age-related changes in salivary constituents, but other contradict this, demonstrating age-stable production of salivary electrolytes and proteins in the absence of major medical problems and medication use (Turner and Ship, 2007). Hence complaints of xerostomia should not be only attributed to age. Salivary disorders in the ageing population usually are caused by systemic diseases and their treatments (e.g. anticholinergic medications or radiation therapy) (Turner and Ship, 2007). Several medical conditions (such as Sjögren's syndrome, diabetes, Alzheimer's disease, and dehydration), medications (e.g. anticholinergics), head and neck irradiation, and chemotherapy can cause or contribute to salivary gland dysfunction (Turner and Ship, 2007). Other medications which are implicated include antidepressants, sedatives, and tranquilizers; antihistamines; antihypertensives (alpha and beta blockers, diuretics, calcium channel blockers, angiotensin-converting enzyme inhibitors); cytotoxic agents; and medications to treat Parkinsonism and epilepsy (Turner and Ship, 2007). Xerostomia is associated with altered taste, difficulty chewing and swallowing food, mucosal breakdown, candidiasis, dental problems, and increased susceptibility to aspiration pneumonia (Turner and Ship, 2007).

Tooth loss prevalence varies between countries, and rates are generally reducing over time (Starr and Hall, 2010). Socioeconomic factors and related lifestyle and behavioural factors remain strong predictors (Starr and Hall, 2010). Ill-fitting dentures also can cause problems with chewing and swallowing. Dysphagia is also prevalent, in particular in those with dementia and stroke (Sura et al., 2012). Percutaneous endoscopic feeding only has a place in specific clinical scenarios, and is unlikely to offer benefit in the person with progressive and far advanced disease (Cullen, 2011).

Dermatological changes associated with ageing, pressure ulcers, and wound healing

The structure and the function of skin change with age (Yaar and Gilchrest, 2001). The epidermis becomes thinner and loses its undulating rete pattern, the stratum corneum loses its ability to retain water, and cell replacement, barrier function, and wound healing decrease (Yaar and Gilchrest, 2001). The dermis thins and loses elasticity, partly because of a decrease in the number of fibroblasts (Yaar and Gilchrest, 2001). Eccrine sweat glands shrink, reducing sweat production, and Langerhans cells decrease in number, affecting immune responsiveness (Yaar and Gilchrest, 2001). This has implications for pressure ulceration and may change absorption of transdermal medications (see Chapter 11.1). Other contributing factors may be corticosteroids, used in the context of COPD or for systemic indications.

Pharmacokinetics and pharmacodynamics and impacts on prescribing

There are pharmacokinetic and pharmacodynamic changes associated with ageing which are important. The effect of ageing on the small bowel transporter mechanism is not fully established, but absorption seems to be minimally effected with age (Cusack, 2004). Ageing is associated with some reduction in hepatic first-pass metabolism due to reduced liver mass and perfusion; hence the bioavailability of some medications can be increased (Klotz, 2009; Shi and Klotz, 2011). Changes in body composition also occur, with body fat and total body water increasing as lean body mass decrease. This leads to hydrophilic drugs having a smaller volume of distribution and lipophilic drugs have an increase, prolonging their half-life (Klotz, 2009; Shi and Klotz, 2011). Drugs with a high hepatic extraction ratio display some age-related decrease in systemic clearance, but for most drugs with a low hepatic extraction ratio, clearance is not reduced with advancing age (Klotz, 2009; Shi and Klotz, 2011). In general, cytochrome P450 enzyme activities are preserved in normal ageing. Drug transporters play an important role in pharmacokinetic processes, but their functional changes related to age are not fully understood. One-third of older people show no decrease in renal function. In the other two-thirds, the age-related decline of renal function is associated with coexisting cardiovascular diseases and other risk factors, rather than age alone (Klotz, 2009; Shi and Klotz, 2011). A progressive decline in homeostatic mechanisms leads to a reduced ability to mitigate many of the adverse effects of medications including hypotension

and electrolyte disturbances (Turnheim, 2003). There is greater inhibition of synthesis of vitamin K-dependent clotting factors at similar plasma concentrations of warfarin in elderly compared with young patients (Mangoni and Jackson, 2004). Advancing age is associated with increased susceptibility to psychoactive medications (antidepressants, antipsychotics, lithium, and benzodiazepines) (Trifiro and Spina, 2011).

Conclusion

The older person presents unique clinical needs, where palliative care can make a substantial contribution. Understanding the epidemiology of the illnesses that cause death, multimorbidity, and the phenomenological manifestations of illness will allow the clinician to individualize care. Key principles include optimizing symptoms and function, supporting caregivers, and proactive monitoring for risks factors for common problems such as frailty, depression, and delirium. Continuity of care is required at points where the older person is most vulnerable: on presentation to hospital and transition to residential care. A multidisciplinary approach is paramount, as is an understanding of the values and beliefs of the individual to plan for future care.

SECTION 17

Psychosocial and spiritual issues in palliative medicine

Spiritual issues in palliative medicine

Susan E. McClement

Introduction to spiritual issues in palliative medicine

The focus of palliative care is the whole person, including biopsychosocial, cultural, and *spiritu*al dimensions of patient needs. That end-of-life care should incorporate some consideration of spiritual issues is consistent with both the vision of Dame Cicely Saunders, champion of the hospice movement (Saunders, 2001), and the World Health Organization's (WHO's) emphasis on integrating spiritual aspects of patient care as part of its definition of palliative care (WHO, n.d.). People confronted by serious illness often draw on religious or spiritual beliefs (Hamel and Lysaught, 1994; Matthew et al., 1998; Ehman et al., 1999), Taylor posits that, 'if left un-addressed spiritual distress may stifle the opportunity for growth at the end of life, lead to poorly controlled symptoms, and result in an "unquiet death"' (Taylor, 2001, p. 395). Clearly, such outcomes are inconsistent with the aims and goals of palliative medicine.

The burgeoning literature examining the topic of spirituality within health care in general, and within palliative care in particular, underscores the notion that attending to patients' spiritual care needs is a vital part of providing optimal palliative care (Chiu, 2004; Chochinov and Cann, 2005; Sinclair et al., 2006a). Competencies for spiritual care have been developed (Baldacchino, 2006); guidance on how to discuss religious and spiritual concerns with dying patients has been published; courses on spirituality are becoming more common in medical schools in the United States; and chapters devoted to spirituality are included within authoritative palliative medicine and nursing textbooks (Ferrell et al., 2001; Cassidy and Davies, 2003; Strang and Strang, 2006). Yet health-care providers frequently report that they feel ill equipped to provide spiritual care at the end of life and wrestle with many questions and uncertainties. What is spiritual care? What is spiritual suffering? Who should provide spiritual care? How is a spiritual assessment conducted? What are some spiritual interventions for end of life care? What are some future research directions in the area of spiritual care? Answers to these questions form the basis of this chapter (see Chapters 2.1, 4.4 and 7.4).

What is spirituality?

An ancient Chinese proverb reminds us that, 'the beginning of wisdom is to call things by their proper name' (Good Reads, 2014). Such wisdom presupposes conceptual clarity. To date, such clarity concerning spirituality remains elusive. Increased secularization of society has resulted in a shift from the traditional explicitly religious meaning given to spirituality (Cassidy and Davies, 2003; Strang and Strang, 2006). Numerous definitions of spirituality exist in the literature such that the concept of spirituality in relation to health research has been plagued by definitional ambiguity (Sinclair et al., 2006a). In an effort to address this issue, key stakeholders participated in a Consensus Conference aimed at improving the quality of spiritual care as a dimension of palliative care. The definition crafted at that conference defined spirituality within the health care context as 'the aspect of humanity that refers to the way individuals seek and express meaning and purpose, and the way they experience their connectedness to the moment, to self, to others, to nature, and to the significant or sacred' (Puchalski et al., 2009, p. 887).

The Consensus Conference definition of spirituality appears to reflect dying patients' perspectives of this concept. The empirical work in this area, though limited, is instructive. A qualitative study conducted by Chao and colleagues examining the essence of spirituality in a sample of terminally ill Buddhist and Christian patients ($N = 6$) identified four broad thematic areas: (1) communion with self (self-identity, wholeness, inner peace), (2) communion with others (love, reconciliation), (3) communion with nature (inspiration, creativity), and (4) communion with a higher being (faithfulness, hope, gratitude) (Chao et al., 2002).

Grant and colleagues identified spiritual issues and needs in a sample of patients with advanced cancer ($N = 13$) and advanced non-malignant disease ($N = 7$) from a variety of religious backgrounds. Content analysis of qualitative interviews revealed three main spiritual issues of concern to patients. These included (1) searching for meaning and identity within the illness experience; (2) searching for peace of mind, and freedom from a pervasive fear of dying; and (3) searching for a guide (e.g. nurse or physician) to help them make sense of what was happening as death drew near (Grant et al., 2004). Being treated as an individual and feeling valued and affirmed by their health-care provider were behaviours that helped address patients' spiritual care needs.

Smith-Stoner's qualitative survey examining end-of-life preferences for atheists ($N = 88$) evaluated the relevance of a threefold definition of spirituality that included domains related to the intrapersonal, interpersonal, and interconnectedness with the natural world (Smith-Stoner, 2007). The intrapersonal domain

speaks to the importance these individuals place on finding meaning in their lives. Interpersonally, atheists identified the importance of maintaining connection with family and friends. Interconnectedness with the natural world concerns maintaining a connection with the natural world through spending time outdoors or with animals.

The notion of interconnectedness identified in studies conducted by Chao et al. (2002), Grant et al. (2004), and Smith-Stoner (2007) is consistent with Burkhardt and Jacobson's (2000) observation that, 'spirituality is known and experienced in relationships' (p. 95). The notions of communion and connectedness underscore the importance of 'relationship' in the spiritual well-being of patients, and the salience of spiritual care interventions that promote such connectedness.

Spirituality and religion

The term spirituality is sometimes used synonymously (and mistakenly) in place of the term religion (Schmidt and Mauk, 2004). Religion is typically equated with an organized system of beliefs, rituals, and practices an individual identifies with, which includes a relationship with a divine being. Religion may or may not be part of a person's spirituality (Smith, 2006), though spirituality is always part of a larger context, expressed within culture, religion, and/or society (Health Care Chaplaincy, 2012). A comparison of the characteristics associated with religion and spirituality identified by Robinson and colleagues (Robinson et al., 2003) is detailed in Table 17.1.1.

Some authors object that describing religion in terms of what it does is functionalist, reductionist, and implies negative attitudes towards religious belief (Clarke, 2006). Our purpose in seeking to distinguish between these two terms has no such nefarious purpose. Clinicians need to be aware of these related concepts because of the relative importance each may play in the lives of their patients. For example, research reviewed by Marler and Hadaway indicates that some patients see themselves as both spiritual and religious (Marler and Hadaway, 2002). Other patients who are religious may express their spirituality through identification and involvement within a particular religion. Other patients may claim to be highly spiritual, yet not religious. For these individuals, an important common denominator appears to be the notion of 'transcending the commonplace and searching their soul for deeper meaning' (Schmidt and Mauk, 2004, p. 3).

The concepts of spirituality and religion are also important because of their impact on health outcomes, though the exact mechanism through which this occurs remains unclear. Research suggests that religion and spirituality play a positive role in individuals coping with cancer and human immunodeficiency virus

(HIV) (Baider et al., 1999; Nelson et al., 2002). Studies among advanced cancer patients report that spiritual well-being and meaning are important buffers against hopelessness, depression, and desire for hastened death (Breitbart et al., 2000; Nelson et al., 2002; McClain et al., 2003). Ai and colleagues demonstrated that secular reverence—the ability for patients to experience deep respect, love, and the sublime in their relationships with others and nature—predicted shorter hospital stays following coronary bypass surgery after controlling for other key variables. Religious reverence showed no such impact on length of stay (Ai et al., 2011). These findings underscore the importance of understanding the various dimensions of spirituality and how interventions can address unmet needs in this area.

Spirituality and patient perspectives

Do terminally ill patients and those with life-threatening illnesses want health-care providers to be attuned to spiritual needs? Public opinion and empirical literature suggest that such attention would be welcomed by at least some patients. A Gallup survey (Gallup International Institute, 1997) examining spiritual beliefs and the dying process ($N = 1200$) indicated that in addition to turning to family (81%), close friends (61%), and clergy (36%) for companionship and support at the end of life, 30% of respondents would look to doctors for such support. Forty per cent of respondents indicated that it would be very important to have a physician who was spiritually attuned to them if they were dying.

King and Bushwick conducted a cross-sectional survey of family practice adult inpatients at two hospitals in the United States ($N = 203$). Though limitations of the study include patient homogeneity and variations in regional religiosity, the findings revealed that 77% of patients felt that physicians should consider patients' spiritual needs, and 37% of patients wanted their physicians to discuss religious beliefs with them more frequently. Of note is the finding that 68% of the patients in the study reported that their physician never discussed religious beliefs with them (King and Bushwick, 1994).

Ehman and colleagues explored the acceptability of physicians asking patients if they have spiritual or religious beliefs that would influence their medical decisions if they became gravely ill. Questionnaires were completed by a convenience sample of 177 ambulatory pulmonary outpatients, half of whom described themselves as religious, and 90% of whom believed that prayer may sometimes influence recovery from an illness. Forty-five per cent of respondents indicated that religious beliefs would influence their medical decisions in the context of grave illness. Ninety-four per cent of individuals with such beliefs agreed or strongly agreed that physicians should ask them whether they have these beliefs

Table 17.1.1 Concepts of religion and spirituality

Religion	Spirituality
Focused in institutions Concerned with defining orthodoxy and orthopraxy	Not institutionally bound
Meaning transmitted through doctrine and stories of the community	Concerned with discovery of meaning in the context of the level individual
May provide a motivational and disciplined framework for spiritual growth	Concerned with self-directed spiritual growth

if they become gravely ill. Two-thirds of patients welcomed the idea of discussing these issues with their doctor, while nearly one-quarter of respondents found this prospect objectionable (Ehman et al., 1999).

Smith-Stoner's research examining end-of-life preferences for atheists identified that spiritual care that acknowledges the patients as caring and moral, focuses on issues of self-acceptance, the importance of family and friends, and connection to nature is welcome. Conversely, spiritual care that fails to respect an atheist's non-belief, or included proselytizing or praying was unacceptable to these individuals and was experienced as a violation of boundaries (Smith-Stoner, 2007).

Not all research regarding patients' attitudes towards spiritual dimensions of care is quite so definitive. A comparative qualitative study conducted by Murray and colleagues that explored the spiritual needs of people dying of lung cancer ($N = 20$) and heart failure ($N = 20$) found the extent to which patients wish to have spiritual care incorporated into their health care was unclear (Murray et al., 2004). Some patients, though in need of spiritual support, either did not see the provision of such support within the purview of the health professional or worried about burdening 'busy' professionals with this issue. That spiritual needs may not be readily expressed speaks to the importance of health-care providers creating a climate wherein patients feel comfortable to discuss spiritual care issues should they wish to do so.

Spiritual pain and existential suffering

The Tibetan Book of the Living and Dying (Rinpoche, 2002) notes that:

> Often we forget that the dying are losing their whole world: their house, their job, their relationships, their body, and their mind—they're losing everything. All the losses we could possibly experience in life are joined together in one overwhelming loss when we die. (p. 176)

Multiple spiritual issues arise in the wake of being diagnosed with a life-threatening illness. Patients, confronted with mortality, limitations, and loss, wrestle with questions about their life's purpose and meaning amidst suffering. But what is suffering? Cassell defined suffering as the state of distress brought about by an actual or perceived threat to the integrity or continued existence of the whole person. Suffering is 'an anguish that is experienced, not only as a pressure to change, but as a threat to our composure, our integrity, and the fulfillment of our intentions' (Cassell, 1991, p. 231).

The Concise Oxford Dictionary defines suffering as 'to undergo, experience, be subjected to (pain loss, grief, defeat, change, punishment wrong, etc.)' (Sykes, 1982, p. 1066). A central notion in this definition is that those who suffer submit (or are forced to submit) to a particular set of circumstances outside of their control. Such a situation has the potential to seriously erode one's autonomy (Younger, 1995), and foster hopelessness and loss of control.

Strang and Strang's study of hospital chaplains', palliative care physicians', and pain specialists' definitions of the term existential pain suggests that the term is used as a metaphor for suffering (Strang and Strang, 2002). This acknowledges that suffering can include physical pain and the reciprocal interaction between somatic pain and existential suffering. Suffering based on a perception of lost autonomy and control may express itself in patient requests for death hastening measures. McClain and colleagues demonstrated significant negative correlations between spiritual well-being and desire for hastened death ($r = -0.51$), hopelessness ($r = -0.68$), and suicidal ideation ($r = -0.41$) (McClain et al., 2003). These findings suggest that spiritual well-being may offer some protection against end-of-life despair based on the additional findings that depression was significantly correlated with desire for hastened death in patients will low spiritual well-being ($r = 0.40$) but not in those high in spiritual well-being ($r = 0.20$).

Research by Chochinov and colleagues also demonstrates the salience of existential issues as they affect the wish to go on living in the face of a progressing terminal illness. Examination of the concurrent influences on the will to live in a sample of 189 end-stage cancer patients revealed that physical issues played a secondary role to existential, psychiatric, and social variables, all of which were highly correlated with the will to live. Stepwise regression modelling was conducted to examine the relationship between will to live and patient characteristics. Hopelessness, burden to others, and dignity entered into the final model, demonstrating the profound influence of existential variables on patient outlook in the context of terminal illness (Chochinov et al., 2005b). Given their prominent influence on will to live amongst patients nearing death, health-care providers are well advised to more fully appreciate their importance.

Providing spiritual care: who, me?

Glass and colleagues note that 'responding to the spiritual needs of patients and families is not solely the domain of the chaplain, clergy, or other officially designated professionals. All members of the health care team share the responsibility of identifying and being sensitive to spiritual concerns' (Glass et al., 2001, p. 40). Numerous barriers to the provisions of spiritual care at the end of life have been identified in the literature. In their qualitative study with physicians ($N = 17$) at a university-based hospital, Chibnall and colleagues identified (a) the marginalization and devaluing of psychosocial and spiritual care during medical training, (b) lack of safe and supportive environment in which to discuss issues of loss and death, (c) time demands and busy clinical schedules, and (d) lack of training and skill regarding communication with patients about existential issues as significant barriers (Chibnall et al., 2004). Lack of training in spiritual assessment and care has also been identified by nurses as barriers to providing spiritual care to patients (Oldnall, 1996).

Research conducted by Sinclair and colleagues provides clinicians with a pragmatic yet empirically based framework for integrating spiritual care into routine bedside clinical care (Sinclair et al., 2012). A qualitative ethnographic study informed by the perspectives of palliative care leaders and front-line clinicians elicited five major categories of skills essential to the provision of spiritual care. These 'five senses' of spiritual care include (1) hearing: listening intuitively; (2) sight: seeing soulfully; (3) speech: taming the tongue; (4) touch: physical means of spiritual care; and (5) presence: the essence of spiritual care.

Health-care providers may assume that issues of spiritual care are best left to clergy or other types of spiritual leaders. Clearly if the results of a spiritual assessment indicate the need for further specialized care, or specific information related to religion, referrals to chaplains and clergy are warranted (Taylor, 2001). The

literature, however, suggests that health-care providers should be able to respond to most of the questions posed to chaplains. In a Swedish national survey of hospital chaplains, religious questions accounted for only 8% of the questions regularly posed to them. Other questions concerned meaning, death and dying, pain and illness, and relationships.

McSherry and Ross caution that health-care providers cannot assume either that all patients have spiritual needs that require attention all of the time, or that they will look to health-care professionals to help meet these needs (McSherry and Ross, 2002). Thus the health-care team must make some determination regarding the extent to which the patient is desirous of their involvement regarding spiritual care issues. Inevitably, it is the clinician's own comfort level with providing spiritual care that will dictate their involvement in it. Palliative care clinicians may have palliative care expertise, but are not necessarily specialists in spiritual assessment and caregiving. It has been suggested that the provision of good spiritual care is dependent on the clinician's awareness of a spiritual dimension in his or her own life, honed communication skills (Tulsky, 2005), and the ability to establish a trusting relationship with patients, and drawing on one' own life experience and maturity (Pronk, 2005). Owing to differing spiritual or religious needs of both patient and caregiver, there will be individuals for whom one cannot provide spiritual care, but other members of the interdisciplinary team may be able to do so. Thus, an important part of spiritual care involves each member of the team recognizing their own limitations and that the needs of the terminally ill require multiple sets of skill and knowledge that may not be present in any one individual (Victoria Hospice Society, 1998; Walter, 2002).

In addition to being aware of the spirituality of their patients, the literature also suggests the importance of care providers being aware of their own spirituality. Kearney suggests that such awareness leads to healthier team functioning and ultimately better patient care (Kearney, 2000). There has been minimal research examining how health-care professionals experience spirituality personally or collectively in the work place. A notable exception is the ethnographic study conducted by Sinclair and colleagues that explored the collective spirituality of an interdisciplinary palliative care team (Sinclair et al., 2006b). The study involved face-to-face interviews and focus groups conducted with 20 participants to explore what members of the interdisciplinary team felt about their own spirituality, and how that related to the care they provided to patients. Content analysis of interview transcripts revealed that participants viewed spirituality as something inherently relational, consisting of wholeness, meaning, and personal journeying. The common goals, values, and belonging experienced by members of the palliative care team contributed to their experience of collective spirituality, which was then was manifest in clinical work through small daily acts of kindness and love, embedded within routine acts of caring. The kindness and respect or 'care tenor' (Chochinov et al., 2002b) that accompany these routine acts of caring are much more than mere niceties. Chochinov and colleagues' programmatic research examining dignity in end-of-life care demonstrates that health-care providers' attitudes and behaviours are integral in bolstering the dignity of dying patients (Chochinov et al., 2002a, 2005a, 2006; Hack et al., 2004; Chochinov, 2012).

Spiritual assessment

Naming and acknowledging spiritual distress allows for a greater awareness of what the patient is experiencing and thus increases possibilities for resolution. Such acknowledgment presupposes that clinicians be able to evaluate spiritual well-being in the patients for whom they are caring. Owing to the sensitive and personal nature of spirituality, prefacing the spiritual assessment with an acknowledgment of the sensitivity of the questions as well as the need for the assessment are important in setting the tone for the conversation to follow. Suggestions regarding how clinicians might preface the spiritual assessment with patients have been published (Maugens, 1996). To the extent that a patient's physiological status will permit it, base-line spiritual assessment data is typically collected from patients at the time of admission to hospital or hospice. Far from being a one-off assessment, continuous evaluation of spiritual care needs should occur.

A variety of models for spiritual assessment exist in the literature. Many of these involve the use of direct open-ended questioning. Maugens recommends the mnemonic SPIRIT as a way of structuring spiritual inquiry (Maugens, 1996). The S in SPIRIT stands for spiritual belief system that is the person's religious affiliation. P stands for personal spirituality and includes the person's spiritual views shaped by a person's unique life experiences. I stands for integration and involvement with a spiritual community and speaks to the importance of assessing the patient's involvement in spiritual communities and other supportive spiritual groups. R relates to ritualized practices and restrictions that individuals embrace as part of their lifestyle that may influence health. I refers to implications for medical care and is concerned with how spiritual beliefs and practices may shape the patient's participation in health care. T stands for terminal events planning and reminds the clinician about the importance of assessing patients' end-of-life concerns.

Puchalski and Romer offer the mnemonic 'FICA' for remembering four components to cover during a spiritual assessment (Puchalski and Romer, 2000). FICA stands for faith or beliefs (e.g. 'What is your faith or belief?'), importance and influence (e.g. 'What role do your beliefs play in regaining your health?'), community (e.g. 'Are you part of a spiritual or religious community?'), and address (e.g. 'How should this issues be addressed by health-care providers?'). Borneman and colleagues conducted a descriptive exploratory study to clinically evaluate the feasibility and usefulness of the FICA assessment tool in an ethnically diverse sample of 76 patients with a variety of cancer diagnoses drawn from an ambulatory medical oncology clinic. The authors found the FICA to be a feasible and effective measure of spirituality, tapping aspects of patients' lives related to spiritual support such as hope, meaning, and relationships (Borneman et al., 2010).

Ferszt and colleagues developed an approach to spiritual assessment that examines the areas of connection, meaning and joy, strength, and comfort. Questions asked within each of these areas of life are designed to serve as a springboard to conversation with the patient and uses language that is accessible and comfortable for clinicians and patients (Ferszt et al., 2001). These questions are summarized in Table 17.1.2.

Many of the approaches to conducting a spiritual assessment described in the literature use a qualitative approach to gathering information from the patient. Paper and pencil questionnaires

Table 17.1.2 Spiritual Assessment Tool

Area of assessment	Related questions
Connection	Who are the persons or communities you look to for support? What role do they have in your care
	Do you have an image of a power greater than yourself?
	Has your life situation now affected your feelings about yourself, your faith, or your relationships?
Meaning and joy	What has been most important in your life?
	What are you most thankful for?
	What makes or has made you happy?
	What do you feel the proudest of in your life?
Strength and comfort	Is there anything that is comforting to you now?
	What helped you get through difficult times in the past?
	Who or what is your source of strength now?
Hope and concerns	Is there anything that you hope for?
	Is there anything that feels unfinished?

to elicit information about spirituality also exist that may serve as a means of identifying and codifying patients' spiritual status, needs, and resources (Taylor, 2001). Such tools are not designed to replace interaction between patient and health-care provider, but rather to facilitate ongoing assessment and communication regarding spiritual care issues.

No single assessment approach, whether qualitative or quantitative, is likely to be ideal in all situations. An assessment method that works well with one client may be inappropriate with another. The ideal assessment tool for use in practice will be 'easy to use, flexible and take little time to assess the spiritual state of patients at different times and in different situations' (Catterall et al., 1998, p. 4).

Spiritual care interventions for end-of-life care

Both general and specific spiritual care interventions are identified in the literature (see Chapter 5.6). Arguably, palliative care in and of itself is a general intervention aimed at improving patients' quality of life, enhancing well-being, and reducing suffering. This finding was demonstrated in a study conducted by Cohen and colleagues of 88 patients admitted to five palliative care units in two distinct regions of Canada from whom scores on the McGill Quality of Life Scale were collected on admission and 1 week later. Qualitative data concerning patient changes in quality of life since admission to palliative care were also collected. The findings from this study indicated improved patient physical, psychological and existential well-being following admission to the palliative care unit, as well as a sense of deeper spiritual awareness (Cohen et al., 2001).

Kissane and associates assert that demoralization syndrome, with its attendant hopelessness and loss of meaning represents an important expression of existential distress in palliative care patients (Kissane et al., 2001). They advocate a broad range of approaches for the hopelessness, loss of meaning, and existential distress palliative patients may experience. These include (a) providing continuity of care and active symptom management, (b) exploring patients' attitudes toward hope and meaning in life, (c) balancing support for grief with promotion of hope, (d) fostering the search for a renewed purpose and role in life, (e) using cognitive therapy to reframe negative beliefs, f) involving pastoral care for spiritual support, (g) promoting supportive relationships and use of volunteers, (h) enhancing family functioning by conducting family meetings, and (i) reviewing the goals of care in multidisciplinary team settings. Preliminary reports regarding the validation of the Demoralization Scale have been published (Kissane, 2004); however, future research is needed to examine the feasibility and efficacy of the various interventions to manage demoralization syndrome.

Cole and Pargament developed a pilot psychotherapy programme of individuals with cancer that explored important existential issues identified to be important in those facing a life-threatening illness: control, identify, relationships, and meaning. Preliminary findings suggest that the majority of participants ($N = 10$) indicated they preferred to participate in this type of programme over others that did not contain a spiritual focus (Cole and Pargament, 1999).

Breitbart and associates have utilized meaning-centred group psychotherapy (MCGP) in ambulatory advanced cancer patients ($N = 90$). Using a combination of instruction, discussion, and experiential exercises, this eight-session group intervention aims to help patients sustain or enhance a sense of meaning and purpose in their lives and to optimize each group member's remaining life span. Patients with advanced solid tumour cancers were randomly assigned to either MCGP or supportive group psychotherapy (SGP). Measures of spiritual well-being, meaning, hopelessness, desire for death, optimism/pessimism, depression, anxiety, and overall quality of life were measured at baseline, upon completion of the 8-week intervention, and 2 months after completion. Compared to those in the SGP group, patients who participated in MCGP demonstrated significantly greater improvements on all outcome measures, suggesting that MCGP is a potentially beneficial intervention that can bolster advanced cancer patients' emotional and spiritual well-being (Breitbart et al., 2004).

Chochinov and colleagues' programmatic work (Chochinov et al., 2002a, 2002b, 2005a; Hack et al., 2004; Chochinov, 2012) examining dignity in the terminally ill has resulted in an empirically derived model of dignity towards the end of life, and the development of a therapeutic intervention called dignity therapy (Chochinov et al., 2005a; Chochinov, 2012) that targets depression and suffering along with enhancing palliative patients' sense of purpose, meaning, and will to live. A more extensive discussion of dignity therapy and the role of dignity in improving quality of life in terminal illness can be found Chapter 5.6.

Directions for future research

Although research from a variety of disciplines has enhanced our understanding about the connections between spirituality and health, many questions remain unanswered. Owing to its subjective, experiential, contextualized nature, some would argue that

spirituality is not amenable to definition or measurement. This does not mean, however, that spirituality cannot be examined empirically. A methodological approach that honours the subjective meaning and experience of the individual within given historical, social, and cultural contexts can be realized through the use of qualitative research methods (Streubert and Carpenter, 1999). For researchers wishing to operationalize and measure spirituality, however, conceptual ambiguity is highly problematic, because approaches to measurement of a given construct follow conceptual decisions (Kristjanson, 1992). Incongruencies in conceptual and operational definitions threaten the validity of the research and pose significant challenges in the development of appropriate spiritual outcomes measures.

A recent survey of spiritual care needs of hospitalized children and their families found that quality of spiritual care was wanting, underscoring the need for ongoing research with this patient population (Feudtner et al., 2003). Future work in this area might include an explication of the spiritual care needs and preferences of hospitalized paediatric and adolescent patients and their parents.

Research points to health-care providers feeling inadequately prepared to address the spiritual concerns of patients, and in need of ongoing education in matters of spiritual care (McSherry and Ross, 2002). The optimal timing, nature, duration, and outcomes of such educational intervention need further examination. Walter asserts that the language or discourse of spirituality and spiritual care is largely restricted to the English-speaking world (Walter, 2002). Accordingly, the search for spirituality in health care has been cast in terms of primarily an Anglo-American debate (Pronk, 2005). Such an approach fails to encompass different notions of spirituality, as understood in many world religions (Markham, 1998). Given that we live and provide palliative care in a multicultural context, research is needed with diverse populations that will broaden our understanding of the relationships between spirituality and culture and the spiritual care concepts and issues that are salient to different constituencies (Chochinov and Cann, 2005).

The provision of spiritual care is a multidisciplinary endeavour (Victoria Hospice Society, 1998). This requires that clinicians and researchers come together to share their perspectives regarding spiritual care and jointly identify fruitful areas of collaborative investigation. There is increasing awareness of the need for palliation of individuals living with illnesses other than cancer (Addington-Hall et al., 2001). Expanding the focus of spiritual care research to include individuals with life-threatening illness apart from cancer is thus indicated.

Finally, a basic tenet of palliative care is that the patient and family constitute the unit of care (Ferrell et al., 2001). Yet, little is known regarding the role that spirituality plays in affecting bereavement outcomes for family members. Retrospective research and prospective cohort studies indicate that the outcome of bereavement is affected by religious belief (Lauer et al., 1989; Rosik, 1989; McIntosh et al., 1993), suggesting that the absence of such belief may be a risk factor for delayed or complicated grief. Ongoing research is needed to examine the extent to which strong beliefs may be a proxy for better adjustment and less psychological distress in the bereavement period. Such work may help to identify those family members who having difficulty in adjusting following the patient's death.

Conclusion

In defining palliative care, the WHO emphasizes that the control pain, of other symptoms, and of psychological social and spiritual problems is paramount (WHO, 2002). Patients experiencing life-threatening illnesses want and need meaning, perhaps more than at any other time in their lives. Thus spiritual care is an aspect of palliative care that must not be undervalued. Attending to the spiritual needs of palliative care patients may provide them with the opportunity 'to find meaning in the midst of suffering and to have the opportunity for love, compassion, and partnership in their final journey' (Puchalski et al., 2004, p. 711).

Coping in palliative medicine

Simon Wein and Lea Baider

Introduction to coping in palliative medicine

Coping is a universal experience which ranges from coping with a rude clerk at the bank to all of the consequences of serious illness. The psychological literature has theorized extensively about coping in an attempt to conceptualize this common human trait. Although most coping is a day-to-day experience, researchers have developed theories and therapies to assist psychologists and palliative medicine health-care workers in managing their patients. The literature on coping comes from various disciplines hence there are many different ways to cope.

Coping in palliative medicine mitigates against anxiety, existential distress, physical discomfort, depression, anger, and the wish to die. Initially the literature looked at coping as simply overcoming stress, maintaining the status quo, and surviving. The literature also addressed failed coping, specifically coping styles that are not beneficial, such as anger. However in recent years, especially as applied to palliative medicine, researchers have emphasized and encouraged 'psychological growth' as a response to the stress.

Many research questions remain: what allows some people to cope better than others? Can coping be measured? What should be the goals of coping? Is coping the same in different areas of palliative medicine? How do different cultures cope differently?

This chapter will present various coping models in palliative medicine and show how eclectic, flexible, and highly individual coping can be and it will also address approaches to augment coping.

Definitions

Wai Man in an article about coping with death defined it as: 'a process by which a person deals with stress, solves problems or makes decisions'. And: 'stress is a particular relationship between a person and the environment that is appraised by the person as taxing or exceeding his or her resources and endangering his or her well-being' (Man, 2009).

Folkman and Moskowitz described coping as 'the thoughts and behaviours used to manage the internal and external demands of situations that are appraised as stressful' (2004). The situation is stressful because personally important goals and values are threatened, harmed, or lost. These assessments often elicit distressing and negative emotions. Carver and Connor-Smith describe coping as 'efforts to prevent or diminish threat, harm, and loss, or to reduce associated distress' (Carver and Connor-Smith, 2010).

It is important to note that often it is not just one stressor that precipitates a crisis but several that have accumulated, often in a short time, and exceeded the usual coping strategies.

Successful coping will see a reduction in the negative emotional response by either a change in self or in the stressor itself. Initially coping can be understood as a cognitive response—'How am I going to manage this problem?'—in order to regulate distressing emotions. Folkman et al. divided coping into two categories: (1) problem-focused coping (which is directed at removing, evading, or diminishing the impact of the stressor itself) and (2) emotion-focused coping (which aims to minimize the distress caused by the stressors, including meditation, crying, yelling, or avoidance). Often these two coping behaviours complement each other (Folkman et al., 1986).

The literature notes that coping is dynamic and fluctuating and each person may use a range of coping strategies and these strategies may change over time (Folkman and Moskowitz, 2004). Coping is an interactive, fluid, and dynamic process especially with friends and family.

Liao and Arnold emphasize that we should be sensitive to the question of what constitutes normal coping. 'Normal' is determined by both the individual and the culture. Conversely our own culture, psychology, and beliefs influence our judgements about 'normal' coping by the patient. They point out that successful coping reflects the balance between how important we think a particular life event is, and how we respond to the stressors (Liao and Arnold, 2006).

A major problem with coping is there is no gold standard of how to measure or assess it. Coyne and Gottlieb emphasize the limitations of standardized checklists or questionnaires currently used to assess coping. They observe that these screening or diagnostic tools often produce 'an incomplete and distorted picture of coping' because they are unable to measure the 'interactional dynamic' of stress and coping. Most of the tools have a lot of recall bias and give inconsistent results. They claim it is better to use semi-structured interviews, specific checklists for testing hypotheses, and diaries (Coyne and Gottlieb, 1996).

Concepts and theories

Specific theories have been developed to explain coping and make it operational for research and treatment. However, other psychological theories not specifically related to coping literature will be presented as they also help us to help our patients cope (Box 17.2.1).

Coping theory

Folkman et al. described two steps in the coping process. They observed that appraisal and coping are iterative processes in response to a stress. First an appraisal or assessment of the stressful

> ◆ Sense of coherence
> ◆ Coping theory
> ◆ Personality.

situation is made, second a coping response is made—and then a re-appraisal, followed by a response and so forth. Thus the appraisal influences the coping and vice versa (Folkman et al., 1986). Along with Greer, Folkman subsequently expanded on this model by noting numerous factors needed to sustain psychological well-being during serious illness. These include personality (optimism, personal control), cognitive appraisal, goal-directed planning, and hope—all involve positive and negative feedback loops which are interactional (Folkman and Greer, 2009). Greer studied these concepts and looked at 62 women with non-metastatic breast cancer in terms of denial (avoidance), fatalism (stoic acceptance), and helplessness/hopelessness. They found that women who coped best, viewed the stresses not as threats but as challenges (Folkman and Greer, 1987).

In subsequent studies, Folkman and Moskowitz confirmed improved psychological coping by applying a three-stage intervention: (1) change the conditions from threat to challenge (by establishing meaning, aims and person control), (2) encourage productive behaviour to achieve goals (address loss of confidence, despair; start with small and concrete goals); and (3) maintain background positive mood (including control of physical symptoms; psychotherapy) (Folkman and Moskowitz, 2010).

Symbolic immortality

Lifton coined the expression 'symbolic immortality' through research on coping mechanisms of survivors of the Hiroshima atom bomb. He viewed 'symbol formation as a fundamental process of man's psychic life . . . a compelling universal urge'. Clearly it is through symbols that we communicate—be they words, music, images. Lifton, however, was not referring to the fixed symbols of society—flags and anthems. Rather he observed the ongoing process of creating new symbols for ourselves as we cope with the challenges of meaning-making. These symbols help us to cope with our mortality, though not as denial. A symbol of immortality helps us to cope with our personal death.

Lifton observed five activities of life which create symbols of immortality: (1) biological: having children ensures our continuity after death; (2) theological belief of life after death via the immortality of the soul or its resurrection; (3) creativity: in a real way Mozart and Rembrandt are alive today through their creations; (4) feeing part of eternal universe, most commonly through nature; (5) experiential transcendence where sense of time is lost: this symbol enables us to connect to a higher power or spirit and escape our earthly fate. All these activities provide tools with which to cope (Lifton, 1976).

Sense of coherence

Antonovsky developed the 'sense of coherence model' which is 'a global orientation that expresses the extent to which one has a pervasive, enduring though dynamic feeling of confidence that one's internal and external environments are predictable and that there is a high probability that things will work out' (Antonovsky, 1979). This concept also underpins coping. He understood from his research that for certain individuals, no matter what terrible circumstances they had experienced (he had researched Holocaust survivors from the Second World War), they coped with life and thrived. His research indicated that the main variable was 'the way of looking at the world'.

A strong sense of coherence means that one responds to stressors with a conviction that life will continue to be meaningful and function in a predictable way—that it 'makes sense' and that tomorrow will be the same as today. One sees the future as reasonably predictable and this security helps one to cope with variables and unbidden stressors. Through his research, three components emerged: the ability for people to understand what happens around them, to what extent they were able to manage the situation on their own or through their social network, and the ability to find meaning in a given situation. These three elements, comprehensibility (cognitive), manageability (instrumental/behavioural), and meaningfulness (motivational), provide a sense of coherence (Eriksson and Lindstrom, 2005).

Personality

Personality is an essential part of our ability to cope. However, defining personality and making generalizations about personalities is problematic. Carver and Connor-Smith suggested that personality 'is the dynamic organization within the persons of the psychological and physical systems that underlie that person's patterns of actions, thoughts, and feelings' (Carver and Connor-Smith, 2010).

There are aspects of personality that are generalizable (part of the biology of human nature). Other aspects emphasize individual differences which have been describes in a five-factor personality model: extraversion (assertiveness, spontaneity, confidence, sociability), neuroticism (moodiness, anxiety, depression, vulnerability), agreeableness (friendly, helpful, empathic, inhibit negative feelings, maintenance of relationships), conscientiousness (planning, goal-making, persistence, reliability, impulse control, optimism), and openness-to-experience (curiosity, flexibility, imaginativeness, intellect) (Digman, 1990).

Challenges (such as threat to life or goals) become a stress when one's resources to manage are stretched or threatened. In terms of personality style extraversion, conscientiousness and openness respond to stressors as challenges and not threats. High neuroticism plus low conscientiousness predicts high stress levels and readily perceiving a stress as a threat (Digman, 1990).

Chochinov and colleagues studied neuroticism (which they defined as a trait with the tendency to experience psychological distress) as a variable in coping. They examined 211 patients towards the end of life and found a significant correlation between neuroticism and increased psychological and existential distress. Identifying the neurotic personality as a marker of poor coping, could help direct resources and be realistic about management goals, given that it is a life-long trait (Chochinov et al., 2006).

Resources and therapies

Applying these theories and concepts to augment coping requires practical items including patients' and carers' internal and external resources and therapeutic interventions by the staff.

Internal resources

Weisman writes with wisdom about coping (Box 17.2.2). In the chapter 'Hoping is Coping' (Weisman, 1979) he notes that most patients cope with anxiety and uncertainty using common-sense interpersonal and intrapersonal resources. He asks how do we judge 'good' coping? 'Good coping regardless of the medical outcome is clearly an extension of how well a patient coped in their healthier days' (Weisman, 1979). Resourceful people cope better because they do not restrict themselves in range of coping strategies whereas more rigid people are confined to a narrow range of tools, are less flexible, and find coping more difficult (Weisman, 1979).

Courage and fighting spirit

Courage is critical to coping. Courage is defined as being aware of the fear but facing the challenge anyway, whether one succeeds or not. If one is unaware of the fear it is uncertain whether that virtue was courage. Many factors contribute to a courageous response to a challenge—character, self-esteem, sense of purpose, culture, hope, love, faith, emotional support, past successes, and dignity (Wein, 2007).

Greer coined the phrase 'fighting spirit' as a coping strategy (Greer and Moorley, 1997). He characterized this as a determination not to give in, an optimism, having a knowledge of the illness, being active in treatment, and living as 'normal a life' as possible in the face of adversity. The utility of courage is to boost a 'fighting-spirit', to resuscitate morale and to enable one to cope.

Clinicians can help to augment courage with prudent inspiration, such as other patients' success stories, and by exploring with the patient previous challenges they have successfully overcome. It is often effective to say to the patient: 'I think you have been very courageous' for some small fear they overcame. The bottom line is to improve their self-esteem and belief in themselves.

Reminiscences

Reminiscences are memories that 'recall past events, feelings, and thoughts in order to facilitate pleasure, quality of life, or adaptation to present circumstances' (Parker, 1995). These memories may be long-forgotten experiences or events frequently recalled. Reminiscing may be dreams, reflections, meditations, art-therapy, talking-therapy, and psycho-analysis.

Reminiscing serves two functions: the first is as a pleasurable way of recalling significant life events, and by placing a perspective on and summing up one's life. The other function is to re-evaluate life with the intention of resolving and integrating past conflicts and finding new significance. The process of recounting the scene and recollected thought and memory helps to put it into a context

---

to enable 'psychological growth'. Reminiscences can process the memory in a psychological-emotional (or spiritual) way (Butler, 1963, 1974; Parker, 1995). Reminiscences can be something one goes over and over, like an artist repainting the same scene again and again until he understands it.

However, not everyone chooses to reminisce, since for some people it is too painful. For others, however, reminiscence have been shown to help families bond or reconcile, even if temporarily, at difficult times by using common 'good' memories to help overcome differences (Butler, 1974).

Reminiscent-based theory and therapy has been described and studied (Haight, 1992; Wholihan, 1992; Haight et al., 2000). It is a cognitive therapy and has similarities to dignity therapy (Chochinov et al., 2011) and life narrative therapy (Viederman, 1983; Pickrel, 1989) which, by expressing and integrating experiences, has been shown to provide meaning, reduce depression, and reverse emotional withdrawal (Haight et al., 2000). Bohlmeijer and colleagues performed a meta-analysis of 25 controlled studies and concluded that reminiscence therapy enhance psychological well-being in older adults (Bohmeijer et al., 2007).

Hope

Dufault and Martocchio describe hope as 'a multidimensional dynamic life force characterized by a confident yet uncertain expectation of achieving a future good which, to the hoping person, is realistically possible and personally significant' (Dufault and Martocchio, 1985).

Using semi-structured interviews, Sachs et al. studied 22 terminally ill cancer patients with the aim of examining the relationship between hope and hopelessness. Positive interpersonal relationships enhanced hope, and uncontrolled physical pain increased hopelessness. They concluded that hope is associated with 'greater psychological and spiritual well-being' and 'more effective coping strategies' (Sachs et al., 2013).

Chochinov (2003) and McLement and Chochinov (2008) reviewed the literature and found 'hope in advanced cancer is a coping mechanism protecting patients from the experience of distress and suffering'. Several studies indicated that positive relationships, living in the moment, cognitive reframing of negative thoughts, and ritual exercises improve hope and thereby aid coping.

Chi noted a positive relationship between a higher level of hope and effective coping style. Hope, they concluded, was essential for coping with chronic stress of serious illness since it enables patients to accept death whilst still engaging in day-to-day living. Hopelessness was a stronger predictor of poor coping in the terminally ill as evidenced by suicidal ideation and desire for hastened death. They noted in their study that uncontrolled pain, disability, depression, and other symptoms caused a sense of hopelessness and poorer ability to cope with illnesses stressors (Chi, 2008).

Eclectic

An interesting qualitative study from Sand et al. analysed 20 non-religious people in Sweden and how they cope despite the threat of impending death. The findings showed that they coped using 'every means available' including cognitive, emotional, other people, animals, nature, a transcendental power, imagination, and magical thinking. The focus of the coping was to keep death at a respectable distance whilst seeking togetherness, involvement, hope, and continuance, as palliatives to the 'hurtful feelings' of dying (Sand et al., 2009).

Maybe this finding best describes the real-life way people cope—as best as they can, and with whatever tools work for them.

External resources and therapies

Many resources and therapies are available to help patients and their families cope (Boxes 17.2.3 and 17.2.4). Typically in a supportive and palliative care service this would include psychotherapy, psychopharmacology, spiritual, religious, social work, physiotherapy, occupational therapy, physical symptom control, and the various supportive and complementary therapies. These all assist coping and should be used in combination as suitable.

Therapeutic relationship

Weisman notes that, in order to maintain morale and facilitate coping, the treating clinicians must develop the trust and confidence of the patient and their family. Coping, he notes, at its most basic is getting from one problem to the next. He calls it 'the enduring and incessant process of coping' (Weisman, 1979). He advocates that the clinician invest in relationship building and that, in the context of a caring relationship, the clinician should enquire about how the patient copes: what problems has the illness created? How do you plan to deal with them? What do you do when faced with a problem? What usually happens? To whom do you turn when you need help? What has happened in the past when you asked for help? What kind of problems make you upset? (Weisman, 1979). Murray-Parkes contends that an important way we have of helping patients cope with cancer and other life-threatening illnesses is to offer frightened or grieving people a 'secure base', a relationship of respect and trust—with a person who has the time, knowledge, and willingness to remain involved—that will last them through the bad times; to explore

the situation they face, share the feelings that arise, and review the implications of loss (Murray-Parkes, 1998).

Weisman also advises of the importance of honesty in coping with stress: 'More problems are solved by awareness and acceptance than by disavowal, avoidance and denial' (Weisman, 1979).

Weisman emphasizes that one cannot cope with the psychological, social, and spiritual stressors of a life-threatening illness if physical symptoms are not properly controlled. Meticulous care of physical suffering is critical to coping. This responsibility lies with the palliative medicine clinicians.

Meaning and dignity-based approaches

An important aspect of coping with stressors is the search for meaning. Greenstein and Breitbart (2000) describe a psychotherapy programme using meaning as a way of coping. Sessions focus on responsibility to self (reappraising the meaning of the problem) and others (survivors, family, legacy), creativity (artistic, work), transcendence, ascertaining one values, and understanding the role of goals—all as means of coping with terminal illness. The power of their programme is its didactic interactions together with experiential exercises.

Chochinov has taken the common concept of dignity, defined and studied it, and developed dignity therapy, a form of cognitive behavioural treatment (Chochinov et al., 2011). His research has shown 'the importance of self-perception and the way in which patients experience themselves to be seen or appreciated, as a powerful mediator of preservation of one's sense of dignity' (Chochinov et al., 2011). The principle is to help patients with a limited life-expectancy to identify values that are important to them. Transcripts of the interviews are prepared and returned to the patients who may then choose to pass on to family and loved ones. This has been shown to help patients cope by improving dignity, self-esteem, meaning, and reinforcing the will to live (see Chapter 5.6).

Information to enhance coping

McPherson et al. made a systematic review of the literature and found ten randomized controlled studies showed that information interventions (over and above usual care) such as audiotapes, pamphlets, and educational programmes improved factual recall, symptoms control, satisfaction, and use of health-care facilities (McPherson et al., 2001). However, the majority of studies showed no benefit on psychological measures. Nevertheless this is a useful activity to encourage coping (Johnson, 1986).

Spiritual care and religious coping and chaplaincy

Hanson studied 103 recipients (seriously ill patients and family carers) of spiritual care in a tertiary medical institution. The 237 spiritual care providers (clergy, family, health-care) provided 21 different types of spiritual care. They found that 87% of the recipients identified 'helped coping with the illness' as the key activity (Hanson et al., 2008).

Religious coping, as an item separate from spiritual coping, has been extensively studied and reviewed in the literature. Pargament et al. (2000) called religion 'a search for significance related to the sacred'. Religious coping responds to the triggering event by creating meaning and purpose, and by reappraising the values and goals of life. Religious strategies have been grouped as follows: spiritual, congregational, moral reframing, orientation to agency and control, and rituals. In a summary of the literature

of the clinical use of religious coping, studies have shown up to 70–80% of patients use religion as a coping strategy, especially in cancer, HIV, and psychotic inpatients (Dull and Skokan, 1995; McClain et al., 2003).

Whilst it is not the role of the clinician to prescribe prayer or other religious practices to the patient, the clinician may refer them to a chaplain or faith-person to assist in coping. Pargament et al. developed a validated measure (RCOPE) for religious coping and showed that in hospitalized, elderly patients, better adjustment (stress-related growth, physical health, emotional health) was found in those who coped by using benevolent religious reappraisal and religious forgiveness/purification. Religious coping offered sense of meaning, comfort, control, and personal growth in face of life-threatening illnesses (Pargament et al., 2000).

Whilst most studies show benefit, some have revealed negative outcome of religious coping because of discontent with god, punishment, guilt, and disappointment with their congregations (Dull and Slokan, 1995; McClain et al., 2003). This together with the move away from formal religious adherence by young people in recent years, especially in Europe, in part explains the greater interest in spirituality, unaligned to formal religion (Pargament et al. 2000; Block, 2006). Tarashekwar et al. studied 170 patients using a structured interview and after controlling for sociodemographic and lifetime history of depression, found that greater use of positive religious coping was associated with better quality of life scores including existential well-being. Rarely, negative religious coping (anger at god, feelings of guilt, or a sense of community abandonment) actually lead to worse quality of life (Tarashekwar et al., 2006). Phelps et al. noted in a study of 345 patients with advanced cancer, that positive religious coping is more likely to be associated with receipt of intensive and more aggressive life-prolonging medical care near the end of life. The study was not designed to analyse the reasons (Phelps et al., 2009).

Positive psychology

Positive psychology prescribes the role of hope, wisdom, spirituality, courage, and responsibility in adapting to stress (Carver et al., 1994). However, Coyne and Tennen vigorously dispute the positive psychologists in cancer care whose claims go beyond achieving coping. Their paper examines and rejects the scientific basis for the claims that a fighting spirit prolongs life, that it influences immune function and cancer progression, and can be shown to contribute post-traumatic growth following serious illness. They carefully reject the scientific basis and therefore reject therapies which advocate these claims (Park et al., 1996; Coyne and Tennen, 2010).

Folkman and Moskowitz argue for the positive outcome of coping—that is, therapists should aim for more than holding (or returning to) the status quo. New life skills, perception of improved self-esteem, spiritual or religious transformation, deeper understanding of life, and improved social relationships are justifiable aims (Folkman and Moskowitz, 2000). They advocate research on how to better understand how people build and maintain positive 'coping' in face of stress. That is, how good can come out of bad (Lazarus, 1968).

However, Parker challenged the ultimate goal of happiness as 'mindless or tyrannical optimism' and 'unthinking positive psychology'. Coping does not necessarily mean happiness, and coping is not the equivalent of a positive psychological outcome. It is distinct, he claims. Coping, he suggests, is used in a narrow sense of 'returning to the mean', that is, to the pre-stress state (Parker, 2011).

Integrative medicine approaches

Many patients use complementary, supportive, and alternative therapies to help cope with their illnesses, so much so that many of the major cancer centres have incorporated these therapeutic options into their institutions in order to provide patients with this care and to supervise the types of therapies they are receiving. Studies have repeatedly shown that patients find therapies that include unproven, alternative, and magic help them cope better by providing a sense of control, better bedside manners, more trusting practitioners, and that the therapies fit in with their world-view and therefore provide meaning (Wein, 2000).

Burstein and colleagues looked at how psychological and physical factors influenced use of unproven therapies in early-stage breast cancer (Burstein et al., 1999). They found that initiation of unproven therapies after surgery was associated with a worse quality of life characterized by depression, fear of recurrence, lower sexual satisfaction, and more physical symptoms. Therefore, Holland editorialized that when a patient reveals use of unproven therapies the follow-up question should be how she or he is coping with the illness especially in terms of anxiety and depression (Holland, 1999). Referral to a psycho-oncology service might be considered next.

Evaluating coping effectiveness

There is no agreed-upon method of measuring coping effectiveness. The effectiveness of a given coping strategy depends on the individual using it, the culture, and the particular circumstance. Thus a strategy may be useful in one situation but not tomorrow. Furthermore, the event causing the stress is variable. Generalizations about what constitutes successful coping should be issued cautiously. Nevertheless, there are some coping strategies that in general are not helpful and should be identified and managed by staff. These include anger, aggression, illicit drug use, and abuse of prescription medications. Weisman listed a number of mechanisms that we use to cope with cancer. The mechanisms he described were both helpful and harmful. General strategies included: seeking information; laugh it off; submit to the inevitable, be fatalistic, do something however impractical; use alcohol, drugs and danger; blame someone or something, and blame yourself. Strategies Weisman considered that good copers used are: 'avoid avoidance: do not deny'; 'confront realities and take appropriate action'; create solutions; consider alternatives; don't stop talking to loved ones; accept support even if against the grain; self-esteem is vital to good health, and 'hope is self-pride, not self-deception' (Weisman, 1979).

Health professionals and coping

Effective coping is important to health-care professionals. Whilst our stressors might be different, failed coping such as in burnout, drug and alcohol abuse, and emotional fatigue are real problems. These topics are dealt with elsewhere in the textbook, however it should be noted that the principles of coping as outlined earlier, including therapies such as meaning, and talking, and issues such as courage, heroism, and religious identity, are also relevant (Khot et al., 2011).

Coping by family and carers

Hudson used a semi-structured interview to study 45 family caregivers of patients with advanced cancer 2 months after the patient died. Only 7% of caregivers met the criteria for traumatic grief and the vast majority identified 'positive aspects associated with the experience'. The repeated message of the caregivers was the importance and value of a 'multidisciplinary specialist care services' and of 'comprehensive information to prepare them for the future' (Hudson, 2006). Notwithstanding the vast literature on coping, its styles, problems, and therapies, most patients, families, and carers seem to cope well.

Conclusion

Although much of the literature on coping appears obvious, it is important to objectively classify and describe our common-sense impression in order to understand the factors that allow some people to thrive under stress and adapt, and to know which therapy works best, with whom, and when (Billings and Moos, 1981).

After reviewing many observations and theories we should take a step back and ask what happens to the individual when s/he says 'I can't cope'. The inability to control the stress in turn threatens the self-esteem of the person. They might start berating themselves and a vicious cycle ensues causing them to be more distressed, more unable to focus on a task, and to feel helpless and hopeless. Conversely when the individual feels 'I can cope', the daily tasks once again fall into place, seem manageable, and one feels in control.

Coping, in its general meaning, implies restoring equilibrium. The equilibrium does not necessarily refer to returning to what was—since often circumstances have changed, such as advancing cancer or indeed personal growth. More precisely it refers to regaining the equilibrium of self-esteem.

A good rule of thumb is, if the mechanism of coping is not causing harm then leave well alone. The patient's choice of coping might not lead to personal growth or deep self-insights—this is not for us to judge—but if it enables survival in the face of threat to life and limb then it is beneficial.

Coping mechanisms can evolve, change, and adapt over a lifespan. Coping is complex because it stands as a sentinel in the ever-changing interaction between the whole person and his/her environment. It demands that we strive to change the stressor if we can, but also change ourselves to fit in to a new reality. Changing ourselves implies acceptance. This process of acceptance in its fullest development demands that as we cope with change, we grow and become more fully aware of ourselves.

Depression, demoralization, and suicidality

David W. Kissane and Matthew Doolittle

Introduction to depression, demoralization, and suicidality

Any loss of happiness, morale, or hope will have a substantial impact on a patient's journey through palliative care. Although under-recognized, depression can generally be well managed with evidence-based strategies and medications familiar to the competent clinician. Restoring threads of coherence to a life torn by illness, pain, and loss may require different skills and greater wisdom. Demoralization may lead to a desire for hastened death, which is one of the greatest challenges a clinician may face, yet successful treatment can help the patient to live life to the fullest extent permitted by sickness and frailty. The worth, dignity, value, and meaning of each person's life are central concerns for palliative care. In this chapter, we examine and compare the nature, diagnosis, and management of depression, demoralization, and suicidality in the settings of advanced and terminal diseases.

Depression

Depression in the medically ill is not only associated with reduced quality of life, but also with decreased adherence to treatments, increased inpatient stays, thoughts of suicide, and poorer survival (Grassi et al., 2005). The profound sadness or pervasive guilt associated with depression can interfere with the integration of information, reduce tolerance for the symptoms or humiliations of serious disease, and contribute to social withdrawal and disengagement from things previously cherished, spoiling what remains of a patient's life.

The nature of depression

Psychiatrists define depression as the loss of interest or pleasure, an anhedonic state, which may be associated with a lowered or sad mood, generally present for most of the day and on most days, and accompanied by a number of additional symptoms, including several somatic symptoms (Dimatteo et al., 1994). Clinical depression is present when this specified combination of symptoms persists for at least 2 weeks but, for most sufferers, depression represents a continuum of unhappiness. The word 'depressed' is used broadly in the community to describe both deep desperation and sad moods, however brief, and this complicates the use of the term and blurs the boundary between 'depression' and appropriate responses to loss or grief.

Diagnosis of depression in palliative medicine

Serious disease and its treatment may cause somatic symptoms that are readily attributed to depression, including changes in appetite, weight, concentration, sleep, energy, and fatigue. Debate exists about including or excluding such symptoms from criteria when diagnosing depression in the medically ill, but somatic symptoms correlate highly with other symptoms and add a worthwhile contribution to diagnostic accuracy (Akechi et al., 2003; Grabsch et al., 2006; Guo et al., 2006). Endicott takes another approach, suggesting alternatives for somatic symptoms in the medically ill: depressed demeanour or appearance; social withdrawal or reduced talkativeness; brooding, self- pity, or pessimism; and loss of responsiveness (Endicott, 1984). Whatever the approach, pervasive anhedonia or sustained low mood are central to the diagnosis of a Major Depressive Episode. Regression-tree analysis has shown *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (DSM-IV) Major Depression to be highly associated with combinations of either (a) pessimism and worthlessness, or (b) pessimism, loss of interest and thoughts of death (McKenzie et al., 2010), and these factors can often be readily identified or excluded in patients with physical illnesses.

Depressive Disorder Due to Another Medical Condition (DSM-5) is a related diagnosis that is understood as a direct physiological result of such conditions as hypothyroidism, chronic uraemia, presence of cancer-induced cytokines, or medication effects of steroids, interferon-alpha, or chemotherapy agents (Miller and Massie 2010). DSM-5 retains a category of Depressive Disorder Not Elsewhere Classified for brief depressive episodes or those with mixed anxiety-depressive symptoms. DSM-5 also allows a diagnosis of Major Depressive Episode even if symptoms result from bereavement (American Psychiatric Association, 2013).

Prevalence of depressive disorders

Prevalence rates for major depression in oncology may be as high as 38%, while the prevalence of depression spectrum disorders has been found to be as high as 58%—compared with 6.6% 12-month prevalence and 16.6% lifetime prevalence in the general community (Hotopf et al., 2002; Massie, 2004). Rates are similarly high in palliative medicine (Massie et al., 2012). A meta-analysis of 94 oncology and palliative care studies suggested that the prevalence of depression spectrum disorders may be 38%, which is comparable to rates found in a general palliative care setting (Mitchell et al., 2011). Depression is associated with greater physical, social,

and existential distress, and with measurable reductions in the quality of life (Wilson et al., 2007).

A diagnosis of cancer may precipitate or enhance risk for depression both directly through the use of treatment agents that have psychiatric side effects and indirectly by posing emotional and logistical challenges that exhaust patients' material and psychological resources. In the classic PSYCOG study, only 11% of cases of depression had evidence of past psychiatric disorder, and most depression seemed to develop in the setting of the cancer (Derogatis et al., 1983; Wilson et al., 2007; Mitchell et al., 2011).

Depression as a cause of cancer

The role, if any, that depression may play in causing cancer is less intuitive and less direct. Depression is not directly associated with an increased rate of cancer in the general community (Sihvo et al., 2010). Moreover, life events such as bereavement do not cause cancer (Ewertz, 1986) and stress is no longer considered a cause of cancer (Li et al., 2002). However, in the third National Health and Nutrition Examination Survey, depression seems to increase the risk of obesity in women (odds ratio 1.82; 95% confidence interval 1.01–3.3) (Onyike et al., 2003). Obesity, in turn, increases endometrial and breast cancer through oestrogenic mechanisms (Kulie et al., 2011). The relationship between depression, obesity, and cancer is less consistent in men. Depression is also associated with smoking and alcoholism (Graham et al., 2007; Azevedo et al., 2010), both of which increase incidence of cancer (Murphy et al., 2010). Co-morbidities associated with depression including obesity, smoking, physical inactivity, and alcohol use do increase risk for malignancies (Chwastiak et al., 2011).

The consequences of depression in cancer or advanced disease

Untreated depression has been associated with worsened medical outcomes. Patients who are helpless, hopeless, depressed (Temoshok et al., 1985; Watson et al., 1999, 2005), socially alienated (Goodkin et al., 1986), and socially deprived (Boesen et al., 2007) have had shorter survival times. Fatalistic and stoical attitudes may also handicap survival (Pettingale et al., 1985; Temoshok et al., 1985). Psycho-oncology has a role in promoting coping, treating depression, and helping patients be connected to supports. Whether group therapy can improve survival remains contentious, but in the advanced cancer setting, it did prevent the development of depression (Kissane et al., 2007).

Box 17.3.1 Associations between depression and treatment adherence

1. Reduced understanding
2. Ambivalent decision-making about palliative treatments
3. Decreased motivation for care and healthy behaviours
4. Pessimism about the outcome and benefit
5. Poorer tolerance of side effects
6. Poorer family support and greater isolation
7. Reduced use of community resources.

Untreated depression affects treatment adherence (DiMatteo et al., 2000). One meta-analysis finds that depressed patients are three times more likely than non-depressed patients to be non-adherent (DiMatteo and Hanskard-Zolnierek, 2011). Depression interferes with adherence via cognitive, motivational, and resource-related pathways (see Box 17.3.1). The goal of psycho-oncology interventions is to treat depression and promote coping and social support that may improve both the quality of life and outcomes.

Contributors to depression in palliative patients

Oestrogen receptors have a significant role in the mood-regulating limbic circuits of the brain and gender is one of the most important risk factors for depression (Cutter et al., 2003; Kendler et al., 2006). In one study of women with breast cancer, patients were found to have double the rate of depression of women in the general community (Kissane et al., 2004). On the other hand, male cancers such as prostate cancer are associated with rates of depression quite close to those seen in the general population (Couper et al., 2006). Rates of depression among wives of men with prostate cancer can approach twice the rates of the general female population (Couper et al., 2006). Research on the husbands of cancer patients is more limited, but seems to show that rates among husbands are either not elevated (Hagedoorn et al., 2000; Hinnen et al., 2008), or that they are elevated to a lesser degree than that found in studies of patients' wives (Langer et al., 2003). Women seem to bear the burden of emotional distress.

Other contributory factors (see Box 17.3.2) include younger age, advanced disease with pain and poor symptom control, co-morbid neurological disorders, and a range of other metabolic and endocrine disorders (Wilson et al., 2009). Many medications have a direct effect on depression or its treatment, including interferon, interleukin 2 (IL-2), steroids, certain chemotherapy agents (vincristine, vinblastine, procarbazine, L-asparaginase, vinorelbine, paclitaxel, docetaxel), hormonal agents (tamoxifen, cyproterone, leuprolide), as well as antihypertensives (propranolol, reserpine, methyldopa) and antibiotics (amphotericin). Specific cancers that have been linked to depression include pancreas cancers, which like lymphomas and lung cancers may increase pro-inflammatory cytokines (IL-1, IL-6, tumour necrosis factor-alpha) (Musselman et al., 2001; Ebrahimi et al., 2004), and many other cancers can be associated with paraneoplastic syndromes that can also cause mood disturbance. Neurodegenerative disorders including Parkinson's disease, endocrine disorders including Cushing's disease and hypothyroidism, metabolic disorders including hypercalcaemia, and such nutritional deficits as pellagra may all cause Depressive Disorder Due to Another Medical Condition (DSM-5).

Barriers to recognition of depression

The potentially confounding effect of medical symptoms is only one of several barriers to the recognition of depression in palliative medicine (Greenberg, 2004). The stigma attached to mental illness may cause the patient to withhold data. For family and medical staff, acknowledging depression may appear to deny the reality of the patient's distress, or seem a criticism of the sufferer's coping. 'Isn't this normal?' or 'Wouldn't you be depressed?' are statements that both reflect suffering and express indignation that it should be observed. In fact, responding to such complicated emotions, or acting in accord with cultural beliefs, family

1. Female gender
2. Younger age
3. Past history and family history of depression
4. Poor social support, including family dysfunction
5. Pain and poor symptom control
6. Illness and treatment-related factors
7. Declining functional status
8. Unaddressed existential concerns.

---

members may deliberately or inadvertently conceal their relative's distress. The most basic barrier to recognizing depression, though, may be the limited time of clinicians. Physicians may be trained to focus on physical symptoms and may avoid opening what is feared to be a Pandora's box of unsolvable problems (Wilson et al., 2007).

Screening for depression

To assist clinicians in recognizing depression, the National Comprehensive Cancer Network Distress Management Panel recommends periodic screening of all patients (National Comprehensive Cancer Network, 2003). Brief self-report instruments are most practical, though they will return more false positives than structured psychiatric interviews (Passik and Lowery, 2011). A systematic review of screening scales suggests that the Beck Depression Inventory (BDI), the General Health Questionnaire-28 (GHQ-28), and Center for Epidemiological Studies—Depression Scale (CES-D) are reliable and valid (Vodermaier et al., 2009). The Patient Health Questionnaire-9 (PHQ-9) is briefer than any of these measures, freely available, highly reliable, and widely used (Passik and Lowery, 2011). The Distress Thermometer is a single unitary measure with less reliability, but is rapid and straightforward (Roth et al., 1998). Even asking the single question, 'Are you depressed?' can identify the majority of patients who should have further evaluation (Miller et al., 2006).

Demoralization

Kissane and colleagues recognized a group of patients who sought hastened death because of their conviction that their lives were pointless and meaningless, even when they were not thought to be clinically depressed (Kissane et al., 1998). Kissane followed others in proposing that 'demoralization syndrome' captures this phenomenon (Kissane et al., 2001). Constructs such as acedia (the tedious meaninglessness of life), spiritual torpor, Engel's 'giving up-given up' complex (Engel, 1967), Gruenberg's social breakdown syndrome (Gruenberg, 1967) in the chronically institutionalized, and Seligman's 'learned helplessness' (Miller et al., 1975) had all identified aspects of demoralization, and some version of the concept has long been recognized clinically. An empirical study identified demoralization as a non-specific form of distress in the community (Dohrenwend et al., 1980). Frank saw its correction as the vital therapeutic component of all successful psychotherapy (Frank, 1974). De Figueiredo suggested with Frank that the development of a state of subjective incompetence was the hallmark of demoralization (de Figueiredo and Frank, 1982).

Nature of demoralization

Folkman's studies of the coping among caregivers of men dying from AIDS in San Francisco in the early 1990s recognized 'meaning-based coping', which had been omitted from her earlier descriptions of 'emotion-based' and 'problem-based' coping strategies (Folkman, 1997). New impetus was given to recognition of the loss of meaning and hope, especially in the medically ill. Clarke and Kissane have described the process whereby sufferers begin to feel they cannot cope with stressful situations, feeling helpless, hopeless, and even ashamed, until the pointlessness of their situation invokes disheartenment and despair (Clarke and Kissane, 2002). Ordinarily a strong generalized hope about the value and worth of life will preserve meaning when illness appears to destroy immediate hopes. Similarly, robust self-esteem will sustain self-worth against the infirmity of illness. Demoralization seems to ensue when these mechanisms break down.

Loss of morale spans a spectrum of mental states, ranging from disheartenment (a mild loss of confidence), through despondency (starting to lose hope and sense of purpose), to despair (where all hope is lost), and demoralization (where meaning and purpose are lost). Psychiatric involvement is indicated in the more severe end of this spectrum, where meaninglessness, pointlessness, and hopelessness can all lead to suicidal thinking. Indeed, suicidality may not follow directly from anhedonia, the inability to take pleasure in the moment, but rather may develop from reflection about worthlessness, hopelessness, or the meaninglessness of life—a conviction that there will be no satisfaction in the future. Indeed, Klein and colleagues thought that a distinguishing feature of demoralization was its loss of anticipatory pleasure (through loss of meaning and hope), although consummatory pleasure remained possible (Klein et al., 1980). In contrast, depression involves loss of available and expected pleasure in the here and now.

Diagnosis of demoralization syndrome

The DSM defines adjustment disorders as impairments and symptoms not meeting criteria for other major psychiatric diagnoses, and which arise in response to an identified stressor. The judgement of the clinician in determining whether an anxious or depressed affect or behavioural change reaches a threshold for disordered 'adjustment' has made this a difficult diagnostic category to apply in the medically ill.

In contrast, a focus on the phenomenology of meaninglessness, hopelessness, and loss of purpose that brings existential dimensions to the fore may enable palliative care clinicians to recognize the lived experience of patients (Fava et al., 1995). More directly reflecting the language actually used by patients experiencing existential distress, the development of a diagnostic category for a demoralization syndrome might facilitate recognition of a significant form of suffering without requiring the complex judgement about adaptiveness currently necessary to identify adjustment disorder (Box 17.3.3).

Prevalence of demoralization

The introduction of methodical instruments including the Demoralization Scale has begun to allow estimates of the extent of the phenomenon (Kissane et al., 2004). The frequency of high demoralization among cancer patients has been estimated at 16% (Mehnert et al., 2011). Among methadone patients in a Dutch sample, rates of demoralization were twice that in the

> **Box 17.3.3** Diagnostic criteria for demoralization syndrome
>
> 1. Loss of meaning or purpose in life
> 2. Loss of hope for a worthwhile future
> 3. Sense of being trapped or pessimistic
> 4. Feel like giving up
> 5. Unable to cope with the predicament
> 6. Socially isolated or alienated
> 7. Potential for desire to die
> 8. Phenomena persist for more than 2 weeks; may be co-morbid or distinct from depressive disorders.

community (Jong et al., 2008). The Bologna group developed diagnostic criteria for psychosomatic disorders and identified demoralization in medical illnesses, reporting for instance a rate of 31% after cardiac transplantation (Grandi et al., 2001) and 29% among breast cancer patients (Grassi et al., 2004). Loss of meaning and hope has been found in 37% of terminally ill patients in Japanese studies (Morita et al., 2000). More elevated rates of demoralization and suicidality have been described in patients with amyotrophic lateral sclerosis, while more elevated rates of anhedonia were found among patients with advanced cancer (Clarke et al., 2005a).

Demoralization has been associated with younger age, female sex, living alone, family dysfunction, high physical symptom burden, use of resignation and avoidant coping, and emotional, spiritual, and practical problems (Kissane et al., 2004; Clarke et al., 2005a; Mehnert et al., 2011). Conversely, lower levels of demoralization have been measured in people with high spiritual meaning and sense of coherence to their life (Lethborg et al., 2006; Boscaglia and Clarke, 2007; Lethborg et al., 2007; Mullane et al., 2009).

Correlation between demoralization, anxiety, and depression

Trait anxiety predicts the development of both demoralization and depression (Clarke et al., 2005b), with anxiety having a higher correlation with demoralization ($r = 0.71$) than depression ($r = 0.61$) (Mehnert et al., 2011). Feelings of helplessness and a sense of existential uncertainty help to explain this association between anxiety and demoralization.

A high correlation has also been shown in several studies between demoralization and clinical depression. Patients can develop major depression with or without demoralization, and some studies have shown cases of demoralization without depression (Kissane et al., 2004; Mehnert et al., 2011), while others have not (Mullane et al., 2009). Mehnert and colleagues found that 60% of subjects with moderate demoralization had no clinical depression, whereas only 5% of patients with severe demoralization (more than one standard deviation above the mean) were without depression. As clinical status worsened, co-morbid states of depression, anxiety, and demoralization all became more likely.

Empirical studies of demoralization

Beck first recognized that hopelessness predicted suicide independently of depression (Beck et al., 1975), and this finding has been replicated among psychiatric inpatients and suicidal adolescents (Wetzel et al., 1980; Dori and Overholser, 1999), and in the settings of cancer (Owen et al., 1994), HIV (Breitbart et al., 1996), and primary care (Gutkovich et al., 1999). Latent trait analyses of psychopathology in the medically ill have shown that demoralization, anhedonia, anxiety, grief, and somatization are distinct, suggesting the existence of an identifiable and measurable phenomenon requiring further study (Clarke et al., 2000). Field trials are needed to examine more comprehensively a typology of existential distress and to identify empirical diagnostic criteria for demoralization.

Suicidality

Nature of desire for hastened death

An intense and abiding desire to die develops from a sense that life is worthless, pointless or hopeless. This loss of the meaning and value of life can lead to thoughts that one might be better dead, and if the process continues, to the development of plans to hasten death. The more abject the sense of loss of purpose, the more agitation and desperation that develops, the more active and consuming these plans may become. When lethal means are available, the danger can be grave. Admission, close observation, and active treatment of depression, hopelessness, and demoralization are needed for actively suicidal patients.

Psychiatrists often receive consultations for 'suicidality' in cases of patients who have no desire to die, but who have instead accepted their own death. Such acceptance is based on awareness of disease progression, frailty, and the inevitability of death. Some patients close to death develop an adaptive conservation-withdrawal syndrome (Ironside, 1980), in which they retreat as they accept the pending closure of their life. Conservation-withdrawal needs to be differentiated from depression. Other patients develop fleeting, passive thoughts of suicide, in contrast to those who develop active plans with intent (Chochinov et al., 1995).

Another variation of the desire for hastened death in palliative care is the request for physician-assisted suicide or euthanasia. Much clinical discernment is needed to differentiate when such a request is based on a philosophical conviction about controlling the dying process and when it has developed from demoralized and depressed themes about the worthlessness, hopelessness, and pointlessness of life, even in the setting of potential for months of further living. Many patients use a question about hastened death as a 'cry for help' to cope with and manage a challenging illness experience. When such a request represents more than a need for better support or for improved control of symptoms, the care paradigms of legally supported physician-assisted suicide and psychiatric care for the suicidal patient appear contradictory and competing (Hamilton and Hamilton, 2005). Optimal psychotherapeutic support for such patients can be handicapped by a physician's willingness to hasten their death (Kelly et al., 2004).

Prevalence of suicidality and suicide

Suicide and suicidality are generally believed to be higher among the medically ill, and the phenomenon seems more significant in the cancer population. Transient wishes to die are frequent in the general palliative care setting. One Canadian study identified a fleeting desire for death in 44.5% of palliative patients, whereas 8.5% developed a more persistent wish (Chochinov et al., 1995).

One study in the United States reported that 25% of cancer patients had seriously thought about euthanasia and 12% had discussed this with their physicians (Emanuel et al., 1996), while another study, also in the United States, found that 17% of hospice patients identified a high desire for hastened death (Breitbart et al., 2000). In the Netherlands, euthanasia and physician-assisted suicide comprise between 1% and 5% of all deaths and 7.4% of cancer-related deaths (Onwuteaka-Philipsen et al., 2003). By 2006, cancer patients comprised 87% of some 292 patients who had used assisted suicide in the US state of Oregon since it was first legalized in 1994 (Oregon Department of Health Services, 2006). Studies have generally suggested an increased rate of completed suicide in the cancer setting, especially for older men (Louhivuori and Hakama, 1979; Fox et al., 1982; Allebeck and Bolund, 1991; Hem et al., 2004). These rates, in the range of 1–2%, are higher than the community prevalence of suicide; for instance, from 1960 to 1999, males in Norway's Cancer Registry were 55% more likely to die by suicide than the general population; female suicides were 35% more likely (Hem et al., 2004).

Risk factors for suicidality

Some of the complex factors contributing to a desire for hastened death are summarized in Fig. 17.3.1. In general, risks for suicidality include depression, demoralization, pain, and poor symptom control, though other important factors include debility, social isolation, delirium, alcohol or other substance abuse, and past history of psychiatric disorder. Such cancers as lung and head and neck cancers are associated with greater physical morbidity and therefore increased suicide rates.

Dutch studies have shown that depressed patients are four times more likely to request euthanasia than are the non-depressed (van der Lee et al., 2005). A series of studies has explored the change that can be seen in patients' interest in life-sustaining treatment when depression is actively treated (Ganzini et al., 1994; Breitbart et al., 1996; Hooper et al., 1996). In these studies, depressed people tended to select only six out of 14 potential medical therapies (e.g. the use of oxygen, blood transfusion, or being treated with antibiotics), whereas when depression was successfully treated, they selected on average ten out of 14 therapies. A study of seven people seeking legal euthanasia in Darwin, Australia highlighted the contribution of inadequately treated depression, unrecognized demoralization and poor symptom control to these patients' desire for death (Kissane et al., 1998; Kissane 2002). Zylicz found that 25% of patients in a palliative care programme in the Netherlands wanted to discuss euthanasia. The most important reasons for their requests included fear of the process of dying, 'burnout' (equivalent to demoralization), need for control, depression, and poor symptom management (Zylicz, 2002). Moreover, Chochinov has described a wide fluctuation in the will to live among the terminally ill, with anxiety, depression, and dyspnoea predicting this variation (Chochinov et al., 1999).

Assessment of the suicidal patient

Whenever patients express a desire to die, clinicians need to evaluate whether this is a readiness to accept death when it arrives or active suicidal thinking. Evaluation for the presence of depression or demoralization is paramount, assessing for meaninglessness, pointlessness, hopeless-helpless thinking, or worthlessness as pathways to suicidal thinking (see Fig. 17.3.1). Ask for thoughts about the mode of suicide—gun, hanging, jumping, car accident, or medications—and enquire about definite plans to act. If a patient appears desperate, agitated, and strongly resolved to act, the danger is grave and warrants urgent management as described later in this chapter.

Treatment of depression, demoralization, and suicidality

Pharmacological and psychotherapeutic treatments are combined in treating depression. Less empirical guidance is available for demoralization, although newer meaning-centred and dignity-conserving therapies are relevant. Creating a safe environment is crucial for those actively suicidal.
Fig. 17.3.1 Factors associated with desire for hastened death, including physician-assisted suicide (PAS).

Pharmacological treatment of depression

Only modest or negligible differences in efficacy have been found among common antidepressants, and as in the general psychiatry setting, the choice of antidepressant medication in palliative care is governed largely by the potential side effect profile, which can be harnessed advantageously (Cipriani et al., 2010; Omori et al., 2010). However, medically ill patients do require additional care to avoid drug interactions and reduced quality of life (see Table 17.3.1).

Selective serotonin reuptake inhibitor (SSRI) medication is the first-line treatment for depression. SSRIs and selective noradrenaline (norepinephrine) reuptake inhibitor (SNRI) medications have been demonstrated to be effective for depression in the settings of cancer, coronary artery disease, and medical illnesses generally (Lloyd-Williams, 2004; Price and Hotopf, 2009; Dowlati et al., 2010; Rayner et al., 2010). Some case reports or smaller studies do support specific palliative care indications of standard medications (e.g. paroxetine and sertraline to prevent and treat depressive

Table 17.3.1 Use of antidepressants in palliative medicine

Class	Action	Advantageous effects or side effects	Harmful side effects	Use in palliative care	Daily dose ranges (may have ER forms)
Tricyclics, e.g. amitriptyline	Inhibits 5-HT and NA uptake, antimuscarinic, antihistaminic, anti-alpha 1	Co-analgesic Sedative	Constipation Dry mouth Urinary retention Hypotension Syncope	Pain Insomnia Depression	Amitriptyline 25–150 mg
Selective serotonin reuptake inhibitors (SSRI), e.g. citalopram, fluoxetine, paroxetine, sertraline, escitalopram	Inhibition of 5-HT reuptake	Citalopram safe with tamoxifen	Sexual dysfunction (5-HT$_{2A}$); GI—nausea, vomiting, diarrhoea (5-HT$_3$); QTc prolongation at higher doses	Depression Anxiety Obsessive–compulsive PTSD	Citalopram 10–60 mg; fluoxetine 10–80 mg; paroxetine 10–60 mg; sertraline 25–200 mg; escitalopram 5–20 mg.
Selective serotonin and noradrenaline reuptake inhibition (SSNRI), e.g. venlafaxine, desvenlafaxine, duloxetine, milnacipran	Inhibition of 5-HT and NA reuptake	Co-analgesic	Hypertension in higher doses Nausea, GI tract	Severe depression Anxiety	Venlafaxine 37.5–450 mg; desvenlafaxine 50–200 mg (care with hepatorenal insufficiency); duloxetine 15–60mg; milnacipran 50–200mg
Selective dopamine and noradrenaline reuptake inhibitors, e.g. bupropion	Inhibition of dopamine and noradrenaline reuptake	Improve attention and concentration; reduce fatigue; lowest impact on sexual function	Anxiety Seizures Agitation	Depression Fatigue	Bupropion 150–450mg
Noradrenergic and specific serotonergic antidepressants, e.g. mirtazapine	Increases 5-HT and NA activity, antihistaminic	Stimulates appetite Helps sleep	Dry mouth Drowsiness Neutropenia rare	Depression Anxiety Appetite and weight gain Insomnia	Mirtazapine 15–60 mg
Serotonin antagonists and reuptake inhibitors, e.g. trazodone	Increases 5-HT activity, anticholinergic	Helps sleep	Dry mouth Constipation Urinary retention Drowsiness	Sleep Depression	Trazodone 50–300 mg
Psychostimulants, e.g. methylphenidate, modafinil, dextroamphetamine	Increase dopamine activity	Counter opioid sedation Alertness Counter fatigue Rapid effect	Agitation Insomnia Anorexia Seizures Hallucinations Psychosis Arrhythmia Nightmares	Depression Opioid sedation	Methylphenidate 5–60 mg; modafinil 100–400 mg; dextroamphetamine 5–60 mg

5-HT, 5-hydroxytryptamine (serotonin); GI, gastrointestinal; NA, noradrenaline.

effects of interferon) (Musselman et al., 2001; Reddy et al., 2008), or indications for non-standard treatments in the medically ill, including, for example, ketamine (Irwin and Iglewicz, 2010) or scopolamine (Furey and Drevets, 2006). Electroconvulsive therapy has also been effective in some medically ill patients (Rasmussen and Richardson, 2011).

Monoamine oxidase inhibitors (MAOIs) should be avoided because of a risk of drug interactions, especially with opiates or other serotonergic medications. Tricyclics, mirtazapine, trazodone, and SSRIs including fluoxetine and sertraline can rarely exacerbate neutropenia (Albertini and Penders, 1978; Kasper et al., 1997; Duggal and Singh, 2005). Anticholinergic side effects of antidepressants can worsen the constipating effect of opiates or complicate painful mucositis, or exacerbate delirium. Constipating effects may be particularly risky in patients with pelvic or abdominal masses.

In patients with brain lesions or other reasons for risk of seizures, bupropion and psychostimulants should be avoided and mirtazapine may also pose a risk; therapeutic doses of citalopram have been associated in most general population studies with no increased risk of seizure, or even with a decreased risk, though studies in the cancer population are lacking (Favale et al., 2003; Waring et al., 2008).

Methylphenidate or other stimulants may be beneficial both for adjunct treatment of depression and for fatigue in the terminally ill (Minton et al., 2008; Hardy 2009). Modafinil is a newer agent that may be better tolerated, but its use may be limited by cost (Breitbart and Alici, 2010). All stimulants may precipitate or exacerbate a delirium. Bupropion may also reduce fatigue (Cullum et al., 2004; Moss et al., 2006).

Mirtazapine or tricyclics may help with sleeplessness, with the added benefit of improving appetite (mirtazapine) or treating pain (tricyclics). Venlafaxine and duloxetine may also be helpful for adjunct treatment of pain along with opiates. The literature supports the use of venlafaxine and mirtazapine for hot flashes in both men and women undergoing hormonal treatments, but other antidepressants may also be helpful if these are not tolerated (Biglia et al., 2007; Loibl et al., 2007; Buijs et al., 2009). Haloperidol and olanzapine have been used for nausea, and atypical antipsychotics may also be effective for anxiety or sleep in medically ill patients (Critchley et al., 2001; Tan et al., 2009). Pruritus from various causes may respond to paroxetine or mirtazapine when standard treatments have been ineffective or are contraindicated (Zylicz et al., 1998; Demierre and Taverna, 2006).

Finally, a trial of steroids to elevate mood and overall well-being may be used in patients with a very short life expectancy. Methyl prednisolone 30 mg per day or dexamethasone 4 mg per day are used, with due care in watching for side effects, as steroids may cause dysphoric mood in some patients. Dexamethasone is metabolized by cytochrome P450 (CPY) 3A4, potentially interacting with venlafaxine, and dexamethasone is less bound to plasma proteins, therefore reaching higher concentrations in the CSF.

Tamoxifen and cytochrome P450 cytochrome interactions

Tamoxifen is a selective oestrogen receptor modulator used to reduce recurrence or treat metastatic disease in oestrogen receptor-positive breast cancers. Most common antidepressants are believed to induce some degree of inhibition of CYP2D6, the enzyme catalysing the conversion of tamoxifen to its active form, and use of the more potent CYP2D6 inhibitors fluoxetine, paroxetine, and sertraline has been associated with increased recurrence and mortality (Aubert et al., 2009; Kelly et al., 2010). Citalopram and escitalopram are less potent CYP2D6 inhibitors, and in retrospective studies they do not seem to be associated with increased cancer risk (Cronin-Fenton et al., 2010). Venlafaxine and mirtazapine are believed to be weak CYP2D6 inhibitors and are generally believed to be safe (Aubert et al., 2009).

Irinotecan and SSRIs

Irinotecan is a colon cancer agent that also requires conversion to its active form by the CYP system. SSRI medications and tricyclics may increase levels of the active drug through CYP interaction, and the combination can also rarely cause rhabdomyolysis by an unclear mechanism. Antidepressants should be used cautiously in the setting of Irinotecan (Richards et al., 2003).

Serotonin syndrome

Serotonin syndrome is a rare but potentially fatal autonomic dysregulation caused by excessive serotonin. Manifestations are usually mild but may become severe, progressing from shivering, sweating, and nausea to tachycardia, mydriasis, myoclonus, and hyper-reflexia, and finally to psychomotor agitation and disorientation, hyperthermia, hypertension, metabolic acidosis, and renal failure leading to possible seizure, disseminated intravascular coagulation, coma, and even death (Kim and Fisch, 2006). Treatment involves withdrawal of the offending agents and supportive management. Linezolid is an oxazolidinone antibiotic with MAOI-like properties that could precipitate a serotonin syndrome when combined with antidepressants; administration within 2 weeks of antidepressant use should be avoided if possible. Antidepressants are generally contraindicated in patients receiving the chemotherapy agent procarbazine, which has well-documented MAOI action. In rare cases, many common medications including opiates (especially meperidine), ondansetron, and granisetron may precipitate serotonin toxicity when given with antidepressants (Lee et al., 2009; Takeshita and Litzinger, 2009).

Psychological treatment for depression

Meta-analyses of psychotherapies in cancer patients document clear benefits (Meyer and Mark, 1995), with communication of specific knowledge through psychoeducation most easily demonstrated (Devine and Westlake, 1995). Both individual and group psychotherapeutic interventions seem to have benefit in proportion to the experience and skill of the therapist and the length of intervention (Sheard and Maguire, 1999). In eight of 13 studies of interpersonal psychotherapy focusing on grief, life transitions, social isolation, and interpersonal conflicts, de Mello et al. showed that the intervention was superior to control at improving depression (de Mello et al., 2005).

Behavioural activation strategies

Depression is readily maintained by social withdrawal and avoidance behaviours. Strategies such as scheduling, self-monitoring, rating daily levels of pleasure and accomplishment, and exploring alternative roles with rehearsal during therapy have been found to help alleviate depression (Dimidjian et al., 2006; Dobson et al., 2008).

Couple therapy

A randomized controlled trial of active coping for couples compared with usual care in the breast cancer setting showed a reduction in women's depressive symptoms up to 6 months after active treatment (Manne et al., 2005). Couple therapy assists adaptation when body image changes (e.g. mastectomy, colostomy, ileal conduit, and limb amputation), when sexuality is affected (e.g. erectile dysfunction after prostate cancer and dyspareunia after gynaecological cancers), or when issues of shame, guilt, doubt, despair, or depression arise, and the partner is a prime source of support (Zaider and Kissane, 2011).

In working with couples to promote effective mutual support, it is important to maintain awareness of patterns of demand–withdrawal that can represent a protest at the burden of illness and lead to disengagement and diminished safety. Couple therapy that identifies existential fears and supports intimacy in the face of death has been shown beneficial in reinforcing resilience and protecting against demoralization and depression (Dobson et al., 2008).

Group therapy

In cognitive-existential group therapy, the goals are to promote a supportive environment, facilitate grief for multiple losses, alter maladaptive cognitive patterns, enhance problem-solving and coping skills, foster a sense of mastery, and encourage review of lifestyle priorities (Kissane et al., 1997). In supportive-expressive group therapy (SEGT), the goals are to build bonds, express emotions, detoxify death, redefine life's priorities, fortify families and friends, enhance doctor–patient relationships, and improve coping (Classen et al., 2001). Through an emphasis on transforming existential ambivalence into creative living and promoting adherence to anti-cancer treatment (Kissane et al., 2004), SEGT has been shown to prevent depression (Kissane et al., 2007).

Family therapy

In a randomized controlled trial targeting 'at-risk' palliative care families, family-focused grief therapy (FFGT) has been shown to reduce depression and support mourning (Kissane et al., 2006). The goals of FFGT are to optimize family relational functioning through promotion of effective communication, enhanced cohesion and adaptive resolution of conflict. The more pronounced the relational dysfunction, the greater the number of family sessions needed during the bereavement phase. In general, families with mild communication breakdown can be aided by four to six sessions, whereas ten to 12 sessions are preferred for severe family dysfunction. Openness to discussion of death and dying and early containment of conflict prove beneficial until improved communication and closeness help family members tolerate differences of opinion (Kissane and Zaider, 2011). Therapists make use of circular questions to reveal family dynamics and offer regular summaries to help families integrate understanding of their patterns of relating and coping with loss and change (Dumont and Kissane, 2009). Commencing therapy while the cancer patient is still alive and present to contribute establishes a model of family care that is preventive, cost-effective, and enables continuity of support to be carried into bereavement.

Pharmacological treatment for demoralization

Where co-morbid major depression and demoralization exist, medications for the treatment of depression are indicated. When demoralization exists without co-morbid depression, the mainstay of treatment is psychotherapeutic, without current research evidence to guide the use of antidepressants or other medications (Angelino and Treisman, 2001).

Psychological treatment for demoralization

New models of treatment including dignity and meaning-centred therapies allow more focus on demoralization and other states of existential or spiritual distress (Griffith and Gaby 2005).

Dignity therapy

Dignity therapy (DT) is a brief focused intervention near the end of life that is designed to address psychosocial and existential distress (Chochinov et al., 2005). Its goals are to sustain generativity and continuity of self, to maintain pride and hope, to preserve the patient's cherished roles, to alleviate concerns about being a burden to others, and, if desired, to leave a legacy document that summarizes the sufferer's accomplishments and values in life. DT seeks to celebrate life and affirm the worth of each person, addressing critical aspects of demoralization and enriching the life lived.

Meaning-centred therapies

Based on Frankl's model of logotherapy, meaning-centred therapy (MCT) has been used with groups and individuals (Breitbart et al., 2004). Its goals are to review concepts and sources of psychological meaning and value, together with the impact of palliative care, and to acknowledge the finiteness of life and therefore highlight its value and worth. The therapy often includes creativity and good deeds, appreciation of nature, art and humour, and a focus on taking stock of the depth of meaning that sustains worthwhile living. MCP is anticipated to be effective in alleviating demoralization and promoting dignity of the person.

The psychodynamic life review is a narrative approach that identifies key accomplishments and personal strengths alongside vulnerabilities, in order to frame the crisis of illness as an opportunity for growth in the setting of an ongoing life story (Viederman 1983). The containing frame of support generated actively by the therapist is intended to maintain adaptive defences and draw attention to the value and meaning of continued life. Meaning and purpose therapy is another brief, individual model that focuses on the patient's intention and ability to derive meaning (Lethborg et al., 2012).

Treatment of suicidality

Many who complete suicide have recently denied the presence of suicidal ideation and have not made prior attempts (Busch et al., 2003). The warning signs of an imminently impending suicide attempt differ from demoralization, depression, and other risk factors discussed above, and include agitation and increasing anxiety, desperation, and easy access to a mode of dying. This is a medical emergency. Immediate admission to hospital, use of one-to-one observation, careful assessment, and active treatment of depression and demoralization are crucial to protect such patients from self-harm (Olden et al., 2009). When patients express a desire for hastened death in the setting of hospice or palliative care, therapeutic communication is central, with empathic responsiveness, active listening, management of realistic expectations, permission to discuss psychological distress, and psychiatric referral as needed (Hudson et al., 2006).

Conclusion

Depression and demoralization are interrelated experiences that have a measurable effect on the lives of cancer patients and their course of illness. Desire for hastened death or even suicidality can develop from severe demoralization or depression. Treatments including medications and psychotherapies with patients and their families have been shown to be both promising and effective in alleviating suffering and improving the quality of cancer treatment and medical care.

Adjustment disorders and anxiety

Simon Wein and Limor Amit

Introduction to adjustment disorders and anxiety

The American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM) has a category called Adjustment Disorders (ADs) (American Psychiatric Association, 2000). This category is problematic because it is not grounded in a body of reproducible research or a clear and agreed-upon definition (Strain 1998; Gur et al., 2005; Laugharne et al., 2009). Being unable to adjust to a stressor may result in the patient developing pathological and distressing symptoms. It is a common clinical observation to see patients who initially cope, but then with another and added stressor are unable to adjust. The category of AD has a practical and intuitive appeal that makes it useful at the bedside.

Anxiety, like the ADs, is a common response to the stressors caused by physical illnesses, especially those that are life-threatening (Noyes et al., 1998; Stark et al., 2002; Lederberg, 2003; Kangas et al., 2007; Teunissen et al., 2007; Roy-Byrne et al., 2008). Anxiety may or may not be pathological. It can be a stimulus to adaptation, or occur along a spectrum of clinical syndromes and diagnoses. Too little anxiety can kill through neglect, whereas too much can lead to decompensation, and psychiatric or even physical illness (Stevens and Price, 2000).

ADs and anxiety, therefore, occupy a grey zone between an individual's healthy adaptation to stressors and pathological decompensation. Given the importance and variability in the stressors encountered by those with serious illness, they are highly relevant phenomena in the practice of palliative care.

Stressors

The precipitating event for an AD or anxiety is a stressor, which is a stimulus that disturbs the normal physiologic or psychological equilibrium (Gur et al., 2005), but may not be objectively quantifiable. Stressors can be internal or external, inherited or acquired, and physical or non-physical. In the medically ill, stressors can be numerous and extremely complex. The specific nature of the stressors may guide therapy.

A case is illustrative: a young, single mother treated for locally advanced cervical cancer presents on the anniversary of her diagnosis with extreme anxiety and severe back pain, requiring intravenous morphine. The morphine lessens the pain, but the patient's distress remains very high. Magnetic resonance imaging shows a ruptured intervertebral disc. After being told, the patient quickly reports symptomatic improvement and a desire to return home.

The stressors in this scenario probably included both physical pain and fear of cancer recurrence. Other stressors may have been prominent but would remain hidden unless elicited through the clinical interview. The complexity of the factors driving this patient's anxiety exemplify the biopsychosocial model of ill health and underscore the potential value of careful assessment and a varied therapeutic response. When enmeshment of different response systems occurs, such as the response to pain and the response to fear of recurrence, no one type of treatment, such as medication alone, should be viewed as the best management (Engel, 1977). Indeed, the complexity of treatment decisions in populations with advanced illness is reflected by the need to understand and address the broad range of emotional reactions, such as anxiety, depression, grief and anger, as well as coping and adaptation, as highly varied stressors wax and wane (Murray-Parkes, 1998; Lederberg, 2003; Jordan and Okifuji, 2011).

In populations with advanced illness, some stressors appear to be relatively common. They include knowledge that death is imminent, family feuds, inability to work, financial crisis, the perception of becoming a burden or losing control due to illness, physical pain or other symptoms, and being unable to complete life's tasks, Other stressors relate to premorbid physical or psychiatric problems, such as obsessive–compulsive neurosis. Yet others occur as system issues, such as the threat of non-coverage by a health insurance company.

In assessing the possibility of an AD, clinicians should seek evidence of the diverse events, situations, conditions and cognitions that can become stressors in the context of medical illness. At the same time, however, this assessment must be informed by the reality that overt connections between stressors and distress may not be found. There is no direct correlation between patients' responses and either the severity or type of stressor, and up to 30% of ADs are diagnosed without an obvious recent (within 3 months) identified external stressor (Gur et al., 2005).

When is adjustment or anxiety psychopathology?

Patients living with progressive incurable illness must continually adjust to new situations, realities, and losses. The psychological processes underpinning coping and adaptation are repeatedly challenged, and the degree of distress and dysfunction that occur may vary with the severity and type of stressor, individual resilience, premorbid psychological health, education, and preparation, support from family and health professionals, and other factors. Distress associated with adjustment is common, and to some extent, entirely normal.

How can a health professional judge that a patient's response is abnormal, that in fact an AD is occurring? The DSM suggests that the distinction can be made by considering (1) the severity of symptoms and (2) the extent of disruption of normal functioning or of homeostatic adaptation (American Psychiatric Association, 2000).

Ideally, the assessment parameters that would distinguish normal from pathological would be defined empirically through research. Unfortunately, it is difficult to conduct quality research in palliative care because of the practical and ethical challenge in recruiting sick patients, short and unpredictable follow-up, difficulty in controlling multiple variables, high attrition rate, and the overlap between psychological and physical symptoms (Grande and Ingleton, 2008). Indeed, a large systematic review of psychological distress and psychiatric morbidity in advanced cancer confirmed the difficulty in recruiting 'large and representative samples' due to patient ill health or refusal, and emphasized the need for greater flexibility in research design and different ethical guidelines (Ryan et al., 2012). Given the limitations in the extant literature, many of the principles for assessment of the ADs and their treatment are extrapolated from the general psychiatric literature and rely on empirical 'N-of-1' studies, and expert opinion.

The type of assessment needed to determine whether a patient's distress in association with a stressor is best labelled an AD is exemplified by grief.

'Uncomplicated grief . . . is an entirely normal emotional response to loss. The medical profession should normalize, not medicalize, grief' (Friedman, 2012). Grieving patients may evince profound sadness, rumination about the loss, and difficulty functioning. Categorizing this phenomenology as a psychiatric syndrome carries the risk of medicalizing emotions and relying on medical therapies, particularly drugs, to address the distress. The symptoms associated with grief can, however, reach a clinical threshold defined by character, severity, or duration that appropriately leads to a diagnosis of pathological grief. The diagnosis, in turn, impels consideration of treatment.

Even in the latter situation, however, treatment should not be taken to mean common medical interventions, like drugs, along. Grieving, like coping with the stress of illness, and indeed dying itself, are life tasks. Health professionals should not presume that the goal is to abort the type of psychological or spiritual work that may be needed by the patient to process, cope, and recover. In a sense, the clinician risks infantilizing the patient by 'doing' the psychological work for them. Recognizing this complexity provides a strong rationale for the use of traditional talking therapy in addressing ADs or uncomfortable emotions like anxiety. Through psychotherapy, uncomfortable emotions can be tools to allow insight (Stevens and Price, 2000).

The clinical assessment of the severity of response is a key to distinguishing an AD from normal adjustment, or identifying times that anxiety calls for clinical intervention. Anxiety, for example, can help or cripple. The clinician must decide whether this particular person in the context of the particular stressor is expressing a degree of anxiety that is pathological, and if so, how best to manage it (McHugh and Slavney, 2012). The assessment may require corroborative evidence from family, friends, or the family doctor (with the patient's consent), so that the presenting symptoms can be contrasted with premorbid behaviour

Adjustment disorder

In DSM-IV, the ADs are divided into subcategories: Depressed Mood, Anxiety, Disturbance of Conduct, Mixed Anxiety and Depressed Mood, and Mixed Disturbance of Emotions and Conduct (American Psychiatric Association, 2000). The literature does not offer a precise definition of AD, but the concept overall, and these phenomenological distinctions, are clinically easy to use by applying DSM criteria (Baumeister and Kufner, 2009). As noted, the assessment should seek to define the stressors associated with a potential AD. Symptoms that suggest an AD can develop up to 3 months after a stressor; the symptoms typically remit by 6 months after the stressor resolves. Identifying a key stressor may warrant a targeted intervention, even if research has not established with any predictive accuracy which stressors are beneficial or destructive (Casey et al., 2001), and the relationship between individual stressors and ADs is indeterminate. For example, marital problems, financial difficulties, and moving place of residence are common stressors in the general population (Maercker et al., 2007), and the specific impact of a disease, such as a cancer or other chronic illness, is a common stressor in hospitalized patients, but neither the development nor the severity of AD is directly related to the existence or severity of these problems (Strain et al., 1998; Gur et al., 2005). Nonetheless, once identified by the patient as a source of distress, clinical efforts to ameliorate a stressor can be beneficial.

The resilience of the individual, which is one determinant of ability to adjust, is influenced by character, 'ego strength', social support, culture, belief system, and past ability to deal with stressors. While overall resilience does not usually change late in life, stressors associated with a fatal illness may precipitate unexpected reactions (Greer and Watson, 1987; Lederberg, 2003). To the extent that efforts to support resilience are possible, they may be worthy to explore if an AD occurs.

To diagnose an AD, the distressing symptoms may not be explicable by another disorder and cannot be due to bereavement. This is problematic, since up to 60% of medically ill patients have another Axis 1 psychiatric disorder, such as Major Depression. Diagnosis is further complicated by the clear potential for overlap between ADs and post-traumatic stress disorder, and later on, with bereavement. It remains unclear whether any particular AD is part of a spectrum of disorders, or is a distinct entity, and as noted, the criteria that define a transition between normal adjustment and psychopathology are ill defined (Strain et al., 1998; Casey et al., 2001; Maercker et al., 2007; Baumeister and Kufner, 2009; Laugharne et al., 2009). Nonetheless, some authors claim that ADs have distinct profiles and represent a category between no mental disorder and affective disorders, specifically depression and anxiety disorders (Fernández et al., 2012). Consistent with the latter view, AD has been labelled a subthreshold disorder (American Psychiatric Association, 2000).

Depending on the specific symptoms, other elements in the differential diagnosis of the ADs may include other types of depression, somatization, personality disorder, suicidality, anger, generalized anxiety disorder, and insomnia. As noted, the information needed for diagnosis must first come from the patient, but also may originate from multiple other sources. If the patient is receiving care from a palliative care team, valuable information

may be forthcoming from any member of the team, particularly social workers.

A high index of clinical suspicion is needed to diagnose, anticipate, and prevent psychiatric problems, including ADs. These disorders may be misdiagnosed as physical complaints or dismissed as 'normal' responses. If one or more of the stressors common in advanced illness, such as progressive disease, physical limitations, dependency, financial stress, anticipatory loss, failed goals, or a family in crisis, has occurred or worsened, this may assist in the diagnosis of an AD or present an opportunity for prevention.

If suspicion is high and assessment is performed competently, the diagnosis of AD can be distinguished from normal adjustment and other psychiatric disorders. The diagnosis of ADs can be made in as many as 13% of inpatients in a general hospital situation, 10% in outpatients, and 13% in emergency rooms, In the general population, AD is associated with suicidal thoughts (30%); 58% of suicide attempters and 9–19% of suicide completers may be diagnosed with an AD. A study of 209 terminally ill cancer patients found that AD was present in 11–17%, compared to a depression prevalence of 7–12%; lower performance status, inadequate social support, and concern about being a burden were significantly associated with the diagnosis (Akechi et al., 2004).

Anxiety

Anxiety, fear, or nervousness is almost universal at some point in life, especially when life is threatened by illness. 'We may take for granted that the fear of death is always present in our mental functioning. . . . It must be properly repressed to keep us living with any modicum of comfort' (Zilboorg, 1943). Anxiety can be adaptive or maladaptive. Too little fear is dangerous, whereas too much (as in a crippling neurosis) can paralyse (Stevens and Price, 2000). DSM-IV subdivides anxiety into generalized, adjustment, panic, phobias, post-traumatic, and due to general medical condition (American Psychiatric Association, 2000).

In the context of advanced illness, anxiety may be linked to a set of thoughts and concerns. Murray-Parkes documented these common fears in a hospice: separation from loved ones, becoming a burden to others, losing control, knowing that dependents will suffer, having pain or other symptoms, being unable to complete life tasks, dying or being dead, and the fears of others (reflected) (Murray-Parkes, 1998).

Although the expression of anxiety varies from person to person, severe anxiety is associated with common symptoms and signs, some of which are related to hyperactivity of the sympathetic nervous system. These include restlessness and irritability, difficulty concentrating, increased muscle tension, somatization, acute stress with nightmares, sleep disturbance, worries that cannot be rationally allayed, and panic-like attacks. The differential diagnosis of anxiety also can include specific phobias, obsessive–compulsive disease, post-traumatic stress disorder, and delirium (American Psychiatric Association, 2000).

Most studies indicate that between 10% and 30% of cancer patients have an identifiable anxiety disorder, as opposed to a prevalence of general anxiety disorder of 5% in the community (Stiefel and Razavi, 1994; Rasic et al., 2008; Wein et al., 2010; Traeger et al., 2012). The prevalence may be underestimated because diagnosis can be difficult if the patient does not have the vocabulary to express an unaccustomed frightening inner feeling. Some part

of the prevalence is a related to an exacerbation of a previous or underlying psychiatric disorder by the stresses of an intercurrent illness, or by the use of medications that can produce anxiety as a side effect (Wein et al., 2010) (Box 17.4.1). The prevalence of anxiety disorder does not include common situational anxiety that may come and go in response to a specific threat such as waiting for results, receiving bad news, experiencing a new symptom, or starting a treatment (Palmer et al., 2004).

Diagnosis

Failure to diagnose anxiety increases the likelihood of anxiety-related problems. These can include trouble making decisions about treatment or adhering to treatment, and more visits to the physician's office and emergency rooms for symptoms such as dizziness, palpitations, breathlessness, insomnia, or pain (Greer and Watson, 1987; Roy-Byrne et al., 2008). In terminally ill cancer patients, depression and anxiety appeared to increase the desire

for hastened death, in contrast to pain alone, which does not (Kolva et al., 2011).

To prevent these problems and directly address a symptom that commonly undermines quality of life, it is essential to diagnose and manage anxiety. Although the prevalence of psychiatric disorders in chronic diseases can be as high as 40% in some studies (Palmer et al., 2004; Kangas et al., 2007; Rasic et al., 2008; Mitchell et al., 2011), the diagnosis can be missed if an assessment focuses on somatic symptoms and comments about the patient's emotional state are narrow ('Wouldn't you be anxious if you were sick?'). There are many physical illnesses with symptoms of anxiety that mimic existential or psychological distress, and these, too, must be evaluated to understand the anxiety. Examples include dyspnoea and uncontrolled pain (Teunissen et al., 2007; Roy-Byrne et al., 2008). In the same way, both premorbid and comorbid psychiatric illnesses must be assessed because many, including depression, demoralization, personality disorder and delirium, are associated with anxiety.

In particular, it is difficult to establish a diagnosis of either anxiety or an AD in patients who are suffering with uncontrolled pain or other physical symptoms. Symptom distress should be promptly relieved if possible, before the psychiatric assessment of an AD or pathological anxiety is done.

The diagnosis of anxiety relies on both verbal and non-verbal cues, and the importance of non-verbal cues may explain the observation that physicians miss the diagnosis in as many as one-third of patients (Stiefel and Razavi, 1994; Kangas et al., 2007). Some authors have found that men are less able to verbally express their emotions and the clinician must rely on collateral information more often when assessing male patients (Wein et al., 2010). Although the Hospital Anxiety Depression Scale (Zigmond and Snaith, 1983) and the Edmonton Symptom Assessment Scale (Jacobsen et al., 1991) are commonly used and validated tools that measure anxiety, the gold standard remains the clinical interview and observation of the non-verbal cues (Mitchell et al., 2011).

As noted, diagnosis of an anxiety disorder in the medically ill patient is predicated on an assessment of premorbid and comorbid psychiatric disorders. This need for a careful psychiatric assessment mirrors the approach taken to diagnose an AD. It should have a high index of suspicion for illnesses such as depression, insomnia and somatization, phenomena like anger and sadness, and altered body image. Common psychological defences are denial and hope. One needs to know the patient's social milieu and to ask leading questions about psychological state, just as one would when taking a history of a physical illness. In assessing anxiety, it is important to know what sort of a person the patient was before the illness began and this may be clarified by interviews with family members or the family doctor, if the patient consents.

In the cancer population, screening for anxiety has not been shown to result in better mental health and lower distress than results obtained by patient self-referral or clinician referral (Jacobsen, 2007). There are many potential reasons for this finding: a person identified with significant psychological symptoms may not want to be referred for treatment, or there may be inadequate resources to cope with the referrals (which raises ethical questions). Screening also may be problematic because the cut-off points in the screening tool for what constitutes psychopathology have not been fixed by research (Jacobsen, 2007; Meijer et al., 2011). These data suggest that the diagnosis of an anxiety disorder in medically ill populations is most efficiently accomplished through astute assessment during routine clinical care.

Management of adjustment disorders and anxiety

Comprehensive palliative care is multidisciplinary care and is structured in varied ways. In all situations, however, the physician who is primarily responsible for the patient should know the principles of diagnosis and management of ADs and anxiety, and help organize and monitor care, even if through collaboration with a mental health specialist (Wein et al., 2010).

Treatment should aim to relieve unpleasant feelings or distress, and improve functioning and adherence to medical care. The goal usually is not to eliminate negative feelings or entirely prevent distress. If anxiety is the target symptom, effective treatment also may improve sleep and enable the patient to communicate more openly with their families and significant others. Given the association between anxiety and an increased desire to die, symptom relief also may reduce the risk of suicidal ideation (Kolva et al., 2011).

Evolutionary psychiatry asks whether there is value in psychological distress. Can it lead to deeper understanding? If anxiety is chemically 'removed,' does this mean the patient will not do the psychological work needed to grow? On the other hand, too much stress can make it difficult to think and function (Stevens and Price, 2000).

The treatment of both ADs and anxiety begins with consideration of primary therapies for those factors identified as stressors, triggers, or aetiologies of the symptoms. It is important not to presume what is causing the anxiety. Asking intimate questions directly with empathy and caring will neither frighten nor offend a patient. If anxiety or distress is related to the perception of imminent death, it may be helpful to describe in detail the process leading to death. Many have not seen death before and Rodin and colleagues showed that discussing life expectancy and prognosis can lead to a reduction in anxiety (Rodin et al., 2009). Yalom (2002) noted that death anxiety is inversely proportional to life satisfaction. Building a trusting relationship with honesty and empathy is important for later on when difficult decisions need to be made. Very attentive control of physical symptoms, especially nausea, pain and dyspnoea, also goes a long way to relieving anxiety.

Symptomatic therapies should be considered even if a treatable source of distress is identified and managed. Therapy is both psychological and pharmacological, with judicious use of alternative therapies (Jackson and Lipman, 2004; Davidson et al., 2012). Effective management may include medications, talking therapy, hypnosis, relaxation, and supportive therapy (McQuellon et al., 1998; Roth and Massie, 2007; Arch and Craske, 2009; Otte et al., 2011; Reinhold et al., 2011). Many patients find other complementary therapies helpful, which may include the entire gamut from meditation and reflexology, to Chinese herbs and spices (Wein, 2000; Anderson and Taylor, 2012).

Talking therapies

Psychoeducational interventions provide information about the nature of the disease, the treatments, side effects, and outcomes. These interventions can facilitate initial adjustment to the new situation and help the patient regain a sense of control (Jacobs

et al., 1983). Discussing with the patient the causes of anxiety and ways people adjust to stress, and providing anonymous examples is extremely helpful. Explaining to the patient that fear of the disease or its treatment, and fear of dying, are common to everyone can often help them feel less isolated and more in control. Every patient (just as every person) has a thought or fear about death. Talking about it will not cause permanent damage. Most patients (as with most people) will activate psychological defence mechanisms according to their needs. Today, much information is available via the Internet and patients should be encouraged to explore this, and discuss it. Some studies have shown that up to 50% make use of these sources, although others show that fewer patients do so (Helft et al., 2005; Hesse et al., 2005). Many of the larger health centres have resources specifically available for patients and families.

Cognitive behavioural therapy (CBT) is a short-term (up to 20 sessions), goal-oriented intervention aimed at changing the patterns of thinking and behaviour that lead to anxiety and distress (Otte, 2011). The cognitive interventions aim to modify maladaptive cognitions, self-statements, or beliefs. Cognitive techniques include thought stopping, prioritizing worries, distraction, disruption of thought patterns, labelling distortions, and development of replacement imagery. Behavioural techniques include scheduling activities, relaxation training, learning social skills, assertiveness training, rehearsing stressful situations, and *in vivo* exposure (Leichsenring et al., 2009). A recent study assessing the efficacy of CBT in the various anxiety disorders showed that it was an effective treatment (Leichsenring et al., 2009). Encouraging physical exercise has also been shown to improve psychological well-being (Helft et al., 2005).

Chochinov and colleagues developed dignity therapy, a form of CBT, for patients with advanced cancer (Chochinov et al., 2005). The principle is to help patients with a limited life expectancy to identify values in their lives that are important to them. Transcripts of interviews are prepared and returned to the patients, who may then chose to pass them on to family and loved ones. This has been shown to improve dignity, self-esteem, meaning, reduce distress, and reinforce the will to live (Chochinov et al., 2011) (see Chapter 5.6).

Group psychotherapy is a well-established method of treating anxiety and ADs (Yalom and Leszcz, 2005). There is some evidence that it can prolong survival, but this is controversial (Yalom and Leszcz, 2005; Stefanek et al., 2009). Group psychotherapy manages a number of patients at a time, uses patient interactions therapeutically, provides social support, offers an opportunity to express oneself in a peer group, and facilitates learning about the disease process from other patients. The limitations include mixing different diseases (e.g. breast and colon cancers), as well as the problem of patients dying and leaving the group. Many people find publically expressing their feelings socially prohibitive.

Breitbart and colleagues developed a group therapy programme for cancer patients based on meaning and spirituality, and the ideas of Frankl (one can achieve meaning and a sense of control in life even in the most dire and extreme situations) (Frankl, 1959/1988; Breitbart, 2002; Breitbart et al., 2012). The programme is a mixture of didactic, psychoeducational, and cognitive therapies. It has been manualized for group psychotherapy over 8 weeks. A recent pilot study showed that, compared with a standard supportive group therapy, meaning-centred group therapy participants had less anxiety, distress and hopelessness, and a greater wish to live

(Breitbart et al., 2010).The therapy may enable a re-evaluation of life's priorities by facing existential concerns, talking specifically about fears, and ultimately detoxifying the fear of death (Lee et al., 2006).

Family meetings with the staff are critical to any therapeutic intervention, including discharge planning. Family is important, for better or worse, and for emotional support and psychological well-being (Gueguena et al., 2009; Hudson et al., 2009).

Regardless of the talking therapy selected, an effective therapist should be flexible in direction, content, and methodology. Therapy should not be theory driven, but rather, relationship driven. Thus the choice of therapy is eclectic. It is the therapist that plays the central role, not the technique (Yalom, 2002).

Psychopharmacology

The pharmacological choices to address the symptoms of an AD, or anxiety specifically, comprise several classes, including the anxiolytics, antidepressants, and antipsychotics (Schwartz et al., 1989; Lederberg, 2003; Breitbart et al., 2010; Davidson et al., 2010; Koen and Stein, 2011; Traeger et al., 2012). All medications should be prescribed initially for a limited time, with regular review to assess effectiveness and side effects. In physically sick patients, delirium, biochemical disturbances, and drug–drug interactions require specific attention. In the elderly, there is no better adage than 'start-low and go-slow', especially if they are also physically ill.

The medications used to manage acute anxiety disorder in populations with advanced illness are those used for general anxiety disorder. There are few studies of psychopharmacology in palliative care populations (Breitbart et al., 2010), and most clinical decisions are extrapolated from studies in the general population. This is based on reasonable assumptions, as long as caution is exercised about specific drug interactions. For example, certain selective serotonin reuptake inhibitors (SSRIs) are strong inhibitors of the isoenzyme cytochrome P450 2D6 (including fluoxetine, fluvoxetime, and paroxetine) and may lower levels of tamoxifen (Kelly et al., 2010; Lash et al., 2010). For this reason, other SSRIs (including sertraline, citalopram, and escitalopram), or venlafaxine should be considered as alternatives.

There is a theoretical concern that SSRIs used together with tramadol may cause a serotonergic syndrome. However, clinical experience shows that if the medications are combined at low doses and carefully titrated and monitored, they can be safely used together (Sansone and Sansone, 2009).

When only a partial response to a specific drug occurs, or intolerable side effects develop, combination therapy may be helpful. It often is prudent to ask for psychiatrist input when considering combinations of psychotropics (Adson et al., 2005; Brawman-Mintzeret al., 2005). For example, an antipsychotic with sedating characteristics, such as promethazine or methotrimeprazine, may be indicated at a low dose if delirium or other cognitive disturbance accompanies anxiety.

Most placebo-controlled studies in general anxiety have shown benzodiazepines and antidepressants are effective for short-term (up to 12 weeks) anxiolytic therapy (Stocchi et al., 2003; Breitbart et al., 2010; Kolva et al., 2011). They often are used for longer periods based on clinical observation.

Benzodiazepines presumably exert their therapeutic benefit by promoting gamma aminobutyric acid (GABA) activity. In addition

to managing anxiety, they can treat insomnia, and in certain circumstances can be antiemetic (e.g. lorazepam). Clonazepam and diazepam have long half-lives and are effective in suppressing symptoms, whilst alprazolam and lorazepam act rapidly, can be given sublingually, and are useful for acute anxiety or panic attack. Benzodiazepines have a particular role in controlling acute anxiety and can be used to manage symptoms until a SSRI or serotonin noradrenaline reuptake inhibitor (SNRI), such as venlafaxine or duloxetine, take effect. After this, they may be used intermittently or as an adjuvant. The main side effect associated with benzodiazepine therapy is sedation. Central nervous system depression is additive to other drugs, including the opioids and anticonvulsants, and this may exacerbate their risks. Tolerance may develop to the sedative effects.

SSRIs and SNRIs have been shown in controlled studies to improve anxiety, especially where there are depressive symptoms (Stocchi et al., 2003; Davidson et al., 2005). These drugs are generally well tolerated, but a significant subgroup of patients (up to 20%) are unable to tolerate them due to nausea, insomnia, agitation, somnolence, or weight gain (Stocchi et al., 2003). Trazodone is useful as second-line antidepressant/anxiolytic, especially if the anxiety is associated with insomnia, sleep disturbance, or hot flashes. Although tricyclic antidepressants (TCAs) are used less often, they too retain a role, especially when there is associated neuropathic pain or when their side effects (such as somnolence) can be used beneficially. Schwartz et al. found support for the use of TCAs to manage ADs in the medically ill (Schwartz et al., 1989).

Antipsychotics are also effective anxiolytics, although the evidence is mainly as augmentation for antidepressants. The atypical antipsychotics, such as risperidone and olanzapine, are generally preferred in the palliative care setting. When patients have comorbid cachexia, the side effect of weight gain can be an advantage (Breitbart et al., 2010).

There is evidence that pregabalin is efficacious in generalized anxiety disorder (Rickels et al., 2005). It is a first-line agent for neuropathic pain. Like gabapentin, this drug is a ligand of the alpha-2-delta protein of specific presynaptic calcium channels. Its mode of action involves inhibition of release of glutamate and other neurotransmitters. The side effects of somnolence and dizziness may be dose-limiting.

Since the 1980s, in part driven by the success of DSM in providing 'diagnostic criteria for all mental disorders' and in part by the pharmaceutical industry's success in promoting drugs for psychiatric disorders, psychiatrists have self-identified increasingly as psychopharmacologists (Angell, 2011). As a consequence, they have less focus on exploring the life stories of their patients and may be less attuned to the human complexities inherent in suffering. The problem of course is that suffering, existential distress, meaning, divorce, death, financial ruin, and losses are not subserved by any specific brain neurotransmitters. Labelling patients as having an anxiety disorder or an AD should not be used as a shortcut to a medication or as a replacement for understanding the person. There is an extensive literature about loss, anger, control, dignity, humiliation, and so forth, which can help guide clinicians in learning how to best communicate with the patient. Psychological techniques, such as Viederman's 'life narrative' (Viederman, 1980; Viederman and Perry, 1983), should be integrated into the management strategy even as drugs are administered to improve symptom distress.

Other therapies

In some countries, medical marijuana (cannabis) is available. In Israel, for example, almost 8000 people have a licence to use it (Y. Baruch, pers. comm.). The main indications are spasticity of multiple sclerosis, chronic non-malignant pain, AIDS-related anorexia, and cancer-related symptoms. In the cancer population, it is used in the management of nausea related to chemotherapy, pain (especially neuropathic pain), anorexia, anxiety, distress, and insomnia (Gray, 1998; Carter et al., 2011; Twycross and Wilcock, 2011). Research in populations with cancer or other serious illness is limited and there are no randomized controlled studies. Unfortunately, commercial interests and widespread acceptance in society make the possibility of randomized studies less likely (Gray, 1998; Tikum Olam, n.d.). Nonetheless, one review found support for cannabis in the treatment of anxiety and insomnia (Robson, 2001), and based on clinical observations, it is likely that cannabis also can be helpful for some patients with insomnia. It is essential that research, preferably blinded studies, be undertaken to document cannabis's role in palliative care.

Complementary therapies play a role in managing anxiety and ADs. Many patients have faith that these therapies help (Burstein, 1999; Holland, 1999; Wein, 2000); that in itself may reduce anxiety and distress. It is important to distinguish between complementary therapies that are provided with the idea of reversing the disease and those that are provided to help cope with the disease. The former, if lacking evidence, have no place in palliative care. Those that may reduce distress or improve quality of life may play a role, as long as they cause no harm, even if they have not been proven in randomized studies. Some complementary therapies, such as art therapy (Oster et al., 2006) and music therapy have been shown in randomized studies to relieve suffering and anxiety.

Rarely, the anxiety and existential distress at the end of life causes severe and intractable suffering, despite medications and talking therapy. In this situation, some specialists in palliative care will consider the use of palliative sedation, as long as the patient consents and the family and colleagues agree (Cherny and Radbruch, 2009). The depth of the sedation is usually just enough to provide sleep, and thus relief, and by agreement may be temporary. Other specialists do not endorse this approach and limit the use of palliative sedation to patients with intractable suffering related to physical problems such as pain, dyspnoea, or delirium.

Anxiety and adjustment of staff

Anxiety, guilt, ADs, personal problems, burn-out, compassion fatigue, and depression are not uncommon in health-care professionals. This is important as regards the health of the professionals, but it can also impact on care of the patients and communication with other staff members. There is a clear role for colleagues to identify staff at risk and departments should have measures and procedures in place to help and assist. Doctors in particular tend to adopt a heroic and a 'never-give-up approach', which can also be their undoing (see Chapter 14.6).

Conclusion

Identifying ADs and anxiety is important in populations with advanced illness because they are common and there are many stressors, both physical and existential, that may precipitate them.

Clinicians must be prepared to diagnose appropriately and treat wisely.

Suffering includes physical and psychosocial components. Physical symptoms, such as dyspnoea and pain, are generally treated with medications or other physical interventions. To manage psychological suffering, both pharmacotherapy and talking therapy should be considered. For patients with advanced illness, for whom many stressors are existential in nature and not due to long-standing pre-morbid psychiatric disorders, it is important to combine the two arms of therapy and not just to rely on psychotropic medications. A family meeting is critical to the understanding of the patient and for developing plans for ongoing care and discharge.

Clinicians need to 'clinically screen' patients by proactively asking about psychological symptoms. There is, however, no strong evidence that formally screening all patients improves outcome.

The clinical significance of ADs and anxiety is based on the assessment of symptoms and the degree of impairment of social or occupational functioning. It is neither a realistic nor appropriate goal to eliminate all symptoms. A sufficient aim is to control the symptoms enough to reduce distress and improve the ability to function. The goal of the palliative medicine clinician is to help the patient move from an AD to adjustment, and from anxiety to acceptance.

Delirium

Meera Agar, Yesne Alici, and William S. Breitbart

Introduction to delirium

Delirium is the most common neuropsychiatric disorder experienced by patients with advanced illness. It is characterized by disturbances in level of alertness, attention, thinking, perception, cognition, psychomotor behaviour, mood, and sleep–wake cycle. Acute onset and fluctuation of symptoms are critical features. Although conceptualized as a reversible process, it may not be reversible in the context of advanced illness, and indeed, may be a harbinger of imminent death (Breitbart and Alici, 2008).

The occurrence of delirium indicates significant physiological disturbance, usually involving multiple aetiologies. It may be associated with significant immediate morbidity, increased costs due to prolonged hospitalization, and long-term cognitive decline (Breitbart and Alici, 2008). It often distresses both families and staff (Breitbart et al., 2002) and can interfere with the recognition and control of other physical symptoms, such as pain.

Unfortunately, delirium often is under-recognized and under-treated. The heterogeneity of neuropsychiatric signs and symptoms, and the fluctuating course, may delay diagnosis and treatment. Specialists in palliative care must be able to screen for delirium, diagnose it accurately, undertake appropriate assessment of aetiologies, and be familiar with risks and benefits of pharmacological and non-pharmacological treatment options.

Definition

Delirium is a complex syndrome with a multifactorial aetiology, characterized by disturbance of cognition, arousal, and attention (Lipowski, 1990a; Caraceni and Grassi, 2011). The term 'delirium' is derived from the Latin word *delirare*, which means to 'go out of the furrow' (Lipowski, 1990b).

Epidemiology of delirium in advanced illnesses

Based on data from five studies, delirium prevalence on admission to palliative care units or hospices ranges from 13.3% to 42.3% and the incidence after admission ranges between 3% and 45% (Hosie et al., 2013). Two studies that explored delirium rates during the period prior to death observed a prevalence of 58.8–88% (Lawlor et al., 2000a; Hosie et al., 2013).

Pathophysiology

Recent studies indicate that delirium has a multifaceted pathophysiology. In addition to perturbations in dopamine-containing and cholinergic pathways, other neurotransmitters and neurobiological pathways have been implicated (Flacker and Lipsitz, 1999; Trzepacz, 2000; van der Mast and Fekkes, 2000; Wilson et al., 2005; MacLullich et al., 2008), Disturbances in serotonin, gamma-aminobutyric acid (GABA), cortisol, cytokines, and oxygen free radicals may be involved (Flacker and Lipsitz, 1999; Trzepacz, 2000; van der Mast and Fekkes, 2000; Wilson et al., 2005; MacLullich et al., 2008). Drug-induced delirium may be related to transient thalamic dysfunction caused by medication-induced interference with central glutamatergic, GABAergic, dopaminergic, and cholinergic pathways at critical sites of action (Gaudreau and Gagnon, 2005).

A recent model classifies the proposed aetiologies of delirium into (a) direct brain insults and (b) aberrant stress responses (MacLullich et al., 2008). Direct brain insults include general and regional energy deprivation (e.g. hypoxia, hypoglycaemia, and stroke), medication effects, and metabolic abnormalities (e.g. hyponatraemia, hypercalcaemia) (MacLullich et al., 2008). Aberrant stress responses may involve systemic inflammation, the sickness behaviour response, and activity of the limbic–hypothalamic–pituitary–adrenal axis (MacLullich et al., 2008).

Delirium assessment: clinical features and phenomenology

The gold standard for clinical diagnosis is a clinician assessment utilizing standard diagnostic criteria, most commonly the *Diagnostic and Statistical Manual of Mental Disorders* (DSM), fourth edition—text revised (DSM IV-TR), or alternatively, the International Classification of Disease, version 10 (ICD-10) of the World Health Organization (WHO) (American Psychiatric Association, 2000; WHO, 2010). The major components of the DSM IV-TR classification are disturbance of consciousness, a change in cognition, short and fluctuating chronology, and presence of an underlying medical condition. The fifth edition of the DSM (DSM-5) was released in May 2013 (American Psychiatric Association, 2013).The term consciousness has been removed from the delirium diagnostic criteria in DSM-5 to avoid diagnostic confusion between delirium and coma states. There has been much controversy and currently no data to inform implications of the DSM-5 for clinical care and research. The ICD-10 classification has the main components of impairment of consciousness and attention, global disturbance of cognition, psychomotor disturbance, disturbance of sleep–wake cycle, and emotional disturbance.

Delirium includes both cognitive and non-cognitive neuropsychiatric symptoms, including changes in motor behaviour, sleep–wake cycle, affective expression, perception, and thinking (Box 17.5.1) (Gupta et al., 2008). Both the frequency and specificity

Box 17.5.1 Delirium clinical features

Disturbance in consciousness

Cognitive deficits

- Attention
- Orientation to time, place, and person
- Short-term, verbal, visual, and long-term memory
- Executive functions.

Perceptual disturbance

- Illusions
- Hallucinations, in particular visual
- Metamorphoses.

Delusions

- Paranoid delusions, poorly formed.

Thought disorder

- Tangentiality
- Circumstantiality
- Loose associations.

Sleep–wake disturbance

- Fragmented sleep
- Reversal of normal sleep–wake cycle
- Sleeplessness.

Language disturbance

- Word finding difficulty
- Paraphasia
- Dysnomia
- Dysgraphia
- Severe delirium can mimic receptive/expressive aphasia.

Altered affect

- Incongruent mood to context
- Anger
- Increased irritability
- Hypoactivity misdiagnosed as depression
- Lability
- Fear.

Motor behaviours

- Increased or decreased activity
- Increased or decreased speed of actions
- Loss of control of activity
- Wandering
- Restlessness

- Combativeness
- Apathy/listlessness.

Source: Data from Trzepacz, P. T. & Meagher, D. J., Neuropsychiatric aspects of delirium, in Yudofsky, S. C. & Hales, R. E. (Eds.), *The American Psychiatric Publishing Textbook of Neuropsychiatry and Behavioural Neurosciences*, American Psychiatric Publishing, Washington DC, USA, Copyright © 2002; and Meagher, D., Motor subtypes of delirium: past, present and future, *International Review of Psychiatry*, Volume 21, Number 1, pp. 59–73, Copyright © 2009 Informa Plc. of these symptoms have been part of the debate in developing a definition of delirium, and approaches to classify and measure it. The frequency of core symptoms varies: attentional deficits 97–100%, thought process abnormalities 54–79%, disorientation 76–96%, memory deficits 88–96%, sleep–wake disturbance 92–97%, motoric alterations 24–94%, language disturbance 57–67%; and the non-core symptoms such as perceptual disturbance 50–63%, delusions 21–31%, and affective changes 43–86% (Webster and Holroyd, 2000; Meagher et al., 2007; Gupta et al., 2008).

Delirium screening instruments can be helpful to characterize clinical symptoms and potentially improve delirium detection rates. Commonly used screening instruments include the Confusion Assessment Method (Ryan et al., 2009) and the Nursing Delirium Assessment Scale (Gaudreau et al., 2005a).

The most studied delirium assessment tools for populations with cancer or advanced illness are the Memorial Delirium Assessment Scale (Breitbart, 1997) and the Delirium Rating Scale—Revised 98 (Trzepacz et al., 2001; Leonard et al., 2008b). These instruments assist clinicians in operationalizing DSM-IV criteria and monitoring severity.

In particular, patients who have predisposing risk factors, such as visual and hearing impairment, age greater than 65, pre-existing cognitive impairment, dehydration, immobility, multiple medications, and comorbid illness, should be monitored closely for delirium symptoms (National Institute for Health and Clinical Excellence (NICE), 2010). The studies exploring risk factors in cancer patients have been small, but implicate psychoactive medication, low albumin, and bone, liver, and intracranial metastases as additional risk factors (Fann et al., 2002; Ljubisavljevic and Kelly, 2003; Gaudreau et al., 2005b).

Delirium subtypes

Three clinical subtypes of delirium have been identified based on psychomotor features and arousal levels (Meagher, 2009). Patients with the hypoactive subtype appear lethargic and drowsy, respond slowly to questions, do not initiate movement, and have reduced awareness of surroundings (Breitbart and Alici, 2012). The hypoactive presentation often leads to misdiagnosis (fatigue or depression) (Meagher and Trzepacz, 2000.). Patients with the hyperactive subtype have restlessness, agitation, and psychomotor overactivity (Camus et al., 2000.). Perceptual disturbance and delusions are more common in this subtype than in hypoactive delirium (Boettger and Breitbart,

2011). More recently, longitudinal studies have demonstrated a group of delirious patients—the so-called no subtype—who have minimal motor activity change (Meagher et al., 2012b). Once established, the type of delirium seems to remain stable over time (Meagher et al., 2012b).

The DSM IV-TR criteria for delirium do not include categories to define psychomotor subtype (Meagher and Trzepacz, 1998, 2000). Methods that have been used include the presence or absence of particular psychomotor behaviours, quantitative measurement of psychomotor activity, validated scales to rate agitated behaviours (not specific for delirium), and most recently, the development of the delirium motor subtype scale (O'Keeffe, 1999; Meagher et al., 2008a, 2008b). There is poor concordance between these different methods of subtyping (Meagher et al., 2008b). It has been suggested that focusing on purely motoric features (Meagher et al., 2008a), and using independent quantitative methods such as electronic motion analysis (accelerometry), may assist in determining the true relationships between clinical subtypes, aetiologies, and outcomes (Leonard et al., 2007; Godfrey et al., 2010).

Increasing subsyndromal presentations also are recognized. For example, some patients with delirium present with symptoms in all core domains of sleep–wake cycle, thought process, language, attention, orientation, and visuospatial ability, but less severe symptoms overall (Meagher et al., 2012a; Trzepacz et al., 2012). This presentation can be particularly difficult to diagnose.

Several studies have explored delirium subtypes in varied populations, including those receiving specialist palliative care, those with advanced cancer, and those with haematological malignancies. These studies suggest that 40–78% of patients with delirium have the hypoactive subtype (Lawlor et al., 2000b; Morita et al., 2001; Lam, 2003; Fann et al., 2005; Gaudreau et al., 2005c; Spiller and Keen, 2006).

There has been much effort to determine if the delirium subtype has implications for differential diagnosis, aetiology, treatment, or prognosis (Meagher and Trzepacz, 1998; O'Keeffe, 1999; Gupta et al., 2008). This work has led to some tentative conclusions.

Differential diagnosis should consider that hyperactive delirium may mimic psychosis or anxiety disorders, whereas hypoactive delirium may be confused with depression or uncooperative behaviour (O'Keeffe, 1999).

It has been postulated that different neurotransmitter abnormalities may associate with delirium subtype (O'Keeffe, 1999.). For example increased GABA and reduced glutamate activity have been demonstrated in hepatic encephalopathy, and this may relate to the high prevalence of hyperactive delirium with this condition (O'Keeffe, 1999.). Some neurotransmitter abnormalities can cause varied phenomenology, for example, anticholinergic medication is typically associated with the hyperactive subtype but also can cause hypoactive and mixed presentations (Itil and Fink, 1966). The concentration of the melatonin metabolite, urinary 6-sulphatoxymelatonin, is highest in hypoactive delirium, lower in delirium with mixed presentation, and lowest in hyperactive delirium (Balan et al., 2003). Interleukin 6 has been associated with the hyperactive and mixed subtypes (van Munster et al., 2008).

Localized neuroanatomical lesions are also associated with particular presentations. For example, hyperactivity has been linked with middle temporal gyrus damage and frontostriatal injury has been associated with hypoactive presentations (Gupta et al., 2008).

In the main, the evidence seems to point to the hypoactive subtype having poorer outcomes (Meagher et al., 2011). Differences in morbidity include more pressure sores and hospital-acquired infection in hypoactive delirium and more falls in hyperactive presentations (O'Keeffe and Lavan).

Diagnostic workup

The presence of delirium implies the existence of an underlying medical disorder and a detailed history and examination should be undertaken to identify the aetiologies and determine whether they are reversible. Most episodes of delirium have an average of three precipitants (Leonard et al., 2008a). Common aetiologies include infection, substance withdrawal (alcohol and nicotine), metabolic abnormalities (e.g. hypercalcaemia), hypoxia, and psychoactive medications (corticosteroids, opioids, anticholinergics, and benzodiazepines) (Lawlor et al., 2000a; Breitbart et al., 2008; Leonard et al., 2008b). Predisposing delirium risk factors should be reviewed including older age, physical frailty, multiple medical comorbidities, dementia, admission to the hospital with infection or dehydration, visual impairment, deafness, polypharmacy, renal impairment, and malnutrition (Inouye, 2006).

The evaluation of delirium may require laboratory test, imaging, or an electroencephalogram. Laboratory tests can identify metabolic abnormalities (e.g. hypercalcaemia, hyponatraemia, and hypoglycaemia), hypoxia, or disseminated intravascular coagulation. Imaging can detect brain metastases or leptomeningeal disease, intracranial bleeding, or ischaemia. An electroencephalogram may rule out seizures. Occasionally, a lumbar puncture is needed to assess the possibility of leptomeningeal carcinomatosis or infectious meningitis (Breitbart and Alici, 2008).

When confronted with delirium in the terminally ill or dying patient, a differential diagnosis should always be formulated as to the likely aetiology or aetiologies. However, consideration of individual goals of care, and prior function and disease trajectory, is needed to determine the extent to which these aetiologies are investigated (Leonard et al., 2008a).

Differential diagnosis of delirium

Many of the clinical features of delirium can be associated with other psychiatric disorders such as depression, mania, psychosis, and dementia (Breitbart and Alici, 2008). Delirium, particularly the hypoactive subtype, is often initially misdiagnosed as depression. In distinguishing delirium from depression, particularly in the context of advanced disease, an evaluation of the onset and temporal sequencing of depressive and cognitive symptoms is particularly helpful. Importantly, the degree of cognitive impairment in delirium is much more severe than in depression, and usually has a more abrupt onset. Additionally, disturbance in level of alertness, which is characteristic of delirium, is not a feature of depression (Breitbart and Alici, 2008).

A manic episode may share some features of a hyperactive or mixed subtype of delirium. The temporal onset and course of symptoms, the presence of a disturbance in level of alertness, as well as of cognition, and the identification of a presumed medical aetiology for delirium are helpful in diagnosis. A past psychiatric history or family history of mood disorders is usually evident in patients with depression or a manic episode (Breitbart and Alici, 2008).

Delirium that is characterized by vivid hallucinations and delusions must be distinguished from a variety of psychotic disorders. In delirium, such psychotic symptoms occur in the context of advanced medical illness with features of disturbance in level of alertness and impaired attention span, as well as memory impairment and disorientation, which is not the case in other psychotic disorders (Breitbart and Alici, 2008).

The most challenging differential diagnostic issue is whether the patient has delirium, or dementia, or a delirium superimposed upon a pre-existing dementia. Both delirium and dementia are cognitive impairment disorders and share such common clinical features as impaired memory, thinking, judgement, aphasia, apraxia, agnosia, executive dysfunction, and disorientation. Delusions and hallucinations can occur in both disorders. To distinguish delirium from dementia, specific differences should be sought. In a study of 100 cancer patients that compared patients with delirium superimposed on dementia to those with delirium in the absence of dementia, the former presentation was characterized by more severe cognitive symptoms, poorer response to treatment, and a lower rate of resolution (Boettger et al., 2011). Clinically, the patient with dementia is alert and does not have the disturbance of level of alertness that is characteristic of delirium. The temporal onset of symptoms in dementia is more subacute and chronically progressive. Delirium is an acute change from the patient's baseline cognitive functioning, even if the patient has dementia or other cognitive disturbances at baseline (Breitbart and Alici, 2008). Treatment may lead to reversal of the symptoms and signs of delirium, even in the patient with advanced illness; this also distinguishes the syndrome from dementia. However, as noted previously, delirium may not be reversible in the last 24–48 hours of life. A number of instruments can aid clinicians in the diagnosis of delirium, dementia, or delirium superimposed on dementia (Wong et al., 2010).

Management of delirium

The management of delirium should include both correction of underlying causes, if possible, and treatment of the symptoms and signs of the disorder (Breitbart and Alici, 2012). To minimize distress to patients, staff, and family members, treatment of the symptoms and signs should be initiated before, or in concert with, a diagnostic assessment of the aetiologies. In the terminally ill patient who develops delirium in the last days of life ('terminal' delirium), management may present a number of dilemmas, and the desired clinical outcome may be significantly altered by the dying process. The desired and often achievable outcome is a patient who is awake, alert, calm, comfortable, cognitively intact, not psychotic, not in pain, and communicating coherently with family and staff (Breitbart and Alici, 2008).

Non-pharmacological interventions

In addition to seeking out and potentially correcting underlying causes of delirium, non-pharmacological and supportive therapies are important (Box 17.5.2). Fluid and electrolyte balance, nutrition, measures to help reduce anxiety and disorientation; interactions with and education of family members may be useful. A quiet, well-lit room with familiar objects, a visible clock or calendar, and the presence of family may help reduce anxiety and disorientation. In non-palliative care settings, there is evidence that these non-pharmacological interventions result in faster

---

> **Box 17.5.2** Summary of non-pharmacological interventions used in the prevention and treatment of delirium
>
> - Reducing polypharmacy
> - Control of pain
> - Sleep hygiene
> - Monitor for fluid/electrolyte disturbances
> - Monitor nutrition
> - Monitor for sensory deficits
> - Encourage early mobilization (minimize the use of immobilizing catheters, intravenous lines, and physical restraints)
> - Monitor bowel and bladder functioning
> - Reorient the patient frequently
> - Place an orientation board, clock, or familiar objects in the patient's room
> - Encourage cognitively stimulating activities.

improvement in delirium and slower deterioration in cognition. However, they were not found to have any beneficial effects on mortality or health-related quality of life when compared with usual care (Milisen et al., 2005; Pitkälä et al., 2006, 2008; Flaherty et al., 2010).

Physical restraints should be avoided in patients who are at risk for developing delirium and for those with delirium (Breitbart and Alici, 2008). Recent evidence suggests that restraint-free management of patients should be the standard of care for prevention and treatment of delirium (Flaherty and Little, 2011). One-to-one observation may be necessary while maintaining safety of the patient without use of any restraints.

Pharmacological interventions

There have been an increasing number of delirium prevention and treatment studies published within the last decade. Although there are no drugs specifically approved by the US Food and Drug Administration (FDA) for the treatment of delirium, antipsychotic or sedative medications often are required to control the symptoms or signs (Breitbart and Alici, 2012). Antipsychotics, cholinesterase inhibitors, and alpha-2 agonists are the three groups of medications studied in randomized controlled trials in different patient populations. In palliative care settings, the evidence is supportive of short-term, low-dose use of antipsychotics in the control of symptoms of delirium with close monitoring for possible side effects especially in older patients with multiple medical comorbidities (Breitbart and Alici, 2012).

Antipsychotics

There have been a number of case reports, case series, retrospective chart reviews, open-label trials, randomized controlled comparison trials, and most recently placebo-controlled trials with antipsychotics in the treatment of delirium (Breitbart et al., 1996; Han and

Kim, 2004; Hu et al., 2004; Jackson and Lipman, 2004; Lonergan et al., 2007; Devlin et al., 2010; Girard et al., 2010; Tahir et al., 2010; Grover et al., 2011; Breitbart and Alici, 2012). Study populations mostly include medically ill patients, postoperative patients, and patients in intensive care unit settings. Only a few studies focus specifically on patients with delirium in palliative care settings.

The American Psychiatric Association practice guidelines published in 1999 recommended the use of antipsychotics as the first-line pharmacological option in the treatment of symptoms of delirium (American Psychiatric Association, 1999).The guidelines recommend low-dose haloperidol (i.e. 1–2 mg orally (PO) every 4 hours as required or 0.25–0.5 mg PO every 4 hours for the elderly) as the treatment of choice when medication is necessary (American Psychiatric Association, 1999).

A 2004 Cochrane review concluded that haloperidol was the most suitable medication for the treatment of patients with delirium near the end of life, with chlorpromazine being an acceptable alternative based on one randomized controlled trial with haloperidol, chlorpromazine, and lorazepam (Jackson and Lipman, 2004).

A 2007 Cochrane review that compared the efficacy and adverse effects of haloperidol and atypical antipsychotics concluded that, like haloperidol, selected atypical antipsychotics (risperidone, olanzapine) were effective in managing delirium (Lonergan et al., 2007). Haloperidol doses greater than 4.5 mg/day resulted in increased rates of extrapyramidal symptoms compared with the atypical antipsychotics, but low-dose haloperidol (i.e. < 3.5 mg/day) was not shown to result in a greater frequency of extrapyramidal adverse effects (Lonergan et al., 2007).

Based on these published data, low-dose haloperidol continues to be the first-line agent for treatment of symptoms of delirium (Breitbart and Alici, 2012). In those with advanced illness, haloperidol is preferred due to its efficacy, tolerability (due in part to few anticholinergic effects), and its lack of active metabolites (Breitbart and Alici, 2008). It also may be given by various routes of administration. When used intravenously, however, the US FDA has warned about the risk of QTc prolongation and torsades de pointes; therefore, monitoring QTc intervals closely during intravenous haloperidol has become standard clinical practice. If haloperidol is not tolerated, the atypical antipsychotics are effective alternatives (Lonergan et al., 2007; Breitbart and Alici, 2012).

Based on clinical experience, lorazepam often is added to haloperidol to manage an acute delirium, particularly when hyperactive. Lorazepam (0.5–1.0 mg every 1–2 hours PO or intravenously (IV)) may be more effective in rapidly sedating the agitated delirious patient and may minimize extrapyramidal side effects associated with haloperidol. An alternative strategy is to switch from haloperidol to a more sedating antipsychotic, such as chlorpromazine. The latter approach is most acceptable when the patient is in a monitored setting and blood pressure can be checked frequently. It is important to monitor for anticholinergic and hypotensive adverse effects of chlorpromazine, particularly in elderly patients (Breitbart and Alici, 2012).

The potential risks associated with antipsychotic drug treatment should be considered before the first dose is given. These risks include the possibility of extrapyramidal effects, sedation, anticholinergic side effects, cardiac arrhythmias, and possible drug–drug interactions. These concerns are particularly salient in older patients with dementia. The US FDA has issued a warning

about the increased risk of mortality associated with the use of antipsychotics in elderly patients with dementia-related behavioural disturbances. This warning was based on a meta-analysis by Schneider et al of 17 placebo-controlled trials involving patients with dementia (Schneider et al., 2005). The risk of death in patients treated with atypical antipsychotic agents was 1.6–1.7 times greater than in those who received placebo. Most deaths were associated with cardiovascular disease or infection. A second, retrospective study of nearly 23 000 older patients found that mortality rates were higher with typical than with atypical antipsychotics—whether or not they had dementia (Wang et al., 2005). This finding led to an extension of the FDA warning to typical antipsychotics, including haloperidol.

Other studies that have evaluated the risk of excess mortality during antipsychotic drug treatment have yielded mixed results. A retrospective cohort study of Medicaid enrolees in Tennessee demonstrated an increased risk of serious ventricular arrhythmias and sudden cardiac death among users of both typical and atypical antipsychotics (Ray et al., 2009). In contrast, a retrospective, case–control analysis of 326 elderly hospitalized patients with delirium at an acute care community hospital included 111 patients who received an antipsychotic and found non-significant odds ratios of dying during treatment of 1.53 (95% confidence interval (CI) 0.83–2.80) in univariate and 1.61 (95% CI 0.88–2.96) in multivariate analyses (Elie et al., 2009). Additional prospective studies with larger sample sizes will be needed to clarify this association further.

In palliative care settings, the evidence is most clearly supportive of short-term, low-dose use of antipsychotics for the control of symptoms of delirium. Close monitoring for possible side effects is essential, especially in older patients with multiple medical comorbidities (Table 17.5.1) (Breitbart and Alici, 2012).

Psychostimulants

The use of psychostimulants in the treatment of hypoactive subtype of delirium has been suggested by case reports and one open-label study (Keen and Brown, 2004; Gagnon et al., 2005). These drugs can precipitate agitation and exacerbate psychotic symptoms, however, should be used very cautiously in palliative care settings.

Cholinesterase inhibitors

Impaired cholinergic function has been implicated as one of the final common pathways in the pathogenesis of delirium (MacLullich et al., 2008). Despite case reports of beneficial effects of donepezil and rivastigmine, a 2008 Cochrane review concluded that there is currently no evidence from controlled trials supporting the use of cholinesterase inhibitors in the treatment of delirium (Overshott et al., 2008). On the basis of the existing evidence from general hospital and critical care settings, and the lack of studies in palliative care settings, cholinesterase inhibitors cannot be recommended in the treatment of delirium.

Dexmedetomidine

Dexmedetomidine is a selective alpha-2 adrenergic receptor agonist indicated in the United States for the sedation of mechanically ventilated adult patients in intensive care settings and in non-intubated adult patients prior to and/or during surgical and other procedures. It has analgesic effects and has been considered for the prevention and treatment of delirium (Riker et al.,

Table 17.5.1 Antipsychotic medications used in the treatment of delirium

Medication	Dose range	Routes of administration	Side effects	Comments
Typical antipsychotics				
Haloperidol[a]	0.5-2 mg every 2–12 hours	PO, IV, IM, SC	Extrapyramidal adverse effects can occur at higher doses. Monitor QT interval on electrocardiogram	Remains the gold-standard therapy for delirium. May add lorazepam (0.5–1 mg every 2–4 hours) for agitated patients. Double-blind controlled trials support efficacy in treatment of delirium. A pilot placebo-controlled trial suggests lack of efficacy when compared to placebo
Chlorpromazine[a]	12.5–50 mg every 4–6 hours	PO, IV, IM, SC, PR	More sedating and anticholinergic compared with haloperidol. Monitor blood pressure for hypotension. More suitable for use in intensive care unit settings for closer blood pressure monitoring	May be preferred in agitated patients due to its sedative effect. Double-blind controlled trials support efficacy in treatment of delirium. No placebo-controlled trials
Atypical antipsychotics				
Olanzapine[a]	2.5–5 mg every 12–24 hours	PO[b], IM	Sedation is the main dose-limiting adverse effect in short-term use	Older age, pre-existing dementia, and hypoactive subtype of delirium have been associated with poor response. Double-blind comparison trials with haloperidol and risperidone support efficacy in the treatment of delirium. A pilot placebo-controlled prevention trial suggested worsening in delirium severity. A placebo-controlled study is supportive of efficacy in reducing delirium severity and duration
Risperidone[a]	0.25–1 mg every 12–24 hours	PO[b]	Extrapyramidal adverse effects can occur with doses > 6 mg/day. Orthostatic hypotension	Double-blind comparison trials support efficacy in the treatment of delirium. No placebo control trials
Quetiapine[a]	12.5–100 mg every 12–24 hours	PO	Sedation, orthostatic hypotension	Sedating effects may be helpful in patients with sleep–wake cycle disturbance. Pilot placebo-controlled trials suggest efficacy in treatment of delirium. However, studies allowed for concomitant use of haloperidol which makes the results difficult to interpret
Ziprasidone	10–40 mg every 12–24 hours	PO, IM	Monitor QT interval on electrocardiogram	Placebo-controlled, double blind trial suggests lack of efficacy in the treatment of delirium
Aripiprazole[c]	5–30 mg every 24 hours	PO[b], IM	Monitor for akathisia	Evidence is limited. A prospective open label trial suggests comparable efficacy to haloperidol. No placebo-controlled trials

[a] Despite shortcomings of the studies described in the text there is US Preventive Services Task Force (USPSTF) level I evidence for the use of haloperidol, risperidone, olanzapine, and quetiapine in the treatment of delirium.

[b] Risperidone, olanzapine, and aripiprazole are available in orally disintegrating tablets. There have been no intervention or prevention trials with the use of recently released antipsychotics including paliperidone, iloperidone, asenapine, or lurasidone in the treatment or prevention of delirium.

[c] There is USPSTF level II-2 evidence for the use of aripiprazole in the treatment of delirium.

2009; Pandharipande et al., 2010; Prommer, 2011). Clinical trials in the intensive care unit have shown mixed results for the prevention and treatment of delirium (Riker et al., 2009; Pandharipande et al., 2010) and there have been no studies in palliative care settings.

Prevention of delirium

The development of effective strategies to prevent delirium should be a high priority in palliative care settings. Promising results in the elderly hospitalized population have been observed with various non-pharmacological interventions (Inouye et al., 1999; Siddiqi et al., 2007; NICE, 2011). In the latter population, the study effect sizes suggest that the incidence of delirium may be reduced by as much as one-third with multicomponent interventions (Siddiqi et al., 2007; NICE, 2012). In contrast, a simple multicomponent preventive intervention was found to be ineffective in reducing delirium incidence or severity among cancer patients ($N = 1516$) receiving end-of-life care; no difference was observed between the intervention and the usual-care groups in delirium incidence (odds ratio 0.94, p = 0.66), delirium severity (1.83 vs 1.92, p = 0.07), total

days in delirium (4.57 vs 3.57 days, p = 0.63), or duration of first delirium episode (2.9 vs 2.1 days, p = 0.96) (Gagnon et al., 2010).

A variety of pharmacological interventions have also been considered for the prevention of delirium. Antipsychotics, cholinesterase inhibitors, melatonin, and dexmedetomidine have been evaluated in randomized controlled studies conducted in different settings (Kalisvaart et al., 2005; Liptzin et al., 2005; Sampson et al., 2007; Gamberini et al., 2009; Riker et al., 2009; Larsen et al., 2010; Pandharipande et al., 2010; Prommer 2011; NICE, 2012). A 2007 Cochrane review concluded that the evidence for the effectiveness of interventions to prevent delirium was sparse and no recommendations could be made regarding the use of drug therapy for delirium prevention (Siddiqi et al., 2007). Studies published since 2007 have shown mixed results with cholinesterase inhibitors, antipsychotics, melatonin, and dexmedetomidine (Breitbart and Alici, 2012), and there continues to be no established treatment to prevent delirium in palliative care settings.

Controversies in the management of terminal delirium

Delirium that evolves to active dying is terminal delirium. The management of this syndrome is controversial. One study showed that physicians from different disciplines manage terminal delirium differently (Agar et al., 2012); medical oncologists were found to be more likely to manage terminal delirium with benzodiazepines or benzodiazepine and antipsychotic combinations, whereas palliative care physicians were more likely to use antipsychotics to manage delirium symptoms, including the hypoactive subtype of delirium.

Some have argued from a philosophical perspective that pharmacological interventions with antipsychotics or benzodiazepines are inappropriate in the dying patient because delirium is a natural part of the dying process and should not be altered. Clinical experience, however, indicates that the development of delirium can be highly distressing to the patient and family and that the use of antipsychotics to manage agitation, paranoia, hallucinations or altered sensorium is safe, effective and often quite appropriate (Breitbart and Alici, 2008). The use of drug therapy in those believed to be approaching death is best managed on a case-by-case basis, balancing a 'wait and see' approach without the use of pharmacological interventions against the level of overt distress and the knowledge that patients with hypoactive delirium—who may not appear distressed—may quickly and unexpectedly become agitated. It is important to remember that, by their nature, the symptoms of delirium are unstable and fluctuate over time.

Perhaps the most challenging clinical problem is the management of the dying patient with a 'terminal' delirium that is unresponsive to standard antipsychotic interventions, whose symptoms can only be controlled by sedation to the point of a significantly decreased level of consciousness. While antipsychotics are most effective in diminishing agitation, clearing the sensorium and improving cognition is not always possible in delirium which complicates the last days of life. Approximately 30% of dying patients with delirium do not have their symptoms adequately controlled with antipsychotic medications (Fainsinger et al., 2000; Rietjens et al., 2008). Processes causing delirium may be ongoing and irreversible during the active dying phase. In such cases, a reasonable choice is the use of sedative agents such as benzodiazepines (e.g. midazolam, lorazepam) or propofol (and sometimes

an opioid, if the drug has proved to be demonstrably sedative) to achieve a state of quiet sedation (Fainsinger et al., 2000; Rietjens et al., 2008). Indeed, delirium has been identified as the main indication for the use of palliative sedation (Fainsinger et al., 2000; Sykes and Thorns, 2003; Lo and Rubenfeld, 2005; Rietjens et al., 2008). Clinicians who are concerned that the use of sedating medications can hasten death via respiratory depression, hypotension, or even starvation, should note that studies in hospice and palliative care settings have not confirmed this association (Bercovitch and Adunsky, 2004; Vitetta et al., 2005).

Before administering a sedative to achieve a calm and comfortable but sedated and unresponsive patient, the clinician must first take several steps. The clinician must have a discussion with the family (and the patient, if there are lucid moments when the patient appears to have capacity), eliciting their concerns and wishes for the type of care that can best honour their desire to provide comfort and symptom control during the dying process. The clinician should describe the optimal achievable goals of therapy as they currently exist. Family members should be informed that the goal of sedation is to provide comfort and symptom control, not to hasten death. Sedation in such patients is not always complete or irreversible; some patients have periods of wakefulness despite sedation, and many clinicians will periodically lighten sedation to reassess the patient's condition. Ultimately, the clinician must always keep the goals of care in mind and communicate these goals to the staff, patient, and family members. The clinician must weigh each of the issues outlined above in making decisions on how to best manage the dying patient who presents with delirium that preserves and respects the dignity and values of that individual and family (Breitbart and Alici, 2008).

Prognostic implications of delirium in the terminally ill

It is important to emphasize the prognostic value of delirium in terminally ill patients. Delirium is a relatively reliable predictor of approaching death in the coming days to weeks (Casarett and Inouye, 2001). In the palliative care setting, several studies provide support that delirium reliably predicts impending death in patients with advanced cancer (Morita et al., 2011). Given the prognostic significance of delirium, recognizing an episode of delirium in the late phases of an illness is critically important in treatment planning and in advising family members.

Conclusion

Palliative care clinicians commonly encounter delirium as a major neuropsychiatric complication of terminal illness. Screening, assessment, diagnosis, and management of delirium are essential in improving quality of life and minimizing morbidity in palliative care settings for patients, families, and health-care professionals.

The family perspective

Carrie Lethborg and David W. Kissane

The family, not just the patient, deals with and attempts to understand the meaning of cancer, and it is the meaning of cancer to the family that sets the context within which dynamic processes occur. (Lewis 1990, p. 759)

Introduction to the family perspective

More often than not, a person's family background, over and above any other factor, influences the meaning they ascribe to a serious illness. Each person is shaped by, and in turn shapes, their world view. A major component of any person's world view is their family, defined here simply as 'those individuals considered as family by that person' (Ferrell, 1998). The family provides the individual with their history, a strong pattern of beliefs (including those about serious illness and its treatment), traditions, and an identity. Each individual is inextricably linked to and affected by the life of their family, which in turn, responds to changes in the individual. In order to fully understand the impact of an illness on a patient then, we do a disservice to them unless the impact on and of the family as a whole is also considered.

If the health-care professional is serious about providing whole-patient care, it is imperative that the context in which patients *live with* their illness is understood. A family-centred approach to palliative care then, is crucial to any comprehensive service (Northouse, 1984; Quinn and Herndon, 1986; Pederson and Valanis, 1988; Zabora and Smith, 1991).

In addition to understanding the patient within their family context, it is also important to understand the impact of serious illness *on* the wider family. According to systems theory, family members are reciprocally affected by illness in each other. Thus, Northouse and (1993) described serious illness as an assault on the entire family. Indeed, throughout the illness trajectory, a family's emotional, physical, and financial resources can be sequentially challenged by a series of medical crises (Jacobs et al., 1998). Failure to understand this impact leads to inadequate support for the complete range of people affected (Hacialioglu et al., 2010).

Moreover, families should be considered an important *resource* to the health-care team. Often providing the majority of home-based care for palliative patients, they form a crucial component of any programme. If patients are viewed in isolation, both the care provided to them and the resources that could be mobilized are limited. Consistently, the literature has strongly argued that in palliative care, treatment of the whole family is the optimal approach (Cassileth and Hamilton, 1979; Rait and Lederberg, 1989; Bluglass, 1991; Baider et al., 1996; Lederberg, 1998).

This chapter will explore the concept of the patient in context, the impact of serious illness on the family, and the family as caregiver. It will also consider the assessment of families and their needs and some of the interventions that clinicians can utilize to better assist the family in the setting of palliative care. Families who are well supported will, in turn, be better able to care for their loved ones.

The impact of serious illness on the family

The key to understanding the way illness impacts on the family as a whole is to make sense of two important characteristics of its overall system: (a) the sharing of suffering and (b) the homeostatic force within the family to maintain its usual patterns of relating and living.

The interchange of suffering within the family

Life with a beloved suffering from serious illness may be more difficult than having such an illness oneself (Hilton, 1993; Marshall et al., 2011). Firstly, there is what the Sutherland group (1956) described as *the intimate reciprocity of suffering*. Levels of despair or optimism in patients and family carers are interrelated and are a significant predictor of each other's mental health (Given and Given, 1992; Kurtz et al., 1995; Wittenberg-Lyles et al., 2011). Relatives of the seriously ill thus have higher levels of depression and anxiety than the general population (Stuber et al., 1991). Rates of psychological distress for spouses of cancer patients, for example, have ranged between 18% and 35% (Buckley, 1977; Plumb and Holland, 1977; Maguire, 1981; Gotay, 1984; Ell et al., 1988; Northouse, 1989; Kissane et al., 1994a). In one Australian study, one-quarter of adult offspring of cancer patients exhibited significant distress (Kissane et al., 1994a).

The suffering of the palliative patient, especially in the face of poorly controlled physical symptoms, is a particular trigger for

increased anxiety and physical concerns for family members themselves (Ferrell, 1998, Lewis, 1986; Northouse, 1988; Sales, 1991; Hilton, 1993, Kristjanson and Aoun, 2004). In fact, the anguish involved in caring for someone who is living with advanced disease promotes such a level of stress that one should think of close family members as 'second-order patients' (Rait and Lederberg, 1989). Hudson et al. (2011) reported that in a cohort of 302 family caregivers of patients with advanced, life-threatening disease, 44% had anxiety and/or depressive disorders.

While family members can provide a type of 'buffering' to protect and sustain patients (Wilson and Morse, 1991; Sabo et al., 1986), this support is not necessarily mutual in that the patient may have a diminished ability to reciprocate. Their carers may thus find they are responsible for the majority of the emotional support in the relationship. Conflict and greater family disharmony can grow from dissatisfaction with these relationships.

The tendency towards sustaining stability

The second important characteristic to understand in relation to the family system in the setting of illness is that in most cases families gravitate towards maintaining equilibrium in its structure. This homeostatic pull promotes the maintenance of a structure of predictability, security, and cohesiveness (including both positive and negative traits), and will often struggle when faced with uncertainty (Lederberg, 1998). The family affected by serious illness must maintain itself through many changes. These include adoption of the role of the ill member (breadwinner, mother, or patriarch), adjustment to loss, meeting the emotional needs of members in crisis, and continuing to perform standard family functions.

The structure that the family strives to maintain is informed by its unique culture, values, attitudes, norms, roles, and the beliefs peculiar to each family. There are unspoken, yet powerful, regulating actions and relationships, based on a power structure whereby decisions are made and consequences enforced. The family's attitudes towards autonomy, desired medical communication, explanatory models of illness, and the roles of its members all influence its harmony and well-being (Gotay, 2000, pp. 99–101).

Family traditions are translated into a 'script' (Byng Hall, 1988), a subtle yet definitive influence on each member, in varying degrees, throughout their lives. These manifest like a tape recording that is played in each individual's mind to guide their choices. An example is the patient who still hears their father's voice saying, 'Don't trust doctors'. Clinicians need to consider that there are specific traditions for each patient and family when providing information and discussing decision-making. The following vignette illustrates how the family's culture can impact on the medical consultation process:

Joseph Ramirez was a 68-year-old man, newly diagnosed with end-stage prostate cancer. He had been married to Maria for 49 years and they had three sons: Michael (aged 48), Marko (45), and Frederik (40). Since Joseph had retired, his health had deteriorated and, as weakness increased, he had begun to hand over his position of 'head' of the family to Michael—asking him to make financial and lifestyle decisions. Maria had always been quite passive in her marriage and she was comfortable with whatever her son decided.

When Joseph was diagnosed, Michael felt quite anxious about the additional burden placed on him—especially given his own responsibilities as a husband, father, and with work. When he and his father attended the first consultation with his specialist, Dr Sinclair, Joseph constantly turned to Michael for advice, causing Michael to take a lead role in the meeting, pre-empting questions and pressing for definitive answers about treatment and prognosis.

Dr Sinclair found this consultation disconcerting and was worried that Joseph was being held back from directing his own care. He tried to redirect questions back to Joseph asking 'Well what do *you* think, Mr. Ramirez?'

At the end of the consultation, all parties left feeling frustrated. Joseph felt confused and pressured; his son Michael felt offended, stressed, and was contemplating getting a second opinion for his father. Dr Sinclair felt annoyed that Michael was interfering with his care of his father.

If Dr Sinclair had taken some additional time to understand the family's dynamics, he may have found it easier to work with them. Recognizing the potential relevancy of the son's attendance, he could have started by asking Joseph about his family and his feelings regarding his illness and then enquired of Michael, asking him about *his* concerns prior to launching into the medical issues of the consultation. Often a short time taken to get to know the family background will save time in the future and avoid both confusion and anger. Clinicians ought not impose their own value systems but be curious about those of the family. Although Dr Sinclair presumed that patients would make their decisions autonomously, he may have foreseen how consultation within the Ramirez family could also work.

This vignette raises a common dilemma in the palliative setting which is worth special mention. Truth telling, or relaying bad news to a patient, one of the most challenging and complex areas of patient/doctor communication, can be further complicated by the request from a relative to not tell the patient specific information such as diagnosis, prognosis, and/or treatment plans. In Western countries, it is generally accepted that it is the patient's right to be told the truth about their diagnosis and prognosis in a manner in which they can fully grasp its consequences and be a full participant in decision-making. Indeed, breaking bad news is a growing aspect of training in both undergraduate and postgraduate medical education. Yet, the idea that full disclosure is 'best' for the patient is not necessarily shared in all cultures or all families (O'Kelly et al., 2011).

Some families believe that full disclosure of a poor prognosis to patients places an unacceptable burden on them, reducing hope and the will to fight their disease. In some cases, the family perceives that the patient will 'give up' and die because of the words of the physician. The family expects to be told the diagnosis and prognosis and make decisions for the patient to 'shield' them (Hook, 2000). These situations raise difficulties for the health-care team and families alike and it is important to develop guidelines to manage this sensitively. The following broad principles can be helpful:

◆ There are legal and ethical standards, which necessitate that the patient is informed about their medical condition and that they understand this information sufficiently to be competent to the extent that they are able to give informed consent about treatment-related issues. In addition, there are privacy laws that govern what information about a patient can and can't be shared with others.

◆ Refusing to take into account the genuine wishes of the family about how they chose to manage a crisis such as serious illness can result in communication breakdown between the patient/family and treatment team. Such tension only adds to the trauma for the family and the level of difference for the treatment team.

◆ Though it should never be assumed, it is important to remember that in many cases, patients who say they don't want to know their diagnosis are in fact aware of it at some level, but chose to manage their illness through avoidance and or denial.

◆ The wishes of families and patients about how information is communicated require compassion on the part of the treating team to understand the issues for each member. Being able to discuss fear surrounding the breaking of bad news or poor prognosis can often dispel myths and enable collaboration about how the family and the team *can* work together.

Keeping these concepts in mind, it is clearly prudent to aim to prevent the situation where the family is at the patient's door asking the physician to not enter and reveal the results of diagnostic and/or prognostic tests. There is benefit, whenever possible, in talking to all patients about *how* they would like to be told the outcomes of various tests *prior* to undertaking them—this would include where and when they would like to be told, the complexity of the information they would like revealed and who they would like to be present (Clayton and Kissane, 2010). When present with the patient, it is always pertinent to start with what the patient already understands and to again ask what they want to know about specific aspects, before launching into giving any information (Kissane, 2010). Families who have raised concerns about truth-telling should be advised that this will be the manner in which the information will be shared, proportional to what the patient requests and with sensitive delivery.

The family as caregiver

At the same time that family members are adjusting to the impact of serious illness and its uncertainty, many are also expected to take on the complex role of primary caregiver (Given and Given, 1992) and, indeed, many see this role as their duty (McLaughlin et al., 2011). Moreover, the medical system is often funded on the premise that patient care will occur as much as possible in the home to reduce the cost of inpatient services.

Increasingly sophisticated treatments such as chemotherapy are now being offered in the home and the philosophy of hospice care emphasizes patient support in this setting. Given the complexity involved, one could argue that never in history has as much been demanded of family members as carers.

In this context, direct care tasks for the family include dispensation of medications, assistance with nausea, vomiting, and pain relief, washing and other personal care tasks, meal preparation as well as tending to laundry, visitors, and answering phone calls from concerned friends. These tasks would require in the inpatient setting a range of staff, but they are provided by the family on a 24-hour basis, often including support during the night.

While the toll from these tasks could be overwhelming even without complications, there are certain activities that are especially complex: (a) provision of medication for pain, (b) maintenance of nutrition, (c) provision of emotional support for the patient, and (d) the practical nursing and care-provision tasks. For example, the introduction of morphine could be wrongly viewed as the beginning of the dying process and the development of cachexia can cause conflict as the caregiver pushes food as a means towards increasing strength (Reid et al., 2009). In addition, regular roles, such as being husband or wife, mother or daughter are easily lost, when intimacy is crucial. However, families

generally make a valiant effort and, in the process, often display great courage.

The longer the caregiving role, the more difficult it is to sustain energy to provide both physical as well as psychological care. Psychological symptoms may increase proportional to the length of illness (Lederberg, 1998). In the article titled, 'Sleeping with one eye open', Hearson and associates (2011) described the extent of the impact of sleep deprivation on family caregivers in palliative care, illustrating that almost 40% experienced excessive daytime sleepiness. The sustained effort, compounded by anxiety, adds to the exhaustion that comes with the burden of care in the palliative setting, and the reluctance of many to ask for help for themselves (Richards et al., 2011).

Yet, though the role of carer is clearly stressful in many ways, it is important to remember the positives involved for both patient and caregiver. There is consistent evidence linking successful family-based support with increased psychosocial adaptation for all concerned (Bloom, 1978; Woods and Earp, 1978; Northouse and Swain, 1987; Northouse, 1988; Mishel and Braden, 1989). Families serve as the primary referent and emotional support base for their members who become medically ill (Litman, 1974). Families also provide essential, instrumental functions that enable patients to adhere to arduous treatment protocols and manage the debilitating side effects associated with modern cancer treatment. The effectiveness of symptom control in palliative care is greatly enhanced by the presence of the family as caregiver (Schachter and Coyle, 1998). Families, in turn, also report a number of positives in their own lives and relationships as a result of their experience (Folkman, 1997).

The needs of the family-based caregiver

Much of the suffering of families in the palliative setting results from being ill prepared and struggling with uncertainty and helplessness (Cherny et al., 1994). Family carers often state that they wish they had been taught some of the skills required for their caring role by health-care providers rather than having to work them out for themselves through 'trial and error'. There are a number of unmet needs among caregivers. Some of the most commonly reported needs include:

◆ information about diagnosis and expected prognosis (Wright and Dyck, 1984; Tringali, 1986; Schofield et al., 1998; Finney Rutten et al., 2005)

◆ assistance in dealing with the patients' physical symptoms (Tringali, 1986; Hileman and Lackey, 1992; Kristjanson and Ashcroft, 1994; Watson, 1994; Harrington et al., 1996; Schofield et al., 1998)

◆ assistance in dealing with feelings such as inadequacy, guilt, anxiety, fear, and grief (Northouse, 1984; Stetz, 1987; Woods et al., 1989; Wingate and Lackey, 1989; Hileman and Lackey, 1990; Nolan et al., 1990; Schofield et al., 1998)

◆ managing the personal impact of caring such as sleep disturbance, weight loss, maintaining family stability, and recognition of altered roles and choices (Northouse and Peters-Golden, 1993; Schofield et al., 1998)

◆ guidance about coping strategies (Klagsburn, 1994; Given and Given, 1996; Schofield et al., 1998, Meyers et al., 2011).

In addition to these psychological and physical needs of the family, there are considerable costs involved with caring for a loved one with serious illness. These can be both direct and indirect, with at least 25% of family carers being unable to continue employment, thus suffering substantial losses of income (Schofield et al., 1998). Many carers also find they lose friends (though others are surprised by those who *are* supportive), and are unable to continue prior levels of involvement with sport or other interests. Given the wide ranging effects of the caregiving role, comprehensive assessment is required when considering supportive care of these families.

Assessing the family for intervention

While the impact of serious illness can be considered to be catastrophic enough to argue for an evaluation of *each* family, this is clearly not a practical option (Zaider and Kissane, 2009). It is more common for staff to develop concerns for family members when they are not providing expected practical or emotional support (Jacobs et al., 1998). This is also not an effective basis for decisions about resource allocation. What *is* necessary is the ability to screen for those families who are at greater risk of maladaptive outcome, so that scarce resources can be allocated to those in greater need (Kissane et al., 2007–2008).

An interesting approach to the identification of those families in most need of supportive intervention grew out of empirical observations about the significant association between family functioning and psychosocial outcome during palliative care and bereavement (Kissane et al., 1994). Dysfunctional families carried significantly more psychosocial morbidity among their members, such that screening for family functioning provided a method of recognition of those in greater need. Indeed, the 12-item Family Relationships Index (FRI) (derived from the Family Environment Scale; Moos and Moos, 1981) provides information on the family's cohesiveness, shared expression of thoughts and feelings, and conflict, and thus serves as a simple pencil-and-paper screening test. Well-functioning families are cohesive and score more than 9 out of 12 on an FRI. Families at risk of poorer outcome have been termed *hostile, sullen*, or *intermediate*, reflecting varying levels of conflict, poor communication and lack of any sense of togetherness (Kissane et al., 1998, 2003). A model of intervention that targets enhancing these dimensions of family functioning has been described as family-focused grief therapy (FFGT) (Kissane et al., 2006). It is initiated during the stage of advanced disease, as the family becomes more involved with care, and is continued into bereavement to maintain continuity of care. Such an approach to screening families, with preventive intervention for those at risk, will become the necessary working model for the future.

Family assessments should be aimed at leading the health professional to an increased understanding of the medical and psychosocial situation of the family system (Schachter and Coyle, 1998). Developing an understanding of the major concerns of individual members and the family as a whole empowers planning of appropriately focused interventions. We find a checklist as portrayed in Box 17.6.1 helpful to ensure that family assessments are thorough in their detail.

Understanding the impact of practical issues on the family is also important for effective functioning. Practical issues include the financial impact of serious illness on the family, the impact on work and home life, division of labour in the family, availability

---

> **Box 17.6.1** Themes warranting evaluation during family assessment
>
> ◆ Family understanding of the illness, key symptoms, and treatment
> ◆ Major concerns at this moment: prognosis, death and dying, caregiving needs

> ◆ Family functioning: cohesion, communication, and conflict
> ◆ Developmental and past history: prior experience of loss and relational strains
> ◆ Useful coping strategies: problem-solving, team work, emotional support
> ◆ Social issues: employment, finances, living arrangements
> ◆ Community resources: meals, cleaning, volunteers, respite
> ◆ Presence of children at home and their needs
> ◆ Spiritual needs
> ◆ Expectations and future concerns, what to expect as death approaches, how to talk with the patient about dying, how to say goodbye and how to manage a death in the home
> ◆ How to help each other in bereavement.

of family members to provide the care needs required, and the appropriateness of the physical surroundings to care for someone.

In addition to the specific concerns of the family, the clinician needs to consider each family's ability to adjust to change that is inevitable during palliative care. While a normal grief response is expected following each change in disease status, the level of intervention required will depend on the ability of family members to comfort and support each other.

Family-centred principles for intervention

In general, interventions for families in the setting of advanced disease are provided in two broad areas: (1) those that are preventive, supportive, and focus on enhancing coping; and (2) those that deal with actual dysfunction in the family. However there are a number of general principles of family-centred therapy that apply to all interventions (Kovacsa et al., 2006). Box 17.6.2 outlines the key goals and principles in conducting family meetings.

Open communication and information provision

Open communication from the health-care team is crucial in attempting to include the family in the treatment plan. To begin with, the provision of information is empowering to the family. Knowledge relieves family anxiety, improves problem-solving, and enhances both emotional and physical well-being (Stewart, 1996). Yet in response to encouraging open discussion of the family's experience, the practitioner must go on to provide emotional comfort and legitimization of their feelings and concerns.

All information about palliative care and advanced disease is value-laden for those living with the disease. Specific discussion about deterioration and dying can be difficult to process. Clinicians need to proceed sensitively, respectfully, and also model

<table>
<tr><td>

Box 17.6.2 Key goals and principles in conducting family meetings

- Open communication and willing provision of medical information
- Identification of issues or concerns held by family members
- Recognition of current and past patterns of relating
- Problem-solving around the provision of instrumental care
- Encouragement of acceptance of community support
- Affirmation of strengths and courage of the family as a whole
- Comfort for the inherent suffering yet optimism about their capacity to cope.

</td><td>

Box 17.6.3 A clinical roadmap to run a family meeting in palliative care

1. Planning and prior set-up to arrange the family meeting—who to invite?
2. Welcome and orientation of the family to the goals of the family meeting
3. Check each family member's understanding of the illness and its prognosis
4. Check for consensus about the current goals of care
5. Identify family concerns about the management of key symptoms and care needs
6. Clarify the family's view of what the future holds
7. Clarify how family members are coping and feeling emotionally
8. Identify family strengths and affirm their level of commitment and mutual support for each other
9. Close the family meeting by final review of agreed goals of care and consensus about future care plans.

</td></tr>
</table>

the openness that is possible. Some families grow closer as a result of this challenge (Bloom, 1982; Neuling and Winefield, 1988), but others get stuck in awkwardness and avoidance (Reiss et al., 1993). Prior patterns of intimacy, comfort, and support can be fostered during this time if information is shared in a sensitive way to promote understanding and teamwork (Griffith and Griffith, 1994).

Recognition of past patterns of relating

Families develop patterns of relating and coping that influence the way they subsequently handle the impact of serious illness (Sales et al., 1992). Past stress and loss affect the attitude and resources a family brings to this experience (Bloch et al., 1994). Recognition and acknowledgment of transgenerational patterns of relating can empower adoption of new choices for mutual support (Kissane and Bloch, 2002).

Encouragement of acceptance of outside support

The emotional cost to the caregiving family is seldom raised by members themselves, whose focus is so clearly on the patient, their relative. It is not surprising, therefore, that families underutilize support programmes and assistance from health providers (Davis-Ali et al., 1993). In one Australian study, Schofield and colleagues (1998) found that 38% of carers reported problems with coping, one-third health concerns, and over half, unmet needs. However, a meagre 12% received counselling! An important challenge may be to get these families to accept outside help.

Struggling to manage the caregiving role without support can bring about a sense of burden, which family members may feel guilty about, but unable to articulate (Given et al., 1993). A comprehensive appraisal of carer needs can ameliorate the fatigue experienced by family members (Jensen and Given, 1991). Community support in the form of respite provided by volunteers, home nursing, or cleaning services are examples of support that may make the difference between families coping with home-based care or not. Careful matching of services to needs and encouragement of their acceptance is critical.

Discussions with the family as a whole

Use of a family meeting is crucial to family-centred care and should be considered a routine component of care today. Box 17.6.3 outlines a useful schema for clinicians to follow in running this meeting (Guergen et al., 2009; Coyle and Kissane, 2010). The presence of all important members of the patient's family (including the patient)

in one room allows the clinician to see how the family relates and provides a multitude of data about who influences decision-making, how open the family as a group is to discuss difficult issues, what their view of treatment is, and so on. This type of information can only be gained by experiencing the family in action.

Many clinicians avoid family meetings as they consider them to be too time-consuming and likely to open up difficult issues with which the team must deal. In reality, a family meeting can be time-saving and allow for many issues to be considered in a short time. Often the clinician finds that the family meeting prevents them from having to answer phone calls from numerous family members repeating the same questions over and over. Such meetings deal with what information can be shared with whom, as the patient is present to provide permission for each topic to be covered. Many issues are resolved in a family meeting more swiftly than when pursued individually. Summarized agreements of these meetings can be included, with the family's permission, in the patient's records to enhance communication throughout the team (Hudson et al., 2008). In addition, a family genogram (Barker, 1986) can be completed and added to records for a succinct visual overview of the family structure. For example, Fig. 17.6.1 illustrates a genogram of the previously mentioned Ramirez family.

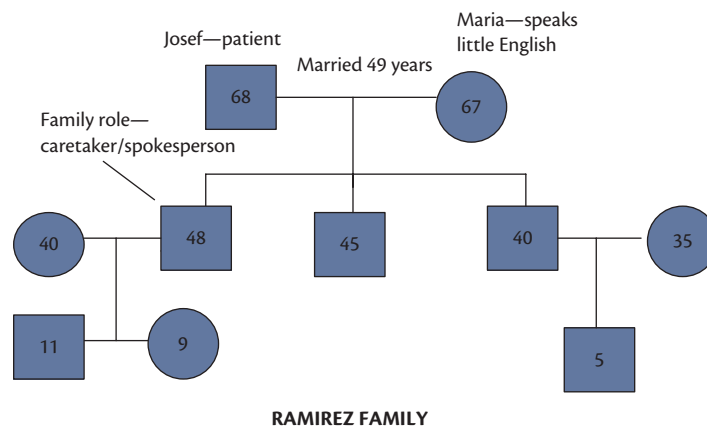
Such a family meeting empowers allocation of tasks among family members and the clinician can understand the impact this will have on each. When roles can be shared among members, so that the family becomes a team, there is reduced burden (Given and Given, 1994). Many of the everyday tasks, exemplified by housework, shopping, and transport, can be sorted out through problem-solving during the session, while the family grows in mutual understanding. On the other hand, when decisions about task allocation are made individually and without full consultation within the family, plans can be unconsciously sabotaged by those who do not feel they were included in the decision-making.


Fig. 17.6.1 Genogram of the Ramirez family described as a clinical vignette, where the eldest son takes up a culturally-consistent decision-making role in the family, a dynamic that the treatment team must recognize.

Box 17.6.4 Specific facilitation techniques used in family meetings

◆ *Circular questions*: ask each family member to comment in turn on the concerns and coping of others to promote curiosity and reflection by the group as a whole. For example, 'How are your parents and sisters coping with Dad's illness? Who is most upset in your view?'

◆ *Reflexive questions*: invite the family to reflect on possibilities, hypotheses, and a range of outcomes to stimulate their internal efforts to improve family life. For example, 'What benefits might come from caring for Dad at home? In what ways might this be hard for you as a family group?'

◆ *Strategic questions*: here a solution might be incorporated into the wording of the question to more directly guide the family toward an outcome that is considered preferable. For example, 'What change in Dad's symptoms (e.g. level of agitation) would need to occur for you to realize that admission to an inpatient hospice bed is necessary?'

◆ *Integrative summary of the family's concerns*: the family's views are reflected back to highlight levels of tension or discordance in different member's opinions, while maintaining professional neutrality, yet inviting further problem-solving by the family. For example, 'As a family, you recognize your father's desire to die at home, your mother's commitment to meet his wishes, and yet your concern that his confusion is becoming unmanageable and a burden to your mother. There is no easy answer here, as whichever solution you adopt will appear to demand more of each of you for a time.'

The family meeting also provides opportunity for the expression of genuine feelings individual members may have, both positively and negatively. For example, the chance is created for adult offspring to reassure their parents about the gratification they derive when reciprocating some of the love and attention they received during childhood (Hinton, 1994). Disagreement about plans or task allocation can be safely raised in this setting and appropriately problem solved. Box 17.6.4 outlines some key skills that clinicians need to facilitate routine family meetings (Dumont and Kissane, 2009). A more detailed coverage of

these skills is found in a series of useful articles by Karl Tomm (Tomm, 1988).

Family meetings may need to be arranged at each juncture of the treatment programme. As the goals of treatment change, or new information is ascertained, the family should be reconvened to review the situation.

Support during unpreventable emotional suffering

There is much distress and suffering that arises from caring for a seriously ill family member, which cannot be prevented or relieved. Though there appears to be an expectation or belief that modern medicine can prevent all suffering, this is an often unrecognized myth (Callahan, 1995). Support throughout the illness that includes frank discussion of side effects and tempering of unrealistic expectations can lessen any consequent emotional impact, but sometimes suffering can only be assuaged (Ferrell et al., 1991a, 1991b, 1991c; Kissane, 1998).

Specific interventions

Preventive and supportive interventions

Most well-functioning families who have become carers benefit from a single family meeting that mobilizes their inherent strengths and resources. Such consultative interventions aim to assist families expand and adapt their own successful problem-solving methods (Jacobs et al., 1998). They would begin where the family is at and provide additional encouragement to enhance coping.

Interventions that challenge dysfunction

Serious illness often provides a timely opportunity to intervene with a dysfunctional family. Indeed, such transition points in the life cycle are fertile occasions to effect change. Hence families that oncology services find challenging because of their long term dysfunction may become amenable to help at exactly this point in their lives—the threat of death of a loved one.

Challenging families include those that are rigid in their structure and processes, and find it difficult to accept change, or where their relationships are chaotic and unstable, with distress generating psychiatric disorder such as major depressive episode. Concern

for these families develops when (a) their conflict and behaviours prevent members from providing effective care-provision, or (b), when the negative impact on the family becomes disruptive and unbearable, producing mental illness. Such difficult families warrant referral to psycho-oncology services for ongoing family therapy. For example:

> Wartime separation had led the parents of this family to be raised in an orphanage during their childhood, challenging their ability to later cope with stress in life. The subsequent illness with advanced breast cancer of the mother brought great worry to the family. Her children teamed reasonably but the father's aloof and retreating manner created a gulf that interfered with effective communication. In family sessions, the construction of a transgenerational geno-gram and sharing of narrative about the deprivations of war helped this family to better understand and tolerate their father's solitari-ness. Thereafter, his children made renewed endeavours to include him in family activities and provided improved support for him during his bereavement.

Interventions with the family of a dying patient

Supporting a family through the chronic phase of advanced dis-ease is largely a matter of maintenance and different to the kind of support required when the patient is dying. Yet a common mistake made by the treatment team is in not being clear about the shift from cure or maintenance to palliative care. While the presence of hope is crucial to all families, and, indeed, many hold onto this hope in the face of extreme deterioration, it is important that it is balanced with some sense of realism, which often needs to come from the health care team (Parkes, 1972). There can be hesitancy in giving an honest appraisal about prognosis because of the emo-tional response involved with anticipatory grief. Yet there are two important reasons for clinicians to be brave and open in this setting.

To begin with, the time that the family spends together when a member is dying can be one of extreme intimacy and poignancy. This period involves finishing-up for the patient and those around them (Lethborg, 1994). As Hinton (1981) suggested, saying goodbye, while often perceived to be a final act, in practice evolves gradually as a temporal process. Finishing-up can include a period of life review, of completing projects, and of saying farewell. Equally, for the family, there can be review of relationships with the ill mem-ber, affirmation of the contribution of each person, completion of unfinished business, and expression of gratitude for the good times shared (Meares, 1981).

This period can also be one of great stress and emotional pain, especially when excessive anticipatory grief occurs. With skilled guidance, this existential pain can be processed through remi-niscence and externalization, eventually leading to increased acceptance (Yalom, 1980; Kissane, 1998; Breitbart, et al., 2010; Chochinov, 2011; Lethborg, et al., 2012). The tasks involved in say-ing goodbye can easily be postponed by well-intentioned families, motivated to protect their dying member from distress. Guidance is distinctly helpful so that families do not misjudge the time remaining for this farewell.

Secondly, successful management of this palliative phase is a form of preventive therapy in relation to the mental health of the family during bereavement. Care provided to families during the course of a terminal illness has a profound influence on bereave-ment following the death (Ferrell, 1998). The experience of a family member dying at home thereafter becomes part of the narrative of the whole family (Coyle, 1996).

By screening palliative care families to identify those 'at some risk' for maladaptive outcomes, randomized trials of family intervention starting during palliative care and continued into bereavement have shown the ability to prevent complicated grief and depressive illness in the bereaved (Kissane et al., 2006, 2012). Palliative medicine presents a unique opportunity to establish a therapeutic alliance with families in need, in a manner that does effectively support their transition through this stressful experience (Kissane et al., 1998). Through a focus on enhancing family functioning, families are helped to support one another, communicate more effectively, tolerate differences and deal with conflict adaptively. This approach is a preventive model that offers therapy through a brief and empirically driven technique, and sustains continuity of care to the family across a period of major change in their lives. While very chaotic families decline to meet, accepting distance and separation as the practical solu-tion to their differences, many other families with more mild to moderate disturbance in their relationships welcome the help delivered through this family-centred model of care. Through this FFGT approach, bereavement care actually begins during palliative care.

Conclusion

Serious illness should be viewed as 'a bio-psychosocial and spiritual problem that occurs in the context of an intense interpersonal rela-tionship that affects, and is affected by, the disease process in recip-rocal circularity' (Northouse, 1993, p. 70). Never is this truer than for the family of a patient with advanced disease. The serious pro-gression of this disease towards terminal events inevitably involves the family in key relationships with the health team and their dying relative. These relationships are pivotal in determining the ulti-mate outcome of the experience for all. Families are second-order patients in their own right, and the bearers of the burdens and joys of loving relationships. Family-centred care is challenging as a paradigm but a useful harness to improved quality of life, one that warrants the effort involved to ease the suffering of all.

Bereavement

David W. Kissane and Talia I. Zaider

Introduction to bereavement

Mourning is an essential adaptive response to the inevitable experience of loss. In many ways it is the debt that has to be repaid for investment in the joys of life. Familiarity with and confidence in responding to grief is a sine qua non for all clinicians working in palliative medicine, including the capacity to differentiate healthy from maladaptive adjustment. Many losses are experienced as patients and their families move through the phases of progressive illness towards death. Related grief is thus current as well as anticipatory of future loss. Support for the grieving process in both the patients and their carers clearly begins during palliative care and places the clinician in an ideal position to sustain continuity of this care into bereavement.

Family-centred care is integral to this supportive process as the family's understanding of the illness and its treatment influences their later adjustment (Kissane et al., 2007–2008). Every word uttered by the treating team, the related tone, and sensitivity shown contributes to the experience for the bereaved, who generally need to understand the process of death and discuss any features of concern. Palliative care teams are ideally placed to recognize those at greater risk of poor outcome and provide care prophylactically to prevent bereavement morbidity (Williams and McCorkle, 2011).

Although words such as grief, mourning, and bereavement are commonly used interchangeably, the following definitions indicate their use in this chapter:

◆ Bereavement is the state of loss resulting from death (Parkes, 1998).

◆ Grief is the emotional response associated with loss (Stroebe et al., 1993).

◆ Mourning is the process of adaptation, including the cultural and social rituals prescribed as accompaniments (Raphael, 1983).

◆ Anticipatory grief precedes the death and results from the expectation of that event (Raphael, 1983).

◆ Pathological grief represents an abnormal outcome involving psychological, social, or physical morbidity (Rando, 1993). Complicated grief and chronic or prolonged grief are variants.

◆ Disenfranchised grief represents the hidden sorrow of the marginalized where there is less social permission to express many dimensions of loss (Doka, 1989).

In this chapter, the theoretical models that have been developed to explain bereavement phenomena and the process of mourning are considered with a view to generating an understanding of the clinical features of grief. Recognition of those at risk of complicated outcome is mandatory to offer preventative interventions (Guldin et al., 2011). Models of follow-up and management of complicated grief are fully explored, as is variation across the life cycle and the impact of stigmatized deaths. Spiritual aspects of bereavement highlight the contributions of the world's major religions in supporting the bereaved. Bereavement research in the future will be aided by use of validated measures, which are summarized towards the chapter's end as a handy resource. Finally, to conclude, the recognition that personal growth is a common outcome despite the sadness of loss reminds us that creativity often emerges as a result of resolution of the mourning process.

Theoretical models of bereavement phenomena

Dating from Darwin's observation of monkeys 'weeping' from grief, ethology has pointed out that social birds and mammals do grieve (Darwin, 1872). Indeed, mourning appears to be the price paid for the evolutionary adaptiveness of social relationships. This universality of grief suggests it is imprinted into the biological processes of the species, consistent with the experience that death seems to be difficult for people everywhere. Yet, social constructionists remind us that the shape and content of grief is culturally determined. It varies markedly across places, times, and social groups, with noteworthy differences in the expression of anger, emotionality, self-mutilation, rituals, and public versus private grief (Rosenblatt, 2001).

A conceptual framework that illuminates what underpins the phenomena of bereavement aids our clinical understanding of the experience of the bereaved (see Table 17.7.1). Explanatory models favoured by bereavement researchers were ranked in the following order of importance: attachment, psychodynamic, sociological, cognitive behavioural, and ethology (Middleton et al., 1993). Although limited by the available list of potential theories (for instance, continuing bonds, interpersonal, systemic, and traumatic were not offered), these models help practitioners work flexibly with pertinent issues.

Attachment theory posits that the development of close affectionate bonds to particular others generates security and survival potential (Bowlby, 1997). From a secure base, the capacity for curiosity emerges to generate creativity in autonomous adult life. Parents, especially the mother, constitute the usual subject of primary attachments, but these behaviours become enduring throughout adult life and the spouse eventually replaces the parents as the recipient of the strongest bonds. The family thus

Table 17.7.1 Theoretical models explaining bereavement phenomena

Name of model	Key contributors	Main features
Attachment theory	Bowlby, Ainsworth, Parkes, Weiss	The bonds of close relationships are severed by loss
Psychodynamic theory	Freud, Klein, Horowitz, Kohut	Early relationships lay down a template that guide future relationships
Interpersonal model	Sullivan, Bonnano, Horowitz, Benjamin	Relational influences are dominant in grief outcome
Psychosocial transition	Parkes, Janoff-Bulman	Changed assumptive world view
Sociological model	Rosenblatt, Klass, Walter	Cultural influences shape the form and content of grief
Family systems theory	Walsh, McGoldrick, Kissane, Shapiro	Family are the main source of support; family functioning determines outcome
Cognitive stress coping theory	Stroebe, Kavanagh	Conditioned or learnt patterns become entrenched
Traumatic model	Horowitz, Pynoos, Prigerson, Jacobs	Intrusive aspects of trauma dominate
Ethology	Darwin, Lorenz	Biological and physiological processes underpin the phenomena across species
Meaning-centred model	Neimeyer, Lichtenthal	Narrative methods guide the reconstruction of meaning after the loss

forms the setting for the major constellation of bonds. Through studying parent–child relationships, Mary Ainsworth differentiated secure from insecure attachments, the latter appearing as either anxious, avoidant, or disorganized/hostile (Ainsworth et al., 1978). A transgenerational influence is evident between the parental style of attachment and that found in children, such that families can transmit insecure patterns of relating through the generations. The nature of attachments in a person's life influences the impact of loss when these bonds are changed, determining the work of mourning as this separation is dealt with (Parkes, 1985; Jacobs et al., 1987/1988).

While related to attachment theory, the psychodynamic model places greater emphasis on the development of the person, with all of their childhood and earlier life influences, including their sense of self, confidence, and resilience that comes with a robust self-esteem, and their learnt capacity to mourn. Schematic representations of early relationships construct a template (technically termed object relations) that lays down the operating principles guiding the emotional experience of relationships. Once the infant has developed feelings of concern for its mother, Klein described the early pining evident when the mother was absent (Klein, 1940). Mourning was thus recognized as a life-long mechanism of adaptation to cope with the inevitable traumas of life.

Interpersonal theories have emerged recently to throw further light on bereavement (Shapiro, 2001) and complement the psychodynamic model. Cyclical relational patterns are understood to result from current relational selections based on their resonance with the past, often confirming previous expectations. Schemas of the 'who the self is' are constructed through relational interactions to establish a role for the person pertaining to these relationships (Young et al., 2003). Horowitz has made particular use of these schemas using a stress–response model for grief (Horowitz, 1989). For instance, ambivalence towards the deceased is associated with greater distress, but restructuring the 'ambivalent' schema is possible through its observation in current relational patterns and the introduction of strategic variations to alter this habitually dysfunctional pattern. Horowitz and colleagues have tested a model of therapy based on these premises (Horowitz et al., 1993).

Transition theorists highlight the adaptation to change that is inherent in any resolution of grief. Parkes suggested that alteration to an individual's set of ideas and beliefs about their environment—their assumptive world—was central to adaptation (Parkes, 1975b). Development of acceptance of change is implicit in such a view. Meaning-making and the reconstruction of a continuing bond help reconfigure the assumptive world (Neimeyer, 2011).

In their contribution to a sociological model of bereavement, post-modern writers emphasize the various discourses that indicate a multiplicity of perspectives. The notion of the 'breaking of the bonds' of relationship, first hinted at by Freud (1912), is thus socially determined. Klass and colleagues highlighted the process of continuing bonds through reverence for the dead as both ancestors and moral guides (Klass et al., 1996). Walter noted that conversations about and with the deceased served as one means of sustaining a relationship (Walter, 1996). It becomes a personal choice whether the bereaved moves on to a new relationship or sustains the attitude of a 'broken heart'.

The sociological view also recognizes the loneliness of the bereaved and the value of groups or networks, including the family, to counter the social isolation that otherwise might prevail. Patterns of socialization of the bereaved vary with cultures, but networks of support have a vital influence on adjustment. The manner in which a family grieves and how its members continue to relate to each other is crucial to outcome. Families wreaked by conflict, reduced cohesion, and poor communication struggle to support each other—high rates of psychosocial morbidity are found in dysfunctional families (Kissane et al., 1996). Family systems theory makes particular use of intergenerational and family life-cycle perspectives (Walsh and McGoldrick, 1991).

Mourning can be triggered by unexpected life events, natural disasters, and traumas that violate the person and introduce an unwelcome element to the experience that is described as 'shocking'. Traumatic grief captures something that is unique to the trauma and challenges the bereaved with the intrusion of any resultant distressing memories. Prigerson and Jacobs have argued for recognition

of the specifically traumatic nature of some deaths and their impact on grief (Prigerson and Jacobs, 2001).

Finally, behavioural models offer their contribution to bereavement theory through the challenge of chronic grief, in which the bereaved become stuck in an entrenched state of distress (Kavanagh et al., 1990). Patterns such as social withdrawal, 'memorialization' of the deceased through preserving their bedroom, clothes, and possessions intact as if a shrine, or chronic weeping upon mention of the deceased's name illustrate these behaviours. Cognitive behavioural approaches such as activity scheduling generate clinical improvement and point to an element of conditioned response in chronic grief.

The number of overlapping dimensions to these conceptual models is noteworthy, yet none by itself is a sufficient and complete explanation of bereavement phenomena. However, the intrapsychic, interpersonal, systemic, and sociological features of these models deliver an intersecting and overall coherence, which aids our eventual understanding of the complex phenomena observed in grief.

Stroebe and Schut have pointed out that while these general theories of grief explain the broad range of phenomena observed, they do not inform fully about the specific coping pathways that grieving individuals go down (Stroebe and Schut, 2001). They have suggested a dual-process model of bereavement-specific coping, in which oscillation occurs between loss-orientation, in which there is a focus on the loss itself, and restoration-orientation, in which the focus shifts to attending to ongoing life. Active 'grief work' occurs when the bereaved are loss-oriented, but excessive negative emotion could lead to a deterioration in coping, and so active confrontation of grief sits in a dynamic equilibrium with some degree of avoidance of grief. The individual needs at times to pull back and take 'time out' from the distress of the loss. They may do so through use of the restorative track in which the negative emotions are countered by some degree of positive reappraisal and of construction of meaning about the event. This promotes positive affects and eventually opens up new goals and plans for the future. Complex regulation exists in getting this balance right between grieving and restoring, with both interpersonal and cultural influences guiding this balance. Dissonance between bereaved members of a family, for instance, will challenge the balance and lead systemically to some readjustment by some or more members.

The bereaved cope therefore through adjusting the balance between expression of negative and positive emotions in emotion-based coping, and incorporating appropriate degrees of problem-solving and meaning-generation to guide their sense of purpose and control. They need to sustain the normal operation and functioning in their lives while also grieving the loss that has occurred irrevocably.

The nature of normal grief

The expression of normal grief is evident through its emotional, cognitive, physical, and behavioural features (Parkes, 1998). Eric Lindemann provided the first systematic study of these through his observations of people who lost a relative in Boston's Cocoanut Grove Nightclub fire (Lindemann, 1944). Somatic distress with numbness, preoccupation with sad memories of the deceased, guilt, anger, loss of the regular patterns of conduct, and identification with symptoms of the deceased formed the key dimensions that Lindemann observed.

Emotional distress occurs in waves that last for minutes at a time and involves unavoidable crying, loss of concentration and purpose while preoccupied with thoughts about the deceased, and a range of associated affects including sadness, anger, despair, anxiety, and guilt. Cognitive processes become dominated by memories, reflected in storytelling, reminiscences, and conversations about the deceased. Physical responses include numbness, restlessness, tension, tremors, sleep disturbance, anorexia, weight loss, fatigue, and a variety of aches and pains. Finally, behavioural aspects are variously reflected in social withdrawal, wandering, searching, and seeking company and consolation.

A number of physiological changes have been identified in neuroendocrine functioning (Jacobs et al., 1997) (e.g. challenge studies like the dexamethasone suppression test), immune indices (Esterling et al., 1996) (e.g. natural killer cell functioning), and sleep efficiency (Hall et al., 1998). Exploration of these physiological changes not only suggests that grief and depression lie on a biological continuum but also provides understanding for the morbidity, both somatic and psychosocial, that is associated with bereavement.

The clinical presentations of grief

As the family journey through palliative care, the clinical phases progress from anticipatory grief through to the immediate news of the death, to the stages of acute grief and, potentially for some, the complications of bereavement.

Anticipatory grief

When news of cancer recurrence or disease progression reaches the patient and family, grief is initiated as they anticipate eventual death. However, not all of this grief is about the final loss, as many changes unfold with the illness and its treatment. Loss of health can be accompanied by loss of work, leisure activities, financial security, independence, sense of certainty about life and further physical impairments, body image change, and altered perception of well-being. The clinician is challenged to understand the meaning of the loss to each person and evaluate therein their grief response.

Anticipatory grief generally draws the supportive family into a configuration of mutual comfort and greater closeness as the news of the illness and its proposed management is grappled with. For a time this perturbation advantages the care of the sick, until the pressures of daily life draw the family back towards their prior constellation. Movement back and forth is evident thereafter as news of illness progression unfolds. Periods of grief become interspersed with phases of contentment and happiness. When the family is engaged in the domiciliary care of their ill member, their cohesion potentially increases as they share their fears, hopes, joy, and distress.

In contrast, difficulties emerge for some families as they express their anticipatory grief. Impaired coping is exhibited through protective avoidance, denial of the seriousness of the threat, anger, or withdrawal from involvement. Sometimes family dysfunction is so glaring that clinicians are rapidly drawn into its snares. More commonly, however, subthreshold or mild depressive or anxiety disorders develop gradually as individuals struggle to adapt to unwelcome changes. While anticipatory grief was historically suggested to reduce post-mortem grief (Parkes, 1975a),

intense distress is now well recognized as a marker of risk for complicated grief.

During this phase of anticipatory grief, clinicians can usefully help the family that is capable of effective communication by encouraging them to openly share their feelings as they pay attention to the material needs of their dying family member or friend. Saying goodbye needs to be recognized as a process that evolves over time, with opportunities for reminiscence, celebration of the life and contribution of the dying person, expressions of gratitude and completion of any unfinished business (Meares, 1981). These tasks have the potential to generate meaningful and positive emotional aspects of what is otherwise a sad time for all.

Grief of family and friends gathered around the death bed

When relatives or close friends gather to keep watch by the bed of a dying person, not only do they support the sick, but they also help their own subsequent adjustment. The solidarity shared through this experience cements these carers into mutually supportive relationships. As staff go about nursing the ill patient, they need to comfortably relate to the family, whether in the home, hospice, or hospital. For years to come, these poignant moments will be recalled in immense detail—the sensitivity and courteous respect of health professionals is crucial (Maguire, 1985). Clinicians can helpfully comment on the process of dying, explaining the breathing patterns, and commenting on any noises, secretions, patient reactions, and comfort (Kissane et al., 2012a). The experience needs to be normalized empathically and the family reassured whenever concern develops. Discussion about pain, reasons for medications, and skilled prediction of events will assuage worry and build a collaborative approach to the care of the dying.

Religious rituals warrant active facilitation, including appropriate notification of a religious minister or pastoral care worker. Respect for the body remains paramount once death has occurred and the expression of sympathy from clinicians is greatly appreciated. The family will be invariably grateful for time spent alone with the deceased, while regard for cultural approaches to the laying out of the body is essential (Parkes et al., 1997) (discussed in the section on cross-cultural bereavement practices in the online Appendix). The bereaved are commonly bewildered and benefit from guidance about what to do next—making contact with the undertaker is an obvious example.

When relatives have not been present at the moment of death, informing them by telephone of the fact is generally undesirable. The invitation for them to attend in person is often based on a stated deterioration in the patient's condition. On arrival, the news can be sensitively shared in an appropriate setting before accompanying them to see the deceased. To help the family to integrate an understanding of all that has occurred, clinicians should explain the sequence of medical events culminating in the death. Questions need to be sensitively answered and time taken to comfort the bereaved in their distress.

From time to time, the cause of death will remain uncertain and an autopsy may be indicated. A senior clinician should outline the pertinent issues, emphasizing the positive aspects of the information that will be gleaned and indicating that it will be subsequently shared with the family in a follow-up meeting. Unless there is a legal requirement for a coroner's post-mortem, the family's views on autopsy need to be fully respected.

Sometimes staff will have concerns about the emotional response of the bereaved. If there is uncertainty about its cultural appropriateness, consultation with an informed cultural intermediary may prove helpful. The prescription of short-acting benzodiazepines will help some, while others will prefer to manage without medication. A follow-up telephone call on the next day is worthwhile to check on coping and identify the need for continued support.

Caution is needed in settings where grief could be marginalized, well exemplified by ageism (Doka, 1989). If a death is normalized because it appears in step with the life cycle, family members can be given less support and reduced permission to express many aspects of their loss. In the process, the disenfranchised can be ignored in their sorrow.

Acute grief and time course of bereavement

The sequence or phases through which the bereaved move over time are never rigidly demarcated but merge gradually one into the other (Raphael. 1983; Parkes, 1998). They assist the clinician to recognize aberration from the normal evolution. From the (1) initial numbness and sense of unreality, (2) waves of distress begin to occur as the bereaved suffer intense pining and yearning for their lost one. Memories of the deceased trigger these acute pangs of grief. Then as the pain of separation grows, (3) a phase of disorganization emerges as loneliness resulting from the loss sets in. Hofer described this phase aptly as a constant background disturbance of restlessness, inattention, sadness, and despair with social withdrawal that can last for several months (Hofer, 1984). Eventually (4) a phase of reorganization and recovery develops as nostalgia replaces sadness, morale improves, and an altered world view is constructed. Personal growth can be recognized at this stage and new creativity is expressed (Polloch, 1989).

The time course of mourning is proportional to the strength of attachment to the lost person and also varies with cultural expression, there being no sharply defined end point to grief. Just as a mother's grief following sudden infant death syndrome lasts longer than grief following a neonatal death, so to with adult loss, the mourning that follows many years of marriage is generally longer than brief relationships. Older widows and widowers may continue to display their grief for several years (Zisook and Schuchter, 1985). This can correspond with a continuing relationship with the deceased, which for some is their choice and leads to chronic grief. The clinical task is then to differentiate those who remain within the spectrum of normality from those who cross the threshold of complicated grief

Pathological grief

Normal and abnormal responses to bereavement span a spectrum in which intensity of reaction, presence of a range of related grief behaviours, and time course determine the differentiation. Psychiatric conditions that commonly accompany grief include clinical depression, anxiety disorders, alcohol abuse or other substance abuse and dependence, psychotic disorders, and post-traumatic stress disorder (PTSD). When frank psychiatric disorders complicate bereavement, their recognition and management is straightforward; subthreshold states present the greater clinical challenge as studies of the bereaved indicate groups in which clusters of intense grief symptoms are distinct from the normal trajectory of grief (Parkes and Weiss, 1983; Prigerson et al., 1995a, 1995b). The *Diagnostic and Statistical Manual*

of Mental Disorders, fifth edition (DSM-5) of the American Psychiatric Association proposes further study on its proposed criteria for what has been called 'Persistent Complex Bereavement Disorder' (American Psychiatric Association, 2013). For at least 12 months following the death, intense longing or yearning for the deceased will be accompanied by intense sorrow and significant social impairment. Recognition of pathological grief calls for an experienced clinical judgement that does not normalize the distress as necessarily understandable. In practice, a set of criteria by which these patients can be identified as high risk and the application of preventive models of bereavement care eliminate some of the academic debate about their characteristics.

Inhibited or delayed grief

While use of avoidance may serve some as a temporary coping mechanism, its persistence is sometimes associated with relationship difficulties or the emergence of a hypomanic state in individuals with bipolar disorder. There are scenarios, however, in which the absence of significant distress and impairment immediately following loss may be understandable, perhaps indicative of resilience. Bonnano cogently argues that the prevailing model of grief that has become popularized in our culture (e.g. the need for 'grief work') is based on poorly supported assumptions, and does not allow for the full range of grief responses that may prove adaptive among the bereaved (Bonnano, 2004). In keeping with this view, Bonnano identifies a subgroup of individuals who show little distress or disruption to normal functioning following a loss, with relatively stable, healthy functioning up to 2 years following the event. Rather than consider them delayed or avoidant in their grief, Bonnano instead refers to this group as resilient, noting that research to date has failed to find any evidence for the phenomenon of delayed grief. On this basis, he challenges the assumption that the absence of grief is necessarily pathological, that it indicates a superficial bond with the deceased or that it necessarily warrants clinical intervention. Still, it is important to highlight that cultural variation influences grief expression. Additionally, among those who present with symptoms of complicated grief (see following section), avoidance of activities or situations reminiscent of the loss is common and may indeed require targeted intervention.

Complicated grief

An impressive body of empirical work supports the validity of complicated grief as a clinical entity, distinct from normal grief responses and related pathological states (e.g. major depression). After an extended debate about whether complicated grief constitutes a bona fide psychiatric disorder (Stroebe et al., 2000; Prigersonet al., 2007), DSM-5 (American Psychiatric Association, 2013) includes a chronic grief syndrome as Persistent Complex Bereavement Disorder (PCBD). For at least 12 months following the death of a close relative or friend, the individual experiences intense yearning or longing for the deceased, intense sorrow and preoccupation with the deceased on more days than not. This reaction must be out of proportion to the bereaved's culture and cause significant impairment in social, occupational, or other important areas of functioning. More significant mental disorders (e.g. major depression, PTSD) take precedence as diagnoses over PCBD (Hogan et al., 2003–2004). A variety of other phenomena may accompany this, including non-acceptance of the death, intense anger, a diminished sense of self, a feeling that life is empty, and indecisiveness

about the future, whether with activities or relationships (Prigerson et al., 1995c, 1996, 2009). Such prolonged grief has been independently associated with risk for a range of health problems, including cardiac distress, hypertension, increased alcohol and cigarette consumption and suicidal ideation (Prigerson et al., 1999).

Using the Inventory of Complicated Grief (Prigerson et al., 1995c), cases of complicated grief were identified with high sensitivity and specificity (Prigerson et al., 1999). Moreover, a substantial and growing number of cross-validation studies have successfully replicated the unique clustering of the proposed criteria as a coherent and distinct syndrome (Prigerson and Maciejewski, 2005–2006). Results from a DSM-5 field trial conducted with a community sample of 317 bereaved persons indicated that the presence of complicated grief at 6–12 months post loss predicted much higher risk for morbidity than its presence within the first 6 months following loss (Prigerson et al., 2007). The diagnostic criteria adopted by the DSM-5 committee stayed with the conservative time frame of longer than 12 months, while opting to further study the predictive nature of intense distress persisting across 6–12 months.

Who is most likely to develop complicated grief in response to the death of a loved one? Attachment processes are believed to play a central role in predicting the grief response, with separation distress most strongly activated following the loss of a 'security-enhancing attachment bond' (Neimeyer, 2005–2006). The loss of a close and stabilizing attachment figure may be especially harrowing to those with a history of childhood neglect or abuse. Indeed, evidence suggests that these subgroups are especially prone to develop complicated grief (Silverman et al., 2001). Bereaved individuals who suffered a traumatic or unexpected loss, had an intimate relationship with the deceased, and experienced little support following the death are also at heightened risk for complicated grief (Silverman et al., 2001; Prigerson et al., 2007).

Chronic grief is particularly associated with overly dependent relationships in which a sense of abandonment is avoided by perpetuation of the relationship through memorialization of the deceased and maintenance of continuing bonds. A stuck situation emerges in which the tearfulness is induced by any reminder of the deceased without any cognitive transition being achieved in the world view of the bereaved. Social withdrawal and depression are common. A fantasy of reunion with the deceased can cause suicide to be an increasingly attractive option. Active treatment using pharmacology for depression and cognitive behavioural therapy to reality test the loss and promote socialization (via activity scheduling) is appropriate for chronic grief. Treatment of complicated grief employs multimodal therapy incorporating retelling the story of loss, written and imaginal exposure exercises and behavioural activation exercises to resocialize (Shear et al., 2005; Boelen et al., 2007).

Traumatic grief

When death has been unexpected or its nature in some way shocking—traumatic, violent, stigmatized, or perceived as undignified—its integration and acceptance may be interfered with by the arousal and increased distress that memories can trigger. Intensive recollections including flashbacks, nightmares, and recurrent intrusive memories cause hyperarousal, disbelief, insomnia, irritability, and disturbed concentration, which distorts normal grieving (Prigerson and Jacobs, 2001). The shock of the

death can precipitate mistrust, anger, detachment, and an unwillingness to accept its reality. These reactions at a subthreshold level merge with the full features of PTSD, but the subthreshold state has been observed to persist for years and contribute substantial morbidity.

Depressive disorders

Rates of major depression in the bereaved have varied between 16% and 50%, peaking over the first 2 months (Stroebe et al., 2000; Bonnano, 2004), and gradually decreasing to 15% across the next 2 years (Hogan et al., 2003–2004; Prigerson et al., 2007). The features of any major depressive episode post bereavement resemble major depression at other points of the life cycle (Prigerson et al., 1995c). There is a tendency to chronicity, considerable social morbidity, and risk of inadequate treatment.

Anxiety disorders

These take the form of adjustment disorders, generalized anxiety disorder, and phobic states and occur in up to 30% of the bereaved (Prigerson et al., 1996). Patients present commonly to general practitioners with a range of somatic concerns. Separation anxiety of a heightened nature can be distinguished from anxiety symptoms of a general kind.

Alcohol and substance abuse/dependence

Typically an exacerbation of pre-existing psychiatric states, individuals predisposed to alcohol abuse or dependence on other substances such as benzodiazepines relapse during bereavement (Prigerson et al., 1996). Other family members often raise the alarm.

Post-traumatic stress disorder

While clearly related to unnatural deaths, deaths involving profound breakdown of bodily surfaces (Rudge and Holmes, 2010), gross disfigurement due to head and neck cancers, or other causes of relatives perceiving the illness to cause loss of dignity may generate traumatic memories in the bereaved. Prigerson and colleagues found that PTSD was often correlated with the perceived inadequacy of the goodbye, and suggested that rituals to complete this be incorporated into related grief therapies (Prigerson et al., 1999).

Psychotic disorders

Bereavement is a common precipitant of relapse of psychotic illnesses such as bipolar disorder or schizophrenia in individuals so predisposed; occasionally, mania presents for the first time in such a setting.

Family grief

The family is one of the primary contexts in which grief is recognized and expressed. As survival time has increased for those with terminal illness, a new grief has emerged for families, reflecting the cumulative losses that families anticipate and cope with across a longer period of time. Indeed, death from illness is less often a sudden and unexpected event. The opportunity to prepare for the dying process enables families to strive for a 'good death', and thus changes the conditions under which subsequent grief unfolds. The extended nature of grief as it occurs across a family's journey with illness underscores the importance of family-centred care from diagnosis to death.

It has long been recognized that the family, when functioning optimally, empowers mutual support, either through direct and open expression of sadness, shared performance of rituals, or informal opportunities for remembrance before and after loss (Kissane et al., 2007–2008). In addition to supporting the adaptation of its individual members, the grieving family faces the task of reconstituting its key roles and functions without the lost member (e.g. parenting and sustaining important traditions). In some cases, grief that is shared brings opportunities to forge or strengthen new relationships among surviving members, and can prompt tremendous growth and resilience (Zaider and Kissane, 2007).

Therapists have long recognized the salience of family processes to mourning and their systemic influence on outcome (Prigerson and Maciejewski, 2005–2006). Exploration of the interplay between family functioning and individual members' bereavement morbidity has highlighted the manner in which dysfunctional relationship patterns predict increased rates of psychosocial morbidity in the bereaved (Kissane et al., 1996). A typology of family functioning during both palliative care and bereavement was created using cluster analysis in the Melbourne-based family grief studies (Kissane et al., 1994, 1996). Dimensions of cohesiveness, expressiveness, and conflict from the Family Environment Scale (Moos and Moos, 1981) determined five classes of families illustrated in Table 17.7.2. While over half the families met in a palliative care setting demonstrate resilience through their family functioning, and do not need particular psychological assistance to achieve an adaptive outcome from bereavement, the remainder have identifiable characteristics predictive of a higher risk of morbid outcome and can be specifically targeted through a preventive model of family care (Kissane and Bloch, 2002).

During early bereavement, families at risk have been shown to decompensate through deterioration in their functioning with loss of cohesiveness, communication breakdown, and increased conflict. A proportion of families with intermediate characteristics of functioning changes to become 'Sullen' or 'Hostile' in type. Importantly, these dysfunctional families carry the bulk of the psychosocial morbidity observed to occur during bereavement, thus highlighting the potential benefits of a family form of intervention. Screening of families on their admission to palliative care through the use of a well-validated measure such as the Family Relationships Index (Moos and Moos, 1981) provides an ideal means to recognize those families at greater risk of morbid outcome during bereavement.

Recognizing those at risk of complicated bereavement outcome

Palliative care teams are ideally placed to recognize those at increased risk of complicated grief and plan preventive interventions in an endeavour to circumvent morbidity. To accomplish this, bereavement care planning does not begin post death but at the point of entry into the palliative care service. The continuity of supportive care that flows from this builds a strong therapeutic alliance, which will be more likely to survive ambivalence about the death than if a bereavement counsellor attempts to begin post death. Avoidance hinders many attempts to engage the bereaved after the death.

In times of resource scarceness and economic rationalism, services are under pressure to direct their clinical staff to appropriate areas of need. When relatives appear resilient and well supported,

Table 17.7.2 Typology of palliative care and bereaved families (Kissane et al., 1994; 1996)

Category: family type	Rate of occurrence (%)	Features
Well-functioning types		
Supportive	32	Strongly cohesive families who grieve adaptively
Conflict resolving	20	Cohesion and effective communication empowers tolerance of difference of opinions
Dysfunctional types		
Hostile	6–12	Poorly cohesive with high conflict, ineffective communication, and fractured relationships; families resist help
Sullen	9–18	Muted anger generates highest levels of depression; families seek help
Intermediate	20–33	Mid-range levels of communication, cohesion, and conflict place these families at risk of deterioration when stressed by life events

clinicians can wisely respect their capacity to cope with loss adaptively. The best predictors of an adaptive outcome include a gradually resolving trajectory of emotional distress that began from a moderate rather than excessive initial level, open communication with others, good supports, robust self-esteem, and evidence of personal competency in the daily tasks that are ordinarily pursued (Lund et al., 1993). Moreover, empirical evidence confirms that when preventive interventions are targeted to those at risk, benefits ensue (Raphael, 1977), whereas when they are broadly offered to a bereaved population regardless of risk, no such benefit is discernible (Parkes, 1981). In the latter type of study, the well functioning dilute any evidence of benefit to those at risk. In contrast with a broadly supportive bereavement follow-up programme that utilizes condolence cards and invitations to memorial services, seriously intended preventive interventions should be directed towards those at increased risk.

Pathological grief can be recognized by the presence of greater degrees of separation distress, emotional numbing and dissociation, mood symptoms, impaired social functioning, and maladaptive coping styles. The coping styles contributing to this include elements of avoidance or denial, distortion through excessive anger, despair, guilt, idealization or somatization, and prolongation that culminates in chronicity of distress.

Risk factors to aid recognition of those at greater risk of complicated grief are summarized in Table 17.7.3. These should be assessed at entry to the service and upgraded during the phase of palliative care, including revision shortly after the death. Completion of the family genogram presents an ideal time for such assessment as relationships, prior losses, and coping are considered. Some palliative care services have developed checklists based on such risk factors to generate a numerical measure of risk. There has been insufficient validation of such scales at this stage, but the presence of any single factor in Table 17.7.3 signifies greater risk. Continued observation of the pattern of grief evolution over time is appropriate whenever such concern exists.

Health consequences of bereavement

Over 15 studies of mortality following bereavement provide evidence for an increased rate of deaths in the 45–75 age range,

Table 17.7.3 Risk factors for pathological grief outcomes

Catagory	Range of circumstances
Nature of the death	Untimely within the life cycle (e.g. death of child)
	Sudden and unexpected (e.g. death from septic neutropenia during chemotherapy)
	Traumatic (e.g. gross cachexia and debility)
	Stigmatized (e.g. AIDS or suicide)
Strengths and vulnerabilities of the carer/bereaved	Past history of psychiatric disorder (e.g. depression)
	Personality and coping style (e.g. intense worrier, low self-esteem)
	Cumulative experience of losses
Nature of the relationship with the deceased	Overly dependent (e.g. clinging, symbiotic)
	Ambivalent (e.g. angry and insecure with alcohol abuse, infidelity, gambling)
Family and support network	Dysfunctional family (e.g. poor cohesiveness and communication, high conflict)
	Isolated (e.g. new migrant, new residential move)
	Alienated (e.g. perception of poor support)

with these occurring over the first year post loss, particularly the first 6 months from acute cardiovascular causes (Stroebe and Stroebe, 1993). While some studies have only identified increased mortality in men, a well-controlled study of 12,522 spouse pairs in a prepaid health-care plan showed increased mortality for both women and men, adjusting for age, education, and other mortality predictors (Schaefer et al., 1995). Other noteworthy causes of death in addition to cardiovascular events include accidents, suicide, alcohol and substance abuse, and cirrhosis while the association evident in large epidemiological studies of increased mortality with social isolation and alienation is also relevant (House et al., 1988).

Early studies by Saunders (1999) and Parkes (1984) identified the increased use of health services—both greater consultations and hospitalizations—by the recently bereaved, with increased psychological distress, somatic health complaints, more days of disability, and greater reliance on medications. Some 20–25% were noted to develop depressive disorders (Clayton, 1990; Harlow et al., 1991; Zisook and Schuchter 1991; Karam, 1994; Zisooket al., 1994), but increased rates of anxiety disorders, including PTSD in settings of traumatic loss, also occur (Hofer et al., 1972). Some of the explanations for these health consequences lie in the development of complicated grief, others in altered behaviours and lifestyle including diet, smoking, and alcohol consumption. Studies have also highlighted effects on the cardiovascular, neuroendocrine, and immunological systems: several studies have shown increased rates of myocardial infarction post bereavement (Stroebe and Stroebe, 1993); altered cortisol levels were seen in parents following death of their children from leukaemia (Hofer et al., 1972); altered lymphocyte response to mitogens and lowered natural killer cell activity were also seen in bereaved spouses (Hofer et al., 1977; Schleifer et al., 1983; Irwin et al., 1987). Immunosuppressed patients, either chemically induced or as a result of AIDS, develop specific malignancies such as lymphomas or Kaposi's sarcomas. However, the clinical relevance of the immunological changes described in bereavement is uncertain in the light of a series of large epidemiological studies that fail to show increased rates of cancer in the bereaved (Helsing et al., 1982; Jones and Goldblatt, 1986; Kaprio et al., 1987).

Bereavement follow-up by the treatment team

Once the patient has died, the palliative care team should routinely review the death and the bereavement-related risk factors in the next available multidisciplinary team meeting. Was the death perceived to impact significantly on key family members? What level of bereavement follow-up should be adopted?

Two broad levels of follow-up are possible. The first involves the expression of condolences via the telephone, sympathy card, visit by the nurse or general practitioner, staff attendance at the funeral, and subsequent family invitation to a periodic commemorative service arranged by the palliative care team. This model provides both encouragement and support while normalizing the grief that relatives express and respecting their mourning process without undue intrusion. Where greater concern does emerge, an opportunity presents to intervene appropriately. The staff who have developed the closest relationships with the family are wisely selected by the team to take up this observing model of follow-up as it provides them with a means of gradual farewell. Their formal identification and documentation is nonetheless important to ensure completion of the process over time. Final contact is often shortly after the first anniversary.

The second model of follow-up is for those individuals or families judged to be at greater risk and thought likely to benefit from a preventive intervention. Studies have shown that such prevention effectively reduces morbidity when delivered to those 20% likely otherwise to develop complicated grief (Schut et al., 1997). Teams vary in their pursuit of this depending on staff availability; in other instances, general practitioners provide active

individual support. Individual, group, or family approaches are valid and selected on the basis of personal needs. Where continuity of involvement of the counsellor from palliative care into bereavement is possible, direct knowledge of the deceased is advantageous, as is the continuing relationship with the bereaved. Attempts to establish bereavement counselling only after the death meet high rates of defensive avoidance blocking this form of support. Where social isolation is noteworthy, the additional support derived from a group approach maximizes connectedness (Yalom and Vinogradov, 1988; Lieberman and Yalom, 1992). Others will seek the personal support of individual therapy.

For many, a family approach is cost-effective in reaching several at risk when the nature of the family's functioning has been shown by screening to be dysfunctional. family-focused grief therapy (FFGT) offers continuity from palliative care through to bereavement and, in promoting family functioning, it fosters the role of the family as a natural and sustainable source of ongoing support (Kissane, 2000). Engaging the distressed family in supportive meetings can prove challenging, particularly for the protective family whose members wish to avoid distressing topics, or for the conflictual family in which the lack of emotional safety is barrier to open communication (Kissane, 1999). A flexible, yet focused model of family support that is guided by a collaboratively formed agenda helps the clinician to establish realistic parameters of care and protects against efforts to resolve more complex, longstanding issues (e.g. prior marital affairs). FFGT is also easily adapted to families of Hispanic and Asian origin, for whom culturally based values that promote family closeness and prioritize the caregiving role are well suited to a model of care that engages the family as a whole (Mondias et al., 2012; Del Gaudio et al., 2013).

The diverse range of clinicians in palliative care teams, including chaplains or pastoral care workers, nurses, social workers, psychologists or psychiatrists, general practitioners, volunteers, and generic bereavement counsellors ensure that there is no shortage of staff to support the bereaved. Nevertheless, staff caught up with the business of acute patient care will neglect the bereaved despite their best of intentions. Team leadership needs to actively monitor programmes of bereavement follow-up to ensure its adherence to an intended protocol and to initiate appropriate cross-referral of those at greater risk.

Grief therapies

Indications

For the majority, although bereavement is painful, their personal resilience will ensure their normal adaptation. There can, therefore, be no justification for routine intervention as grief is not a disease. Those considered at risk of maladaptive outcome are the ones that should be treated preventatively and those who later develop complicated bereavement need active treatments.

General considerations

The spectrum of interventions spans individual-, group-, and family-oriented therapies, and encompasses all schools of psychotherapy as well as appropriately indicated pharmacotherapies. Adoption of any model is predicated on the clinical issues and associated predicaments that arise. Thus, variation will be influenced by age, perception of support, the nature of the death, the

personal health of the bereaved, and the presence of co-morbid states. Clinicians generally plan for an intervention to proceed as six to eight sessions over several months and do well to map this out at the beginning. In this sense, grief therapy is focused and time limited, but multimodal therapies are commonplace. Thus, group as well as individual therapies better support the lonely so that socialization complements interpersonally any intrapersonal change. As loss is so ubiquitous within palliative care, all clinicians need skill in the application of grief therapies.

General supportive aids

Basic aids to any form of grief counselling include the use of evocative rather than sensitive language to assist the expression of feelings, the sharing of photo albums and special letters from the loved person, writing about any unfinished business to draw it to a close, and optimizing attendance at cultural or religious rituals to support the process of mourning. Children can be encouraged to make up a 'scrap' or memory book about a deceased parent as an aide to their adaptive mourning. Complementary forms of therapy such as art (Simon, 1982) and music (Bright, 1986) therapy can also make a valuable contribution to any programme for the bereaved. Any individual differences in the intensity and progress of mourning need to be normalized as appropriate. For instance, research has repeatedly confirmed that mothers express grief more intensely than fathers do (Kissane and Bloch, 1994). Time must be allowed to permit the process to unfold naturally and the length of mourning is helpfully appraised as proportional to the strength of attachment to the deceased.

Supportive–expressive therapy

The most basic model is a supportive–expressive intervention in which the person is invited to share their feelings about the loss to a health professional, who will listen and seek to understand the other's distress in a comforting manner. The key therapeutic aspects of this encounter are the sharing of distress and, through the relational understanding that is acknowledged, some shift in cognitive appraisal of the reality that has been forever altered. In supportive therapy, guided mourning is an approach to 'grief work' that promotes narrative review of the story, with repetitive recollections of the deceased being actively encouraged to relive and eventually revise the relationship experienced, ultimately redefining the reality of self and situation (Melges and Demaso, 1980; Mawson et al., 1981). In the process, Worden emphasized the accomplishment of four basic tasks of mourning: accepting the reality of loss, working through the pain of grief, adjusting to a new environment without the loved person, and establishing a collection of positive and useful memories of the deceased for future reference (Worden, 1991).

Reality testing and adaptation to the separation leads to what Parkes termed an altered assumptive world in which the ideas, attitudes, and beliefs about the self and the world are fundamentally altered (Parkes, 1975b; Janoff-Bulman, 1989, 1992). The inherent cognitive change is vital to future equanimity. Even when culture prescribes some level of continuing bonds with one's ancestors, creativity and generativity emerge from resolution of the mourning process (Parkes et al., 1997). Raphael has tended to understand much of this guided grief therapy within the rubric of 'crisis' intervention, placing additional emphasis on the mobilization of support to assist and comfort the bereaved (Raphael, 1983).

Interpersonal psychotherapy

This places emphasis on the nature of relationships and how the bereaved functions within these (Klerman et al., 1984). Any psychodynamic understanding of the patterns of relationship from childhood that repeat in adult life will inform these interpersonal approaches (Horowitz et al., 1984). The mixed feelings underpinning ambivalent relationships warrant expression and understanding, while the past influences on insecure and overly dependent patterns of relating help to consider future needs. The nature of the continuing relationship with the deceased is explored alongside any desire to replace the lost person. The urge for reunion with the deceased merits active discussion as suicidal desire easily grows out of persistence of such ideas. Gersie highlighted the dangerous pull that reunion fantasies can have when the dependent bereaved lament their loss and search to re-establish connection (Gersie, 1991). Increased suicide risk also occurs among socially isolated, elderly widowers, those who abuse alcohol, and those with a current or past history of depressive disorder.

Cognitive behavioural therapy

This offers a special contribution to chronic grief (Kavanagh, 1990; Shear et al., 2005; Boelen et al., 2007). Here, continued connectivity with the deceased may be valued, promoting some memorialization as 'stuckness' that prevents other progress in life. Repeated exposure to cues that induce sadness may deepen depressive illness in these circumstances. Behavioural approaches regulate exposure to these cues, optimize socialization through activity scheduling, moderate inappropriate drug and alcohol use, and promote graduated involvement in new roles and experiences. Related cognitive reframing of negative ideas such as unfairness and hopelessness steers towards a constructive adaptation.

Complicated grief treatment

This form of therapy was recently developed and evaluated by Shear and colleagues (Shear et al., 2005), and integrates techniques from interpersonal and cognitive behavioural therapies in order to specifically target symptoms of complicated grief. It draws upon the dual-process model of adaptive coping (Stroebe and Schut, 2001), thus focusing simultaneously on discussion of the loss and restoration of adaptive functioning. Attention to the loss and associated affect is alternated with pragmatic facilitation of identified life goals. In order to address the trauma-like symptoms presented in complicated grief (e.g. intrusive thoughts of death, avoidance of reminders of death), exposure-based exercises are adapted from cognitive behavioural therapies for PTSD. To address loss-related symptoms (e.g. yearning and longing for deceased) and encourage a revised connection to the deceased, the bereaved is invited to engage in an imaginal conversation with the deceased and to generate a list of positive memories. A randomized controlled trial compared standard interpersonal psychotherapy (IPT) with complicated grief treatment (CGT) among men and women who met criteria for complicated grief (Shear et al., 2005). Treatment response was evident in 51% of participants who received CGT, compared to only 28% of those treated with IPT. Furthermore, CGT was associated with significantly better outcome than IPT on self-report measures of complicated grief symptoms, depression, work and social functioning. Interestingly, among participants who had experienced a violent or traumatic loss, response rates were higher for CGT than for

IPT. Furthermore, response to CGT varied by type of loss, with loss of a spouse, friend or relative associated with higher response to CGT than loss of a child. In their trial, Boelen and colleagues found that exposure was more potent than cognitive restructuring; exposure is importantly located early in the therapy (Boelen et al., 2007).

When an overly dependent relationship has formed the basis of a complicated grief reaction, the bereaved's self-image changes from 'being valued and cared for' to being now 'alone and useless'. Patterns of perceived abandonment may re-emerge from earlier relationships. Therapy needs to target boosting self-esteem, confidence, and sense of security. The combination of both group and individual therapy has special merit since the group process promotes socialization in an individual otherwise at risk of isolation (Vachon et al., 1980). Brief group psychotherapy (Lieberman and Yalom, 1992) can be offered as a complementary programme of support for the more needy, and both variety and creativity can enhance such programmes, exemplified by one programme that combined group behaviour therapy with art therapy (Vachon et al., 1996).

Family-focused grief therapy

This family approach to grief intervention is a brief, manualized model of therapy (Kissane and Bloch, 2002). It aims to improve family functioning while also supporting the expression of grief and, as mentioned, can be applied preventatively to those families judged through screening to be at high risk of such morbid outcome (Kissane, 2000). Evidence from two randomized controlled trials of FFGT suggests that this model of care can benefit highly distressed families, is easily applied by clinicians of various disciplines and training backgrounds, and can be delivered in the outpatient setting, at the hospital bedside, or in the home (Kissane et al., 2006; Del Gaudio et al., 2012). Working with distressed families in the context of grief presents multiple challenges, such as how to sustain a systemic view, remain neutral to family conflicts, formulate realistic goals and be mindful of boundaries, particularly when working in the home. Peer support for clinicians in the form of supervision groups is an invaluable resource when conducting FFGT (Del Gaudio et al., 2012).

Commencing thus during palliative care and including the ill member in the family work, FFGT continues through the early phases of bereavement until there is confidence that morbidity has been prevented or appropriately treated. This approach invites the family to identify and agree to work on aspects of family life that they recognize as a cause of concern. Through enhancing cohesion, promoting open communication of thoughts and feelings, and teaching effective problem-solving to reduce conflict and optimize tolerance of different opinions, the improved functioning of the family as a unit becomes the means to accomplish adaptive mourning. The continuity of care and the personal knowledge that the therapist achieves of the dying family member empowers considerable maturation in the family unit not only as carers but also as comforters of the bereaved. Parentally bereaved children can also be greatly helped by family therapy (Sandler et al., 2010).

Pharmacotherapy accompanying grief therapies

Pharmacotherapies are widely used to support the bereaved—judicious prescribing is nonetheless important. Benzodiazepines allay anxiety and assist sleep, but words of caution should be offered about intermittent use to avoid tachyphylaxis and dependence. Antidepressants are indicated whenever bereavement is complicated by the development of depressive disorder, panic attacks, and moderate to severe adjustment disorders (Jacobs et al., 1987; Pasternak et al., 1991). If insomnia is prominent, tricyclics (e.g. dothiepin, nortriptyline, desipramine) or tetracyclics (e.g. mianserin) are beneficial; otherwise, selective serotonergic reuptake inhibitors (e.g. sertraline, paroxetine, citalopram, fluvoxamine, or fluoxetine) or combined noradrenergic and serotonergic reuptake inhibitors (e.g. venlafaxine, duloxetine, or mirtazapine) are indicated. Occasionally, antipsychotics are needed for hypomania or other forms of psychosis.

An integrated approach to the treatment of complicated grief incorporates balanced combinations of pharmacology (e.g. antidepressants or antianxiety agents), individual psychotherapy, and socialization through family or group work (Jacobs, 1993). Where the experience of death has been in some manner 'shocking', incomplete assimilation of the event can develop, leading to intrusive recollections and numbing. Here, the bereaved need to make clear sense of the loss, understanding the mechanisms involved in the death, and attributing responsibility to appropriate factors (Rynearson, 1987). Benzodiazepines have a particular role in reducing autonomic arousal, lessening intrusive symptoms, and allaying anxiety so that avoidant responses are minimized (Jacobs, 1993). The treatment team helps further by bringing the bereaved back in the weeks after the death to review overall understanding of events and report on findings from any autopsy. Whenever a coroner's inquiry follows a death, the bereaved are to be encouraged to attend to increase their integration of understanding of such events.

The notion of recovery is important and recognized by the return of equanimity in discussion of the deceased. A process of social transition has been accomplished (Silverman, 1986). New interests or roles are adopted, with new friendships emerging. Eventually, the bereaved see their future with reprioritized and altered world views. As ultimate evidence of completed mourning, new generativity and creativity emerges in the activities and lives of the bereaved (Polloch, 1989).

Special types of loss

Particular needs arise for bereaved children, the very elderly, and when loss is especially stigmatized, for instance, death from AIDS. The timing of such deaths within the life cycle explains some of the special considerations that arise.

Children and bereavement

The general principle of open communication with children about cancer or serious illness, its nature and meaning, treatment, and prospect of death is important (Adams-Greenly, 1984; Eiser and Havermans, 1992) (see also Chapter 16.1). Concepts need to be presented in an age-appropriate manner, recognizing that the finality of death only becomes more completely understood around the age of 9–10 years (Rowland, 1989). Younger children believe that death is reversible; after age 5, the understanding is more in terms of separation with a gradual recognition of its irreversibility. Families can teach children a healthy understanding of the life cycle and support the child through identification of and reassurance by available, surviving adults who commit to remaining involved

with the child in the future. Such processes may help a child to mature more rapidly and grow in their appreciation of death as cessation of life. Children display a variety of bereavement symptoms including sadness, fear, guilt, insecurity, and behavioural problems (Webb, 1993). A programme that guides parents in what to say and do to assist their children was found to be helpful (Adams-Greenly and Moynihan, 1983; Moore and Rauch, 2010).

The death of either a parent or sibling is a significant and distressing occurrence that prompts many children to ask questions such as: 'Why? Did I cause it? Who will care for me?' Careful discussion of death causation is worthwhile to avoid prophylactically any misinterpretation by the child. In the setting of advanced cancer, when death can be anticipated, preparation of the child through involvement in care activities and open discussion of realities facilitates acceptance and adjustment. Subsequent involvement of children in funeral and anniversary rituals (Silverman and Worden, 1992) normalizes the experience of loss and promotes the family as the continuing, supportive environment (Wells, 1988).

The long-term effects of childhood bereavement are not completely clear, as studies have been hampered by being retrospective, but they have suggested that the loss of a mother prior to age 12 predicts an increased risk of adult depression. However, the quality of the relationship to subsequent care providers may be more significant in determining outcome than the parental loss (Tennant et al., 1980). Nonetheless, should such children develop cancer themselves in adult life, their memories of their dying parent and related identifications are powerful influences on their overall adjustment.

After accidents, cancer is the second leading cause of death in childhood. The family typically focuses on the dying child with the risk of relative neglect of other children. They in turn may try to replace the dead child and experience survivor guilt. Openness of family communication about all aspects of the illness and death is the best formula to promote normal grieving and family meetings can especially model this. The grief of the parents needs support alongside the grief of the children, empowering the parents to attend to their children's grief, rather than the children being parentified as a support for their parents. Parents may become hypervigilant about their surviving children's health, unwittingly promoting hypochondriasis in later life if too much attention is placed on somatic symptoms and fear of cancer. Attention to the functioning of the family provides the most useful model for recognition of those at greater risk of poorer outcome (Davies et al., 1986). Families that block discussion, suppress sharing of feelings, and concentrate rigidly on concrete events fare more poorly than families that comfort one another with empathy and teamwork.

The elderly and bereavement

When couples have been married for many years, the length and depth of their attachment may predispose them to profound grief, further complicated by the acute loneliness they can experience if many of their friends and sources of support have already died. Elderly bereaved men can have particular needs in these circumstances (Byrne and Raphael, 1994). Moreover, despite apparent support from within the family, the bereaved spouse may carry an especially painful level of loneliness (Large, 1989). The social support of the elderly bereaved warrants special consideration, including use of volunteer programmes (Lopata, 1986).

Bereavement during adulthood

Although the loss of a spouse has received most attention in research, loss of a parent or sibling during adult life is a common event and will generate distress proportional to the degree of emotional closeness to the deceased. Increased maturity is one potential outcome of such losses (Malinak et al., 1979). Where there is a high familial incidence of cancer raising questions of genetic risk, as in familial polyposis, breast, or colon cancer, the death of a sibling increases the sense of vulnerability of family members and highlights the importance of genetic testing and counselling when relevant.

When comparisons have been made between the death of a spouse, parent, or child, the most intense bereavement reactions are found following the death of a child, an event clearly out of step with life-cycle expectations (Saunders, 1979; Saunders et al., 1998). Parents have a strong and powerful investment in their children such that their premature death shakes the adult personality to its very roots (Rubin, 1993). Its impact is life-long—although the distress slowly declines with the passage of time, it plateaus eventually to a steady state of continued influence, although the meaning of this continues to change throughout the life cycle (Neimeyer et al., 2000). For many it is a disruptive and life-shattering experience, necessitating a continuing life-long accommodation, but this is affected to some degree by the quality of the relationship before the child's death and the relationship that exists with other surviving children (Dyregrov and Dyregrov, 2008).

Aware of such inherent challenges, palliative care teams do well to involve parents in the care of terminally ill children (including adult offspring), foster open communication of feelings about the death, and seek views on their philosophy of life. Where parents can find some meaning and sense of purpose in their child's life, their acceptance of the death, despite its inherent unfairness, is likely to be greater (Spinetta et al., 1981). The incorporation of parents into the model of family-centred care remains important when a middle-aged adult is dying and predeceasing elderly parents; often the focus of the palliative care team is on the nuclear family, supporting the spouse and children to the neglect of parental grief.

Hospices for dying children allow particular care to be taken of the family, including continuity of this care into bereavement. Active discussion of the choice between death at home or in the hospice is important and a family-centred model of care will consider the potential impact on usually three generations of family membership. Well-functioning families are perceived to cope better with death in the home, while respite admissions can bring relief to those families more stressed by the emotional demands of caring for the dying child. Irrespective of whether death is affecting a young child, an adolescent or young adult, grief is intense and potentially protracted; sustained support of family members is especially important when the functioning of the family has been stressed or is clearly dysfunctional.

Bereavement and AIDS

The stigma associated with human immunodeficiency virus (HIV) infection handicaps the adjustment of both patients and their families and adds a risk factor for complicated grief. Caregiving partners of men with AIDS experience several stressors that induce role conflict and burden (Folkman et al., 1994). Mean scores for depressive symptoms were found in one longitudinal study to remain at one standard deviation above the general community

norm 3 years after the death (Moskowitz et al., 1988). The families also display complex dynamics related to their degree of acceptance of a homosexual relationship, any ambivalence about which potentially complicates the mourning process (Wolfe, 1993).

Spirituality and bereavement

The existential quest to understand the meaning of life creates an endeavour to understand the uniqueness and special contribution of each and every person. This spiritual orientation influences adaptation both to dying and to bereavement. Clinicians do well to inquire about the spiritual dimensions and philosophy of life of both their patients and families (Doka, 1993). For some, this will be expressed in the language of their religious beliefs; for others, cultural custom and traditions will inform their set of values and the philosophy by which they have lived. Using these values to understand the life of the deceased helps in appraising their accomplishments, the sort of person they were, and the meaning their life had. When consensus about this can be achieved with the bereaved, it assists their acceptance of the death. Moreover, when the latter has been peaceful, this will console the bereaved, but when the death was difficult, disappointing, or in some manner horrifying, there is considerable work to do in helping the bereaved to understand and come to terms with this final outcome. A spiritual understanding of the person's life may help in accepting the limitations of palliative care or coming to terms with any unfinished business that remained in the deceased's life. Philosophically this may be akin to letting go of the ideal and accepting a life lived with a goodness that is sufficient (Kissane et al., 2012b).

Ritual is an important component of religious and cultural tradition as it creates a proven pathway down which the bereaved tread (Faschingbauer, 1981). The wisdom of centuries is often woven into such rituals as a means of assisting the bereaved to mourn. Respect for such ritual is important and clinicians help the bereaved by endorsing its value. Familiarity with different ethnic traditions is worthwhile in palliative care. Nonetheless, should a clinician meet an unfamiliar ethnic group, they should seek from the relatives an understanding of their tradition and strive to cooperate with them in a culturally sensitive manner.

Positive outcome and personal growth

The adaptation that follows the wrenching loss of bereavement is associated with personal growth for a sizeable proportion. Although this personal growth manifests itself most clearly after the acute pain of grief, it is actually identifiable across all phases of the bereavement process (Hogan et al., 1996). Renewed sense of meaning, self-awareness, increased empathy, appreciation of family and relationships, independence, reprioritized goals and values, deepened spirituality, and increased altruism can all result from positive reappraisal, seeking for help and enhanced social resources.

Clinicians can helpfully reassure bereaved people about these beneficial outcomes, especially at times when the going is hard. Providing information about the longitudinal course of the mourning process including the prospect of such personal growth creates a feedback loop that nurtures adaptive recovery through cognitive appraisal and active coping.

Conclusion

Bereavement care is an integral dimension of palliative medicine as clinicians sustain continuity of care in assisting the family or carers of their deceased patient. Knowledge of and competence in assessing grief is essential to enable recognition of the 20% of the bereaved who get into difficulties and need additional assistance. Routine assessment of the bereaved for risk factors for complicated grief provides a responsible method through which treatment teams can intervene preventatively or early to reduce unnecessary morbidity. Effective therapies are available to assist in the management of complicated grief and palliative care practitioners should be skilled in their application or understand the circumstances when referral for further specialist help is appropriately made. Grief is an inevitable dimension of our humanity, an adaptive adjustment process, and one that with support can be approached with courage. Grief that is shared is grief that is healed.

SECTION 18

The terminal phase

Management of the actively dying patient

Judith Lacey

Introduction to management of the actively dying patient

Just as each phase of the illness journey has its unique challenges, so too does the care of the actively dying patient. The period leading to death is characterized by increasing prevalence and intensity of physical, psychological, existential, and social concerns, and it is often a challenging time for patients, their families, and health-care providers.

Addressing the whole-person needs of the patient at this time with excellent clinical skills, compassion, and understanding can greatly reduce the suffering experienced as well as support and maintain patients' dignity and autonomy (Cassem, 1991; Thompson and Chochinov, 2010). The goal of care during this phase is to minimize distress for patients and their families by meticulous symptom control and supportive care, while maintaining the well-being and moral integrity of all.

Ethical and relationship issues in the transition to end-of-life care

The premises that underlie end-of-life care are:

- the ethical imperative to provide adequate relief of suffering
- that dying patients should not be subjected to ineffectual treatments which cause further distress
- that all patients have a right to adequate relief of physical and psychological symptoms, and social support
- that all patients have the right to care that enables them to have the best possible life given the constraints of their prevailing circumstances (Cherny et al., 1996).

The idea of a 'good death' is a concept that medicine is trying to identify and quantify, although the construct is itself also controversial (see Chapter 2.4) (Miyashita et al., 2007; Hughes et al., 2008). Whilst ensuring that goals of care shift to allow for those priorities that contribute to a 'good death'—this transition must also be characterized by non-abandonment.

Specific skills and knowledge to ensure high-quality end-of-life care

Assessment and prognostication

Recognizing that a patient is imminently dying is the prerequisite for providing appropriate end-of-life care. Indeed one of the common problems in the care of the dying is failure to appreciate that the patient is indeed close to death. Prognostication and recognizing that death is near is, therefore, a cardinal clinical skill (Glare and Sinclair, 2008).

Establishing a short-term prognosis is part of the therapeutic alliance and yet is one of the most challenging aspects of care for many. Using and communicating this knowledge requires an individualized, patient-centred, and culturally appropriate approach (see Chapter 2.3).

Defining and recognizing the terminal phase

The terminal phase is defined *as a period of irreversible decline in functional status prior to death.* The terminal phase can last from a few hours to days and very occasionally to weeks. Worsening of certain symptoms is indicative of entering the terminal phase (Pitorak, 2003):

- weight loss
- profound weakness and fatigue
- social withdrawal
- disinterest in food and drink
- dysphagia and difficulty in swallowing medication
- refractory delirium
- changes in breathing
- drowsy for extended periods
- reduced urine output
- skin that is cool to touch
- a waxy look to the skin.

Recognizing this phase allows for the pre-emptive planning of care for the patient, preparation of family, patient, and staff, and may involve discussions around preferences for end-of-life care, place of death, and anticipated symptom control.

Whilst there are situations where it is possible to identify the terminal phase with some accuracy, many diseases have a natural history of progression and exacerbations that make the terminal phase difficult to identify (Lunney et al., 2003).

Communication with patients and families about end-of-life care

End-of-life care discussions make a difference. Well-conducted discussions about end-of-life care foster trust and non-abandonment

for patients and carers and improve end-of-life outcomes for both the patient and the bereaved (Steinhauser et al., 2000; Detering et al., 2010). Discussing the approaching terminal phase and end of life with patients and families reduced the number of aggressive medical interventions near death, and, compared to those who had not had these conversations, reduced distress and improved quality of life of both patient and family/caregiver. Importantly, recent studies have demonstrated that end-of-life discussions were not associated with increased patient emotional distress or psychiatric disorders (Emanuel et al., 2004; Wright et al., 2008; Mack et al., 2010) and Mack and colleagues found a reduction in family/caregiver bereavement morbidity when the dying patient had the benefit of end-of-life discussions (Mack et al., 2010).

When the terminal phase is recognized, this needs to be communicated to the family and patient with empathy and equanimity. This is a task requiring sensitivity and skill, which can be improved with specific training. It is important for health-care professionals to be aware of their own feelings of grief, fear, anxiety, and guilt, and to acknowledge the impact this can have on the way they approach this conversation and ongoing communication (Curtis et al., 2004; Hancock et al., 2007).

Cultural awareness is extremely important and influences how and what information is communicated. Using interpreters can be vital (Crawley, 2005; Searight and Gafford, 2005; Volker, 2005). Frequently patients and families fear uncontrolled pain and other distressing symptoms, and should be confidently reassured about the management of these. When discussing future care planning and possible symptoms to anticipate, the family and the patient may have different information needs. Ideally the aim is to maintain a balance between supporting the patient's and family's sense of control and dignity, reducing their fear of suffering, and maintaining the hope for good quality of living, whilst preparing for death (Steinhauser et al., 2001).

Preparing the family and family well-being

Care of the family is integral to caring for a dying patient. Surveys of families of patients dying from advanced cancer have identified a series of critical needs (Table 18.1.1). These can be used as a checklist for assessing family needs, preparing for terminal care at home, and promoting family well-being. Families with dependent children have complex needs and make choices around end of life that have been found to differ from others (Nilsson et al., 2009).

Discussing advanced care planning and resuscitation

Among patients with chronic disease, life-threatening events and death occur in two distinct situations:

Anticipated dying

In patients with terminal illness, cardiopulmonary resuscitation (CPR) may prolong, but cannot reverse, the dying process; however, the patient, family, and indeed some health-care professionals may not fully comprehend the ineffectiveness of this intervention for the patient. It is important to discuss with patients, family, and team members the role of CPR and not for resuscitation/do not resuscitate orders as failure to discuss these may result in patients receiving unwanted interventions

Table 18.1.1 Families' support and information needs during the terminal phase

Patient comfort	Prompt and effective relief of patient symptoms is essential to support the family as a whole
Information and communication	Communication needs to be honest, direct, and compassionate, and must allow for the concerns and opinions of the family to be heard and appreciated. Family members need information about the likely course of the patient's illness. Potential symptoms and plans for their monitoring and management should be explained
Evaluation of family needs and resources	The degree with which the family is able and willing to participate in care is a major determinate in formulating a care plan.
	If the family are considering caring for a patient at home, family members need information regarding the daily care needs of the patient, likely clinical problems, available resources for routine care, and availability of emergency care
Care education	Irrespective as to whether the patient is at home or in hospital, family members require guidance regarding ways in which they can contribute to the comfort care of the patient
Emergency provisions	If the family are considering caring for a patient at home, the family need to know what to do and who to call in case of uncontrolled symptoms and when the patient dies
	Link to a 24-hour phone support service is important in this situation
Review of family coping	Family coping should be regularly assessed to enable early intervention to address unmet emotional or supportive needs of the family or previously unappreciated patient problems
Care of the family when the patient is unconscious	Continued vigilance and reassurance that comfort is being achieved are essential for the well-being of the family
Preparing the family for the dying process	When death is imminent, the family should be forewarned of the process that they are likely to witness

Adapted from Hematology/Oncology Clinics of North America, Volume 10, Issue 1, Cherny, N. I et al., Guidelines in the care of the dying cancer patient, pp. 261-86, Copyright © 1996, with permission from Elsevier, http://www.sciencedirect.com/science/journal/08898588.

(Hofmann et al., 1997; Loggers et al., 2009). This conversation is particularly difficult because it highlights the reality that the person's death is imminent. Such discussions are frequently avoided until the days just before death. However, these discussions have not been found to change patient or surrogate satisfaction with the clinician (Anderson et al., 2011). Despite being extremely unwell and aware of their disease process, dying patients differ in their capacity to acknowledge prognosis, with the majority only partially aware of the proximity of death (Chochinov et al., 2000; Mack, 2010).

The conversation should focus on the positives of what can and will be done for the person at the end of their life (Harlos, 2009)—with the emphasis on their dignity, comfort, and the prevention of distress. This should be done with sensitivity and empathy, allowing time to deal with the questions, concerns, and sometimes strong emotions associated with this issue (Lacey and Sanderson, 2010).

Advanced care planning for patients with unanticipated threatening events

The effect of the illness on the body and, sometimes, its treatment can cause sudden life-threatening medical crises for patients with advanced chronic illness. Some of these events may be reversible, some may have a very small chance of being reversed, and some may not be reversible at all.

Given their state of chronic ill health and ultimate incurability, patients vary in their approach as to how they would want to be treated in this situation. Opinions are often influenced by any one of many factors, such as religious or cultural beliefs, fear of suffering, fear of death, unfinished life plans, or the advanced stage of the disease:

◆ Some patients would want every possible treatment tried.

◆ Some would want to try some treatments but not others. For example, some patients give advanced directives that they would want to have artificial feeding, but would not want to be dependent on a machine to help them breathe.

◆ Some say that they would want aggressive treatments to be tried but, if they were not responding, they would want these stopped and replaced with comfort measures only.

◆ Some patients indicate that they would not want aggressive therapies, rather comfort measures only, allowing them either to recover with simple measures or to die in comfort.

The issues regarding advance care planning for patients with anticipated dying from vital organ failure as a consequence of their disease are different from the issues of those patients with unanticipated, acute life-threatening events. It is inappropriate to conflate these two issues in ascertaining patient preferences for end-of-life care.

It is important that this discussion and any subsequent decision is clearly documented in the patient's medical records and communicated to other health-care providers.

Identifying substitute decision-makers and advance care planning

As a person approaches death, their ability to make decisions may become impaired. Encouraging advance care planning, directives, or discussions with the patient prior to the terminal phase

greatly reduces the burden on the substitute decision-maker and ensures the patient's choices are respected (Detering et al., 2010; Keating et al., 2010).

Symptoms management in the final days of life

Addressing psychosocial and existential concerns at the end of life

At the end of life, studies clearly suggest that existential and psychosocial issues greatly concern dying patients (Boudreau and Cassell, 2010). Through understanding and addressing factors that may potentially overwhelm the patient, family, and/or health-care providers, the necessary preconditions for coping can be established (Chochinov et al., 2008; Cherny, 2009; Cassell, 2010; Cassell and Rich, 2010). This is a vital and integral part of the care of the actively dying person and is discussed in detail in Section 17 of this textbook.

General principles for management of physical symptoms in end-of-life care

Problems of weakness, fatigue, and loss of appetite become more evident as death approaches. In the terminal phase, these problems usually start to assume relatively less significance for patients—although not necessarily for families. Comfort-related symptoms become increasingly important—particularly pain, dyspnoea, delirium, fear/anxiety, and respiratory secretions. Active assessment and pre-emptive management of these problems is crucial, especially as the patient becomes less able to communicate. Whilst the overall approach to managing these problems is presented elsewhere, the following discussion relates to the end-of-life setting, which creates some specific challenges.

Discontinuing non-essential medications

Only essential medications should be given and they should be administered by the least invasive route that can provide adequate relief. An appropriate rule is to identify and cease any drug which does not contribute to the patient's immediate comfort. Likewise observations and investigations that do not contribute to comfort should be ceased. Families will need reassurance that meticulous care continues with comfort being the goal of care (Abrahm, 2005). If persistent reservations about the withdrawal of a medication that is not causing the patient harm (such as an antibiotic) are expressed by the patient and/or family, the medication may be continued. It is often helpful to set a time limit on such treatment, whilst identifying specific improvements that would justify further treatment beyond that point.

Medications for pain and symptom control should be continued and the route converted from oral to transdermal and/or parenteral (the subcutaneous route is preferred wherever possible as it is less traumatic for the patient). Loss of the ability to swallow in the terminal phase should be anticipated and planned for by provision of as-needed (PRN) medications so that patients are not left without adequate symptom control, especially for a crisis (e.g. seizure, airway obstruction, bleeding, and so on). As a person's physical condition changes so too can their renal function and metabolism of medications. Careful monitoring and adjustment of medications is frequently required (see Table 18.1.2).

Table 18.1.2 Essential medications for management of symptoms in the actively dying patient

Symptom/indication	Medication	Application route	Dosage	Over 24 hours via syringe driver (SD)
Pain				
	Morphine or opioid equivalent	SC /IV injection or transdermal fentanyl	Convert oral medication to parenteral equivalent	Morphine compatible in SD with most medications
Neuropathic pain	Lignocaine/ketamine	SC/IV	Continue as previously or initiate if required for neuropathic pain	Yes
Breathlessness				
	Morphine or equivalent opioid	SC/IV injection	1–2.5 mg q4 h SC for breathlessness in the opioid naïve	24 h total dose in SD
With anxiety	Lorazepam	Tablet for SL	0.25–1 mg tds	
Refractory breathlessness	Midazolam	IV or SC	1–5mg q4 h	Estimate 24 h total dose and add to SD
Nausea				
Useful if prokinetic required	Metoclopramide	SC or IV	10–20mg tds–qid or via SD over 24 h	30–80 mg/24 h via SD
Primarily central	Haloperidol	SC or IV	0.5–1.5 mg bd–tds	1–15 mg over 24 h via SD. Usually up to 5 mg
Primarily central	Levomepromazine	SC	6.25–12.5 mg qid	25–100 mg/24 h
Primarily central	Cyclizine	SC	25–50mg	300 mg/24 h via SD. Compatibility issues
Gastrointestinal obstruction				
With colicky abdominal pain	Buscopan (hyoscine butylbromide)	IV or SC	20–40 mg qid	Up to 240 mg/day
With refractory vomiting	Octreotide	IV or SC	100–300 micrograms tds	Up to 1200 mg/24 h
Terminal restlessness/agitation/refractory hyperactive delirium				
Antipsychotic required	Haloperidol	SC or IV	1.5–5 mg tds SC	3–15 mg/day
	Levomepromazine	SC	25–50 mg qid	Up to 200 mg/day
	Olanzapine wafers	PO	2.5–10 mg bd	
	Chlorpromazine HCL	PR	50–100 mg bd	
Benzodiazepine required	Midazolam	SC/IV	2.5–5 mg q4 h	Up to 60 mg/day
	Clonazepam	SL/SC	0.5–1 mg bd	SC via SD. Compatibility issues
Other sedation required	See section on terminal sedation			
Respiratory secretions				
When unconscious	Hyoscine	SC	0.4 mg q2–q4 h	2.4 mg/24 h
When conscious	Glycopyrrolate	SC	0.2–0.4 mg q2–4 h	2.4 mg/24 h
Acute crisis episode				
Sedation required (also see other sedatives)	Midazolam	SC or IV	2.5–10 mg stat and q2 h PRN	Consider continuous dose
Acute pain syndrome	Morphine or parenteral opioid equivalent	SC or IV	10 mg in opioid naïve or 1/6 total opioid dose	Consider increasing baseline 24 h dose

Table 18.1.2. (Continued)

Symptom/indication	Medication	Application route	Dosage	Over 24 hours via syringe driver (SD)
Seizure				
Acute and maintenance	Midazolam	SC, IV, buccal	2.5–10 mg stat or continuous	10–20 mg maintenance for seizure prevention
	Clonazepam	SL drops, or SC amps	0.5–1 mg stat, bd	1–2 mg continuous for seizure prevention
Anxiety/distress	Midazolam/clonazepam/lorazepam	IV/SC or SL	See 'Breathlessness' and 'Agitation'	Continuous if sedation required

bd, twice a day; h, hour; IV, intravenous; mg, micrograms; PO, orally; PR, rectally; q, every; qid, four times a day; SD, syringe driver (e.g. Grasby); SC, subcutaneous; SL, sublingual; tds, three times a day.

Pain

Pain management continues to be crucial. Based on a precautionary principle, it is important not to discontinue analgesics in the dying patient. Ensure availability of medications to be given by a non-oral route (preferably subcutaneous) and review the clinical need for any medications for which there is no parenteral form available, for example, some of the adjuvant analgesics. Whilst decreased levels of physical activity may mean that pain control is adequate despite ceasing oral adjuvants, if this is not the case, opioids may need to be increased to cover additional requirements. Alternative adjuvant medications, for example, anti-inflammatory or antineuropathic agents that can be delivered subcutaneously may be required (see Section 9 of this textbook for details of pain management).

Dyspnoea

Up to 70% of patients experience dyspnoea in the last 6 weeks of life, and its prevalence, severity, and associated distress increase as death approaches (Ben-Aharon et al., 2008; Kamal et al., 2012) (see also Chapter 8.2). It is usually multifactorial. Though it may be clinically appropriate to manage reversible causes of dyspnoea, in the final days of life dyspnoea can be more refractory to interventions, as the dominant causes become less amenable to modification (e.g. obstructing tumour; general weakness and frailty; restrictive conditions, including chest wall disease; lymphangitis carcinomatosis; pleural infiltrate or refractory effusions; diffuse extensive lung pathology or infection.) In this setting, pharmacological management with oral or parenteral opioids to reduce the distress of dyspnoea has been shown to be of benefit (Allard et al., 1999; Ben-Aharon et al., 2008) (see Box 18.1.1). Benzodiazepines may be useful for reducing panic and anxiety frequently associated with dyspnoea but have not been shown to improve dyspnoea itself. Oxygen therapy has been found to improve dyspnoea in the hypoxic patient (Booth and Wade, 2004; Gallagher and Roberts, 2004; Cranston et al., 2008; Uronis et al., 2008). Whilst non-pharmacological measures such as a fan and positioning are simple techniques that can improve the patient's comfort, in contrast, relaxation and breathing techniques take considerable concentration and are difficult to initiate late in the terminal phase (Zhao and Yates, 2008). For the patient with refractory dyspnoea and severe distress in the terminal phase, sedation is an option to consider for maintaining adequate symptom control and reducing suffering (see Chapter 8.2).

Delirium and agitation

In the terminal phase, delirium has been found to be present in up to 88% of patients when carefully screened for (Lawlor et al.,

2000a, 2000b) (see also Chapter 17.5). Delirium may be hypoactive or hyperactive (de Rooij et al., 2005). Although witnessing agitated delirium is upsetting for family, caregivers, and health-care professionals alike, the degree of patient distress associated with the thought-disordered states of hypoactive delirium should also not be underestimated (Leonard et al., 2008; Chochinov and Breitbart, 2009). Refractory delirium is a poor prognostic factor and often heralds the terminal phase (Maltoni et al., 2012).

In a patient with hours to days to live, the key issue is deciding whether to symptomatically manage delirium rather than burdening the patient and family with a search for causes or

---

Box 18.1.1 Pharmacological options for management of dyspnoea at the end of life

For the opioid naive patient

Starting dose of 2.5–5 mg morphine PO every 4 hours regularly or PRN may be sufficient. Alternative opioids at an equivalent dose can be tried if there is intolerance to morphine; however, most studies on dyspnoea have used morphine and evidence for other agents is lacking. Titrate upwards as tolerated.

For the patient already on opioids

Increase the usual morphine (or alternative opioid) dose by 25% (and up to 50%)—shown to be effective and tolerated, although evidence as to what dose increment is most effective is limited. Therefore starting lower and titrating up or adding a 25% of total dose PRN initially is acceptable, safe practice.

Addition of benzodiazepines

Used as second-line management of refractory dyspnoea associated with distress. Midazolam 2.5 mg four times a day is a reasonable starting dose. Lorazepam can also be used 0.5–1 mg three times a day sublingually.

Refractory dyspnoea

A combination of opioids and benzodiazepines/sedatives can be used to manage distress (see Chapter 18.2).

Reproduced from Judith Lacey and Christine Sanderson, The Oncologist's Role in Care of the Dying Cancer Patient, Cancer Journal (ISSN: 1528-9117), Volume 16, Issue 5, pp. 532-541, Copyright © 2010, with permission from Lippincott Williams & Wilkins, Inc. trial of management for reversibility. The aim is to maintain the patient's dignity, reduce any agitation and associated risks to the patient and caregivers, and to ease distressing hallucinations, delusions, and restlessness (Caraceni and Simonetti, 2009). The symptoms of delirium at the end of life need to be palliated confidently, with compassion, reassurance, and clear explanation of the impact of pharmacological and non-pharmacological strategies to improve symptom control (Breitbart and Alici, 2008). Medications for treating agitation and delirium in the terminal phase include antipsychotics able to be given parenterally—such as haloperidol, levomepromazine, risperidone, or olanzapine (by sublingual wafers) and chlorpromazine (which can be given rectally). Benzodiazepines may be required for more rapid control of agitation and anxiety, but can potentially worsen delirium if used alone. The doses used should be the lowest dose that is effective for the symptoms of concern (see Chapter 17.5).

The condition identified as 'terminal restlessness' is a frequently described though little-studied state of agitation and reduced conscious level which appears to be closely associated with the onset of the terminal phase (Brajtman, 2005). Diagnostically it is most consistent with a refractory agitated delirium in an actively dying patient, possibly triggered by the onset of the terminal phase itself. However, before making this diagnosis it is worthwhile to consider, and exclude if clinically appropriate, other physical, medication-related, or medical causes of agitation. The latter includes status epilepticus, akathisia, serotonergic syndrome, myoclonus, hypoxia, physical pain or discomfort in an obtunded patient (e.g. from itch, urinary retention, or faecal impaction), medication toxicity, or paradoxical reaction (White et al., 2007). If no other cause is found and the clinical context is consistent with the onset of the terminal phase, palliation should be prompt and effective using sedating antipsychotics with or without benzodiazepines to reduce patient awareness and motor agitation.

Terminal secretions (death rattle)

During the last hours to days of life, terminal secretions (the 'death rattle') may become evident. They have been found to occur in around 44% of dying patients (Morita and Hyodo, 2004). The mechanism remains uncertain, but it may be due to pooling of saliva and secretions in the upper airways along with reduced swallowing reflexes, dysphagia, and inability to expectorate. This has been called type I death rattle or 'true' death rattle (Bennett et al., 2002; Wildiers and Menten, 2002) in contrast to type II rattle, which is due to pooling of bronchial secretions. Type II or 'pseudo' death rattle can appear over days and may not respond as well to antimuscarinic/anticholinergic medications. Included in type II are other causes of retained secretions, such as bronchorrhoea from primary lung tumour, infection, dysphagia, bleeding, airway obstruction, pulmonary oedema, or tracheo-oesophageal fistula (Bennett et al., 2002; Mercadante et al., 2011). No significant association has been found between hydration status and the development of death rattle (Ellershaw et al., 1995; Morita and Hyodo, 2004). The true death rattle is a strong predictor of approaching death—in one study 76% of patients died within 48 hours of its onset (Wildiers and Menten, 2002).

Antimuscarinic agents can be used to reduce the salivary secretions. Although most studies of the efficacy of antimuscarinic agents on reducing salivary secretions are mostly based on single-dose studies, a randomized trial of three anticholinergic agents in 333 patients (Wildiers et al., 2009) showed beneficial responses in up to 76% of patients by salivary secretion reduction. This was less marked in secretions thought to be of bronchial origin or 'pseudo death rattle'. The evidence supporting this practice is not robust but therapeutic trial is reasonable, paying attention to the adverse effects profiles (Wee and Hillier, 2008; Mercadante et al., 2011,). It is important to reassure families that terminal secretions are rarely distressing for the patient, although they may be distressing for the family.

Addressing functional decline and increased need for assistance

With progression of illness and reduced overall function there is an associated reduced ability to carry out independent activities of daily living. Transferring may require assistance and the environment of care may often require modification to improve access, safety, and comfort. If available, the input of an occupational therapist and physiotherapist is very useful preferably prior to the onset of the terminal phase.

Mobility, skin, and mouth care

Meticulous nursing and active monitoring for symptom distress is essential in the care of dying patients. Common problems include immobility, pressure area care, care of bladder and bowel, secretions, xerostomia, and odours. For the imminently dying patient, measuring and recording patient data not directly related to comfort (such as pulse and blood pressure) is superfluous and can be discontinued unless there are religious, cultural, or other concerns (Cherny et al., 1996).

Bowel and bladder function

Incontinence of urine, reduced mobility impacting on toileting options, and urinary retention are all potential problems. These can impact on a person's sense of dignity and should be dealt with sensitively. Catheterization or, if no retention, incontinence pads, are often required. Ultrasound bladder scanning is a valuable investigation to minimize inappropriate catheterization. Judicious rectal intervention may be appropriate to maintain regular bowel motions if the patient is uncomfortable. Faecal impaction and urinary retention can cause severe distress and should always be excluded as a cause of agitation in the obtunded patient.

Refractory symptoms and suffering: approach to care

Uncontrolled suffering in a dying patient is considered a medical emergency (Cherny, 2009), but suffering cannot be treated unless it is recognized and diagnosed (Cassell, 1999) (see also Chapter 18.2). Occasionally in the terminal phase, symptoms and suffering are refractory to all standard palliative interventions. Suffering is considered refractory if, despite use of aggressive and concerted efforts to determine and treat the cause, suffering persists. Refractory suffering can relate to intractable symptoms including complex pain, severe dyspnoea, nausea and vomiting, neuropsychiatric symptoms including agitated delirium, fitting, and very occasionally severe anxiety or depression, or other irreversible crises. All available and appropriate diagnostic, therapeutic, and consultative processes need to be exhausted (including

Box 18.1.2 Criteria for determination of refractoriness of a severe symptom

Diagnosis

Aggressive efforts to diagnose the severe symptom are either successful or are exhaustive but unsuccessful within a reasonable time frame

Treatment

Aggressive efforts to relieve the severe symptom using all available resources are unsuccessful within a reasonable time frame

Consultation

All available colleagues who might assist in diagnosing or treating the symptom or in providing psychosocial support to the patient or family within a reasonable time frame have been consulted

Transfer

Transfer to another location where more potentially helpful resources are available is either not feasible or has been refused by the patient

Persistent suffering

The patient continues to report intolerable suffering despite all above interventions, or a patient lacking the ability to communicate verbally appears to the surrogate decision-maker, the responsible physician, and at least one other clinician to be in severe distress despite all above interventions

Originally adapted from Eric L. Krakauer and Quinn E. Thomas, Sedation in palliative medicine, Table 19.2.1, pp.1560–1588, in Cherny et al. (Eds.), Oxford Textbook of Palliative Medicine, Fourth Edition, Oxford University Press, Oxford, UK, Copyright © 2010, by permission of Oxford University Press.

consultation with pain, palliative care, psychiatry, and other relevant experts if available) before classifying suffering as refractory (Krakauer and Quinn, 2009) (Box 18.1.2).

The role of sedation in the care of dying patients

Palliative sedation is an option in the terminal phase if refractory suffering is present. The importance of using the minimum level of sedation required to adequately manage refractory symptoms and suffering is stressed. Existential distress and suffering can be viewed as intrinsically linked to the impact of terminal illness on the whole (Cassell and Rich, 2010) (see Chapter 18.2 for further discussion on sedation).

Symptom crisis at the end of life and contingency planning

Identification of patients at high risk for uncontrolled pain, dyspnoea, nausea and vomiting, agitated delirium, acute airway obstruction, or massive haemorrhage is crucial. It allows contingency planning for a crisis, and occasionally prophylactic

management. This usually enables a family to often care for their dying relative at home or in the desired setting with minimal angst and distress.

The specific drugs, doses, and routes of administration ordered as part of a crisis plan should be appropriate to the clinical situation. If severe symptoms requiring rapid relief are anticipated, maintenance of parenteral access is recommended. This might include a subcutaneous butterfly. In the home care situation, whenever possible, family members/carers must be instructed in preparation and administering medications for an emergency (see Table 18.1.2).

Discussing specific issues in end-of-life care—nutrition and hydration

In the last days to weeks of life, anorexia, weight loss, and swallowing difficulties are common. In patients with disease-related dysphagia or bowel obstruction, the ability to maintain adequate nutritional intake is reduced. Weakness, cognitive deterioration, or other factors increase aspiration risk and further compromise a person's ability to eat.

Reduced oral intake is often distressing for the family. Requests for artificial nutrition via enteral or parenteral routes are common. As the patient's conscious level deteriorates, aspiration risk is greater and the risk versus benefit of oral intake with regard to aspiration needs to be explored with the family. Often compromises are reached at this stage. However, concerns about cessation or non-initiation of enteral or parenteral feeding often poignantly relate to the expectations and hopes that patient and family still hold (McClement et al., 2003, 2004).

The discussion needs to be centred on the ineffectiveness and burden of artificial nutrition versus any likely benefit. If there are religious or culturally based reservations about discontinuing nutritional support, it may be maintained, unless there is evidence of patient harm from the intervention (Cherny et al., 1996).

In the actively dying patient who is comatose or poorly responsive, the decision to provide artificial hydration is based on clinical judgement, and assessment of the burden of the intervention. Where families are concerned about the need for fluids, provision of gentle hydration is reasonable. Excessive hydration, particularly in the hypoalbuminaemic patient, may exacerbate oedema and discomfort, and if a trial of therapy is offered, the family should be warned that worsening oedema or other signs of fluid overload would be a reason to cease the treatment (Hanks et al., 2009). Reassurance can be given, particularly in the last days, that maintaining good mouth hygiene alleviates much of the sensation of thirst and discomfort. The majority of trials conducted at the very end of life show no significant burden nor benefit from hydration. If it is decided to administer fluids in the last days or weeks of life, the subcutaneous route is a well-tolerated and minimally invasive option. 1–1.5 L over 24 hours of normal saline can be delivered in this manner (Dalal et al., 2009).

At the bedside of the dying patient

The clinician at the bedside of the dying patient should ensure adequate relief of patient distress, and provide support and guidance to the grieving family. This often includes responding to family members who ask what to expect, and how to recognize the dying process. The physician and nurse's role is

to evaluate and treat the patient for pain, dyspnoea, agitation, or any other distressing symptoms. Once adequate comfort is achieved, the clinician can reassure the family that the patient is not distressed.

Families vary in the degree of professional support necessary at this time. Increased involvement is valuable when family supports are limited or coping is frail. In other situations, it may be enough for the clinician to acknowledge the primacy of family and friends in this moment, taking a background role, but available if necessary.

At and after death

If it is clear that breaths are agonal and the patient is about to die, explain this to the family with the reassurance, again, that the patient appears comfortable. Adequate provision for family privacy and time with the patient is crucial. Awareness and respect for cultural and/or religious practices related to death is important. If the death occurs in an institution, provision for necessary cultural practices should be made and the family should be reassured of this. At the time of death, families often talk and cry over the dead person, and kiss and hug them. An offer of condolences from clinicians may be very comforting for a distressed family.

Most palliative care services provide bereavement support, and can refer those affected by the patient's illness and death to an associated bereavement service after the patient has died. Adults need to recognize when a dependent, grieving child needs help. When a parent of dependent children is dying, offering their children age-appropriate grief and bereavement counselling and education may be very reassuring for the dying parent (Auman, 2007; Sandler et al., 2010).

Difficult end-of-life scenarios

It is important to prepare for some of the more difficult and unusual end-of-life care scenarios. These include unanticipated sudden events, such as trauma, postoperative overwhelming sepsis, or failure of treatment for acute potentially reversible disease as well as other treatment-related deaths. Young parents and other young people (adolescents), children, the isolated, incarcerated, or mentally ill, those in care isolation wards, and those in an intensive care unit are other unique groups whose end-of-life care may require a unique and thoughtful, planned approach. The unanticipated sudden event requires action to be taken with care to alleviate suffering and provide appropriate support to the family and carers. For those with advanced care plans, communication and respect for the plans is key to provision of care. 'Crisis medications' should be available on the hospital wards and in the home for adequate symptom control for those at risk of an acute event. Preparing a patient, family, and team may not always be possible and the grief and bereavement support become a very important part of care.

Young people and young children and their families may request more active management even at the end of life. Here, care for the family and early psychosocial support is vital with many wishing to return home (or remain at home) for end-of-life care in the final days. The isolated or incarcerated person may have little access to adequate multidisciplinary care and modifying limited resources and mobilizing adequate support may prove the greatest

challenge. Provision of the minimal essential drugs is imperative and may require thoughtful proactive intervention.

Professional aspects of end-of-life care

Communication between colleagues

It is the role of the treating team to ensure that all of their colleagues are 'on the same page', and that at this advanced stage of illness the patient and their family are receiving the same message regarding stage of disease, prognosis, and goals of care. The nursing and allied health professionals involved in the care of the patient should also have a clear understanding of goals of care and approach to the patient entering the terminal stage.

Despite sounding straightforward, much conflict and angst between staff members stems from lack of such communication. Furthermore, for staff faced with a dying patient on their ward, particularly nursing staff who do not often care for dying patients, the entire process may be distressing and confronting. It can be worthwhile to acknowledge the impact the patient's dying and the family's distress could be having on the team. For many treating team members, there are long associations with their patients and close relationships formed. Grieving needs to be recognized and space provided for this to occur.

Support for junior staff and distressed staff members

As a member of a team caring for patients at the end of life, the anticipated and non-anticipated death can have a significant impact on staff and team members. Junior staff are often more vulnerable. It is important to recognize this and for appropriate support to be offered in the form of structured professional supervision, a time and space for debriefing, discussions, and willingness of senior team members to be available to respond to the distressed staff member. Many resources are available that may assist and these should be chosen based on suitability to staff and service needs.

Conclusion

Care of patients in the final stages of a life-limiting illness requires a high level of clinical vigilance and skill in order to ensure that the passage from life to death is as free from suffering as possible. Patients who are dying have a right to adequate relief of physical and psychological symptoms, and they and their families have a right to adequate support. The care of patients and their families requires (a) interdisciplinary cooperation of a health-care team incorporating physicians, nurses, social workers, and other allied health staff, and (b) a high level of clinical flexibility to address the evolving needs of the patient and family. Contingency planning and communicating expected symptoms and signs to family and carers, coupled with provision of adequate access to medications and non-pharmacological resources, can allow a person to die peacefully at home or in the desired setting with minimal distress. Participation in this process challenges the clinician's emotional resources and medical skills. There is, however, much professional satisfaction in helping to ensure a 'good death' since relief of suffering is at the very heart of medicine. Familiarity with guidelines in the care of the dying can reduce the potential for distress in this important clinical endeavour.

Sedation at the end of life

Eric L. Krakauer

Introduction to sedation at the end of life

The need for palliative sedation at the end of life

The most fundamental task of palliative medicine, and indeed of medicine in general, is to relieve suffering (Cassell, 1982). Among terminally ill patients whose primary goal is comfort, severe suffering occurs occasionally that is refractory to standard palliative interventions. Controlled sedation, sometimes to unconsciousness, may be the only effective means of relieving suffering in these unusual situations.

Patients and their families fearful of severe, refractory terminal suffering may feel quite relieved when informed that palliative sedation is available as an option should all standard interventions fail. Thus, clinicians who are fully prepared to provide sedation for refractory terminal suffering often will be able to comfort fearful patients simply by discussing it with them (Cherny, 2006).

While there is consensus in the literature about the need for and permissibility of sedation for refractory suffering of a terminally ill patient, there remains debate about nomenclature, about the definition of palliative sedation, and about the ethics of specific practices (Quill et al., 2009). This chapter will provide guidance for palliative sedation based upon a synthesis of current debates.

Definitions

Palliative sedation may be defined as controlled induction of sedation, sometimes to the point of unconsciousness, to relieve severe refractory suffering of a terminally ill patient.

Severe, refractory suffering may be a result of severe, refractory physical symptoms such as pain, dyspnoea, or vomiting or severe, refractory neuropsychiatric problems such as seizure, agitated delirium, anxiety, or depression. While severe social problems such as discrimination or rejection, and 'existential' distress due to loss of dignity or of a sense of meaning in life, also may cause severe suffering in a terminally ill patient, they may respond to intensive interventions including 'dignity therapy', psychological counselling, spiritual guidance, and social interventions such as emotional, legal, and financial support (Chochinov, 2007; Schuman-Olivier et al., 2008; Cassell and Rich, 2010). Thus, palliative sedation should be considered as a response to social or 'existential' problems only in the most extraordinary circumstances.

Suffering is refractory when it cannot be adequately relieved despite aggressive and concerted efforts both to determine its causes and to treat them using standard palliative interventions without inducing sedation. Adequate relief is reduction of the patient's suffering to a tolerable level. Because pain, many other physical and neuropsychiatric symptoms, social suffering, and 'existential' distress are subjective and not amenable to easy measurement, both 'tolerability' and 'adequate relief' can be defined only by each individual patient. Aggressive and concerted efforts are those that make use of the best available diagnostic techniques, palliative medications, and other interventions and have enlisted the help of the best available experts (see Box 18.1.2 in Chapter 18.1).

Nomenclature

Various names have been used for sedation for refractory suffering of dying patients (Claessens et al., 2008). It is important to distinguish between ordinary palliative sedation and palliative sedation to unconsciousness. Ordinary sedation is sedation that occurs commonly in the standard practice of palliative care for a variety of reasons. Palliative sedation to unconsciousness designates deep sedation for severe suffering that is refractory to all reasonable and aggressive interventions including ordinary sedation (American Academy of Hospice and Palliative Medicine, 2006). The key point is that the level of sedation should be proportional to an individual patient's suffering in that it should be just deep enough to provide the desired relief. By definition, death is never intended by palliative sedation. Thus, the term 'terminal sedation', that inevitably connotes sedation intended to terminate or euthanasia, should not be used in palliative care (Krakauer, 2000).

Experience with palliative sedation

The frequency and success of palliative sedation is impossible to determine accurately because of lack of consensus and clarity in the literature about the definition of palliative sedation and about indications, goals, and appropriate medication regimens. Reports of the frequency of palliative sedation in palliative care programmes range from 1% to 88% (Sykes and Thorns, 2003). Practice patterns vary widely in part due to differing cultural beliefs and values (Fainsinger et al., 2000a; Moyano et al., 2008). In some studies, it is unclear whether patients received light or deep sedation or were sedated to varying degrees. The frequency of palliative sedation also may be changing in settings where palliative care is becoming more available, where physicians of more specialties are providing palliative sedation, and where guidelines for palliative sedation have been established (Fainsinger et al., 2000a; Rietjens et al., 2008a; Seale, 2010; van Deijck et al., 2010).

There is some consistency in the literature about some aspects of palliative sedation. Multiple studies list some or all of the same refractory symptoms as the most common indications for

palliative sedation: pain, dyspnoea, agitated delirium, or vomiting (Fainsinger et al., 2000b; Rousseau, 2001; Van Deijck et al., 2010). Studies of physicians from multiple countries and cultures reveal a widespread opinion that palliative sedation for refractory suffering is sometimes needed and is ethically acceptable (Chater et al., 1998; Morita et al., 2002; de Graeff and Dean, 2007; Claessens et al., 2008). In addition, there is some concurring evidence that palliative sedation may not hasten death (Sykes and Thorns, 2003; Rietjens et al., 2008b; Mercadante et al. 2009; Maltoni et al., 2012).

Ethical issues

Moral imperative

There is broad agreement that physicians have a moral imperative to respond to the suffering of terminally ill patients, particularly when the suffering is extreme (Wanzer et al., 1989; Hasselaar et al., 2009; Russell et al., 2010). While severe refractory suffering is uncommon, it demands that physicians be prepared to provide palliative sedation as 'the end of the continuum of symptom management' (Quill and Byock, 2000).

Informed consent

The physician should determine the goal or goals of care for any patient with a terminal illness in consultation with the patient or surrogate. When a terminally ill patient is experiencing severe, refractory suffering, palliative sedation should be considered only if the overriding goal of care is comfort and the patient or surrogate has decided to forego life-sustaining treatment (Cherny and Portenoy, 1994).

Even when these conditions obtain and palliative sedation is being considered, it may not be initiated without informed consent (Quill et al., 1997b). The patient or surrogate should be informed of and capable of understanding both the clinical predicament that makes palliative sedation a legitimate treatment option and any alternative options. Religious or ethical concerns of the patient should be explored and religious counselling from a chaplain should be offered if appropriate. Because a decision about palliative sedation may have a lasting emotional impact on the patient's family and loved ones, efforts should be made to achieve consensus (Cherny, 2006). However, the clear request of a competent patient or a legal surrogate decision-maker should be honoured even over objections of other family members or friends.

In the rarest of cases, there may be a terminally ill patient with severe, refractory suffering who lacks both decision-making capacity and any surrogate decision-maker. If palliative sedation is being considered in such a case, consensus should be sought from at least one other senior physician—a palliative care specialist if possible—and from the hospital ethics committee.

Principle of double effect

The principle of double effect provides guidance for decisions when all possible actions risk bad consequences. Its applicability to decisions about treatments to relieve suffering in dying patients is widely accepted. The principle states that an action with two or more possible effects, including at least one possible good and one possible bad effect, is morally permissible if four provisos are met (Quill et al., 1997a; Sulmasy and Pellegrino, 1999):

- The action must not be immoral in itself.
- The action must be undertaken with the *intention* of achieving only the good effect or effects. Possible bad effects may be *foreseen* but must not be *intended*.
- The action must not achieve the good effect by means of a bad effect.
- The action must be undertaken for a proportionally grave reason (the rule of proportionality).

When palliative sedation is considered in cases of severe refractory suffering of terminally ill patients, sedation as a means to relieve suffering would be the intended good effect. Possible side effects of the sedative such as respiratory depression, hypotension, and hastening death may be foreseeable but not intended. The act of giving medication to relieve suffering is not immoral as long as the patient or surrogate requests relief and accepts the risk of side effects, and there are no safer means to achieve an acceptable degree of relief. Such serious side effects must be risked only for a proportionally grave reason such as the relief of severe refractory suffering of a terminally ill patient who does not wish to suffer (Krakauer et al., 2000).

Some have criticized the principle of double effect or questioned its applicability to palliative sedation in part because the principle relies on the distinction between the intended and the merely foreseen (Quill et al., 1997a). It is argued that clinical intentions may be ambiguous and difficult to discern. Because of the complexity and potential ambiguity of clinical intentions, physicians working to relieve the suffering of frail terminally ill patients should think through their intentions carefully, document them in the medical record, and demonstrate them with their actions (Hallenbeck, 2000). The least toxic medications should be used at the minimum doses that achieve the desired effect. The patient's response to the medication and level of comfort should be assessed and documented frequently and changes in the dose or type of medication should be made and documented based on these assessments. In this way, clinical intentions are made as clear as possible, the benefits of the intervention maximized, and the risk of bad effects minimized (Cherny et al., 2009).

Distinction from voluntary active euthanasia and physician-assisted suicide

Application of the principle of double effect to palliative sedation also has been criticized because of the assumption associated with the principle that intentionally hastening death is always wrong. It is argued that some patients wish for death and that intentionally helping a patient to shorten an intolerable existence may not be wrong (Quill et al., 1997a). However, it is widely accepted that palliative sedation can and should be clearly distinguished in theory and in practice from both voluntary active euthanasia and physician-assisted suicide (see Chapter 5.7) (Cowan and Palmer, 2002; De Graeff and Dean, 2007; Russell et al., 2010).

In palliative sedation, the physician's intention or goal is only to relieve severe refractory suffering using sedation as a last resort. The goal is not to end the patient's life as in euthanasia and physician-assisted suicide (Cherny, 2006). In practice, palliative sedation entails titration of medications to achieve the goal of comfort. The physician administers just enough medication to induce adequate sedation and thereby assure comfort. Once

comfort is achieved, the lowest doses that maintain comfort are used. Euthanasia and physician-assisted suicide entail no titration, no calculation or maintenance of minimum doses needed for comfort, because the goal is death (Hallenbeck, 2000).

Withholding and withdrawal of artificial nutrition and hydration

The decision whether or not to use any medical intervention, including artificial nutrition and hydration, should be based on the patient's values and medical condition and on agreed-upon goals of care. Frequently, patients who have a terminal illness and are unable to eat decline artificial nutrition and hydration. To provide these interventions against patients' wishes would not only infringe on their right to autonomy. Because these interventions also may cause harm by prolonging the dying process or by exacerbating pulmonary oedema, pleural effusions, respiratory secretions, ascites, or anasarca with resultant dyspnoea or pain, providing them also risks violating the principle of non-maleficence.

The situation is morally no different when a patient is receiving palliative sedation for severe refractory suffering. For patients still able to eat prior to sedation, it is the patient's terminal illness that makes the sedation necessary and thereby precludes further eating. When the overriding goal is comfort and the patient or surrogate does not request artificial nutrition or hydration, there should be no presumption that an unwanted and potentially noxious intervention should be provided. When artificial nutrition and hydration are withheld or withdrawn in this situation, the patient dies of the terminal illness, not at the hand of the physician by euthanasia, nor by physician-assisted suicide (De Graeff and Dean, 2007; Cherny et al., 2009; Kirk and Mahon, 2010). When palliative sedation is being considered, the physician should suggest to the patient or surrogate that artificial nutrition and hydration be withheld or withdrawn if palliative sedation is implemented.

There may be patients or surrogates who believe that artificial hydration and/or nutrition should not be withheld or withdrawn during palliative sedation based on religious beliefs, cultural norms, or personal history. There should be no absolute prohibition of artificial nutrition and hydration in patients receiving palliative sedation as long as the harms of these medical interventions do not grossly outweigh the potential benefits by the patient's values (Cherny, 2006). The patient's personal beliefs should be explored as carefully as possible and every effort made to assure that palliative sedation or any proposed treatment is compatible with cherished beliefs and values.

Misuse of palliative sedation

Studies from several countries have revealed that physicians occasionally intend to hasten death even where euthanasia and physician-assisted suicide are illegal (Meier et al., 1998; Rietjens et al., 2004; Seale, 2010). These data raise the concern that palliative sedation may be used to intentionally hasten death and that physicians may try to hide their intention by invoking the principle of double effect. Therefore, it is extremely important for physicians who provide palliative sedation to demonstrate their intentions as clearly as possible by documenting carefully in the medical record the regimen used and the patient's response.

Informing other clinicians

It is often helpful to involve key members of the patient's care team such as the primary nurse and social worker in the process of decision-making about palliative sedation. Before initiating palliative sedation, the physician always should inform all members of the patient's care team of the plan, the indication for palliative sedation, and the receipt of informed consent (Cherny, 2006). No clinician should be required to participate in non-emergent palliative sedation—or in withdrawal of life-sustaining treatment—if they conscientiously object (Quill and Byock, 2000).

Legal issues

Laws in most rich Western countries recognize the right of a competent patient to refuse any medical treatment including life-sustaining treatment. In the same countries, interventions to relieve the severe, refractory suffering of terminally ill patients generally are permitted even if they might unintentionally hasten death (Van der Heide et al., 2004). In criminal law in the United States, for example, actions that might put another's life at risk are justifiable if the potential benefits of the action are likely and important enough. This precept reflects the rule of proportionality that is part of the principle of double effect (Quill et al., 1997a).

Practical guidelines for palliative sedation

Indications and prerequisites

Palliative sedation should be considered only under the following circumstances:

1. The patient must have a *severe, chronic, life-threatening illness* such as, but not limited to:

   a. advanced incurable cancer

   b. end-stage major organ failure, and organ transplantation and organ replacement therapy either are not feasible or have been declined by the patient

   c. advanced AIDS, and antiretroviral therapy either is no longer effective, causes intolerable side effects, or has been declined by the patient

   d. advanced neuromuscular disease

   e. advanced dementia, unable to take adequate oral nutrition.

2. The patient must be suffering from one or more *severe physical or neuro-psychiatric symptoms* such as, but not limited to pain, dyspnoea, vomiting, seizures, agitated delirium, anxiety, or depression.

3. The distressing symptom or symptoms must be *refractory to standard palliative interventions* such as, but not limited to:

   a. medications such as opioids, neuroleptics, anticonvulsants, anxiolytics, and antidepressants

   b. neuromodulatory procedures for pain such as nerve block and intrathecal analgesia

   c. palliative radiation therapy

   d. palliative endoscopic or surgical procedures

   e. consultation by the best available medical specialists from disciplines relevant to the patient's disease or symptoms such

as palliative care, pain medicine, or psychiatry and by those who can provide psychosocial support such as social workers and chaplains.

4. *Comfort must be the overriding goal* of the patient's care as determined by the responsible physician in dialogue with the patient or, if the patient does not have capacity to make medical decisions, with the legal surrogate decision-maker.

   a. If there is doubt about a patient's capacity to understand her diagnosis and prognosis, to explain her values, or to make a specific decision, psychiatric consultation is recommended (Cherny et al., 2009).

   b. If a patient does not have capacity and there is no legal surrogate decision-maker, the goals of care should be determined by the responsible physician in discussion with a non-legal surrogate who is the most knowledgeable person available about the patient's values regarding healthcare and suffering.

   c. If no surrogate decision-maker is available, consensus on the goals of care should be sought from at least one other senior physician—a palliative care specialist if possible—and from the hospital ethics committee if one exists.

   d. In any case, both the goal of comfort and the discussion in which this goal was decided upon must be documented in the medical record.

5. Where possible, *an active order must exist to withhold life-sustaining treatments* including at least the following:

   a. chest compressions

   b. defibrillation

   c. endotracheal intubation

   d. mechanical ventilation

   e. non-invasive ventilatory support.

6. *Informed consent* for palliative sedation that may unintentionally hasten death must be obtained in advance from the patient or from an appropriate surrogate decision-maker identified following the procedure outlined in item 4 (a–d) above. The informed consent or decision-making process must be documented in the medical record.

7. If possible, all *staff members involved in caring for the patient should be informed* in advance of the plan to initiate palliative sedation. In particular, the patient's nurse, respiratory therapist, and pharmacist should be informed.

   a. Once palliative sedation has been initiated, clinical staff who will be assigned to the case should be informed in advance of the plan of care.

   b. In non-emergent situations, staff members who conscientiously object to the care plan should be given the opportunity to excuse themselves from participation in the patient's care once a replacement is found. Every effort should be made in keeping with any institutional policies on conscientious objection to find a replacement for any essential staff member.

Special circumstances

Severe, refractory social or 'existential' suffering

Very rarely, a patient's severe social or 'existential' problems such as social isolation, loss of dignity, or loss of a sense of meaning in life may cause severe suffering that is refractory to intensive and sustained intervention by the best available clinicians and supporters. In these very rare cases, respite sedation to unconsciousness may be considered (see following section). Only after respite sedation has been tried at least once in addition to all other intensive palliative interventions without an acceptable reduction in the patient's suffering should permanent palliative sedation be considered (Cherny, 1998; Rousseau, 2001).

Respite sedation

Time-limited sedation to unconsciousness or respite sedation may be used for terminally ill patients with severe refractory suffering in a variety of situations:

◆ *Incident pain*: some patients may experience particularly severe pain or other symptoms due to therapeutic or diagnostic procedures or to necessary movement for other clinical care (Del Rosario et al., 2001).

◆ *Severe refractory social or 'existential' suffering*: one or more trials of respite sedation may 'break a cycle of anxiety and distress' that has evoked a request for palliative sedation (Cherny, 1998; Rousseau, 2001).

◆ *Patient requests trial of temporary sedation to unconsciousness*: some patients with severe refractory physical or neuropsychiatric symptoms who are not imminently dying may benefit from a temporary respite from their discomfort. The respite may relieve severe fatigue that could influence the patient's perception that the symptoms or the attempts to alleviate them are intolerable (Cherny 2006). The patient may then decline further palliative sedation.

The mandatory informed consent discussion for respite sedation to unconsciousness should include the possibility that the patient may not reawaken and that death may be unintentionally hastened. Respite sedation may be provided for as little as a few minutes or as long as a few days. In general, artificial hydration should be provided if respite sedation is expected to last longer than a few hours. A decision on monitoring of heart rate and rhythm, blood pressure, and oxygen saturation should be based on the patient's values, the agreed-upon goals of care, and the clinical situation.

Terminal discontinuation of mechanical ventilation

In terminally ill patients receiving mechanical ventilation for respiratory failure, terminal extubation of the trachea or discontinuation of mechanical ventilation without extubation is likely to cause dyspnoea unless the patient is well pre-medicated, unconscious, or in a persistent vegetative state (see also Chapter 15.7). Some patients may wish to receive only enough medication to reduce to a tolerable level the feeling of air hunger in the hope that they can remain awake during the process. However, it is reasonable to consider palliative sedation to unconsciousness when a patient or the surrogate of a patient not in a persistent vegetative state decides to terminally discontinue mechanical ventilation (Billings, 2012; Truog et al., 2012).

Palliative sedation for terminal discontinuation of mechanical ventilation is medically and ethically slightly different from palliative sedation for severe refractory symptoms:

◆ Sedation may be intended not to relieve existing severe refractory symptoms but rather to assure that the patient does not experience severe dyspnoea in the time between removal of the ventilator and death. The other prerequisites for palliative

sedation apply in this situation as well: terminal illness, a decision that the overriding goal of care is comfort, an order to withhold or withdraw life-sustaining treatment, informed consent, an informed and prepared staff.

◆ If the patient already is receiving sedation to treat or prevent discomfort from mechanical ventilation, this sedation should continue and adjustments should be made to assure comfort during and after the removal of the ventilator.

◆ Because most agents used for palliative sedation have no analgesic effect and some do not specifically relieve dyspnoea, opioid therapy usually should be continued or added to the sedative regimen. In the absence of pain or other indications for opioid therapy, the opioid dose should be titrated to a normal respiratory rate and the absence of laboured breathing while the sedative is titrated to the appropriate depth.

◆ Sedation and opioid therapy should be initiated before the ventilator is removed. The adequacy of the treatment should be checked with a trial of reduced ventilatory support. This can be done by setting the fraction of inspired oxygen at room air and changing the ventilation mode to pressure support at a setting adequate only to overcome the resistant of the endotracheal tube (approximately 5 cmH$_2$O for a tube 7.5 mm in internal diameter). Patients should be observed for 10–15 minutes on this ventilator setting (to allow their arterial partial pressure of oxygen to decrease and the partial pressure of carbon dioxide to increase).

  • If the patient develops tachypnoea, agitation, grimacing, or other evidence of discomfort, the previous level of ventilatory support should be reinstituted, the doses of sedative and/or opioid should be increased and the assessment repeated.

  • If the patient is apnoeic and is not thought to have pain, the opioid dose and/or sedative dose should be reduced and the trial repeated once the effects of the higher opioid and/or sedative doses have worn off. However, the sedative should not be reduced to the point of allowing the patient to awaken if the goal is unconsciousness.

  • If the minimum opioid and/or sedative doses necessary to control the patient's pain and/or maintain comfort also cause both unconsciousness and apnoea, and there are no other reversible causes of apnoea, the removal of the ventilator may proceed.

◆ Any neuromuscular blocking agents should be stopped and the effects allowed to wear off before initiating palliative sedation so that the patient's respirations are not unnecessarily depressed and the effects of the sedation can be assessed.

  • If the effects of a neuromuscular blocking agent persist longer than 24 hours after the last dose and there is a compelling reason to withdraw the ventilator quickly, the withdrawal may proceed but care must be taken to assure that the patient is sedated to unconsciousness since the patient will be paralysed and unable to show any signs of discomfort (Truog et al., 2000).

Medications

Ideal medications for palliative sedation have a rapid onset of action and a short duration of action that facilitate titration to the desired effect. They should reliably induce sedation and, if necessary, unconsciousness, and cause minimal side effects. Agents mentioned in the literature include opioids, benzodiazepines, neuroleptics, barbiturates, and other general anaesthetic induction agents (Krakauer et al., 2000). In general, medications for palliative sedation should be given via continuous and/or intermittent intravenous or subcutaneous infusion. Intramuscular injections generally should be avoided as the injections themselves may be painful. Administration of sedatives transdermally, rectally, or via tube gastrostomy or jejunostomy generally is not suitable for palliative sedation to unconsciousness because of the delayed onset of action and the greater difficulty in titrating the dose to the desired effect.

Opioids

Strong opioids such as morphine, hydromorphone, or fentanyl are the best available agents to relieve dyspnoea and many types of pain, but they are not reliable sleep-inducing agents by themselves. While opioids often cause drowsiness and may occasionally induce unconsciousness, especially in patients obtunded by other medications or by their medical conditions, increasing the opioid dose beyond that needed for relief of pain or dyspnoea puts the patient at increased risk of counter-productive and uncomfortable side effects such as myoclonus, hyperalgesia, and agitated delirium. Thus, opioids should not be used alone for palliative sedation. When pain or dyspnoea are present or expected, opioid therapy should be continued or added in combination with a sedative.

Benzodiazepines

Several benzodiazepines are cited in the literature on palliative sedation, lorazepam and midazolam most frequently. Midazolam has the most rapid onset of action and is the easiest to titrate and is widely used. However, benzodiazepines sometimes fail to provide adequate sedation (Krakauer et al., 2000; Cheng et al., 2002). They also may cause paradoxical agitation and psychotic reactions particularly in elderly patients and those with impaired liver function (Breitbart et al., 1996; Shafer, 1998). Therefore, benzodiazepines should be used with caution for palliative sedation and are not ideal agents for palliative sedation to unconsciousness.

Neuroleptics

Antipsychotic drugs available in parenteral forms such as haloperidol, chlorpromazine and levomepromazine (formerly called methotrimeprazine) are cited in the literature on palliative sedation. Levomepromazine also has analgesic properties while haloperidol and chlorpromazine are good treatments for agitated delirium. However, none of these drugs alone reliably induce unconsciousness.

Barbiturates

Barbiturates including pentobarbital, thiopental, and phenobarbital reliably induce unconsciousness. All are available in parenteral form. Pentobarbital and especially thiopental have rapid onset and short duration of action for ease of titration. Pentobarbital also has beneficial antiemetic and anticonvulsant properties. Either thiopental or pentobarbital are excellent agents for palliative sedation to any degree including unconsciousness (Truog et al., 1992). Pentobarbital may be easier to obtain outside of an intensive care unit.

Anaesthetic induction agents

Anaesthetic induction agents that have been used for palliative sedation include propofol and ketamine. While ketamine has both sedative and analgesic properties and is less likely to cause

Table 18.2.1 Protocol for palliative sedation to unconsciousness using continuous intravenous infusion of midazolam, pentobarbital or propofol

Physician responsibilities

1. Confirm that:
   a. the patient's overriding goal of care is comfort
   b. the patient has an advanced terminal illness
   c. the patient is suffering from severe refractory physical or neuropsychiatric symptoms or psychosocial problems
   d. there is an order to withhold life-sustaining treatment
   e. informed consent for palliative sedation to unconsciousness has been obtained
2. Document all of the above in the medical record
3. Inform the patient's clinical team of the plan
4. Specify in the orders:
   a. the loading dose, if any
   b. the initial infusion rate
   c. the amount of drug in mg/hour and time interval for infusion rate increases
   d. the dose and time interval for any bolus doses
5. Ensure that the medication is titrated optimally by frequent assessment of the patient and/or by reading the documentation by nurses of all dose adjustments and of comfort levels before and after dose adjustments
6. Document in the medical record the efficacy of this therapy at least daily

Nurse responsibilities

1. Administer the medication as a continuous infusion by an infusion pump that is clearly labelled with the name of the medication
2. Once the desired level of sedation is achieved, reduce the infusion to the lowest rate that maintains the desired level
3. Should the patient exhibit any evidence of pain or other distress, increase the infusion rate as ordered
4. Once an initial steady dose rate is found that maintains the desired level of sedation, document the reason (intention) for any dose adjustment and the level of comfort before and after the adjustment
5. Do not reduce the infusion rate for low blood pressure, low respiratory rate, or other abnormal vital signs if the patient exhibits any evidence of pain or other distressing symptoms
6. When the medication is running out, call for additional medication well in advance so that there is no interruption in the infusion

Midazoam administration	**Pentobarbital administration**	**Propofol administration**
1. Inspect midazolam solution prior to administration. If precipitation is present, do not use	1. Inspect pentobarbital solution prior to administration. If precipitation is present, do not use	1. Use strict aseptic technique when administering propofol. Change infusion tubing every 12 hours. Discard vial and any unused drug if not fully infused after 12 hours
2. Loading dose for benzodiazepine-naïve patient: 0.03–0.05 mg/kg slow intravenous push (over 2–5 minutes)	2. Loading dose: 2–3 mg/kg slow intravenous push (no faster than 50 mg/minute)	2. Infuse only through central venous catheter.
3. Loading dose may be repeated every 5 minutes to achieve desired effect	3. A physician should give loading dose and remain at bedside for 15 minutes to observe the effect	3. Start infusion at 2.5–5 micrograms/kg/min (for adults approximately 10–20 mg/hour) and titrate to desired level of sedation every 10 minutes by increments of 10–20 mg/hour
4. A physician should give each loading dose and remain at bedside for 10 minutes to observe the effect	4. At time of loading dose, start infusion at 1–2 mg/kg. Titrate to desired level of sedation	4. Use bolus doses of 10–20 mg every 10 minutes only for rapid control of extreme symptoms
5. At time of loading dose, start infusion at 0.02–0.1 mg/kg/hour depending on patient's prior exposure to and tolerance for benzodiazepines. Titrate to desired level of sedation	5. Because tolerance may develop rapidly, assess the patient's comfort level frequently and adjust infusion rate as needed	5. During initiation of therapy, a physician should be present and remain at the bedside for 5 minutes to observe the effects. Any initial bolus doses should be given by a physician
6. Additional bolus doses equal to the hourly infusion dose may be given as often as every 15 minutes. A physician or nurse should remain at the bedside for 10 minutes to observe the effects of each bolus dose		6. During subsequent dose titration and bolus dosing, a physician or nurse should remain at the bedside for 5 minutes to observe the effects
		7. The infusion should not be interrupted longer than 60 seconds when changing vials or tubing

hypotension and respiratory depression than propofol or barbiturates, it commonly causes unpleasant dissociative or dysphoric reactions. It is not recommended as a single agent for palliative sedation. Propofol has an onset of action, duration of action, and half-life shorter than midazolam and any of the barbiturates. This greatly facilitates titration to the desired effect. Liver disease and renal disease do not appear to significantly affect its pharmacokinetics (Mirenda and Broyles, 1995). It also has anxiolytic, antiemetic, antipruritic, anticonvulsant, antimyoclonic, and muscle relaxant effects. Propofol therefore appears to be an excellent agent for palliative sedation to any degree including unconsciousness (Krakauer et al., 2000; Lundström et al., 2005).

Combinations of sedatives

Many patients who require palliative sedation already will be receiving standard palliative medications such as an opioid and/ or a benzodiazepine and/or a neuroleptic. Opioid therapy for pain should be continued despite the risk of hypotension and respiratory depression when a barbiturate or propofol is added because these latter agents have no analgesic effect. A benzodiazepine generally may be tapered once adequate sedation is achieved with another agent. However, if the sedative does not have strong anticonvulsant properties, the taper should proceed slowly to minimize the risk of seizure. Neuroleptic therapy may be reduced or discontinued provided adequate sedation can be maintained easily without it. Ketamine should be used only in combination with a benzodiazepine.

Recommended protocols

Recommended protocols for palliative sedation with midazolam, pentobarbital, and propofol are provided in Table 18.2.1.

Conclusions

Palliative sedation is a well-accepted therapy that should be considered in the rare situations when a terminally ill patient whose overriding goal is comfort experiences severe suffering that is refractory to all available standard palliative interventions. Its availability alone may be very comforting to patients fearful of terminal suffering. Informed consent must be obtained and strict medical and ethical guidelines for providing, monitoring, and documenting palliative sedation should be followed.

SECTION 19

Research in palliative medicine

Research in palliative care

Stein Kaasa and Karen Forbes

Ignorance has risks, but they are largely unseen and unnoticed. Gaining knowledge has risks which are noticed, but largely unpredictable, and it is very costly (though less so than prolonged ignorance). It focuses blame, whereas ignorance dispels it. So, maintaining ignorance often seems more attractive than gaining knowledge. (Vere, 1981)

Vere, D., Controlled clinical trials: the current ethical debate, *Journal of the Royal Society of Medicine*, Volume 74, Number 2, pp. 85–8, Copyright © 1981 by The Royal Society of Medicine. Reprinted by Permission of SAGE.

Introduction to research in palliative care

Duncan Vere was Professor of Clinical Pharmacology and Therapeutics at the London Hospital and one of the key advisors to Cicely Saunders when she founded St Christopher's Hospice in 1967. Vere is an expert in clinical trials and analgesic clinical pharmacology and was one of the first people to undertake and supervise research in a hospice setting. The quotation is taken from a paper he presented at the Royal Society of Medicine in London in 1981 in a debate about the ethical aspects of randomized controlled trials (RCTs). He was not talking specifically about research in palliative care but making a general point that it was easy to be deterred from undertaking rigorous scientific research in a clinical setting. He went on to highlight that such research is crucial to the advancement of reliable knowledge.

We have used Vere's quotation to open this chapter on research in palliative care in all four of the previous editions of this textbook because it is an apposite comment on the relatively slow progress of research in palliative care. The initial enthusiasm and urgency to gain a basic understanding of the physiology and pharmacology of the dying or severely ill patient and to evaluate the care provided and the treatment that was given did not grow and mature as Cicely Saunders had wished. Research in palliative care has remained in the doldrums until relatively recently, in spite of wide recognition of its importance amongst palliative care practitioners. In contrast, the continued development of new clinical services has continued apace around the world.

The provision of new services has not been driven by research findings. We do not have data which demonstrate the most cost-effective model of service delivery of palliative care (Grande, 2009), nor can we answer the more fundamental question of what models are effective. There remain large areas of clinical practice in palliative care that are founded on clinical experience and anecdote rather than high-quality evidence, and this has applied even to core activities such as the control of pain.

Recently a debate about whether the Liverpool Care Pathway (LCP) is relevant for routine use in palliative care has been ongoing (Fainsinger, 2008). One element in the debate is the lack of scientific evidence supporting the content of the pathway, and there has been a lack of scientific evidence in the effect of implementation of the pathway into clinical practice until recently (Costantini et al., 2014).

This frustrating state of affairs has changed and is changing (Fainsinger, 2008). During the last decade there have been major developments in palliative care research in terms of funding, and the development of infrastructure and support for academic teaching and research. Substantial investment in departments that have the critical mass and facilities to allow high-quality research to be undertaken would take research in palliative care a quantum leap forward. During the last decade, in different parts of the world, new funding streams for palliative care research have become available.

Obstacles to research in palliative care

It has taken much time for research to become embedded within the culture of palliative care. The issues of the primacy of the individual and whole-person care versus the 'greatest happiness of the greatest number' are brought sharply into focus in palliative care. The physician's obligation to privilege the patient's best interests is a fundamental precept of medical practice which is given great emphasis in palliative care. However, the physician also has an obligation to promote the acquisition of scientific knowledge. These obligations constitute a real conflict and raise difficult ethical dilemmas; in time-pressured, daily clinical practice, patient care will always take precedence over research.

There have been problems in attracting high-quality researchers into palliative care. This is partly a consequence of the uncertain career structures and a relative lack of training opportunities (which reflects the lack of funding and investment). The need for academic palliative care researchers affiliated to formalized research

groups within the main academic hospitals, made up of a sufficient number of scientists representing a variety of disciplines working together has been highlighted in a topical review (Kaasa et al., 2006). Research groups need to have core funding to enable them to apply for further project grants. Symptom control research is always likely to be less attractive to grant awarding bodies than molecular genetics, however, it is increasingly apparent that molecular biology may be a fertile area for exploring research questions of direct relevance to palliative care clinical practice. For example, a recent review summarizes the available evidence for the influence of human gene polymorphisms on variability in response to opioid analgesics in terms of both analgesia and side effects (Skorpen et al., 2008). There is some evidence in palliative care patients that mu opioid receptor polymorphisms may be related to the need for higher doses of morphine (Klepstad et al., 2004) and a catechol-o-methyl transferase (COMT) polymorphism may influence morphine requirements in cancer pain patients (Rakvåg et al., 2005). Translational research is thus one of the priority areas for palliative care: academic departments of palliative care may need to broaden their base to include laboratory scientists as well as social anthropologists, ethicists, and clinicians.

National and international organizations have a key role to play in palliative care research. The European Association for Palliative Care Research Network (EAPC RN) was established in 1996, implicitly recognizing that networks are essential for palliative care research (Blumhuber et al., 2002). The number of patients available for clinical research in any one centre is always relatively small which means that collaborative studies are necessary to recruit sufficient patients in a reasonable period of time. It became clear in the mid 1990s that palliative care research activity and expertise in different countries in Europe varied considerably, and it was not feasible to launch large multi-centre clinical trials at the outset of the EAPC RN because only a handful of centres were in a position to participate in them; this had been one of the initial ideas behind the setting up of the Research Network.

The EAPC RN therefore adopted a different strategy in its early years. Expert working groups were set up to review areas of clinical controversy or areas that were particularly topical, and to draw up clinical guidelines based on the available evidence. These guidelines have generally proved to be highly influential (1996) and, for the researchers, were useful in identifying gaps in the evidence base and prioritizing areas for research. Latterly the EAPC RN, supported by the European Palliative Care Research Centre (PRC) (2009), has conducted one large cross-sectional study (CSA study) (Hjermstad et al., 2012), and the first large international prospective study on multiple symptoms in advanced cancer patients is about to be finalized. A multicentre randomized feasibility study of the management of cachexia (Clinicaltrials.gov, 2011) is to be followed by a larger ($N = 300$) prospective randomized study with participating institutions from Europe and Canada. These, among other clinical studies, show that palliative care research can be undertaken through collaboration and international networking. The future for palliative care research lies with networks, be they local, regional, national, or international.

Consolidating for future developments in palliative care research

Reports from the United Kingdom and Canada have identified a number of needs: the need to establish multidisciplinary research groups of sufficient strength and size, the need for long-term planning, and the need for international as well as national collaboration reflected by the membership of the groups. Some groups individually, or in collaboration with others, are working for international consensus on patient-centred outcomes (e.g. health-related quality of life and subjective symptoms) and patient cohort classification. The long-term goal for clinical palliative care research should be to move from descriptive to interventional studies. New research initiatives as well as the establishment of new academic chairs of palliative medicine and palliative care nursing will enable researchers to address complex research questions in the field of palliative care.

The most urgent needs for the future, which should be partly realized through the output of the new collaboratives/collaboration are that:

◆ groups of sufficient size and sufficient output need to take the responsibility for further development of research

◆ national and international funding needs to continue, and successful collaboratives need to achieve further funding without unnecessary gaps

◆ it is vital to train a sufficient number of clinicians and scientists in palliative care research.

Research governance

In recent years there has been a trend towards increasingly explicit guidelines and regulations relating to research involving patients. In the United Kingdom, these guidelines are described under the heading of 'research governance'. Research can involve an element of risk regarding both the safety and well-being of participants and the return on investment. Research governance guidelines are designed to minimize risk and improve research performance and they provide a useful framework, particularly for those new to research, which has general applicability and is also relevant outside the United Kingdom.

Research governance is the means by which we ensure high scientific, ethical, and financial standards for the conduct of research and involves transparent decision-making processes, clear allocation of responsibilities, and robust monitoring arrangements. The research governance framework for health and social care in the United Kingdom encompasses five domains. These are ethics (the dignity, rights, safety, and well-being of participants); science (the quality and appropriateness of research); information (the requirements for free access to research information); health, safety, and employment (of participants and research and other staff); and finance and intellectual property.

In the United Kingdom the introduction of these regulations and procedures added considerable time to the process of having an application to do research approved by the various bodies involved. The changes have not been universally welcomed (Jones and Bamford, 2004; Reid, 2004) because of their potential negative effects, not merely on the research process but also on researchers, particularly junior staff first embarking on a research career. It is crucial that some balance is maintained in striving to make the process as safe and as user-friendly as possible for patients, remembering that researchers too need to be supported and not deterred from doing research because of the bureaucracy and inevitable delays that are involved.

Controlled clinical trials and informed consent in palliative medicine

Austin Bradford Hill set out the ethical precepts for RCTs in his Marc Daniels Lecture at the Royal College of Physicians in London in 1963 (Hill, 1963). In the United States, Henry Beecher had a similar influence on the development of ethical guidelines for clinical research (Sackett et al., 1996) and the subject has been debated in many places since. It is not appropriate to discuss this subject in detail here, but the reader is referred to these reviews, which make two important points. The first is that the prospective RCT is the most efficient, scientific way of evaluating a new treatment or of comparing alternative treatments, and the second is that it is not the only way of ensuring the advance of reliable knowledge.

Controlled clinical trials are necessary in palliative medicine, and the usual guidelines and ethical principles apply. Some points need particular emphasis in the palliative care setting. Patients are invariably unwell and many are elderly and frail; most have a multitude of physical and emotional as well as social and spiritual problems. When they come to the palliative care unit or team, many of these problems will be dealt with, and some, particularly the psychosocial issues, may receive attention for the first time. The supportive environment in palliative care may make patients particularly keen to give something back to their carers, to show their gratitude for the care they are receiving. All of these factors make patients particularly vulnerable when they are asked to participate in any sort of research project; many will feel almost obliged to accede to such a request. Researchers in palliative care must be on their guard not to take advantage of this situation.

In palliative care, cognitive impairment and often frank confusion are encountered in many patients; when this is obvious, they will be excluded from consideration for entry to a study. However, the impairment may be mild or variable. Such patients need careful assessment, and, wherever there is any doubt that the patient is able to understand what is being asked of them, he or she should not be considered for inclusion.

There is a fine balance that needs to be achieved. The special vulnerability of patients receiving palliative care dictates the need for great care in obtaining consent to participate in research but at the same time the researcher must enable those patients able and wishing to take part to do so.

Evidence-based palliative care

The principles of evidence-based medicine underpin our day-to-day clinical practice. Evidence-based medicine 'is the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients. The practice of evidence-based medicine means integrating individual clinical expertise with the best available external clinical evidence from systematic research' (Beecher, 1966).

Evidence-based medicine is not new. The evolution of current thinking about evidence-based medicine is described in Chapter 19.2.

Evidence-based medicine is about finding ways in which to bridge the gap between the huge amount of published data and its application to clinical practice, and encompasses a number of strategies. One of these has been the development of scientific

methods (systematic reviews and meta-analyses) to combine data from a number of different randomized studies of the same or similar treatments in any particular condition. Systematic reviews differ from other types of review in that they adhere to a strict scientific design in order to make them more comprehensive, to minimize the chance of bias, and so ensure their reliability.

Taken at face value, it seems reasonable to assume that the data from several studies, which have been combined according to agreed scientific methodology, should be more meaningful than the evidence from single studies. This is increasingly accepted; however, there is no doubt that the methodology and application of these techniques must continue to be looked at critically. Systematic reviews and meta-analyses are, however, powerful tools in aggregating and evaluating large amounts of data and have become an important area of research activity in palliative medicine. One function they serve is to highlight research questions and thus contribute to the research agenda by careful and comprehensive review of the available evidence.

Evidence-based medicine and the future of palliative care

Evidence-based medicine has already had a major impact on the development of health care in a time of ever-increasing demands and limited resource. It is likely that resource allocation will increasingly be based on evidence, not just of efficacy, but also of cost effectiveness. Where proof of efficacy is lacking, funds will not be provided by government or other health-care agencies. This has particular implications for palliative care because where such research-based evidence is sparse. There are many activities within palliative care which are not amenable to investigation by randomized controlled studies; however, as noted earlier, the RCT is not the only valid method of ensuring knowledge advances. The focus on evidence-based medicine makes investment in high-quality palliative care research all the more urgent.

The scope of research in palliative care

One of the challenges in palliative care research is setting boundaries around the field. Because death and dying are at the centre of practitioners' concerns, it can be tempting to include all dimensions of scholarship related to 'death' within the field of interest. Death, as a major rite of passage for individuals, families, and societies, attracts research on its many ramifications, manifestations, and meanings in everyday life. The cultural context in which people present themselves as patients, come to approach death, and are cared for through their dying, is open to wide and varied interpretations drawn from historical, sociological, anthropological, theological, philosophical, and psychological perspectives; each with its own research traditions. Understanding the significance of death as a rite of passage as well as a biological or medical event is important for the practitioner when faced with the challenges raised by dying patients and their families, and so it could be argued that the field of palliative care research is in fact immense. Practically, however, the field is generally focused on a narrower range of interests of immediate concern and relevance to practitioners and planners.

The principal questions that face palliative care professionals are those of clinical effectiveness and acceptability, service efficiency

and organization, and meeting the changing needs of the population. These are basic questions concerned with what palliative care practitioners do, and how they do it. The research skills to answer these questions are commonly drawn from the traditions of clinical research (medical, nursing, and allied health professional), health services research, and also epidemiology.

Epidemiological research

Descriptive epidemiology seeks to describe the prevalence and incidence of conditions within defined populations. Assessing the need for palliative care in different sectors of the population is clearly important for informing the process of service development and planning. In relation to palliative care, epidemiological research has been hampered by an absence of clearly defined population indicators linked to levels of clinical need, as well as changing perceptions within the profession of palliative care as to the appropriate 'catchment population'. The extended application of palliative care from its original main constituency of cancer patients at the end of life, to patients with any life-limiting illness, from point of diagnosis onwards, poses problems of classification. The majority of health service utilization data and measures of morbidity and mortality are based on disease categories. These do not give an indication of symptom burden or dependency levels, and thus little indication of the need for different forms of palliative care.

Clinical research

Clinical research traditionally tends to focus on biochemical, microbiological, and physiological processes and the effect of pharmacological and other therapeutic agents. In palliative care, this focus is much broader because of the complexity of advanced disease and the high prevalence of psychological and existential distress. Clinical trials are based on an experimental approach and will often use outcomes from the laboratory derived from body samples (blood, tissue) or images (X-rays or scans) as well as patient responses recorded by questionnaire or structured interview. It is at the level of clinical research that trial based research methodologies are most effective and applicable. The need for access to skilled technicians and laboratory facilities may limit research capacity for researchers working in non-academic or community settings.

Health services research

Health services research is primarily focused on the evaluation of the organization and delivery of health care. Frequently, the research is applied to particular problems faced by policymakers, managers, practitioners, and patients, and can range from questions of cost and effectiveness, policy formulation and implementation, the evaluation of new technologies, through to patient and public preferences and perceptions. Research approaches include those that underpin the social sciences as well as the more experimentally based approaches of the natural sciences. Much of the multidisciplinary research carried out in palliative care is focused on questions of innovation and organization in services, and assessing the need for and access to different types of intervention.

Humanistic research

The contribution of other disciplines and research traditions to the body of research in palliative care is well recognized and valued.

Concern with the ethical, moral, spiritual, and philosophical dimensions of care for the dying and bereaved from all perspectives informs a body of scholarship, which broadens out the focus of research that can be relevant to palliative care practitioners. However, lack of familiarity with disciplinary roots and epistemological theory can make the contributions from the social sciences and humanities more difficult to assimilate for practitioners schooled in the natural sciences.

Defining the patient population

A particularly complex issue is the definition of a palliative care patient population. The lack of strict criteria for defining the patient population is a threat to both the internal and external validity of research in palliative care. In this context, internal validity can be understood as the ability to define the cohort of patients included in a given study. For example, if the true patient population is more heterogeneous than the one defined, the heterogeneity might obscure, or even obliterate the positive effect of a particular intervention. External validity is about the representativeness of the sample. Research data might be inappropriately applied in clinical practice if the precise characteristics of the population included in a particular research project are not accurately described. Research methods are generally predicated on the comparison of one population with another; studies of effectiveness are only meaningful when one treatment is set against another within similar or homogeneous populations. Palliative care populations are difficult to standardize however, since referral to a palliative care team is made for a wide variety of reasons, most of which will be patient-generated, but will also include reasons that involve the patient's family and professional carers, and the facilities available to the patient. Prognosis on referral is one way of categorizing patients, however this is generally a matter of clinical judgement and use of dependency scores, while time from referral to death is another way; but this is only possible retrospectively. Another possibility is symptom burden—which is in most cohorts closely related to expected survival (Kaasa et al., 1989; Maltoni et al., 1995; Vigano et al., 2000).

Methodology

In a recent European study, a basic set of core variables were identified as necessary and sufficient to describe a palliative care patient population (Sigurdardottir et al., 2014). This EAPC basic dataset consists of 31 core variables divided into patient and health-care professional forms.

The evaluation of the effectiveness of treatments in palliative care has either not been undertaken or has been conducted using poor or inadequate research methodologies. This was also the case in clinical medicine generally until the late 1960s and early 1970s. Only in recent years has it become evident that properly designed and well-conducted clinical trials are needed in palliative care as much as in any other area of medicine. Most of the published studies of the effectiveness of treatments in palliative care have been related to pain and often the patients included have been at an early stage of their disease. Whether the results of these studies can be extrapolated to palliative care patients is open to question.

A clinical trial is any investigation that follows the principles of a scientific experiment, allowing for the evaluation of the clinical effect of an intervention in a valid and reliable way. The term

'clinical trial' is not synonymous with 'randomized controlled trial' (RCT). A clinical trial in the broadest sense of the term may mean any kind of planned experiment in patients, ranging from open descriptive studies to RCTs. The trial design will, and should be, determined by the research question.

The choice of an appropriate study design will depend on what is already known about the particular question to be investigated. With the recent emphasis on evidence-based medicine, there has been much discussion about the need for RCTs with reference to the RCT as the 'gold standard' and the most robust method for evaluating new treatments. However, many research questions do not need to be answered by an RCT. Furthermore, when attempting to design a randomized study, a lack of sufficient descriptive data may make it difficult to decide upon a study design and appropriate outcomes, or to perform a valid sample size calculation. This is commonly the case in palliative care research. The choice of trial design is crucial and, in this process, collaboration between experts is essential. This is the stage at which a project group should be established, at the very beginning of the planning process of a study.

In palliative care, a pilot study or simply a non-systematic observation of a particular intervention is not a rigorous research experiment but is the first step in the research plan. A step-by-step approach is necessary and highlights the fact that clinical research is a time-consuming process. Researchers and clinicians should not expect too many answers from each study.

Guidelines and books (Pocock, 1984; Karlberg and Tsang, 1998) on clinical trial methodology are widely available. The objectives and design of a study will be driven by the research questions and the resources available. This is not just about funding but also about academic and clinical resources and the availability of sufficient patients. A common problem in clinical research (not unique to palliative care) is that investigators invariably and substantially overestimate the number of patients they are likely to see who would be suitable for a particular study. Changes in treatment policies might influence the availability of patients for a particular study even more if the entry criteria are based on previous policy.

A general criticism of palliative care research is that too many small studies are performed with an open non-comparative design, and thus the impact of the results in terms of changing practice will be limited. For example, in a recent systematic review of ketamine in cancer-related pain, the reviewers found 32 case series, but only two RCTs of good quality (and these involved a total of only 20 patients). This makes it impossible to draw firm conclusions about the efficacy of ketamine (Bell et al., 2003).

How to plan a clinical trial

The planning process of any clinical study often starts with new encouraging data from the laboratory or, probably more often in palliative care, from chance or non-systematic observations in the clinic. Aside from the need to collect together background information, the planning process involves a series of basic steps, which will need to be considered to provide the framework for the study (Box 19.1.1).

Usually one will start with a literature review to see what is known about an intervention and the target condition or symptom. If the review indicates that a formal study is necessary or worthwhile, a research question or hypothesis should be formulated and this will determine the aim of the study.

Box 19.1.1 The evolution of a research project in palliative care

1. Describe clearly the clinical problem or observations which prompted the idea for a study.
2. Discuss the relevance and validity of the observations with clinical colleagues.
3. Carry out a comprehensive review of the literature to find out what is already known about the topic.
4. Formulate the research question(s). These will define the aim of the study.
5. Define the patient population.
6. Decide on the appropriate study design.
7. Decide on the outcomes to be measured.
8. With these decisions made, write the protocol.

A common mistake in clinical research is to bring too many ideas together and try to answer too many questions at the same time. Many studies are too complex, with many research questions, which cannot be answered with a limited number of patients.

Explicit definition of the aim of the study is crucial. Many clinical research projects are undertaken without a clear and concise aim, and the consequence is a lack of precision in the subsequent planning process, and ultimately a poor study or one that is impossible to complete. The aim should be written in clear and understandable language and, ideally, it should be easily understood by a lay person. It should be possible to formulate it briefly in one or two sentences. It is often expressed as a general question and this is broken down into specific research questions or hypotheses.

The research questions will determine the patient population to be studied. There are several factors to take into consideration such as 'Which group of patients will best give an answer to these questions?' For example, if a study was designed to examine patients' attitudes toward euthanasia and physician-assisted suicide in palliative care, the researchers would need to decide whether to ask the patient directly. In similar studies, patients themselves have not been asked, but the questions have been put to proxies or the general public. If the researchers decide to ask patients, they must then decide how to select patients, (in this example perhaps 'not too ill, but not too far away from being confronted with death and dying'). The patient sample must also be representative of the population of patients to whom the results will be applied. In other words, if a selected sub-group of the general population is recruited to a study, the usefulness and applicability of the results (the external validity or generalizability) will be compromised.

In studies evaluating the effect of adjuvant chemotherapy in breast cancer or combination therapy for HIV, the primary outcomes are easy to select, for example, tumour response or survival time (Early Breast Cancer Trialists' Collaborative Group, 1998). However, more recently, in oncology trials, criticisms have been made about limiting the outcomes to survival or cure and not taking account of late side effects of the treatment. During the last decade, for example, several studies have described the high prevalence of subjective side effects, such as fatigue, in Hodgkin's disease survivors (Loge et al., 1999). These experiences emphasize that the selection of outcomes, even in curative

treatment studies, might be less straightforward than it at first appears. In palliative care, the patient population is complex and studies have been reported with ten to 20 and even more outcome measures. This multiplicity of outcomes is further driven by the multidimensionality of the concept of health-related quality of life and the range of scales and single items found in these measures (Aaronson et al., 1993; Cohen et al., 1995). It is important not to fall into this trap. In general, one or two primary outcomes and perhaps two to three secondary outcomes are the most that should be included.

All of these issues should be thoroughly discussed by the researchers and the involved clinicians, together with the larger study group, before the research protocol can be finalized.

Randomization and blinding

The concept of random allocation of patients when comparing different treatments (or any other intervention) is important in the design of a clinical experiment. The purpose of randomization is to reduce selection bias. Non-randomized trials have a tendency to overestimate the effect of treatment. Randomization also provides a basis for the use of standard methods of statistical analysis. When a new treatment is introduced, enthusiastic clinicians and researchers tend to overestimate its beneficial effects. For example, in the early open studies of cisplatin in the treatment of non-small-cell lung cancer, the response rate was double what was found in later randomized studies (Kaasa et al., 1988). The same tendency is also seen when using historical controls as a comparison group or when using other quasi-experimental designs.

In palliative care, randomized studies are particularly difficult to undertake and complete. Therefore, other types of study must be considered and might be preferable. Caution needs to be exercised in the analysis and interpretation of data from non-randomized studies. Other designs may be appropriate and may represent a slightly less robust option than an RCT but still produce persuasive data. For example, in the evaluation of palliative care programmes, cluster randomized designs have been used (Jordhøy et al., 2000; Costantini et al., 2014).

Unblinded trials also overestimate the effect of treatment. Blinding may be difficult to achieve and needs to be thought about early in the planning process, particularly if it involves the manufacture of placebo formulations or other manufacturing processes to conceal the identity of treatments. Palliative care researchers should consult with statisticians and clinical trial methodologists early in the planning process of the study, and preferably include these advisors in the project group. There are useful texts on clinical trial methodology (Pocock, 1984), study design (Rothman and Greenland, 1998), introduction to statistics (Rosner, 2000), and more comprehensive textbooks on medical statistics (Altman, 1991). Such texts provide useful basic background reading for researchers.

Statistical considerations

The project group will need to consult with a statistician, or preferably include a statistician. Medical statisticians have skills and expertise in several areas of clinical research, that is, study design, sample size estimation, and in the analysis of the data. A statistician should be consulted early in the process of designing the study and should have continuing input throughout the project.

One essential step in the planning process of any clinical study is to decide how many patients will be needed to get a valid result.

The purpose of this 'sample size' calculation is to ensure that the study is large enough to detect a clinically important difference should one exist, or exclude the possibility of such a difference should none be detected. In order to estimate the sample size, the statistician will want to know how small a difference it is important to be able to detect in the main outcome measures in terms of clinical significance. For example, the number of patients treated with a new opioid, reaching a numerical rating scale (NRS) score below three within 2 weeks of the initiation of treatment. In comparative studies of pain relief, the mean value of the NRS is often used as a primary outcome. The clinicians need to specify how small a difference between groups will be considered to be of clinical significance (e.g. 2 on a 0–11 NRS scale). It would also be helpful to have information about what could be expected to happen in the control group (mean and standard deviation) and this information may be derived from a pilot study or from published literature. The required number of patients is calculated according to how confident one wants to be about detecting a difference between interventions if one exists (the power of the study).

The protocol

The process of developing a rough draft of a study protocol through to a stage where all aspects of the study have been considered and piloted is a major research effort on its own. In theory, it means that short of actually carrying out the study, everything that could be done has been done. In practice, researchers who skimp on the protocol and associated development work will often find themselves faced with untenable or impractical research studies.

Access to patients

A major challenge in palliative care research needing to involve relatively large numbers of patients is in identifying the patient population and gaining access to them. When research involves selected patients in a clinic, or on a ward, identifying those appropriate for research may not be problematic, especially if the clinician involved is carrying out the research. However, for non-clinical researchers, or for clinical researchers wanting to recruit patients from settings other than their own, identification and access are crucial aspects of patient recruitment. In these situations, cooperation will be needed from other health-care professionals caring for the patients. To gain access to patients may require lengthy negotiation, involving presentations at clinical meetings, permission from professional bodies, as well as a strategy for communication and keeping the research project uppermost in clinicians' minds.

It can be useful to develop information sheets, specific for each professional concerned, early on in the stages of introducing a project to those who are affected. Thinking through likely questions and their answers can help to take the project off the drawing board and ground it in the reality of clinical life. Colleagues and peers will be concerned that the research is well designed and addresses a clinically important question. Justifying the purpose and value of a research project to one's peers is particularly critical in relation to palliative care research where non-palliative care colleagues may question the probity of carrying out research with this patient group. There are probably few palliative care

researchers who have not, at some time, had their research intentions questioned. In addition, it will be important to listen to colleagues' concerns and offer flexibility in carrying out the research. Colleagues will be particularly resistant to participating in anything that involves more paperwork or disruption to routines. The effort and time involved in securing access from professional colleagues should not be underestimated.

It is also important to feed back to practitioners who have been involved in the research through facilitating access to patients, or providing information, at the end of the research. Knowing what the findings are, and what importance they hold for future service configurations, helps make the research a collaborative experience, and can be an element in service development and change where that is indicated. This affirms the stakeholder role, which professional carers hold in the research process.

Significant others to the patient— non-professional carers

Care at the end of life embraces not only the patient, but also those close to him or her. Supporting family carers in their caring role is important in relieving some of the practical difficulties and burdens that are encountered during protracted periods of high-dependency care in the home, as well as addressing the psychological distress which is associated with the loss of a close relative. Research similarly may involve not only the patient but also those close to the patient in a primary caring role. Research interest may take several forms; it may focus on the long-term health of those who survive the patient (bereavement studies), but it may also focus on how patients and their home carers cope with the illness together, or the perceptions of the home carers of the professional care received by the patient. Even when research is solely concerned with patient-based indicators, those close to the patient are important in the research process by acting as intermediaries. Home or family carers can take on a number of roles in relation to patients' involvement in research and each role needs to be appreciated by the research team.

Gatekeepers/protectors

Family members adopting a primary caring role act as 'gatekeepers' to patient. This is likely to be increasingly critical as the patient declines, when dependency increases, and when the patient him/herself may have delegated certain aspects of decision-making to a trusted family carer. When patients are approached for recruitment into a research study, it is generally advisable, therefore, to approach also whoever appears to be most in contact with the patient (in hospital or at home), with the patient's consent. Research can appear threatening to those who are striving to care for the patient; primarily they may worry about the research tiring the patient, or about questions upsetting the patient—either by providing too much information or opening up areas of contemplation that may further disturb the patient. When time is perceived to be short, carers may well resent the patient's attention being taken by people outside of the family. How family carers weigh up the benefits of participating in a research study (short-term benefits of additional monitoring and attention versus the long-term benefits to society) against the costs to the patient (and themselves) of time commitments and possibly extra upset will be pivotal in the recruitment process.

The family carer's role as gatekeeper is often regarded negatively by researchers, as one of the barriers to achieving adequate sample sizes. While researchers should regard adult patients as autonomous, self-determining individuals who can decide for themselves whether they want to participate in research, the vulnerability of some palliative care patients can make this problematic. The tensions between dealing with a patient as a family member rather than as simply an individual are all too apparent. Participation in research is an intervention in itself (patients are not 'passive subjects') with consequences that cannot be wholly predicted, however meticulously procedures are followed. Being involved in research can involve the wider family context, and so the extended boundaries of the palliative care patient need to be appreciated by researchers, with procedures in place to inform and include family members.

Interpreters, substitutes, and advocates

When patients have difficulty communicating their thoughts and feelings, family members may take on the role of interpreter and substitute (proxy). Interpretation can be needed for both speech and language difficulties. In the face of cognitive impairment, the views of family carers may be used as a substitute for the patient's views. A number of studies have investigated the validity of proxy ratings, concluding that proxies tend to underestimate the severity of certain symptoms (pain and depression) but that in the absence of patient derived data, proxy data is valuable.

A role that sits between gatekeeper and interpreter is that of advocate. The extent to which family carers take on this role varies with their own confidence and the situations within which they find themselves. Researchers should be aware that advocacy can work in different ways; at times making sure that the patient's best interests are promoted, at others, following an agenda that is not the patient's but that of the family member. This is another reason for extreme sensitivity to be exercised by the research team.

Significant others to the patient—professional carers

Professional carers can also act as gate-keepers, interpreters, substitutes, and advocates, with all the cautions outlined above. Similarly, they are also a subject of great interest in their own right from the point of view of service/practitioner efficiency and effectiveness, and understanding the process of delivering high-quality palliative care. There is a growing body of research on the training and educational needs of practitioners, the dynamics of inter-professional and multidisciplinary team working, and management processes to preserve and enhance occupational health.

Finance and management

There are many sources of funding that are relevant to palliative care, but securing funds for research in this area is a competitive exercise, as it is in any area of health care. As indicated at the beginning of this chapter, palliative care research is a relatively neglected area as far as the major funders of cancer research are concerned. The great majority of patients currently being treated by palliative care services are patients with cancer and funding for studies in non-cancer patients is in even shorter supply. However, the climate is changing, and this is happening in many different parts of the world. It is not possible here to give detailed information about funding sources since these will vary from country to country. This sort of information is obviously of considerable relevance to future researchers and it is one area where the scientific journals available in palliative care could play a useful role.

Finance for individual projects: the length of time between securing financial support for a project and actually starting data collection is always underestimated. This period can be divided into two main phases: the time before project funds are actually drawn upon, when research staff are being recruited and when a considerable amount of planning and groundwork is being carried out; and phase two, when the funds are being disbursed and piloting work is being undertaken. It is crucial that as much work as possible is carried out in the first phase, even though the work is essentially not funded. Efficient management of time and resources from the very start of a project are obviously key factors in its successful running.

Project group

All research projects benefit from being exposed to a group of people who have experience in the subject under research and who are interested in the project. This is particularly important for large studies. The role of a project group can vary from being highly involved in the administration and day-to-day concerns of the project, to being relatively distant, and receiving information about the project on a regular though infrequent basis.

Depending on the size of the project, it can sometimes be helpful to institute a steering group of key stakeholders who are sympathetic to the research but who do not have much time to devote to it, and a management group of people who are accessible regularly and become close to project and data collection, and who report back to the steering group.

Piloting the study and study procedures

Research studies do not start as fully formed projects. Indeed, it is impossible to anticipate all the challenges that a study will face at the planning stage. The word 'pilot' derives from the job of steering a boat on its course and the metaphor of guiding a ship through uncertain and troubled waters is an apt one. Without preliminary studies, it is difficult to steer the course of a large project. Pilot work is important for testing all aspects of research design, from the face validity and acceptability of data collection procedures, to the workability of allocation schedules and administration tasks. Dealing with the questions and issues raised by pilot studies can be demanding at a stage when there is impatience to start the main study, not least due to the pressure of obtaining funds for research and the need to work to deadlines. However, learning the lessons from pilot work can be critical to the success of the project. For researchers working alone, the use of a research journal can encourage a reflective attitude to pilot work, and help to refine the research design. For researchers in a team, frequent meetings at this stage, with records made of the discussions and decisions will help to re-define and re-model the research into a workable proposition. Re-writing the protocol with the findings of the pilot work is important for the auditing of the research project.

Administration and paperwork

It will be readily appreciated that a research study will quickly develop different strands of paperwork, reflecting the different administrative tasks:

- Background work relating to the development of the study, reviews of the scientific literature, and any position papers and early proposals.

- Paperwork relating to the funding and approval of the study (sponsors, ethics committees, other professional and regulatory bodies).

- Correspondence and paperwork relating to the formation of the steering and project groups, together with the minutes and agendas of each formally convened meeting.

- A record of the protocol as it develops through successive drafts with careful version control.

- Sources of information targeted at specific sectors of the study population: information sheets for patients and their professional and non-professional carers, information posters for hospital or hospice wards or other settings, information in local media about the study.

- Paperwork used for collecting data, ranging from consent forms and case record forms, to questionnaires and data abstraction forms. This might also include letters or cards sent by the research team to patients and carers after data collection, to thank them for their participation, as well as any correspondence from the study population regarding the research, including letters of complaint or inquiry. Restricting access to this kind of documentation is central to preserving patient confidentiality (lockable rooms or filing cabinets).

- A developing account of the way the study is progressing. Most projects benefit from regular review, although this will depend on size and timescale. Even in the absence of interim analysis, it can be important to monitor recruitment rates, protocol deviations, and any other problems with the management of the project. This can also be an opportunity for informal reflections on the study, particularly from the point of view of the day-to-day researchers.

- Paperwork relating to data preparation and data analysis, including any conventions used in coding data, and where the data are held and in what form. This aspect of project administration is most important for the understanding and interpretation of data in analysis.

- Finally, the project will be written up as a report in various formats for various audiences, and it is important to keep records of the drafts as they develop and become finalized.

Efficient administration is essential for two main reasons. One is where a project is required to audit its activities and give an account of the funds that have been used and the procedures that have been followed. This can happen as a result of a rolling programme of research audit within an institution or sector, or can happen as a result of a special investigation, triggered by a number of different concerns (perhaps unrelated to the study). Another more common scenario is where researchers move away from the project before its conclusion; this may seriously affect the smooth running of a study, but the effect can be minimized by comprehensive paperwork. Again, the role of a project group is critical to the orientation of a new researcher, mid-study, with the dangers of keeping decision-making and discussion to too small a group all too evident.

Monitoring of study

Supporting researchers and the clinical team (keeping it going)

The initial rush of enthusiasm for a project is difficult to sustain over time without conscious management of the research team.

Box 19.1.2 Submitting a paper for publication

1. Decide which journal to go for. Are the data relevant to a general journal (*The New England Journal of Medicine, The Lancet, BMJ*) or a specialist journal (*Cancer, Journal of Clinical Oncology, Palliative Medicine*)? It is more difficult to achieve publication in the general journals.

2. Aim high (but appropriately so) because sometimes you will catch an editor's interest. With the leading journals you will usually get a very rapid response if the paper is rejected.

3. Try to learn from rejection. Usually authors will get some feedback explaining why the paper has been rejected. This should enable them to improve the paper before submitting it to another journal.

4. Before submission to any journal, study the 'Instructions to Authors' and abide by them strictly, particularly in terms of length, style, and references.

5. In general, it is not worth arguing with editors if they have made it clear that they do not wish to publish your paper. However, if you believe the comments of referees or editors are unreasonable or erroneous it is perfectly legitimate to challenge them. Occasionally an editor may change their mind!

6. If your paper is accepted but the referees or editors suggest changes which you are not happy with, respond and explain why you feel the changes are not justified.

7. After publication, make sure you read the journal (even if it is not one you regularly take) so that you can respond to any correspondence about your paper.

Studies can get into difficulty quite quickly when unexpected problems start to shake the confidence of the supporting clinical teams or the front-line researchers. Encountering slow patient recruitment or high dropout rates, for example, can be disillusioning and demotivating. However, a project that is conceived as a collaborative venture, where support from others is openly valued, and where there is a commitment to teamwork, is likely to develop mechanisms for keeping the study going. Attention needs to be focused on the individual needs and group dynamics of the research team, as well as the wider group of staff who are involved in facilitating the study. Morale and support for the study can be promoted in a number of ways:

◆ For clinical staff, provision of regular feedback and direct contact with the study team to answer queries and address any concerns is desirable. This is also important considering the high turnover of clinical staff; new staff will need to be identified and inducted especially during a long-running study. Busy clinical staff will tend to forget about studies, and an important aspect of regular contact is to remind them that the study is still running.

◆ Within the research team, time should be set aside for team-building activities (e.g. away days and social events), and to help prevent 'burn-out', the provision of mentoring, co-counselling, or debriefing should be considered.

Submitting a paper for publication

Much research is undertaken and completed, and even presented at scientific meetings, but is never published in a peer-reviewed journal. There may be many reasons for this and it is not possible briefly to discuss them all here. However, Box 19.1.2 gives some advice about submitting papers for publication.

Conclusions

Research in palliative care is essential for maintaining standards and advancing knowledge and improving practice. It is challenging, sometimes daunting, often frustrating, but always exciting and rewarding when a study is successfully completed, whether the outcome is positive or negative. We hope that this chapter will help those who are new to research to get started, to proceed and complete it, and contribute to improving outcomes for patients with advanced disease, which is ultimately the aim of this endeavour.

The principles of evidence-based medicine

Amy P. Abernethy

Introduction to the principles of evidence-based medicine

Originally introduced by Thomas Kuhn in the 1960s, the term 'paradigm' refers to a frame of reference in the sciences. In the vernacular sense, it has come to mean a global framework for organizing current information and understanding reality (Kuhn, 1962). A paradigm shift occurs when a new global framework, and its corresponding way of thinking, supplants an old one. In this process, inadequacies, defects, and errors in the prevailing paradigm make it no longer tenable. The new paradigm emerges not as incremental change but as a discontinuity.

In medicine, the emergence of evidence-based medicine (EBM) can be viewed as a paradigm shift encompassing philosophical, cultural, and logistical changes that are transforming medical practice.

As defined by Kuhn, a paradigm shift is irreversible. Once a new paradigm permeates a field's consciousness, individuals are no longer able to revert to their prior way of thinking. For example, germ theory completely and irrevocably replaced the previous view of disease as caused by spontaneous generation, a hypothesis that had held sway since Aristotle's time. Likewise, the basic concept of EBM, described below, is here to stay. Embracing this paradigm will be essential if palliative care is to establish itself as a peer to other medical disciplines, communicate and collaborate with them, and progress as a field in the contemporary biomedical research and health-care environment. Arguably, as well, adoption of EBM in palliative care represents the current best approach to improving quality of care and patient outcomes in this, as in other, disciplines.

What is evidence-based medicine?

EBM was first defined, and described as a global approach to medical practice, in the 1990s. In a seminal manuscript published by the *British Medical Journal* in 1996, David Sackett and colleagues provided the most commonly cited definition of EBM: 'Evidence-based medicine is the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients' (Sackett et al., 1996). Here Sackett set down the central parameters of EBM: it is a personalized approach to patient care, in which the physician determines the best treatment plan for each patient, based on best research data, and tempered by clinical experience and wisdom.

A more general term than EBM is evidence-based practice (EBP), defined by Muir Gray in 2001 as follows: 'Evidence-based clinical practice is an approach to decision making in which the clinician uses the best evidence available, in consultation with the patient, to decide upon the option that suits that patient best' (Muir Gray, 2001) (Fig. 19.2.1). The terms EBM and EBP are often used interchangeably, acknowledging the distinction between them. For simplicity's sake this chapter will use the term EBM throughout.

Sackett's now-classic definition of EBM clearly specified the aim, but did not spell out the processes by which to attain it. Meanwhile, between 1993 and 2000, Gordon Guyatt and colleagues in the Evidence-based Medicine Working Group published, in the *Journal of the American Medical Association* (*JAMA*), a seminal series of 31 articles designed to provide educational content, tools, and strategies that could enable clinicians to interpret evidence from published research and integrate it into their care of patients. These 'User's Guide to the Medical Literature' articles, now compiled and published as a text (Guyatt et al., 2008) by the American Medical Association Press, rapidly attained the status of a classic in medicine.

What is evidence?

The practice of EBM requires, first, a clear understanding of what constitutes 'evidence'. In the history of medicine, the conviction that clinical care should be based on data from research studies is quite new. The modern clinical trial, characterized by the use of eligibility criteria, concurrent comparison, placebo or control conditions, randomization, and blinding, emerged in the late nineteenth and early twentieth century. Prior to that time, medical knowledge accrued through, and medical decisions were largely based on, observation and anecdote often painstakingly assembled. Though these forms of information served as 'evidence' in earlier times, today they are generally considered to be of lesser value than information derived from more quantitative or standard scientific methods.

The boundaries circumscribing what will be included in the evidence considered, and what will be excluded, vary. Some authors narrow Sackett's definition to only include evidence from clinical trials, randomized controlled trials (RCTs), or secondary clinical research based on RCTs (Hampton, 2002). These requirements narrow the definition of evidence and exclude much non-trial evidence such as observational, epidemiological, and qualitative studies (Giacomini, 2001; Hampton, 2002). Other authors seek to expand the definition of evidence so as to include the basic sciences
Fig. 19.2.1 Core inputs to evidence-based medicine.

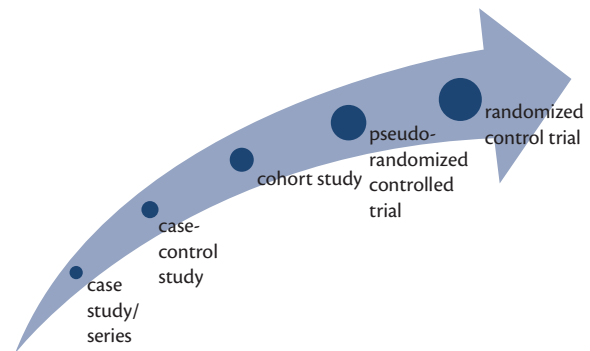
Fig. 19.2.2 Evidence hierarchy for primary clinical research into new interventions.

and clinical knowledge (Sackett et al., 1996; Guyatt et al., 2000; Youngblut and Brooten, 2001). With the advent of medical informatics and administrative databases, the definition of evidence is being expanded further to include aggregated data from multiple patient encounters with a clinician or across a health system or of multiple experiences of an individual patient accumulated over time (Bakken, 2001). The *N*-of-1 trial may be the ultimate evidence source for an individual patient (Guyatt et al., 2000). Qualitative studies that explore social phenomena and enlighten clinicians about why, when, and how treatments take effect are increasingly recognized as important sources of supportive information (Giacomini and Cook, 2000a). In the future, 'evidence' may even encompass information appearing on bulletin boards, global chat-rooms, and personal electronic databases (Abbasi et al., 2002). Today, a massive volume of evidence is available and pertinent to virtually every discipline, specialty, and subspecialty. In palliative care, it is often not the availability of evidence, but rather the availability of reliable evidence and the clinician's ability to differentiate between high- and low-quality evidence and apply this knowledge into practice for the individual patient, that is critical to EBM.

Quality of evidence

General consensus holds that not all evidence is of equal strength or quality. As methods of generating evidence have developed and evolved, an evidence hierarchy has taken shape to assign relative merit to different sorts of evidence (Fig. 19.2.2). In general, experimental studies are believed to generate higher-level evidence than comparative (observational and non-randomized) studies. Among the latter, study designs are ranked in quality (low to high) as follows: case series, historical controls, case–control, cohort study. The RCT remains the 'gold standard' of study design, considered to generate the highest-quality and most reliable evidence for evaluating interventions.

Generally, the quality of evidence reported in a clinical trial is defined by its 'internal validity', a term referring to the extent to which the investigators have minimized bias in study design and execution (Juni et al., 2001). Various types of bias can threaten the internal validity of a study. *Selection bias* results when participants in a sample do not truly represent the baseline population, population of interest, or population to which results should pertain. *Performance bias* occurs when participants receive unequal care, apart from the treatment under evaluation. Potential


for procedure selection bias is present when the intervention is chosen in a non-random way for or by the participant. For example, healthier patients may preferentially select or be selected for a particular treatment, and study results may be correspondingly skewed. In post-entry exclusion, certain patients are omitted from the final analyses often due to missing data points or deviation from protocol by introducing significant bias making the study's results no longer legitimately generalizable to the target population. *Attrition bias*, in which certain participants are lost to follow up, causes similar effects. In *assessment bias*, participants, investigators, or both are aware of intervention assignments and this awareness can affect outcome assessments.

Biases lower the quality and reliability of evidence by decreasing the confidence that the observed effect is the true effect (Sackett et al., 1991). Non-randomized studies are prone to selection and assessment bias. Compared to RCTs, non-randomized studies can dramatically under- or overestimate the treatment effect; they most commonly show that the treatment is far better than it really is (Kunz and Oxman, 1998). Chalmers et al. documented this trend as early as 1983, in their review of 145 clinical trials of treatment for acute myocardial infarction. Outcome differences between treatment and control groups were identified in 9% of studies that were blinded and randomized, 24% of unblinded but randomized studies, and 58% of non-randomized studies (Chalmers et al., 1983). A review of RCTs versus historical control trials from the same time period reported that most of the positive findings of historical control trials were later repudiated by RCTs (Sacks et al., 1982, 1983). These findings were corroborated in 1995, with estimations of treatment effect exaggerated by 41% in inadequately concealed trials (Schulz et al., 1995).

There is also the potential for bias after the study is completed. The most relevant example in EBM is *publication bias* in which the results of only a portion of trials relevant to a clinical question are available in the published medical literature (Dickersin et al., 1994; Piantadosi, 1997). In general, positive results are more likely to be published than negative results (Song et al., 2009).

Specific skills required for evidence-based medicine

The 'information paradox', another term that has joined the lexicon associated with present-day medicine, refers to the current situation in which clinicians face an exploding volume of information but, despite a wealth of information, they have trouble

finding and understanding pertinent information both at the time when it is needed and especially at point-of-care (Muir Gray and de Lusignan, 1999). Information access, apprehension, and application are key challenges to clinicians seeking to implement EBM. To overcome the information paradox—a plethora of evidence, but an inability to use it—clinicians need a new set of competencies that enable them to ask explicit questions, access relevant evidence, evaluate its quality, critique it in light of what is currently known, and assess its applicability to the patient at hand.

Basic steps in practising EBM have been defined beginning with *The Users' Guide to the Medical Literature* series (Table 19.2.1) and in books by Sackett, Guyatt, and colleagues: *Evidence-Based*

Table 19.2.2 Critical appraisal skills

ASSESS the patient	The process begins with the patient who has a clinical problem or question arising from their care
ASK the question	A well-constructed clinical question is derived
ACQUIRE the evidence	Conduct a search and choose the most appropriate resources
APPRAISE the evidence	Appraise the evidence: valid and applicable?
APPLY: talk with the patient	Integrate: evidence and clinical expertise with patient's preferences and apply
EVALUATE: review outcomes and process	Evaluate the patient's outcomes and performance

Medicine: How to Practice and Teach EBM (Sackett et al., 1997, Sackett et al., 2000), *Clinical Epidemiology: A Basic Science for Clinical Medicine* (Sackett et al., 1991), and *Users' Guides to the Medical Literature: Essentials of Evidence-Based Clinical Practice* (Guyatt et al., 2008). Subsequently, the core approach and skill set, commonly termed 'critical appraisal skills' have been well described (Table 19.2.2).

1. Assess

The starting point of EBM is genuine clinical equipoise: what is the best course of treatment for the patient at hand, or a class of patients? Methods of patient assessment, and thus of defining the clinical scenario and pinpointing the clinical need or question, are addressed in other chapters. In the practice of EBM, the use of robust, validated assessment instruments to fully describe the patient's condition will yield information vital to tailoring the course of care to the individual, in light of best available evidence.

2. Ask

Once the patient's situation has been assessed, clear articulation of the clinical question is a next step essential to EBM. A well-built clinical question includes four elements, usually collapsed into the acronym 'PICO': (1) the specific clinical *Patient, Problem Population*; (2) the *Intervention* in question, including aetiology of the illness in question, prognostic factors, and treatments; (3) a *Comparison* intervention when relevant; and, (4) the clinical *Outcome* or outcomes of interest (Sackett et al., 1997). A helpful framework for categorizing questions about managing specific clinical scenarios appears in Table 19.2.3 (Sackett et al., 2000). Clarification of the question at hand, with respect to a particular patient, focuses the practitioner on the most appropriate intervention, alternative actions (i.e. comparison interventions), and outcome(s) of interest. This, in turn, helps determine the best study design, that is, the study type most likely to generate evidence that will help answer the question (Sackett et al., 1997). Once the question has been formulated, the practitioner is ready for the next step, searching for relevant and appropriate evidence.

3. Acquire

Successful practice of EBM requires the identification of appropriate, high-quality evidence. Pragmatically, for EBM to become the modus operandi of palliative care, clinicians must have convenient access to the evidence (Rubin et al., 2000). The quantity of current evidence may seem to make the task of accessing relevant evidence highly burdensome, time-consuming, and even frustrating. Information technology (IT), however, has dramatically simplified the 'Acquire' step of EBM. Given the volume of evidence that may or may not be relevant to any given clinical question, mastery of this third critical appraisal skill in today's health-care environment requires the ability to use computerized evidence resources and to apply a stratified approach to these resources (Guyatt et al., 2000).

A '4S Model' has been suggested as a hierarchical approach to evidence acquisition. In this model, evidence sources are prioritized in the following order (lowest to highest priority): *S*tudies (published reports of clinical trials and other original research), *S*yntheses (meta-analyses and systematic reviews), *S*ynopses (evidence-based abstracts printed in journals and other credible sources), and *S*ystems (computerized search and decision support systems) (Haynes, 2001).

The clinician seeking evidence begins at the Systems level. Several computerized decision support systems are currently available, such as *Up-to-Date*. The practitioner should note, however, that these sites can lack explicit detail as to how studies were selected for inclusion (Haynes, 2001; Up-to-Date, 2003; WebMD Professional Publishing, 2003). Evidence-based clinical practice guidelines are also at this level of the 4S ladder, especially when IT-enabled, however, such guidelines have varying levels of reliability depending upon approach to development and updates.

At the second level of evidence acquisition, the practitioner accesses synopses of individual studies and reviews, provided in secondary publications such as *ACP Journal Club* (Sackett et al., 1997; Haynes, 2001; Up-to-Date, 2003). The *ACP Journal Club* reviews over 6000 original internal and general medicine articles published each year and from these, culls approximately 300 highest-quality studies (Davidoff et al., 1995). A virtue of these resources is that the publisher has performed an initial review of each study for quality and validity.

Syntheses such as the *Cochrane Database of Systematic Reviews*, exemplifying the third level in the 4S model, incorporate specific methods of review and assembly of data (Haynes, 2001; The Cochrane Collaboration, 2003). Addressing a great number of common clinical concerns, these evidence-based reviews provide an efficient and invaluable resource to busy practitioners. They are however limited to the studies available, and still have a process of selecting the studies to be included.

Finally, in seeking evidence to support EBM, practitioners often go directly to the ever-expanding volume of original studies. Various search tools, such as MEDLINE, Google Scholar, and other electronic bibliographies, are available to facilitate this task. Many universities have proprietary search engines that assist institutionally affiliated clinicians in performing targeted searches of the literature. Subscription services and search tools offered to members by professional associations are also available.

In using the 4S approach to seek evidence, the practitioner looks for the highest-level evidence available for the clinical question at hand (Haynes, 2001; Hunt et al., 2000), considering first what is the highest and likely most accessible level on which to find the answer to the problem, searching for evidence at that level, and if there is no answer there, moving to the next-highest level.

Table 19.2.3 Categories of common clinical questions

Category	Possible questions
Clinical findings	How should findings from the history and physical be interpreted?
Aetiology	Can any causes for the disease be identified?
Clinical manifestations of disease	When, and how often, are clinical manifestations of disease present?
	Can this information help classify the patient's illness?
Differential diagnosis	What other diseases might manifest similarly?
	How do we select those that are likely serious and responsive to treatment?
Diagnostic tests	How are diagnostic tests selected and interpreted?
	How are selected tests used to confirm or exclude a diagnosis?
	What is the precision, accuracy, acceptability, expense, safety, etc. of selected tests?
Prognosis	Can the clinical course of a patient's disease be estimated?
	How likely are complications to occur?
Therapy	How are treatments selected?
	How likely are selected treatments to do good or harm?
	What is the cost/benefit relationship?
	Is the treatment worth the effort?
Prevention	What are the risk factors of the disease?
	Can the risk of the disease be reduced by modifying the risk factors?
	Can the disease be diagnosed early with screening and if so, what screening tests are best?
Experience and meaning	How can we as caregivers empathize with our patient's situation?
	How can we appreciate the meaning that our patients find in their experience?
	Can we improve our understanding of how this meaning influences healing?
Self-improvement	What is the best way for we caregivers to keep up-to-date?
	How can we improve our clinical and personal skills to run a better and more efficient practice?

Adapted from Sackett, D. L., et al., *Evidence-based Medicine: How to Practice and Teach EBM*, Second Edition, Table 1.2, p.19, Churchill Livingstone Edinburgh, UK, Copyright © 2000, with permission from Elsevier.

Evidence can be sought at more than one level to confirm conclusions, and/or to provide depth and nuance to findings.

However, clinicians should beware of the frustration of 'no evidence is available'. The concept of 'best available evidence' implies that the EBM-practitioner uses the best information that is available—which may be a trial, a summary in *Up-to-Date*, or anecdote relayed by a close colleague. The tenets of EBM risk 'lack-of-evidence paralysis' unless the EBM practitioner can confidently adapt the evidence hierarchy to the realities of day-to-day care, and acknowledge that there is not a study to guide every scenario.

4. Appraise

Once evidence has been identified, it must be evaluated before it is applied to a patient in clinical practice. Evaluation of evidence from a study involves assessment of both (a) the appropriateness of the study's methodology to the problem at hand, and (b) the study's methodological quality. Consideration of the former requires an understanding of study type and the outcome(s) being studied. For example, a cross-sectional survey design is an appropriate gold standard design to answer clinical questions related to disease burden, symptom prevalence, or an intervention's acceptability, whereas an RCT is the best design to answer questions related to treatment effectiveness or assess any intervention in the most rigorous way (National Health and Medical Research Council, 2000; Muir Gray, 2001). If the study's methodology appears appropriate to the clinical question, then the EBM practitioner proceeds to consider the validity of its results that depends, fundamentally, on the study's methodological quality.

Assessment of methodological quality demands a systematic approach to reading an article, with a focus on the methods section. Initial review should take note of the study's design, recruitment procedures, eligibility criteria, intervention and comparator, outcomes, measures to assess them, methods to reduce bias (e.g. randomization, blinding), calculation of sample size, duration, and completeness of follow-up (Greenhalgh, 1997). If these aspects appear rigorously described and reasonable, a more in-depth examination begins. Main questions to answer (sometimes referred to as 'primary guides') include:

> Were patients randomly assigned to treatments under study?
>
> Was randomization concealed from patients and investigators?
>
> Were all patients enrolled in the trial included in analyses, in the groups to which they were randomized?

A valid study will yield a 'yes' answer to each of these questions. If any of these questions is answered in the negative, the study design is fatally flawed. A finer level of questions to be asked ('secondary guides') include:

> Were patients and investigators kept 'blind' to the treatment being received?
>
> Other than the intervention under study, were patients in each group treated equally?
>
> Were groups similar at the outset of the study?

These questions represent important but non-essential elements that may or may not invalidate a study. If a study fails to meet these criteria, the practitioner should critically consider whether or not to use the study in decision-making for a patient (Guyatt et al., 1993, 1994; Guyatt et al., 2008).

What happens when a practitioner encounters a 'no' answer to one or more of the validity questions? Perhaps the study chosen is not a RCT, but no RCT is available and the study being evaluated is the only one published about the clinical question at hand. How does the practitioner resolve this dilemma? Guyatt et al's 'Users' Guides' help the practitioner work through the implications of a negative result (Guyatt et al., 2008). The Users' Guide focused on studies of harm offering instruction for critical evaluation of cohort studies, case-control studies, case series, and case reports (Levine et al., 1994). The practitioner examines studies with an eye to potential sources of bias and discounts studies early if they are not valid. When only lower-quality evidence is available, the

practitioner must ask whether or not reliance on best clinical judgement can value add to the decision-making process.

5. Apply

Application of evidence, and in particular the results of a specific study, to an individual patient entails consideration of the generalizability and applicability of the results. Generalizability, also termed external validity, refers to the extent to which a study's findings can be extrapolated beyond the study setting and study population (National Health and Medical Research Council, 2000). Applicability refers to the extent to which a study can be applied to an individual or to a specified group of patients (National Health and Medical Research Council, 2000)

A study's inclusion criteria are the usual starting place for determining whether results are applicable to a patient or clinical population. However, rather than dismissing a high-quality study simply because its eligibility criteria and setting were not consistent with characteristics of the individual patient in question, the practitioner should consider, based on the study's external validity, whether there is a compelling reason that it should not be applied to this individual (Guyatt et al., 1994). In order to be relevant to the individual, the study must consider potential outcomes, harms, and costs that would be important to this individual (Guyatt et al., 1994). Key factors to consider include the individual's risk of a target disorder, likelihood that the biology of the treatment effect will be similar in this individual, risk to this individual of adverse effects, and local availability of the intervention (Dans et al., 1998).

Questions to guide the practitioner's evaluation of applicability include:

Can the intervention be reproduced in this setting?

Can the results be applied to this setting?

Can the results be applied to this individual?

If these questions can be answered affirmatively, then the clinical option should be discussed with the patient (and loved ones, where appropriate) in the context of the patient's preferences and values (National Health and Medical Research Council, 2000; Sackett et al., 2000). Together, the clinician and patient should consider the full range of outcomes that the patient values, and whether, in the case of the clinical option being discussed, the potential benefits outweigh the potential harms and costs (Guyatt et al., 1994).

Both the founders of EBM and its current advocates have underscored the point that EBM is not 'cook book' or 'one size fits all' medicine. The individualized nature of this clinical paradigm is most apparent at the 'Apply' stage, where evidence deemed to be relevant, appropriate, and valid is considered in the process of making clinical decisions, with a specific focus on the patient's unique circumstances, goals of care, values, and preferences.

In EBM, the practitioner integrates valid and meaningful results with knowledge of the individual patient. Chris Silagy, a leading international expert in EBM, noted several important points to be heeded when applying the evidence in patient care. Good doctors and nurses listen and listen and listen to their patients.

- Trust is essential to a good doctor–patient relationship.

- Honesty is important but so is some hope . . .

- Treatment choices need to take account of a patient's values and preferences.

- Survival statistics are just that—probabilities of what may happen not what will happen . . .

- One can learn to live with uncertainty (Silagy, 2001).

These poignant statements based, in part, on Silagy's experience as a cancer patient are especially salient to the practice of EMB in palliative care.

Practitioners, and palliative care clinicians in particular, must be sensitive to patients and their emotional needs. Even the early publications about EBM remind us that, 'Understanding patient's suffering and how that suffering can be ameliorated by the caring and compassionate physician are fundamental requirements [of evidence-based practice]' (Evidence Based Medicine Working Group, 1992). EBM in practice is about explicitly integrating the findings from systematic acquisition and appraisal of the literature or other evidence resources with patients' needs, fears, desires, and preferences.

Recognizing the paramount importance of the patient's unique characteristics, the initial step in individualizing care in an EBM approach, is to determine the extent to which the individual wants to be involved in decision-making (McAlister et al., 2000). Shared decision-making entails three principal components: (1) disclosure of information, (2) exploration of values about the therapy and potential health outcomes, and (3) actual decision-making (Elwyn et al., 1999; McAlister et al., 2000). Each of these steps requires excellent communication skills as the practitioner must translate concepts and results described in the evidence base into meaningful information that the patient (and his or her loved ones, as appropriate) can understand. Formal decision aids and other forms of evidence-based patient education are available to help the practitioner communicate choices to patients and families (O'Connor et al., 1999; McNutt, 2000; O'Connor, 2001).

In palliative care, the evidence often contains uncertainty about prognosis; 'difficult conversations' are a standard aspect of clinical practice. EBM is well aligned with the principles and practice of palliative care in stressing the need for partnership with patients and/or family members, sensitive communication of relevant information even when it is uncomfortable or entails uncertainty, truthfulness, and respect for the patient's communication preferences. Thus the art encompassed in EBM resides in the integration of science with compassion to guide sensitive communication and optimal, individualized decision-making.

6. Evaluate

Evaluation is an iterative, ongoing process in EBM. With respect to patient outcomes, the practitioner should systematically collect data that can be analysed to evaluate the benefit, and relative harm, of applied interventions. Electronic health records (EHRs) are making this process more efficient, enabling more ready access to data, and facilitating real-time review of the results of intervention. In the future, interoperability of EHR datasets will add power to retrospective analyses of intervention results. Once the practitioner has applied evidence in practice, routine evaluation of the effects of the clinical choice can inform future practice. This continuous feedback guides and improves clinical practice and is the essence of 'learning health care'.

A model advanced by the Institute of Medicine and other agencies, learning health care describes a system in which (1) processes of care are standardized, based on the latest research evidence;

(2) each patient's care is routinely documented in an electronic health record; (3) patients' data are secure, standardized, and interoperable; (4) clinicians have ready access to real-time data and other information relevant to the each patient's care; (5) outcomes of care are regularly assessed to evaluate effectiveness and to identify opportunities for improvement; and, (6) the system 'learns' by refining its activities and functions based on results (Abernethy et al., 2010b; Abernethy, 2011). Although currently most health-care systems fall short of this ideal, the concept of learning health care is gaining traction and will likely provide a powerful framework to house the practice of EBM in years to come.

Self-evaluation, on the part of the practitioner, should take place at each step in practising EBM. The most important evaluations are likely those that the practitioner designs and carries out in his or her own clinical practice, to assess both process and outcomes. Formal audit processes and feedback systems can support self-evaluation, and these methods should constitute the backbone of the practitioner's regular self-evaluation. However, a process for ongoing informal self-evaluation can also provide a framework in which to consider a current situation, a mode of continuous review of care process and results, and insights to guide the development of strategies to improve care.

Principal categories of questions for self-evaluation include:

How well did the EBM process go?

How well was the information applied to the patient?

How well does the practitioner perform in this area for all patients? (Sackett et al., 2000)

The importance of IT to evidence-based medicine

The nature, locus, and quantity of evidence available to support twenty-first century medical care makes IT an indispensable tool for EBM, and IT fluency a necessary skillset for the EBM practitioner. Without an adequate IT infrastructure, clinicians will remain mired in the 'information paradox', unable to implement critical appraisal skills well and in a timely way (Rosenberg and Donald, 1995; Muir Gray and de Lusignan, 1999; Rubin et al., 2000; Bakken, 2001).

Medical informatics, a new and rapidly growing discipline, is the science of information and communication in health care. Recent advances in medical informatics relevant to EBM include a surge in resources available via the internet, computer-based reminder systems for clinicians, secondary databases of summarized evidence that is ready for clinical application, secondary publications, and a host of applications for mobile devices and new software solutions (Haynes et al., 1997). Due to differences in their organizations and clinical environments, palliative care clinicians will vary in the extent to which their practice of EBM is supported by IT infrastructure. Best IT-supported EBM will rest upon five building blocks of an informatics infrastructure: (1) standardized technologies, (2) electronic data, (3) data exchange standards, (4) informatics processes, and (5) informatics competencies (Bakken, 2001).These elements facilitate both the execution of EBM and the generation of evidence to support it. The creation of this infrastructure within any institution requires both considerable investment in terms of resources, education, and leadership, while simultaneously considering critical issues such as the quality of electronic data, methods for synthesizing and presenting evidence, debugging and maintaining IT systems,

and the requirements of multi-disciplinary teams (Haynes et al., 1995). IT systems should be designed with close attention to the information needs of all relevant health-care professionals, rather than unquestioningly choosing the latest technology available (Smith, 1996).

Regardless of their institution's IT infrastructure, all clinicians can avail themselves of the Internet and administrative databases. Web browsing and hypertext links provide convenient portals to an ever-increasing amount of information, though identifying appropriate and reliable content quickly is difficult for the unskilled searcher and busy clinician (Muir Gray and de Lusignan, 1999). Synthesized access points such as the Health Information Resources (formerly National Library for Health) maintained through the National Health Service in the United Kingdom, (National Health Service Information Authority, 2003). PubMed Clinical Queries (National Center for Biotechnology Information, 2003) and the National Guideline Clearinghouse (National Guideline Clearinghouse, 2003) can provide busy practitioners with quick access to high-quality clinical information. For-profit sites such as *Up-to-Date* (<http://www.UpToDate.com>) may provide more extensively synthesized information, although the requirement to join and log on may create a barrier to use (MDConsult, 2003).

The digitalization of health-care data, made possible through IT, has created phenomenal new opportunities for examining various types of evidence. Administrative databases house demographic, organizational, financial, and basic clinical data elements such as deaths, in-hospital complications, hospital length of stay, and readmissions. Insurers and hospitals maintain these databases for administrative tasks like billing, patient flow, and strategic planning. While these databases provide valuable opportunities to review and compare outcomes for large populations, issues related to data quality must first be addressed, including the following (Naylor and Guyatt, 1996b):

◆ Important patient outcomes such as disability, performance status, distress, and satisfaction are generally not entered

◆ Coded outcomes may not be measured or entered consistently across the population, inhibiting comparisons

◆ Interventions may be administered differently, but the variability of administration is often not recorded

◆ Inaccurate recording and poor data quality ('dirty data') are rampant.

The rationale for EBM in palliative care

Several compelling arguments underlie the effort to promote EBM in palliative care. First in importance is the argument for quality of care. As defined by the Institute of Medicine, 'quality of care is the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge' (Chassin and Galvin, 1998). Embedded in this definition are the concepts of effectiveness and standards of care, both of which are commonly understood to be closely related to evidence. One could make the claim that, indeed, this definition of quality care comes close to restating the original definition of EBM. EBM, and in particular a reliance upon highest-quality available evidence, clinical practice guidelines, and evidence-based decision aids, has been proposed as one method to improve and uphold quality of care. The

assumption is that provision of best evidence and convincing information will lead to optimal decision making and thus optimal care (Grol, 2001). Evidence-based secondary research methodologies are critical to quality-focused tasks such as highlighting the most effective interventions, critiquing inferior ones, and identifying areas in which the evidence is inconclusive and which warrant further research.

A second rationale for advancing EBM in palliative care is the argument that increased demand will lead health-care systems to offer more palliative care services and that health-care systems should do so in a rational manner. Demand for palliative care is increasing worldwide, fuelled by ageing of national populations, longer lifespans, and a shift in disease burden from primarily acute illnesses and events to predominantly chronic conditions. Growing public awareness, and expectations on the part of both patients and providers, are also cited as factors helping to increase demand (Muir Gray, 2001), as are trends in disease management, earlier detection of cancers and initiation of palliative care throughout the duration of curative treatment for these patients, and increased referral of non-cancer patients to palliative care. As demand increases, health-care providers will seek to offer services that meet it—to the extent that those services effectively, demonstratively, meet population needs. EBM offers a system for intelligently and intentionally selecting the services that will be made available.

The increasing need and demand for palliative care, leading to provision of more services, will result in greater overall costs of care. In this context, the presence of an evidence base supporting palliative care services and interventions will be critical for sustaining funding and government support. Naturally, health systems of the twenty-first century are striving to restrain potential increases in costs through rational approaches to service delivery, including the practice of palliative care. They are looking for 'best value' health care, wherein an intervention is provided to an individual based upon the physician's advice, evidence that benefits outweighs adverse effects, and 'value for the money' in relation to other interventions (Muir Gray, 2001). In short, in an effort to enhance the value of medical care attained for the expenditure made, they are beginning to require EBM.

As health-care funders begin to mandate an evidence-based approach to care, palliative care will not be immune. The EBM framework synthesizes efficiency, quality, and effectiveness into a systematic process for medical decision-making. For this reason, private and public health-care funders increasingly look to EBM as an effector of health-care reform (Muir Gray, 2001). The practice of EBM provides a mechanism for optimizing value in health care, one physician at a time. When each physician evaluates the effectiveness of interventions using explicit criteria and matches interventions to appropriate clinical patients and settings, aggregate medical care will achieve best results cost-efficiently (i.e. with minimal waste).

EBM offers a viable mechanism for palliative care to meet new performance and reporting requirements. Organizational expectations and policies are changing in ways that emphasize evidence-based practice, with accountability distributed across all levels and types of medical practice. Health care today, a highly competitive and market-driven system, faces increasing directives from financiers to control escalating costs (DeBourgh, 2001). It is no longer sufficient to provide safe and individualized patient care. While managing complex acute and chronic caseloads, practitioners must also demonstrate that the desired patient outcomes are attained in a cost-effective manner, and they must show improvement in the quality of care—all to the satisfaction of regulatory agencies and increasingly informed health-care consumers. EBM can help palliative care practitioners, and palliative care as a discipline, meet these emerging expectation.

Next, to evolve further as a medical discipline and on a par with numerous other specialties and subspecialties, palliative care will need to join its peers in the current paradigm shift. EBM is now commonly recognized throughout medicine as a new paradigm, replacing the long-standing perception of medicine as a healing art with its blended scientific/systematized/personalized basis. Palliative care has been slower to adopt EBM due to the lack of high-quality evidence, numerous barriers to scientifically conducted research, cultural barriers, and difficulty implementing new knowledge into practice (Lunder et al., 2004; Abernethy et al., 2007). As the new paradigm undeniably takes hold, health-care systems, regulatory agencies, and patients will insist upon evidence-based practice in all realms of care and by all practitioners. Credibility of the field of palliative medicine is at stake. Unless palliative care embraces the movement toward EBM, it stands to be relegated to second-class status, marginalized as 'unscientific' at a time when the need for its services is growing exponentially. A similar challenge has been described in the field of nursing: 'Important areas of nursing practice are blighted by the stigma of poor evidence and subtly devalued' (Forbes and Griffiths, 2002). Without EBM, palliative care risks a similar fate.

A final rationale for the adoption of EBM in palliative care is that EBM provides a structured framework to constantly improve the care provided. As new data supporting (or refuting) inventions become available, the explicit EBM approach provides a mechanism to update response to a clinical question with contemporary information. Research advances palliative care interventions and knowledge, while EBM provides the mechanism to advance palliative care practice and policy.

Barriers to evidence-based medicine in palliative care

Estimates claim that only half of palliative care decisions are evidence based, at best. As Irene Higginson highlighted at the end of the past century, part of the problem is a paucity of convincing research evidence in palliative care (Higginson, 1999). The evidence base in this discipline has been expanding over recent years, but even when evidence exists, palliative care practitioners do not consistently apply a systematic, evidence-based approach to the care of patients with advanced and/or life-limiting illness (Lunder et al., 2004). The overall prevalence of palliative care practitioners who possess EBM skills and who routinely implement an EBM approach would be difficult to quantify, but likely remains low.

A variety of philosophical, organizational, and practical reasons have hindered the incorporation of EBM into palliative care. The most important of these barriers have been the lack of a high-quality body of evidence upon which to base clinical practice, barriers to the conduct of rigorous scientific research, and challenges to translation of new evidence into meaningful changes in clinical

practice (Lunder et al., 2004; Abernethy et al., 2007). A major task of the palliative care community is to demand research that brings evidence to practice. International clinical trials groups such as the Palliative Care Clinical Studies Collaborative (PCCSC) in Australia (Shelby-James et al., 2012), the Palliative Care Research Cooperative Group (PCRC) in the United States (Abernethy et al., 2010a), and the European Association for Palliative Care Research Network (<http://www.eapcnet.eu/Home.aspx>) are starting to generate the large-scale evidence needed to answer commonly encountered questions.

Traditional critical appraisal skills have seemed ill-suited to the palliative care literature. The perception is that these skills need to be adapted to accommodate the heterogeneity of palliative care scenarios and the nuances of palliative care practice (Lunder et al., 2004; Abernethy et al., 2007; Currow et al., 2009). Rather than denounce EBM critical appraisal skills as irrelevant, the palliative care community must develop tailored solutions fit requirements for working with this population. For example, Currow, Abernethy, and colleagues are developing a templated framework for reporting clinical studies in palliative care so that users of new research data can efficiently generalize and apply findings within their local practice (Currow et al., 2009, 2012; Wheeler et al., 2012). Similarly, the team with (<http://www.caresearch.com.au>) is developing, validating, and curating a portfolio of pre-defined search strategies to support efficient searching of the medical literature for topics pertinent to palliative medicine (Tieman et al., 2005, 2010; Sladek et al., 2006). Suppose a user is looking for palliative care relevant clinical trials about anorexia; a click on the 'anorexia' link will provide a real-time search of PubMed using a validated search string that will identifies trials, sorted by strength of evidence and toggled by timeframe.

Medical disciplines face common challenges as they move toward more evidenced-based approaches, including: unmotivated clinicians, deficiencies of research and critical appraisal skills, unsupportive organizational cultures, inconsistent approaches to evidence, and inadequate IT. EBM cannot be implemented equally well in any practice setting. Prerequisites to the success of EBM, according to Muir Gray, are motivation, competency, and overcoming of the barriers to the EBM approach (Muir Gray, 2001). Evidence-based decision-making requires that clinicians be not only motivated but also equipped with key skills such as critical appraisal, astute clinical judgement, and ability to elicit and incorporate patient preferences (Sackett et al., 1996; Sackett et al., 2000). Muir Gray also emphasized the role of barriers in impeding, or facilitating (if they are overcome), EBM and good clinical decision-making.

Barriers to EBM must be tackled for the clinician to perform well in this new paradigm. The lack of a body of evidence and easy access to the evidence—key requirements of evidence-based practice—represent current and formidable barriers to EBM in many palliative care settings (Rubin and Thomas, 1996). Clinician-level barriers such as inadequate skills, over-reliance on authority, or disinterest (Sackett et al., 1997) also serve to slow the adoption of EBM in this field. The organization within which the palliative care practitioner works can be either a motivator and facilitator, or a barrier, to EBM. Ideally, the organizational culture will support EBM, offer institutional endorsement and incentives, and provide resources and mechanisms, such as IT infrastructure, to facilitate its uptake.

Limitations of evidence-based medicine

As EBM becomes the dominant paradigm across medical disciplines including palliative care, it is important to recognize its inherent limitations. No approach to patient care, old or new, will be without limitations, and conscious attention to these can improve the integrity and quality of care.

In 1999, Straus and McAlister prepared a structured review of published criticisms to evidence-based practice (Straus and McAlister, 2000). Abernethy recapitulated the Straus and McAlister literature search in 2007, focusing on papers written after 1999 (Greenhalgh and Meadows, 1999; McAlister et al., 1999; Woolf, 1999; Trinder and Reynolds, 2000; Scott et al., 2000; Bakken, 2001; Kerigan, 2001; Caplan, 2001; Forbes and Griffiths, 2002; Ford et al., 2002; Hampton, 2002; Temple, 2002; Guyatt et al., 2008; Montori et al., 2008) Principal limitations included the following:

◆ Shortage of coherent, consistent, scientific evidence to inform clinical practice in a variety of areas.

◆ Difficulties in applying evidence to the care of individual patients. There is, as yet, no rubric that provides definitive guidance on how to extrapolate from data presented in studies to its application in the individual patient and variation from individual to individual will continue to make this step challenging. Some interventions supported by the evidence may be unavailable or impractical.

◆ Dependence on physician factors, including willingness to develop new skills and to change modes of practice.

◆ Time and resource constraints. EBM requires time and resources that the busy clinician may not have. IT infrastructure may be insufficient while access to digital libraries and librarians may be unavailable.

◆ Weaknesses of currnet EBM tools. Secondary research methodologies are still crude. Secondary studies quickly become out-dated, and their design poorly accommodates subjective outcomes or a variety of primary outcome measures—which are critical in palliative care. Clinical practice guidelines are relatively new, and are frequently consensus-based rather than evidence-based (with varying levels of embedded conflicts of interest).

◆ Potential for distortion of purpose and principles. Health-care systems can use the banner of EBM as justification for cost-cutting measures. Expansion of for-profit research, and its inclusion as 'evidence' in EBM, could threaten the quality and integrity of the evidence base. A focus on IT, quantitative research, and critical appraisal skills could overshadow other elements of EBM that are also vital, such as traditional skills of performing a physical exam and interviewing patients and families for an adequate and detailed history.

Palliative care practitioners intending to adopt EBM as their mode of practice should be advised that there is a paucity of evidence that EBM works. Because it is hard to conceive of a high-quality RCT of EBM versus usual care, this evidence may not be forthcoming. Moreover, use of an evidence-based approach does not always ensure good decisions (Kerridge et al., 1998). In the delivery of high-quality palliative care, the practitioner's wisdom, human perceptiveness, and judicious and thoughtful consideration of the

individual patient must help shape the path indicated by robust evidence.

Concluding remarks

Evidence-based medicine has become the norm across medical disciplines. Its principles are becoming inextricably interwoven into clinicians' expectations of approach to decision-making, organizations' expectations of providers' performance, and patients' and families' expectations of the care they will receive. The many potential advantages of EBM over the previous paradigm include greater effectiveness of the treatment(s) selected for the individual patient, greater consistency in the application of interventions, with interventions being applied in appropriate patients and populations, a studied and conscientious blend of science and compassion, and ultimately, better outcomes for patients, populations, and health-care systems.

The adoption of EBM in palliative care will benefit the field since wide adoption of EBM principles will help establish the position of palliative care among other medical disciplines in which EBM is now the dominant paradigm. Practitioners will benefit from their integration of EBM into their clinical care because its framework will provide them with a systematic and manageable approach to the overwhelming and increasing quantity of available evidence. Patients will benefit when their palliative care providers employ evidence-based best practices by receiving care that is most likely to be effective for them specifically, and that is tailored to their personal needs, characteristics, and preferences.

Understanding clinical trials in palliative care research

John T. Farrar

Introduction to understanding clinical trials in palliative care research

Components of the randomized, controlled trial (RCT) have been part of clinical research for several centuries but the modern concept of the importance of the random selection of a control group can be traced to one of the first studies of streptomycin for pulmonary tuberculosis conducted by the British Medical Research Council and published in 1948 (Anonymous, 1948, 1998). Prior to that time, the evaluation of health care relied on what today would be considered anecdotal evidence. The RCT represents the gold standard for the evaluation of the efficacy of new medical therapies. Despite their status, several potential scientific and ethical difficulties continue to limit the use of RCTs in some clinical contexts such as palliative care, and hinder the generalizability of their results in others. Understanding these limitations and how to apply the results of such studies to clinical care is important.

By presenting the various strengths and limitations that are common to all RCTs and how they apply to trials of palliative care interventions, we will be considering how decisions made regarding trial design, conduct, and analysis can influence the trial's results. Basic issues in the analysis of clinical trial data as they apply to the interpretation of RCT results will also be considered. This chapter will provide palliative care clinicians with a proper understanding of the structure and inherent problems with clinical trials. No research experiment can ever be perfect, but the information provided by RCTs is extremely useful as a basis for evidence-based approaches to clinical care. With this knowledge, the reader of science should be able to ascertain whether the results of published trials are (1) likely to be valid and (2) likely to apply to their patients.

The anatomy of a trial

To maximize the usefulness of clinical trials, study design issues must be considered from conceptualization, through implementation, and ending with the interpretation of results. Decisions made regarding every component of an RCT can dramatically influence the quality of the data and the outcome of a trial. Subtle flaws at any stage may lead to inappropriate conclusions.

Even when a clinical trial is perfectly designed, there is no guarantee of finding the right answer to a specific research question. Because of random variation from a sample of the whole population of interest, there is always a probability of reaching a false positive or a false negative conclusion simply by chance. Statistical analyses are necessary to define the extent of this probability.

A statistical analysis is conducted primarily to (1) summarize the data by estimating the size of the effect being observed that can be attributed to the treatment being tested and (2) to estimate the probability that the results obtained occurred simply by chance. The conventional selection of a p-value cut-off point of 0.05 means that we are willing to accept a 1/20 probability of getting a false positive answer by chance alone. The selection of the power for the study to detect a true change if one exists (often set at 90%) accepts a 10% chance of a false negative. As a result, replication of a trial's results is always preferable before clinicians can confidently make decisions about patient care, since no single trial should ever be considered definitive proof of the presence or absence of efficacy.

The question

The initial step in designing any trial or understanding the results is to define what research question is being asked. This can seem like a relatively simple process, but it is often a tremendous challenge to replicate a clinical reality in the research setting. To properly design a clinical trial requires reducing an important clinical question into a testable hypothesis. Many clinically relevant questions cannot be studied because the appropriate population is not available, the number required may be prohibitively large, or for ethical issues.

In such situations it is often necessary to modify the research question to one that is more readily answerable or to choose a different clinical study design, such as an observational cohort study. It is important to understand that getting an answer to a different question, may or may not allow its application to the original clinical scenario. Attempting to answer the right question may result in compromises in the study design, sacrificing either precision or protection from bias. In some cases, alteration of the design may reduce the value of the knowledge, and hence alter the risk–benefit calculation used to justify the research (Freedman, 1987; Emanuel et al., 2000). From the outset, an alternative design should be considered if the investigators are not clear about the clinical importance of answering the proposed question.

The choice of an appropriate outcome and choice of the measure to be used to collect the data are important steps. To ensure that the research question can be answered a clinically relevant primary outcome must be selected that can be appropriately measured, analysed, and the results interpreted. This must be done a

priori, that is, before the data are collected or analysed. In order to maintain acceptable limits on the probability of arriving at an incorrect result by chance both the clinical importance of the effect of an intervention and the characteristics of the data to be collected must be defined. Although multiple secondary outcomes are often also tested within a single trial, each should be identified at the outset, and none should subsequently be designated as the primary outcome after the data have been collected and analysed (a posteriori).

Choosing outcomes is often dependent on the disease area to be studied. A recently published summary of outcomes created in conjunction with the Agency for Healthcare Research and Quality (AHRQ) have specified areas, including symptom management, quality of life (QOL), function and satisfaction, family burden, and quality-of-death measures. There are a number of evaluative tools that have been used over time or recommended by various groups, but they are beyond the scope of this chapter and well described elsewhere (Mularski et al., 2007). Almost all of the measures used for palliative care studies are patient-reported outcomes, which require a thoughtful approach to collection, analysis, and interpretation.

Types of trials

Part of the process of answering the appropriate clinical question is choosing the correct design of the trial. While there are many different variations on an RCT, the two basic formats are to design a trial to demonstrate an effect (either beneficial or harmful) of an exposure (or treatment) over no exposure; or to design a trial to demonstrate equivalence between two different treatments. In both cases, the goal is to demonstrate a difference in outcome between the treatment groups that usually has a less than 5% probability of occurring by chance (i.e. a p-value < 0.05) and with an appropriate probability of detecting a difference, if one truly exists (i.e. a power of > 80% or 90%). While the statistical issues need to be determined appropriately, the more difficult concerns usually involve other issues in clinical trial design. The majority of this chapter will focus on the other issues involved in the design and interpretation of clinical trials.

Efficacy trials

An efficacy trial is designed to demonstrate that the two groups are not the same (i.e. also described as rejecting the null hypothesis). This trial benefits from the fact that demonstrating two things are different is substantially easier than proving that two things are the same. The determination of an appropriate sample size is based on established probability calculations that take into consideration the underlying variability of the measurement and the size of the effect to be evaluated, in addition to the appropriate p-value and power.

Non-inferiority and equivalence trials

When there are significant concerns about the difficulties in conducting a placebo-controlled trials, investigators may design a clinical trial to show that a new drug is 'no worse than' a treatment that is commonly accepted as effective (i.e. a non-inferiority or equivalency trial). In evaluating therapeutics for conditions in which the risks of placebo assignment are widely regarded as too great, such as thrombolytic agents for acute myocardial infarction

or stroke, active-controlled, non-inferiority trials are the standard (Anonymous, 1997a, 1997b).

These trials are presently not considered standard for problems such as hypertension, hyperlipidaemia, and pain, because there are several potential problems with interpreting such studies (Jones et al., 1996; Temple, 1996, 1997; Van De Werf et al., 1999; Fleming, 2000). The first problem is that equivalence trials essentially aim to confirm the conventional null hypothesis of no treatment difference. Since a lack of difference in the outcomes detected between treatment groups can be the result of an inappropriate study design, problems with the study conduct, or other unexpected difficulties with the clinical trial, questions frequently remain about the validity of the results of such trials. This may create inappropriate incentives for conducting 'sloppy' research (Ellenberg and Temple, 2000). Secondly, such trials generally require larger numbers of participants, because equivalence or non-inferiority must be documented within relatively narrow margins to be clinically relevant. Thirdly, demonstrating that two treatments have the same outcome does not show that either of them work. This problem is related to 'assay sensitivity', because such trials require the assumption that the standard therapy would have proven superior to placebo had a placebo arm been included in the study design used (Temple, 1996). Because of these concerns, current regulatory guidelines still call for placebo-controlled trials to evaluate treatments for problems such as pain and other symptoms (Food and Drug Administration, 2001) where no established gold standard therapy exists.

Randomization

The most important feature of an experimental clinical trial is the equivalence of the comparison groups at baseline such that any differences measured at the end can be attributed only to the differences between the treatments administered. Random selection of subjects from a sufficiently large single population equally distributes known and unknown factors that might otherwise influence the outcome, such as age, sex, race, and disease severity.

This is in contrast to observational studies (e.g. case–control, cohort, or cross-sectional studies) which depend on nature to set up the experiment. In these types of studies, there is a substantial possibility that known or unknown factors may create differences between the comparison groups at baseline, limiting our ability to attribute any subsequent changes to the treatment. By using statistical methods to adjust for potentially important confounders, some of these factors can be taken into consideration; however, unmeasured confounding or bias can potentially lead to the wrong conclusion from the study. In experimental studies, randomization is the primary mechanism used to create equivalence between the comparison groups. By minimizing the possibility of differences at baseline, an RCT enables investigators to more confidently attribute observed changes over time to the assigned treatments.

True randomization is accomplished by generating a set of random numbers, and distributing them via a mechanism that protects the integrity of the random assignment. A centrally managed randomization scheme may help to ensure consistent application of the procedure across sites and staff. Central control of the randomization will also prevent members of the study team, from knowingly or unknowingly influencing the assignment, especially if they are not be blinded to a patient's treatment allocation.

Randomization works correctly only when sufficient numbers of patients are enrolled to ensure an equal distribution of all important factors. In smaller trials, or in large, multicentre trials with few participants from a given centre, chance alone may cause significant differences in the distributions of important demographic or disease-related characteristics between groups. In order to reduce the likelihood of such occurrences, investigators can use a block randomization scheme to ensure that selected participant characteristics will be equally distributed. For example, if investigators wished to guarantee an equal sex distribution among two treatment arms at multiple sites, they may randomize in blocks of six participants each, within each of which three participants would be male and three would be female. To assess the success of the randomization process, the analysis of all clinical trials should include a careful comparison of the baseline characteristics of the treatment groups to assure that they are approximately equivalent.

Control group

The purpose of the control group is to provide an appropriate comparison for the treatment group, in order to be able to attribute causality to the treatment if a difference is found. The treatment can be as specific as an individual medication such as an opioid (Abernethy et al., 2003), a physical treatment modality such as massage therapy (Kutner et al., 2008), or as complex as a whole-system approach such as inpatient hospice care (Gade et al., 2008). Assuming that the treatment groups are equivalent at baseline (through randomization), then the differences seen in outcome of the groups can be attributed to differences in the treatment. The degree to which blinding is applied to each group is important in defining what aspect of care is being studied and for the ability to interpret the resulting data (see following paragraphs).

There are three primary types of control groups that have a role in clinical trials: (1) a no-treatment control, (2) a placebo control, and (3) an active control. Each type provides different information in comparison to the active treatment group, and the usefulness will depend on the research question that is being explored by the study. The unblinded no-treatment control group can provide information about changes that happen based on the (1) natural history of the disease (i.e. normal variation in the status of any disease state) and (2) regression to the mean (i.e. patients with severe symptoms tend to get better), but does not control for the effect of patient's knowing their treatment group (i.e. a mind–body interaction). The placebo treated control group, when properly blinded, also controls for the mind–body interaction that occurs either from participating in a clinical trial or because of the subject's belief in the therapy. The mind–body response is an especially important part of many symptomatic therapy trials. An active control group is best thought of as a standard to test if the design and conduct of the clinical trial was to detect a difference if the study treatment has a real effect. By administering a drug known to be active in the disease being tested, a positive result provides evidence that the study has been properly designed and conducted. If the experimental agent then does not demonstrate an effect, the negative result is more convincing. Conversely, if the active agent does not produce an effect, the design and conduct of the trial are called into question. In this situation, a negative result with the experimental agent is as likely to be due to the problems in the design as a true lack of efficacy.

No-treatment-controlled trials

An unblinded no-treatment or standard of care control group, where participants receive no intervention or a delayed intervention, is applicable in two primary situations. The first situation arises when there are practical and/or ethical problems with using a placebo or sham control. For example, it is often difficult to construct an appropriate sham intervention for many trials of surgical interventions. Even if adequate shams could be constructed, some feel that assigning patients to receive an invasive, but non-active, intervention is unethical (Hrobjartsson and Gotzsche, 2001). A randomly assigned control group is still a major advantage over not having a control group, but the results must be viewed cautiously since there are many factors that can affect a subject's response to a treatment, when both the subject and the investigator know the group assignment. As discussed in the following paragraphs, it is important that the study staff that collect and record the outcome measures are blinded to the subject's group.

The second situation occurs when one of the goals of the trial is to determine the magnitude of the mind–body placebo effect. The placebo treated group will have a response that is a mix of the natural history of disease and regression to the mean, along with the mind–body placebo effect. By having a no-treatment-control group, the mind–body placebo effect can be estimated. In a meta-analysis of 114 trials employing both placebo- and no-treatment-controls, the placebo effect was less than might be expected, but in symptomatic relief the effect can be large (Hardy et al., 2012). In pain research, the placebo-control group patients typically have a more favourable outcome than those in no-treatment-control groups (Chaput de Saintonge and Herxheimer, 1994).

Blinded placebo-controlled trials

A blinded placebo control group is the best known and most widely used of the possible control groups. A placebo is defined as an inactive treatment designed to mimic as closely as possible, the characteristics of the active treatment. The purpose is to have the control group treated exactly the same as the treatment group except for the specific component being tested. The usefulness of a placebo assumes that at least the study subject and data collector will be blinded to the type of therapy being administered. Creating a placebo for a drug trial is relatively straightforward. An inactive substance is formulated to have similar appearance, route of administration, and, if appropriate, taste as the active treatment. Procedure-oriented therapies are much harder to mimic and therefore, it is significantly harder to obtain true blinding (see following paragraphs). In the absence of blinding, the placebo group is equivalent to the no-treatment group.

The primary benefit of using a blinded placebo control group, rather than a no-treatment control group, is that it enables the specific efficacy of the new intervention to be distinguished from the many non-specific effects that occur with most therapies, including the well-known mind–body interaction (also called the placebo effect) (Freedman et al., 1996a, 1996b). The placebo control group is a group of patients who are treated with a placebo. The response measured in this group results from all three separate processes, namely (1) natural history of the disease, (2) regression to the mean, and (3) the mind–body interaction. The mind–body interaction is a change in brain function that, at least temporarily, leads to improvement in the bodily signs or symptoms. The

mind–body interaction is also sometimes known as a non-specific action of treatment, while the direct effect of the therapy on the disease is known as a specific action of the therapy.

Assuming a simple additive model of treatment effects, the magnitude of the placebo effect in a given study can be estimated by the mean (or median) response in the placebo group and subtract the response in the no-treatment group. In addition, the placebo group response can be subtracted from the mean response in the active treatment group to estimate the specific efficacy of the new intervention. Though the existence of true placebo effects across a broad range of clinical interventions can vary depending on the disease being treated, the treatment modality, and the outcome expectation of the patients, the effect is generally larger in studies of the treatment of symptoms and in the management of pain (Hrobjartsson and Gotzsche, 2001). In such therapy trials, it is unclear if this additive model applies, complicating the assessment of the specific effect (Enck et al., 2011).

A placebo control group assumes the study will be conducted in a double-blind fashion. This helps to avoid the biases that may ensue if patients, investigators, or both, knew who would be receiving which treatment. But there are also costs to using a placebo control. The first, and most obvious, is that placebo-controlled trials require that some patients be given an inactive treatment. This is ethically questionable if there are effective interventions in existence, especially in palliative care trials, and remains a hotly debated topic (Rothman and Michels, 1994; Freedman et al., 1996a, 1996b; Temple and Ellenberg, 2000), and is considered further elsewhere in this book. The second cost to conducting placebo-controlled trials is that, while they remain the gold standard for documenting absolute efficacy, they do not always answer a clinically relevant question. For practising clinicians, who have several symptomatic therapies at their disposal, knowing whether another medication works better than nothing is not as important as knowing how the new therapy compares to the existing standard of care (Halpern and Karlawish, 2000).

Participant selection

Another critical decision for investigators designing trials, and for clinicians who use the data, regards the selection of study participants. There are two conflicting priorities: (1) ensuring similarities between participants in the experimental and control groups and (2) testing a new treatment in a sample of patients likely to reflect all those who could benefit from using the intervention. To meet the first goal, investigators would attempt to enrol patients who are relatively homogenous so there are fewer differences to equalize with randomization. Strict inclusion and exclusion criteria allow greater confidence that the observed differences in outcomes are attributable to the treatments being compared, rather than to undetected confounding variables related to the compositions of participants in each group.

By contrast, meeting the second goal requires enrolling participants from a more heterogeneous population. Because of the large interpersonal variability inherent in such a population, this approach can substantially increase the number of participants required to assure that the trial has adequate statistical power to document a treatment difference, if one exists. If a large enough sample size is available, a heterogeneous sample allows subgroup analyses to be conducted, and so potential variations in a treatment's efficacy among higher- and lower-risk patients may be identified. As a result, early investigations of efficacy are commonly conducted using a select group of participants, whereas later, more definitive trials attempt to enrol more broadly representative patient samples often termed effectiveness studies. Physicians should, therefore, consider the composition of a given trial's sample in order to determine the extent to which the results are applicable to their own patients.

In palliative care populations, there is the additional issue of the frailty of the population and the potential lack of stability in their disease state over time. Finding patients who will remain relatively stable for the duration of the trial can be a difficult challenge. In addition, vulnerable populations may make choices that are not always consistent with the goals of a trial, either to participate out of desperation or to not participate because they do not want to be part of an experiment. There is frequently the additional problem of the ability of some patients to understand enough about their disease to be able to give an informed consent. When patients are cognitively challenged in addition, the process of recruitment can become a seemingly overwhelming task. The ethical issues surrounding these problems are considered elsewhere in this book (White and Hardy, 2010).

Blinding

Over the last century, a growing understanding of the ability of the mind to influence functions of the body, along with the desire to enhance the experimental rigor of clinical trials has increased appreciation of the need for blinding. Recall that the primary goal of a clinical trial is to ensure that any changes between groups seen at the end of the trial may be attributed to a specific treatment being studied. To accomplish this, not only must all comparison groups be similar at the start, but participants in all groups should feel that they have the same probability of getting the real treatment. Thus, the blinding of the study participants is of substantial importance, and investigators must design the study to prevent the participants from unblinding themselves. In particular, if a medication has a specific taste, common side effects, or other distinctive traits, it is important that the placebo treatment mimic these characteristics as closely as possible. Although the evaluation of more invasive interventions for some medical conditions have occasionally used sham procedures (Cobb et al., 1959; Macklin, 1999) this has no place in palliative care research.

In addition to creating a suitable placebo, investigators should plan to determine whether the blinding was maintained by asking participants what treatment they think they received and why. Such questions should be posed to participants occasionally during the trial, and at the trial's completion (Morin et al., 1995). If the blinding is successful, the participants' guesses should be no more accurate than chance (e.g. 50% in a typical two-arm trial). Blinding can be difficult to maintain (Karlowski et al., 1975; Brownell and Stunkard, 1982; Howard et al., 1982; Byington et al., 1985; Rabkin et al., 1986; Moscucci et al., 1987; Fisher and Greenberg, 1993; Basoglu et al., 1997). Study participants can often predict their receipt of placebo due to the absence of side effects, or their receipt of the real treatment by noting adverse effects of the intervention. However, common side effects often occur in the placebo group by chance helping to blind the patients (Sanderson et al., 2013).

When only participants are blinded to the treatment received, the study is labelled as a single-blind trial. The standard use of the term double-blind applies when both the participants and investigators are blinded, assuming that the investigator is collecting the outcome data. If the investigator is not collecting the data, it is critical to blind the person who is, so as to minimize the chance that evaluators will more favourably rate those receiving the innovative treatment, thereby biasing the trial toward finding a benefit of that treatment. Even in studies where the subject fills out their own forms, blinding of the investigator remains important to minimize the possibilities that they would impart different levels of enthusiasm, or prescribe different co-interventions, to patients in the different treatment groups.

Sample size

The statistical power of an RCT to show a difference between treatments is determined by:

1. The size of the effect—treatment effect (i.e. difference in the response among groups) that is deemed to be clinically important to be able to detect.

2. The variance—variability of the outcomes in each treatment group.

3. The p-value (α or type I error rate)—probability of *finding* a difference in the treatment effect of the size detected in the study or larger by chance alone when *there is not* a true effect. This is usually chosen to connote statistical significance and typically set at 0.05.

4. The power $(1 - \beta$ or $1 -$ type II error rate)—β is the probability of *not finding* a difference in the treatment effect of the size detected in the study or smaller by chance alone when *there is* a true effect. Power is $1 - \beta$ and adequate power is usually set to be 80–90% (i.e. β is set to 10–20%)

In general, the size of the sample to be tested (i.e. sample size) is the variable investigators most commonly adjust to obtain adequate power to detect a meaningful treatment difference when one truly exists and the p-value is outcome of the statistical test conducted upon completion of the clinical trial. It is a truism that with a sufficiently large sample size, any real difference between groups, no matter how small or clinically irrelevant, can be shown to be statistically significant. The converse is also true: a large, clinically important difference (CID) between treatments can fail to reach statistical significance when inadequate numbers of participants are enrolled.

The most common method of calculating the sample size required to achieve 80% power (or greater) is to first determine (1) the size of the effect that would be considered clinically important, (2) the anticipated response in the control group, and (3) the expected variability of the outcomes among the groups. This last determination may be particularly difficult to estimate, and should, when possible, be based on evidence from prior studies of similar diseases and/or treatments. An alternate method used when the sample size is fixed is to calculate the size of the effect that would need to be present to produce a statistically significant outcome. This approach is rarely preferable to setting the sample size to detect a specified difference but is commonly used when the available population is fixed.

Outcome measurement

Another critical decision to be made in planning an RCT involves how to measure the chosen outcome of interest. For example, if investigators are interested in studying the effects of a new antihypertensive agent on systolic and diastolic blood pressure, should they measure these values with a mercury sphygmomanometer or via an arterial line? In addition to how the outcome will be measured, investigators must further consider when and how often to measure the outcome. Are single readings once each week adequate, or should participants be equipped with ambulatory blood pressure monitors to obtain multiple readings throughout the day? Finally, investigators must consider how to account for other variables that could alter the measurement, such as body position, when the blood pressure is assessed. In palliative care, a frequent concern about the outcome is whether to measure a specific symptom (e.g. pain) or sign (e.g. physical function) or the more general outcome of quality of life. Similar to the hypertension model, the question of which measure to use and time period to consider is an important decision to consider in the design of a trial. Ultimately this decision is best made based on the clinical or scientific question that is primary reason for conducting the clinical trial.

Regardless of what measurement technique is chosen, it should be characterized by three features. Firstly, the measurement should be reliable—if the same measure is used repetitively in the same person under identical conditions without this person's condition changing, then the measure should produce the same results each time. Secondly, the measure should be valid—it should measure exactly what it is intended to measure. Thirdly, the measure should be responsive—it should change over time if the condition being measured has truly changed. Though a full discussion of these concepts is beyond the scope of this chapter, the topics are well covered in many textbooks (Streiner and Norman, 2003). If the outcome measure has been not routinely used in other similar research, its reliability, validity, and responsiveness should be formally tested and documented in the intended population.

The criteria of reliability, validity, and responsiveness also depend on what form the outcome takes. For example, in pain management, the primary goal is to improve the patient's subjective sense of comfort. For this purpose, investigators might ask a simple question, such as, 'Do you feel better, yes or no?' Because such a measure has only two possible responses, it may not provide an adequately responsive measure of pain relief.

To help differentiate the level of response, investigators might ask, 'What percentage of pain relief do you get from the treatment?' However, such questions require patients to remember their previous conditions in order to report the change over time. Alternatively, investigators could use a 0–10 numerical rating scale at both the beginning and end of the study to calculate the change in pain over time. Deciding which measurement is most appropriate for a given situation should be informed by considerations of how much change in the measure would be important to the patient, and the ability of the chosen scale to detect such a change.

Another measurement concern in palliative care trials relates to the fact that a change in pain or nausea may only provide one component of an overall change in quality of life. Thus, symptomatic reports may be incomplete surrogate markers for changes in the more complete outcome, the overall quality of life. The use of

surrogate markers is a widespread practice in clinical trials. For example, investigators routinely monitor changes in serum cholesterol as a surrogate measure for one of the risk factors for myocardial infarction. However, using this surrogate measure requires making the assumption that a reduction in cholesterol will lead to a reduced risk of myocardial infarction. Similarly, if the use of an experimental analgesic agent relieves pain but produces substantial side effects, the patient may not consider its use as an improvement in quality of life. Therefore, if investigators wish to know an intervention's effects on both the level of pain and the overall quality of life, then they must employ tools to measure both. Since there is no single measurement strategy that is universally applicable, it is important to carefully consider whether the measured outcome is appropriate to answer the research question being posed in the clinical trial. The systematic reporting of the benefits and harms of an intervention allows a net effect to be calculated.

Analysis

Like other aspects of a clinical trial, the specific analytic strategy should be defined before commencing the study. Many different analytic approaches are possible and each will produce an answer to a slightly different research question. It is important that the chosen strategy be appropriate to evaluate the primary research question, and be compatible with the numerical distribution of the data collected. The primary role of the analysis is to summarize the data (size of the effect) and to provide an estimate of the likelihood that the result was obtained by chance alone (i.e. statistical significance).

Effect size

The first, and most important, result of any analysis is a summary value of the size of the effect resulting from the experimental therapy. In RCTs, the size of the effect is estimated by determining a summary value for the primary outcome in each treatment groups, and then calculating the difference between these values to reveal the difference in the treatment effect. There are only two primary forms for the summary value for a set of trial data: (1) the central tendency (e.g. mean, median, or mode) of the response among participants, or (2) the proportion of participants who achieve a defined level of response.

For example, in a hypertension trial, investigators can report the mean change in diastolic blood pressure (central tendency), or the proportion of patients who achieve a diastolic blood pressures below 90 mmHg (proportion of responders). If one were interested in the effect of a hospice intervention on hospital length of stay, it might be acceptable to report either the median time spent in the hospital for each group (central tendency), or the proportion of patients in each group who die before discharge or some other predefined time period. Finally, in trials of pain management, in which the outcome of reported pain symptoms is provided on a numeric scale, investigators might either report the mean response in each group, or the percentage of patients in each group reporting pain reductions of 33% (or 50%) or greater in pain intensity. In each case, the units of these summary values should correspond to the units of the outcome measure.

Choices regarding how to best present the summary measures should reflect the type of information that is most relevant for the scientific or clinical question. In addition, ultimately results will need to have applicability to practising clinicians. For most health-care providers, the question of interest is whether a given treatment will work for a given patient rather than the average change that is likely in a population. The average change does not provide a unique answer to the question of the number of people who are likely to improve. For example, suppose investigators reported that the mean response in the active treatment group was an improvement of 10% on a standard pain scale. This same result could apply to data indicating that (1) every patient in the active treatment group improved by 10% (a unimodal distribution), (2) half of the patients in the treatment group improved by 20% and half had no improvement (a bimodal distribution), or (3) half of the patients in the active treatment group improved by 40%, and half deteriorated by 20% (a bimodal distribution in which some patients improve and other deteriorate). Because these three descriptions of the underlying data could yield strikingly different clinical decisions, it is important to present an analysis of the proportions of patients in each group who improve or deteriorate by a clinically important amount.

What is a clinically important difference?

A common concern about presenting the proportion of 'responders' in each group is the need to define a level of response to be considered clinically important. Thus, the determination of a CID in a patient's symptoms plays a key role in the interpretation of symptomatic studies. Two methods for determining the CID are 'expert opinion', and an assessment of how changes in symptom scales correspond to responses to global questions (Jaeschke et al., 1989, 1991; Todd, 1996). Regardless of the method used, however, each requires that a somewhat arbitrary decision be made in defining the scale to be considered the standard.

Recent studies of pain have adopted an alternative method of displaying response data, but graphing the proportion of responders at each possible outcome level for all the groups in a clinical trial (Farrar et al., 2006). This display is a form of a cumulative distribution and allows the readers of the published report to select the level of improvement that they feel is clinically important and then determine the difference between the various groups at that level.

Statistical considerations

Statistical significance (p-values and confidence intervals)

A p-value of 0.05 or higher is the most commonly accepted statistical test of the probability that a given result occurred by chance. However, this value is strictly arbitrary and is an indication that we are willing to accept a 1/20 chance of getting the wrong answer. This traditional method of hypothesis testing, in which p-values are reported to quantify the significance of a result, is gradually being replaced by methods used to gauge the range of plausible results that are compatible with the data. The most common method for presenting this range is to report a point estimate of the effect size, along with a 95% confidence interval around this estimate. A 95% confidence interval will include the true population value of the effect 19 times out of 20 (95%). Thus, it can help readers determine the uncertainty inherent in any result—the narrower the interval, the more precise the estimate of the true effect, and thus, the more confident readers can be that the reported result is 'correct'.

Multiple comparisons

It is also important to realize that when investigators choose a p-value of 0.05 as an acceptable type I (false positive) error rate, this value only applies to a single comparison between groups. In most clinical trials, however, performing multiple comparisons can be informative. However, the greater the number of comparisons, the more likely it is that at least one of them will be spuriously positive by chance alone. If an a priori decision is made to perform multiple comparisons, the p-value must be adjusted. Of the several available methods for adjusting this value, the simplest is to divide the p-value for one comparison by the number of comparisons to be performed, and to then use this new p-value as the cut-off for statistical significance across all analyses, called the Bonferroni adjustment (Hilsenbeck and Clark, 1996). While valid, this is a very conservative estimate, and alternative methods have been developed to deal with multiple comparisons (Liu et al., 1997).

A related issue regards the distinction between comparisons chosen a priori, and those which investigators choose to conduct post hoc, or after the data have been collected. There are times when post hoc comparisons can be informative, but the results of such analyses should never be considered conclusive because they were not explicitly planned at the outset. Rather, results of post hoc analyses may be considered exploratory, intended to guide future investigations by defining or refining new hypotheses. Authors can help highlight this distinction by reporting which comparisons were chosen a priori, and which were not.

Evidence from secondary measures

In addition to the reported effect size and statistical significance of the primary outcome results, corroborative evidence from secondary outcome analyses should be used to support a study's hypothesis. If multiple related measures are obtained, and the analyses of each show similar results, then it is less likely that any one of the positive results arose by chance. While there is no specific statistical test to document this phenomenon, showing that multiple related measures, all producing similar types of effects, lends support to the conclusions drawn from the primary outcome.

Evaluating side effects

Evaluating side effects of interventions tested in clinical trials is subject to the same considerations as those used to evaluate measures of efficacy. It is important to compare the relative incidence in the active treatment and control groups. Differing rates of side effect must be evaluated with caution, since clinical trials are rarely powered to detect such differences, and the large number of different side effects that are possible make it likely that one or more of the differences observed, will be due to chance. Such differences should not be ignored; but observing similar results in multiple trials can increase one's confidence that the findings may be specifically attributed to the treatment received.

Publication

Thorough presentation of methods and results

Given that many components of a trial are central to interpreting the results, it is vital that trial reports be accurate, complete, and objective in their presentation of all important aspects of the trial. In particular, the a priori hypothesis should be clearly stated, and the discovery of other findings properly identified. All randomized participants must be accounted for in the publication, and an intention-to-treat analysis of all participants is typically appropriate. Subsequent subgroup analyses can focus on those who complete the trial, but these should not be considered as the primary result. A careful description of the randomization and blinding procedures is also important to assure readers that the trial was properly conducted. Finally, brief descriptions of the rationale behind the choice of measurement tools and analytic strategies can be helpful.

Negative studies are as important as positive ones

There is now good evidence for a publication bias against negative studies, since authors prefer to write up positive ones and editors prefer to publish them (Begg and Berlin, 1988; Reidenberg, 1998). This can lead to difficulties for clinicians who want a true picture of the nature of the evidence for a particular treatment.

Potential limitations of RCTs

There are several issues inherent in the design and conduct of RCTs that may threaten the internal validity of the results—that is, the likelihood that the treatment comparison is free from bias. Furthermore, even when the comparison is internally valid, the external validity, or generalizability of the results, can be limited. Finally, because the conditions in which trials are conducted only weakly approximate clinical reality, physicians must be cautious in using the results as the only guide in clinical decision-making. We will briefly discuss each of these potential problems in the following paragraphs. More detailed discussions of these issues are provided by Feinstein (1983) and by Kramer and Shapiro (1984).

Under-enrolment

Under-enrolment occurs when too few research participants are enrolled to provide adequate statistical power to answer the study's primary research questions. The inability to recruit sufficient numbers of eligible patients is the most common cause of insufficient statistical power in RCTs (Freiman et al., 1978; Altman, 1980; Collins et al., 1980; Meinert, 1986; Hunninghake et al., 1987; Nathan, 1999). Such under-enrolment has been attributed to characteristics of (1) clinicians who refer their patients (Taylor et al., 1984, 1994; Taylor, 1992), (2) patients who choose to be screened (Greenlick et al., 1979) or enrolled (Barofky and Sugarbaker, 1979), (3) investigators who design the trials (Collins et al., 1984), and (4) institutions at which the trials are conducted (Begg et al., 1982; Shea et al., 1992).

Among the challenges to adequate participant recruitment, potential participants' reluctance to enrol in RCTs is likely to be the most formidable, especially in palliative care populations. Ways of addressing these issues specifically in palliative care studies have been carefully codified (LeBlanc et al., 2013). It has been observed that patients are generally less willing to participate in RCTs than in non-randomized, observational studies (Kramer and Shapiro, 1984). In addition to yielding unacceptably high probabilities for type II errors, the resulting under-enrolment substantially reduces the trial's precision in quantifying the treatment effect.

Selective enrolment

Even when properly designed and carefully conducted, clinical trials can only provide information specific to the population from

which the study participants were drawn. Selective enrolment occurs when particular subgroups within the target population enrol in proportions greater or lesser than their representation in that population (Mant, 1999; Halpern et al., 2001). If this population does not include, for example, elderly patients, or children, then applying the results to these clinical populations requires extrapolation. While extrapolating results may sometimes be reasonable, it must always be done cautiously because both the beneficial and adverse effects of an intervention can vary across populations.

The level of response detected by a single trial will depend on the patient population enrolled. For example, when first studying a novel treatment for a condition for which there is no adequately effective treatment, all patients with the condition are more likely to be willing to volunteer. By including people with relatively early or mild symptoms, the response rate may be higher than expected, although the response in the placebo group may also be larger. In contrast, when a treatment is tested in a population where an effective treatment already exists, only people who do not obtain a response to the available treatments are likely to enrol. This more recalcitrant group may have a lower response rate than expected in the total population, thereby underestimating the treatment's potential usefulness.

Poor participant adherence

In RCTs, participants may not adhere completely to their prescribed treatment regimens (Kramer and Shapiro, 1984). Especially if participants believe they are receiving a non-preferred treatment, their enthusiasm for the trial, and subsequent adherence to their assigned treatment, may wane. This is further complicated if the participants have access to and decide to take either the experimental therapy or a concomitant additional therapy outside of the trial. This occurs more frequently in trials where participants are able to overcome the blinding. There is accumulating evidence that a significant number of study participants make concerted efforts to unblind themselves, and that participants who become aware of their treatment assignment maybe more likely to drop out of the study. For example, many participants assigned to the placebo groups in both the initial phase II trial of AZT (azidothymidine/zidovudine) for patients with AIDS (Fischl et al., 1987), and in a randomized trial of vitamin E for patients with Alzheimer's disease (Sano et al., 1997), appear to have become unblinded, and even to have obtained the active agents outside the trial (Kodish et al., 1990; Epstein, 1996; Karlawish and Whitehouse, 1998). Even more problematically, widespread unblinding in one AIDS Clinical Trial Group study (Volberding et al., 1990) not only allowed approximately 9% of those assigned to the placebo to receive AZT, but contributed to the drop-out rate in the placebo group being one-third higher than it was in the active treatment group (Merigan, 1990).

Participant non-adherence and drop-out can substantially bias the results of a trial (Peto et al., 1995). Though intention-to-treat analyses may mitigate this bias, if non-adherence or drop-out rates are higher in one group than in the other, such analyses may also prevent a true effect of treatment from being detected. Thus, investigators should make concerted efforts to monitor participant adherence and drop-outs. When such problems exist, the results of the trial must be interpreted cautiously.

Ethical issues in palliative care research

As with all clinical research, palliative care studies require informed consent of the participants and, when cognitive impairment is an issue, from the appropriate family member or medical surrogate. Especially in situations where curative therapies are not likely to be effective, there are a number of important issues to consider and detailed discussions of this topic are covered in Section 5 of this book. The most important issue is to consider the balance between the ethical issues of right of the individual to receive compassionate care and the needs of the population for information on the efficacy and safety of specific therapies. When conducting clinical trials, the investigator must carefully protect the rights and well-being of the subjects in the study. One possible alternative is the use of innovative approaches for the conduct of clinical trials (Streiner, 2007). Although beyond the scope of this chapter, trials designs such as response-adaptive randomization procedures (e.g. 'play-the-winner' or 'drop-the-loser') may be more ethically appropriate for the testing of therapies in conditions that may have significant consequences on the quantity and/or quality of life that may result in the palliative care population. Such designs focus on minimizing the expected treatment failures while maintaining the power and randomization benefits (Rosenberger and Huc, 2004). 'Add-on' trials, where a new treatment is added to the current treatments the patient is receiving, may reduce the consequences to the individual patients from being randomized to a placebo treatment. Building in rescue strategies to the trial design can also reduce the potential risk to study participants (Boers, 2003). Crossover trial designs may also be useful in studies of diseases but are only applicable when symptoms are relatively stable. Using patients as their own control markedly increases the power of the study, but concerns about carryover effects between treatment periods are a serious risk to the validity of the study (Garcia et al., 2004; Simon and Chinchilli, 2007).

Conclusions

This chapter has outlined several fundamental considerations for investigators planning clinical trials, and for clinicians attempting to discern the applicability of such trials to their practices. There has been special consideration to the nuances of clinical trials for palliative care interventions. In summary, randomized, controlled trials remain the best available means of evaluating novel palliative care interventions, and for determining how these interventions may be optimally used. Despite the strengths of the design, readers of trial reports should be mindful of the many difficulties inherent in extrapolating from the results obtained in a trial setting to the use of these same interventions in clinical practice. Further advances in our understanding of how best to apply clinical trials in the evaluation of pain and palliative care will depend on improved understanding of the underlying pathophysiology and the anatomy of clinical trials (Farrar, 2010).

Qualitative research

Kate Flemming

Introduction to qualitative research

This chapter will seek to explore the role for qualitative research within palliative care. It is not a chapter about how to 'do' qualitative research, as there are numerous texts that provide detailed information on the design and conduct of qualitative research to answer questions for practice and policy. More, it is a chapter that seeks to outline the role and purpose of qualitative research for palliative care by looking at the kind of questions qualitative research can answer; exploring qualitative research and its relationship to evidence based practice; the role of qualitative research within mixed methods research; the synthesis of qualitative research; and perhaps most practically how to go about finding qualitative research and undertaking an appraisal of its quality.

What kind of questions can qualitative research answer?

Qualitative research is a form of naturalistic enquiry, which seeks to study people in social settings and to collect data on the meanings people attach to their social world. Qualitative research relies on the power of words to describe social phenomena, rather than numbers.

Traditionally there has been seen to be a division between qualitative and quantitative research methods. Each has been identified by a distinct paradigm (Flemming, 2007). Research has been conducted within the constraints of these paradigms with the differences apparent at a number of levels, from epistemology and theoretical framework, to methods and data collection techniques (Brannen, 1992). Whilst the distinction between qualitative and quantitative research should be informed by epistemology and theory, it most commonly occurs at the level of method. There have been ongoing debates as to the role and purpose of each approach since the mid-nineteenth century (Flemming, 2007). Historically, quantitative methods dominated enquiry at this time and developed further during the early part of the twentieth century, as more complex statistical methods developed. This continued until the mid 1960s, when qualitative research underwent resurgence, though predominantly at this point in the disciplines of anthropology, sociology, and psychology (Brannen, 1992; Hammersley, 1992). By the 1970s, researchers in social work, nursing, community services, and health promotion were embracing qualitative methods. By the late 1980s, a substantial body of methodological writing on qualitative research was in evidence (Clark, 1997).

As the modern hospice movement developed in the United Kingdom, so research in palliative medicine developed. In the early 1970s, randomized controlled trials (RCTs) in palliative medicine were undertaken by Dr Robert Twycross at St Christopher's Hospice, London (Twycross, 1972, 1976). Alongside this, narrative methods of research were also developing. Kübler-Ross's seminal work *On Death and Dying*, published in 1969, was developed through interviews with people who were dying talking about their experiences. In 1974, John Hinton published work in which he explored dying patients' perceptions of their conversations with doctors and nurses. These early examples of qualitative research in palliative medicine, demonstrate its potential to answer many of the questions fundamental to the care of people receiving palliative care.

How research is carried out should be determined by the nature of the research question being posed, rather than it being driven by a particular theoretical or methodological assumption (Hammersley, 1992). Research questions which are best informed by qualitative methods are those which seek to explore processes and/or meanings: the 'why' type questions (Payne, 2007). These questions can then be answered through a number of different qualitative approaches.

Qualitative research is an umbrella term representing a range of epistemologies (theories of knowledge), which subsequently inform methodologies, which themselves dictate the types of methods used to collect qualitative data. There are a core set of methodological approaches to conducting qualitative research which commonly feature in health research and that have relevance to palliative medicine (Table 19.4.1). Once the methodology is established, this justifies the data collection techniques used by the researchers. Some methodologies are more prescriptive than others about method, but all should 'provide researchers with an overall strategy for formulating, articulating, analysing, and evaluating their methods' (Carter and Little 2007, p. 1318). The practicalities of research in health care, however, often mean that the supposed linear relationship from epistemology to method often becomes interrupted or distorted as different influences such as funding sources, social organization, political orientations of research teams, and clinical speciality, exert forces over the research process (Bryman, 1988).

Qualitative research and its relationship to evidence-based practice

The aim of evidence-based practice (EBP) is to reduce uncertainty in clinical decision-making by incorporating appropriate, current research evidence in decision-making processes (Flemming, 2008). What constitutes 'best evidence' is dependent on the question being asked. Whilst qualitative research did not feature prominently in the early development of EBP, since the late 1990s

Table 19.4.1 Methods of data collection used in qualitative research (Clark, 1997; Bowling, 2002; Carter and Little, 2007)

Methodology and aim	Data collection method	Examples
Phenomenology: aims to understand the lived experiences of individuals or groups	Interviews: *unstructured, structured, individual, conjoint, group* Focus groups	A phenomenological study to understand patient and family experiences of health care services in the palliative stages of Parkinson's disease (Giles and Miyasaki, 2009)
Grounded theory approaches: aim to generate analytical categories and dimensions and the relationships between them in order to understand social processes	Observation and Participant observation Focus groups Interviews (see above)	A grounded theory study to explore attitudes and beliefs among emergency care providers regarding the provision of palliative care services in the emergency department (Grudzen et al., 2012)
Ethnography: aims to understand the social world of people from a cultural perspective	Observation Interviews Documentary analysis Case studies	An ethnographic study tracing the changing notions of a good death held by hospice and palliative care practitioners (McNamara, 2004)

Source: Data from Bowling 2002; Carter and Little 2007; Clark 1997; Giles and Miyasaki 2009; Grudzen et al. 2012; and McNamara 2004.

it has started to contribute in a number of traditional and more novel ways (Murphy et al., 1998).

EBP began with the development of evidence-based medicine (EBM) in the early 1990s. At this time, medicine was seeking to ensure continuing medical education was effective and that new types of research evidence were being translated into clinical practice (Sackett et al., 1997). Positivist research methods evaluating the effectiveness of health-care interventions through RCTs and systematic reviews emerged as the core of EBM. Critics of EBP have focused on this perceived over-emphasis on RCTs and systematic reviews, citing a privileging of 'science' over other forms of knowledge in clinical decision-making (Freshwater, 2004). RCTs are, however, the most appropriate research design for evaluating the effectiveness of interventions and provide an evidence base appropriate to the kinds of questions for which clinicians need answers. A common problem with RCTS, particularly in trials of palliative care interventions, is inadequate sample sizes leading to different or discrepant findings between seemingly similar studies (Ciliska et al., 2008). Systematic reviews of primary research can overcome some of the limitations associated with single studies, by using rigorous methods for searching, research retrieval, appraisal of quality and validity, data extraction, and synthesis. Systematic reviews provide summaries of research-based knowledge on a topic, and their usefulness to clinicians has led to their privileged position in the hierarchy of evidence in EBP.

Qualitative research has not traditionally fitted into the evidence hierarchy proposed by EBP. Whilst qualitative research will never be able to answer effectiveness questions, its focus of obtaining insightful and rich data on complex issues (Bowling, 2002) ensures it has a role in contributing to the evidence base for practice, answering clinical questions quite different to addressed by RCTs.

The role of qualitative research within mixed methods research for palliative care

There is a growing appreciation that health care needs to be evaluated and informed through a variety of research methods and that it is clinical uncertainty or policy requirements that need to drive evaluation, rather than an allegiance to a particular research methodology. Clinicians can face a multitude of decision challenges within a single consultation (Thompson et al., 2004) and need an evidence base which supports this complexity.

The best available evidence should be used to inform and provide insight into decision-making processes. The Medical Research Council (2000, 2008) produced guidance on evaluating complex interventions recommending that researchers recognized and adopted appropriate methods for evaluation. Using multiple methods to evaluate health-care is now part of mainstream research funding and practice.

Circumstances of research, rather than methodological or epistemological positions, are beginning to drive research agenda. By removing some of the distinctions between qualitative and quantitative research, a greater range of options for evaluating the complex nature of health care have become available. Quantitative and qualitative research methods are gaining an independence from their original epistemological positions. Each approach has its own strengths and weaknesses for conducting health-care research and this is behind the rationale for their integration (Bryman, 1988). The conventional distinction of two opposing standpoints is being replaced by the idea of a range of positions which are located in more than one dimension, particularly as all research assumes there is a social reality which is amenable to observation (Hammersley, 1992).

Qualitative research is gaining increased prominence as mixed-method approaches to research have become more popular. The traditional gulf between qualitative and quantitative methods has narrowed, as the consensus of two methodological paradigms has been challenged (Hammersley, 1992). The previously mentioned difficulty in maintaining the linear relationship between epistemology, theory and method, is another factor that has led to an increased interest in mixed-method research to evaluate health care.

Evaluation of the effectiveness of palliative treatments has been central to the speciality since its inception in the late 1960s, but has been beset with difficulties. Conducting research with dying patients and their families is difficult. Broad ethical dilemmas and methodological issues need to be overcome, for example, poor recruitment leads to under-powered trials and unreliable results. Employing qualitative methodologies in the planning and

execution in trials of palliative care interventions may overcome many methodological and ethical issues. The process of a clinical trial begins with its inception and ends with its dissemination and implementation. Incorporating qualitative research into study planning, recruitment, conduct and implementation has the potential to enhance the final outcomes of the research and ensure it has meaning beyond its initial conduct (Flemming et al., 2008). An example is the recognition that few palliative care patients participate in trials for which they are eligible (Grande and Todd, 2000).

The ability to answer complex questions is crucial in the evaluation of palliative care. It is essential to understand not only which treatments are effective in palliative care, but also how the context of delivery can influence implementation. Improving the quality and relevance of research by ensuring that the methods employed answer clinical questions in their totality, can help ease the ongoing and dynamic tension surrounding the role of research in palliative care, the maintenance of an ethical stance and developing an evidence base for practice. Good quality evidence is needed on which to base future interventions, but at the same time researchers need to remain sensitive about involving people (and their families) in research when they are facing the end of their lives (Flemming et al., 2008). Using qualitative research to enhance the utility, effectiveness, and applicability of findings from RCTs and other methods, may start to ease some of the tensions arising from patient participation.

There are some very practical challenges to conducting qualitative research alongside other research methods. These include ensuring research teams have relevant expertise to conduct the research; persuading research commissioners to fund longer, more expensive projects; difficulties in publishing mixed-methods research in its entirety; and mixed-methods research being used inappropriately in favour of more traditional approaches, to the detriment of outcomes.

While combining qualitative and quantitative research will not eradicate all methodological problems associated with palliative care research, there is definite potential to enhance the utility of RCTs. Doing this may assuage some of the ethical concerns regarding participation in research, and reduce the ongoing tension which exists between providing care for the individual now, and improving care for the patients of the future.

Synthesis of qualitative research

Earlier in the chapter it was discussed about the role of systematic reviews of effectiveness have played within EBP. More recently, methodological developments have occurred that enable the synthesis of qualitative research.

Interest in the development of methods to synthesize qualitative research developed for a number of reasons. Some mirrored the drive behind the synthesis of RCTs, that is, the need to overcome problems associated with isolated, single, primary studies that individually have little impact in practice. Another driving factor is the recognition that a range of evidence is required for health care, beyond those established for the systematic reviewing of RCTs. The synthesis of qualitative research complements the 'rationalist' model of synthesis provided by traditional systematic review methods (Flemming, 2007).

A number of different methods have been developed for the synthesis of qualitative research, each of which produces a

different type of review. How the synthesis of qualitative research is approached is driven by the research question (Dixon-Woods et al., 2005). Approaches to research synthesis can be viewed as a continuum, with aggregative reviews at one end, and interpretative reviews at the other (Noblit and Hare, 1988). Aggregative reviews are those which assemble and pool data and use techniques such as meta-analysis to summarize data. Interpretive reviews seek to develop concepts and theories that integrate those concepts. The end point of an interpretive synthesis is the development of theory grounded in the studies included in the review (Dixon-Woods et al., 2006). The synthesis of qualitative research naturally sits at the interpretive end of the continuum. In reality, however, many syntheses include elements of both interpretation and aggregation, seen as a principle of good synthesis (Flemming, 2007).

Many aspects of the methods associated with systematic reviewing of RCTs such as question formulation, literature searching, appraisal of studies, and methods of synthesis are in the early stages of development in the synthesis of qualitative research. It is unlikely that a standardized set of procedures will ever be developed in quite the way that has been achieved with systematic reviews of RCTs. More probably, a 'methodological palette' will be developed from which reviewers can draw methods most relevant to the focus of their review (Flemming, 2007).

Interest in the use of multiple and mixed-methods in primary research to develop the evidence base for practice has also manifested itself at the level of synthesizing research (Pope and Mays, 2006). Methods for synthesizing RCTs are well established, with organizations such as the Cochrane Collaboration producing and disseminating systematic reviews of effectiveness (Khan et al., 2003). As previously mentioned, this 'rationalist' model of synthesis may not provide answers to the complex, multifactorial decisions posed by health care. Therefore interest has developed in producing techniques for the synthesis of wider research methods to address such limitations.

Methods for synthesizing qualitative research have been developed over the last decade. In 1998, the Cochrane Qualitative Methods Group was formed to advance the synthesis of qualitative research and to develop methods for including qualitative syntheses into effectiveness reviews. Others, including the Joanna Briggs Institute in Australia and specific research groups in the United Kingdom, have developed a variety of methods for synthesizing qualitative research. Many of these syntheses have contributed to the evidence base for palliative care, for example:

◆ Do hospital-based palliative teams improve care for patients or families at the end of life? (Higginson et al., 2002)

◆ Health professionals' knowledge of, attitudes towards, and ability to deliver educational interventions for symptom and disease management (Flemming et al., 2012)

◆ Patients' experiences of breathlessness (Gysels et al., 2007)

◆ Preferences for place of care and death among advanced cancer patients (Higginson and Sen-Gupta, 2000)

◆ Knowledge and information needs of informal caregivers in palliative care (Docherty et al., 2008)

◆ The use of morphine to treat cancer related pain (Flemming, 2010).

Synthesizing qualitative research is not universally accepted. For qualitative researchers who consider that each piece of qualitative

research is a unique representation of multiple truths or realities, synthesis is an anathema (Pope and Mays, 2006). Those that do accept synthesis of qualitative research as a feasible methodological option acknowledge that all research studies try to capture an underlying social reality, albeit in different ways (Pope and Mays, 2006). Adopting this pragmatic position of 'subtle realism' (Hammersley, 1992) ensures that the synthesis of qualitative research may be seen as acceptable in contributing to the evidence base for practice, which is in keeping with the interpretive approach advocated by qualitative research.

It is recognized that considerable work is needed to create mutually agreed upon approaches to the synthesis of qualitative research. Any resolution of debates will be driven by the pragmatism required for successful health services research. Despite the current lack of consensus, the potential for syntheses of qualitative research to influence clinical practice and policy in health care is beginning to be realized.

Finding qualitative research

One of the key aspects of using qualitative research to inform practice is to be able to identify the research in the first place. Whilst it is increasingly acknowledged that qualitative research has an important role of play in developing the evidence base for practice, there is consensus that searching for and identifying relevant qualitative research can be both frustrating and difficult (Campbell et al., 2011).

One of the commonest approaches to identifying research literature of any sort is by searching electronic databases. As the EBP movement began to grow, so did work by information specialists on how best to retrieve research evidence from databases. It was increasingly apparent that there were potentially detrimental effects of missing key research articles through using poorly constructed searches (Grant, 2004). In keeping with the development of EBP, initial work focused on developing strategies for identifying quantitative research. More recently, and alongside developments for synthesizing qualitative research, work has been undertaken to optimize ways of searching for qualitative research. Some of this work has highlighted the following challenges (Evans, 2002; Campbell et al., 2011; Saini and Shlonsky, 2012):

Non-specific titles

While many reports of randomized controlled trials include the research method in the title for example, 'The imPaCT study: A randomised controlled trial to evaluate a hospital palliative care team' (Hanks et al., 2002), this is not the case for many qualitative research publications. Such reports often use quite descriptive titles, reflecting the focus of the research undertaken, but not identifying the methodology used (Evans 2002). Some examples include: 'Negotiating leave-taking events in the palliative medicine unit' (Hadders, 2011); 'Striving for emotional survival in palliative cancer nursing' (Sandgren et al., 2006); 'Relieving existential suffering through palliative sedation: discussion of an uneasy practice' (Bruce and Boston, 2011). Such titles make the selection of papers by key terms quite difficult, leading to potentially relevant studies being missed (Evans, 2002).

Abstracts

The content of abstracts within qualitative research can also vary greatly. As electronic databases include abstracts as part of the information retrieved about publications, these also form part of the search. If the abstract contains no mention of the research method, then there is increased difficulty in locating these studies (Evans, 2002). In contrast, searches that are too broad to capture the variety of ways that concepts are defined by authors, may result in the retrieval of many thousands of irrelevant papers (Saini and Shlonsky, 2012).

Indexing within electronic databases

The quality of indexing of qualitative research is another well-documented problem that besets those searching for qualitative research (Dixon-Woods et al. 2001; Evans 2002). Index terms are those that identify both the subject and method of research publications (Evans 2002). Databases vary in the way that use methodological indexing terms to describe qualitative research designs (Campbell et al., 2011) with some databases using many more index terms for qualitative research than others. For example when the index terms for the same piece of qualitative research were compared, it was found that the Cumulative Index for Nursing and Allied Health Literature (CINAHL) used twice as many terms as MEDLINE, including many methodological terms (Evans, 2002). Indexers are, however, reliant on authors providing enough detail of their methods to enable accurate indexing, and this can be problematic if insufficient detail is provided (Flemming and Briggs, 2007). Given the range of methodologies that sit under the umbrella term 'qualitative research' and the variety of ways these are enacted and reported, the complexity of indexing of qualitative research becomes apparent.

Strategies for searching for qualitative research

Searching for research takes place for a number of different reasons. Those wanting information to find an answer a question arising from clinical practice will need a different approach to searching than someone undertaking a systematic review of qualitative research. Some good texts are available to guide readers in more detailed and complex searching (e.g. McKibbon and Marks, 2008a, 2008b; Finfgeld-Connett and Johnson, 2012; Saini and Shlonsky, 2012). There are however some core principles that are relevant to both and it is worth focusing on an answerable question when thinking about developing an efficient search strategy. For example, it is worth establishing:

- Who are the population I am interested in?
- What aspect(s) of their health care experience am I interested in finding out about?

An example of a searchable question is: 'What are health professionals' attitudes towards delivering educational interventions for symptom management to patients with advanced cancer?'

In this there are two *populations*:

1. The group whose experiences you are interested in establishing, that is, health professionals

2. The 'clinical' focus of the type of patients, that is, those with advanced cancer.

The focus of the *aspect of health-care experience* is health professionals' attitudes towards delivering education.

A focused question becomes the basis for literature searching in order to identify relevant evidence from research. Framing the question in a way which lends itself to searching while still

reflecting the specific patient or service focus is an important stage to get right. That way, when searching for evidence on a chosen topic, the volume of research will be more manageable than if non-focused searching had been undertaken (Flemming, 2008).

The individual parts of the question are vital aspects to remember when it comes to searching for evidence. Sometimes reading some background research papers can help to focus the question and to identify the search terms required, which arise from the clinical question. Question formulation is fundamental to searching, as it converts situations and problems from practice into the focus of searching. The keywords of the question become the key terms for a search; time spent developing a focused question can save a great deal of searching time. In addition, consulting a health information specialist can help develop a search strategy and to identify and target the best places to search (Flemming, 2008).

When searching electronic databases, search strategies are best constructed using a combination of the relevant 'clinical' terms identified through focussing an answerable question and 'qualitative' terms in the form of a filter (Shaw et al., 2004; Flemming and Briggs, 2007). Both research and personal experience of the author has shown that a simple three-line search strategy using broad-based terms can identify most qualitative research for both clinical and systematic review purposes (Flemming and Briggs, 2007; Flemming, 2010; Flemming et al., 2012). These terms are:

◆ qualitative

◆ findings

◆ interviews.

More detailed filters are also available. Shaw et al. (2004), when evaluating qualitative filters to identify research on breastfeeding, found three separate search strategies were required to optimize searching for qualitative research: thesaurus terms, free text terms, and broad-based terms. It was concluded that relying on any one strategy risked missing relevant records. As with many methodological developments in qualitative research, there is a lack of consensus as to the best way forward, and it is down to individuals to decide the optimum way of searching that matches the purpose of their search.

Other forms of searching exist such as footnote chasing, hand searching, use of personal knowledge, reference chaining, and consultation with experts. These additional methods of searching may be needed when undertaking a detailed systematic search in order to locate studies that may have been missed by electronic searching (Saini and Shlonsky, 2012). It can be important also to identify grey literature, that is, those studies more difficult to retrieve through conventional searching methods. Grey literature consists of conference proceedings, research reports, government reports, book chapters, policy documents etc. and can be found through grey literature websites. Up-to-date information about such websites can be accessed through locally based information specialists.

Appraising the quality of qualitative research

Once qualitative research has been identified, it is helpful to be able to appraise its quality, in order to determine its usefulness in practice. It has to be noted that appraisal of the quality of qualitative research remains a contentious issue, reflecting some of the tensions apparent in qualitative research itself (Dixon-Woods et al., 2007). A pragmatic approach is, however, often taken, in that there is utility in establishing a set of appraisal criteria that are unique to qualitative research (Saini and Shlonsky, 2012).

The most common approach to appraisal has been in the form of structured checklists. As with methods of searching for qualitative research however, there is lack of consensus on an actual tool to guide decision-making when trying to establish quality, with over 100 quality appraisal lists available (Saini and Shlonsky, 2012). Given that 'qualitative research' is an umbrella term for a range of methodologies, it is perhaps not surprising that there is a lack of consensus as to which single quality appraisal checklist is deemed suitable against all methodologies, nor that so many exist. Certainly there is no analogous 'quantitative research' appraisal checklist; different checklists are available for RCTs, cohort studies, surveys, etc.

Having said this, qualitative appraisal checklists do exist, and they are deemed important for ascertaining the merits and limitations of qualitative studies on their own terms (Drisko, 1997). Due to space constraints within journals affecting the potential to adequately address qualitative standards of reporting, it is recognized that quality appraisal may become an exercise of judging the quality of the published report, rather than being an evaluation of the research process itself (Sandelowski and Barroso, 2002; Atkins et al. 2008).

For a clinician trying to ascertain the quality of an identified piece of qualitative research in order to inform practice, these academic debates may seem a distraction from getting the job done. There are well established appraisal tools, which have been developed to enable EBP and qualitative research is included in these. One of the longer standing and more commonly used has been developed by the Critical Appraisal Skills Programme (CASP). The programme aims to enable individuals to develop the skills to find and make sense of research evidence, helping them to put knowledge into practice.

The checklist begins with two screening questions which enable the reader to quickly determine whether it is worth reading the paper in more depth:

1. Was there a clear statement of the aims of the research?

2. Is a qualitative methodology appropriate?

These are followed by more detailed questions:

3. Was the research design appropriate to address the aims of the research?

4. Was the recruitment strategy appropriate to the aims of the research?

5. Were the data collected in a way that addressed the research issue?

6. Has the relationship between researcher and participants been adequately considered?

7. Have ethical issues been taken into consideration?

8. Was the data analysis sufficiently rigorous?

9. Is there a clear statement of findings?

10. How valuable is the research?

Reproduced with permission from Critical Appraisal Skills Programme (CASP), 10 questions to help you make sense of qualitative research, Copyright © CASP, – www.casp-uk.net, available from http:// media.wix.com/ugd/dded87_951541699e9edc71ce66c9bac4734c69.pdf.

The checklist is particularly helpful for those less experienced in appraising research. Within each question prompts are provided as to what to look for in the paper to help ascertain its quality, enabling clinicians to establish whether the paper is worthy of informing practice.

Conclusion

This chapter on qualitative research has outlined its importance as a research methodology that can provide answers to clinical questions arising in palliative medicine. The roles of qualitative research as a primary research method, within systematic reviews and also alongside quantitative methodologies have been discussed, and the place for qualitative research within EBP has been established.

The chapter has also addressed some of the more practical aspects of searching for qualitative research and undertaking an appraisal of its quality, whilst acknowledging that these are contested areas undergoing methodological development.

Research into psychosocial issues

David W. Kissane, Annette F. Street,
Erin E. Schweers, and Thomas M. Atkinson

Introduction to research into psychosocial issues

Psychosocial research examines issues and concerns in the psychological, social, spiritual, and existential domains of human experience, including quality of life studies and interventions that seek to optimize outcomes. Psychosocial research needs to be conducted in accordance with the core values and principles of palliative care. Patient- and family-centred care acknowledges the unique experience of each person and their family members. Key values include respect for the dignity of all, advocacy on behalf of their expressed wishes, and equity in access to services. In response, psychosocial researchers seek not only the most effective interventions, but are also concerned with the meaning such treatments have for patient and family. To do so, psychosocial researchers increasingly create multidisciplinary teams and draw on a variety of methods.

In this chapter, we want to highlight the scope of psychosocial questions and interests by drawing on a number of different methods that have formed the basis of psychosocial research. In doing so, we have made choices. Detailed explanations of relevant methods are covered in detail in other chapters in this section on research. We highlight formative and current research, delineate the problems involved in conducting research with dying people, and make some suggestions about where future psychosocial research should be directed. A feature of the chapter is a section analysing the various instruments in use in psychosocial research. Sometimes, researchers are unaware of the potential range of validated questionnaires that can aid psychosocial research. Similarly, we have analysed a range of computer-assisted qualitative analysis programmes

The scope of psychosocial research in palliative medicine

Research activity can be grouped into broad domains or themes of inquiry. Many interesting questions and controversies arise in each domain. These are listed in Box 19.5.1.

The choice of research issue is commonly determined by awareness of unmet needs, concern about the standard of care, or a desire to improve the outcomes of treatment. We illustrate pertinent issues about a number of these domains and useful methods for addressing them and return to the challenges for the future at the end of this chapter.

Literature review and meta-analysis

A comprehensive literature review is a *sine qua non* as many ideas have been considered before. Exploring the boundaries of knowledge necessitates firstly identifying what is known, what aspects remain unclear, and thinking through where the benefits of further study will lie. A formal literature search is thus crucial before the hypothesis is generated or aims and objectives of the study are delineated.

While the history of any construct and its application is of interest, the recent emphasis on a clinical approach that is evidence-based (see Chapter 19.2) requires a systematic approach to any literature review. Recently, more systematic reviews of psychosocial palliative care topics have been conducted. Systematic reviews have explored the effects of multidisciplinary palliative care teams (Hearn and Higginson, 1998; Higginson et al., 2003), the level of need for palliative care (Franks et al., 2000), and effective methods of information giving to cancer patients (McPherson et al., 2001). Meta-synthesis of qualitative studies can also inform understanding of patient experiences (Seymour et al., 2003).

Concept and construct development

The building up of a theory provides a conceptual framework on which further observations can be based and ultimately delivers an empirical basis for the development of interventions. The qualitative approach to concept development begins in grounded theory, while quantitative methodology creates instruments to measure constructs, which in turn need to be carefully validated and demonstrated to have reliability for recurrent use.

Instrument development

The commonly used rating scales used in psychosocial research in palliative medicine have been summarized in Tables 19.5.1, 19.5.2, 19.5.3, 19.5.4, 19.5.6, 19.5.7, 19.5.8, 19.5.9, 19.5.10, 19.5.11, 19.5.12, 19.5.13, 19.5.14 and 19.5.15. Instruments that measure distress, mood states, coping, quality of life, support, and family functioning tend to be well validated, while measures of spirituality, dignity, and existential domains warrant further work.

Rating scales can be used for screening, diagnosis, measurement of severity, and change—attention needs to be paid to the purpose for which any instrument was designed and its reliability and validity in that role. In choosing an instrument, the researcher needs to consider what they seek to measure and for what purpose. For instance, sensitivity of scales to detect small changes will vary, sometimes at the expense of specificity, and the scales' practicality

Box 19.5.1 Domains of psychosocial research in palliative medicine

◆ Communication studies: breaking bad news, discussing prognosis and dying
◆ Coping and adaptation to change
◆ Cultural issues including those of indigenous peoples
◆ Dying process
◆ Ethics of end-of-life care
◆ Family studies: carers, family support
◆ Grief and bereavement
◆ Interventions: psychotherapy, pharmacological, and physical
◆ Lived experience of illness: impact on self, the body, dignity, and burden on others
◆ Paediatric aspects of adaptation, coping, and care
◆ Psychiatric disorders: anxiety, depression, delirium, etc.
◆ Quality of life
◆ Sexuality and intimacy
◆ Social issues: relationships, recreation, work, and living arrangements
◆ Suffering, existential and spiritual distress.

and brevity will often be important when considered for use with palliative patients. It is also important to evaluate the content/face validity in detail for each study by asking the question: 'What is the real content of this instrument and will it apply to my study?' Such an examination needs to be in detail and each question should be evaluated by the researcher in order to have insight into the content validity of any assessment scale.

Grounded theory studies (see Chapter 19.4) have provided understanding of psychosocial concerns such as 'enduring', 'uncertainty', 'suffering', and 'hope', and then examining their interrelationships (Morse and Penrod, 1999) or exploring how decision-making occurs at the end of life for family caregivers and health-care providers in long-term-care settings (Caron et al., 2005).

Cohort and longitudinal studies

Observational studies may be either retrospective or prospective. In the former, past events are studied through case notes or by interview. They may be limited by incomplete recording or biased recall, but are inexpensive and serve as a useful beginning. Such studies should probably be regarded as hypothesis-generating and be carefully applied when one wants to change practice, for example, in the development of evidence-based guidelines. In contrast, prospective studies eliminate the bias of memory and permit examination of a number of associations, but may be limited by the availability of suitable subjects for recruitment within a reasonable time frame. In many studies, due to low recruitment rates, one needs to consider collaboration between centres, that is, by conducting national, or international, multicenter studies. In addition, subjects may be lost to follow-up.

Cross-sectional studies

Cross-sectional studies are both observational and descriptive, typically being used to measure the prevalence of a symptom or illness. They can be further used to identify clinical associations, well exemplified by the study of the 'desire for death' by Chochinov and colleagues in 200 Canadian hospice inpatients, which was found to be genuine and persistent in 8.5% and significantly associated with depressive disorder, isolation from family, and pain (Chochinov et al., 1995).

Table 19.5.1 Instruments measuring *anxiety* and *fear*

Instrument name	Item number (response style)	Factor structure	Reliability	Validity	Comments on utility
Beck Anxiety Inventory (BAI) (Beck et al., 1988)	21 items (4-point scale)	1. somatic 2. panic symptoms	$\alpha = 0.92$; test–retest = 0.75	r = 0.51 (HAM-A)	Designed to assess anxiety in a clinical population
Death Anxiety Scale (DAS) (Templer, 1970)	15 items (true/false)	1 factor	$\alpha = 0.76$; test–retest = 0.83	Well validated	Designed to assess preoccupation with and anxiety about death
Generalized Anxiety Disorder-7 (GAD-7) (Spitzer et al., 2006)	7 items (4-point scale)		$\alpha = 0.92$	r = 0.72 (BAI)	Designed as a self-assessment of anxiety
Hamilton Anxiety Rating Scale (HAM-A) (Hamilton, 1959)	14 items (5-point scale)	1. psychic anxiety 2. somatic anxiety	$\alpha = 0.79$–0.86	r = 0.56 (BAI)	Clinician-administered measure designed to assess global anxiety
Hospital Anxiety and Depression Scale (HADS) (Zigmond and Snaith, 1983)	14 items (4-point scale)	1. anxiety 2. depression	$\alpha = 0.89$; test–retest r = 0.74	Well validated	Designed as a rapid assessment tool in a non-psychiatric setting
State Trait Anxiety Inventory (STAI) (Spielberger et al., 1970)	40 items (4-point scale)	1. state 2. trait	$\alpha = 0.83$–0.92 on subscales	Well validated	Designed to assess how subjects respond to psychological stress. STAI-Y (revised) available.

Table 19.5.2 Instruments measuring *depression*

Instrument name	Item number (response style)	Factor structure	Reliability	Validity	Comments on utility
Beck Depression Inventory (BDI) (Beck et al., 1961)	21 items (4-point scale)	1. cognitions 2. somatic symptoms	α = 0.81	r = 0.62–0.66 with clinician ratings	Designed to assess depressive symptoms. BDI-II and BDI-SF available
Brief Case Find for Depression (Jefford et al., 2004)	4 items		Sensitivity = 67%; Specificity = 75%	Satisfactory	Designed to screen for depression in medical patients
Geriatric Depression Scale (GDS) (Yesavage et al., 1982)	30 items (yes/no)		α = 0.94	r = 0.84 (Zung SDS) and 0.83 (HAM-D)	Designed to assess depression in a geriatric population. GDS-15 and GDS-5 available
Patient Health Questionnaire (PHQ-9) (Kroenke et al., 2001)	9 items (4-point scale)		α = 0.86	r = 0.73 (BDI); r = 0.59 (GHQ12)	Designed to assess depression. Self-report subscale of PRIME-MD
Brief Zung Self Rating Scale for Depression (Dugan et al., 1998)	11 items (4-point scale)	1 factor	α = 0.84	r = 0.92 (SRS-D)	Designed to assess depression in the medically ill (eliminates somatic symptoms)

Table 19.5.3 Instruments measuring *distress*

Instrument name	Item number (response style)	Factor structure	Reliability	Validity	Comments on utility
Brief Symptom Inventory (Zabora et al., 2001)	18 items (5-point scale)	1. anxiety 2. depression 3. somatization	α = 0.89	r = 0.84 (GSI of BSI)	Designed to assess symptoms of distress. 53-item BSI available.
Distress Thermometer (DT) (Roth et al., 1998)	1 VAS (+34) (yes/no)	Domains related to distress can be endorsed	Sensitivity = 84%; Specificity = 61%	Well validated in cancer studies	Designed for rapid assessment of patient distress. New variation uses an additional impact thermometer (Akizuki et al., 2005)
General Health Questionnaire (GHQ 12) (Johnstone and Goldberg, 1976)	12 items (4-point scale)	1 factor	Split-half = 0.95	Well validated	Designed as a distress screening measure. GHQ28 and GHQ60 available
Impact of Events Scale Revised (IES-R) (Creamer et al., 2003)	22 items (5-point scale)	1. intrusion 2. avoidance 3. hyperarousal	α = 0.79–0.90	r = 0.84 (PCL-C)	Designed to assess subjective distress and intrusive thoughts. IES available

Table 19.5.4 Instruments measuring *pain* and *symptom management*

Instrument name	Item number (response style)	Factor structure	Reliability	Validity	Comments on utility
Brief Pain Inventory (Cleeland and Ryan, 1994)	23 items (11-point scale)	1. severity 2. interference	α = 0.95	r = 0.71 (VAS)	Brief measure of pain. Short form available
Brief Pain Inventory for Ambulatory Care (Maunsell et al., 2000)	5 items (4-point scale)		α = 0.87–0.92	r = 0.65 (EORTC pain)	Designed to assess pain intensity, impact, and medication doses
Edmonton Symptom Assessment System (ESAS) (Bruera et al., 1991)	9 items (11-point scale)		Satisfactory	Well validated	Designed to assess symptoms in palliative care patients
Memorial Symptom Assessment Scale (MSAS) (Portenoy et al., 1994)	32 items (4-point and 5-point scales)	1. psychological 2. physical	α = 0.58–0.88	Well validated	Designed to assess cancer related symptoms. MSAS-SF available

Table 19.5.5 Instruments measuring *suffering, existential,* and *spiritual* issues

Instrument name	Item number (response style)	Factor structure	Reliability	Validity	Comments on utility
Demoralization Scale (DS) (Kissane et al., 2004)	24 items (5-point scale)	1. loss of meaning 2. dysphoria 3. disheartenment 4. helplessness 5. sense of failure	α = 0.94; 0.71–0.89 on subscales	Good concurrent validity	Designed to assess existential distress in palliative care patients
Functional Assessment of Chronic Illness Therapy-Spiritual (FACIT-Sp) (Peterman et al., 2002)	12 items (5-point scale)	1. meaning 2. faith	α = 0.81–0.88	r = −0.54 (POMS)	Designed to assess spiritual well-being in the general population. Expanded version available
Meaning in Life Scale (Warner and Williams, 1987)	15 items (5-point scale)		α = 0.78	r = 0.53 (PIL)	Designed to assess sense of purpose and beliefs of hospice patients
Posttraumatic Growth Inventory (PTGI) (Tedeschi and Calhoun, 1996)	21 items (6-point scale)	1. relating 2. new possibility 3. strength 4. spiritual 5. appreciation	α = 0.90	r = 0.23 (LOT) and r = 0.50 (religious participation)	Designed to assess perceived positive outcomes from traumatic events
Sense of Coherence/Orientation to Life (Antonovsky, 1993)	29 items (7-point scale)	1 factor	α = 0.84–0.93	r = 0.39 (Rotter's I-E)	Designed to assess sense of coherence/meaningfulness
Shame and Stigma Scale (SSS) (Kissane et al., 2013)	20 items (5-point scale)	1. shame with appearance 2. sense of stigma 3. regret 4. speech/social concerns	α = 0.94	r = 0.60 (DS)	Designed to assess adaptation after treatment of patients with head and neck cancer
Spiritual Involvement and Beliefs Scale (Hatch et al., 1998)	26 items (5-point scale)	1. ritual 2. fluid 3. existential 4. humility	α = 0.92	r = 0.80 (SWB)	Designed to assess spiritual beliefs across religions
System of Beliefs Inventory (SBI-15) (Holland et al., 1998)	15 items (4-point scale)	1. beliefs/practice 2. social support	α = 0.93	Well validated	Designed to assess spiritual beliefs in medically ill patients

Table 19.5.6 Instruments measuring *coping* and *adaptation*

Instrument name	Item number (response style)	Factor structure	Reliability	Validity	Comments on utility
Brief COPE (Carver, 1997)	28 items (4-point scale)	1. substance use 2. religion 3. humour 4. disengagement 5. support 6. coping 7. venting 8. denial 9. acceptance	α = 0.50–0.90 on subscales	Well validated	Designed to assess coping strategies of individuals. Original version available
Life Orientation Test Revised (LOT-R) (Scheier et al., 1994)	10 items (5-point scale)	1 factor	α = 0.78; test–retest = 0.79 at 28 months	Well validated	Designed to assess optimism
Mini Mental Adjustment to Cancer (Mini-MAC) (Watson et al., 1988, Watson et al., 1994)	29 items (4-point scale)	1. fighting spirit 2. preoccupation 3. fatalism 4. help/hopeless 5. avoidance	α = 0.62–0.88 on subscales	Well validated	Designed as to assess responses to a cancer diagnosis

Table 19.5.7 Instruments measuring *delirium*

Instrument name	Item number (response style)	Factor structure	Reliability	Validity	Comments on utility
Confusion Assessment Method (CAM) (Inouye et al., 1990)	9 items		Sensitivity = 94–100%; Specificity = 90–95%	r = 0.82 (VAS)	Designed to assess delirium
Delirium Rating Scale (DRS) (Trzepacz et al., 1988)	10 items	1 factor	α = 0.90	r = 0.66 (Trailmaking)	Designed to clinically assess delirium
Memorial Delirium Assessment Scale (MDAS) (Breitbart et al., 1997)	10 items (4-point scale)	1 factor	α = 0.91	r = 0.88 (DRS)	Designed to assess medically ill patients for symptoms of delirium
Mini Mental State Exam (MMSE) (Folstein et al., 1983)	Interviewer administered		α = 0.82–0.84	Well validated	Designed as a quick standardized assessment of mental status

Table 19.5.8 Instruments measuring *social issues*

Instrument name	Item number (response style)	Factor structure	Reliability	Validity	Comments on utility
Bottomley Social Support Scale (Bottomley, 1995)	9 items (5-point scale)		α = 0.78; test–retest = 0.73–0.79	r = 0.38 (DHD)	Designed to assess social support in cancer patients
Duke-UNC Functional Social Support Scale (Broadhead et al., 1988)	8 items (5-point scale)	1. confident 2. affective	Test–retest = 0.66	Well validated	Designed to assess perceived social support
MOS Social Support Scale (Sherbourne and Stewart, 1991)	19 items (5-point scale)	1. emotion/information 2. tangible 3. affectionate 4. positive social interaction	α = 0.97	r = 0.67 (loneliness)	Designed to assess the perceived availability of social support
Multidimensional Scale of Perceived Social Support (Zimet et al., 1988)	12 items (7-point scale)	1. family 2. friends 3. significant others	α = 0.88	Well validated	Designed to assess the perceived availability of social support
Short Saranson Social Support Questionnaire (SSSSQ) (Sarason et al., 1983; Sarason et al., 1987)	6 items (6-point scale)	1. number 2. satisfaction	α = 0.94–0.97	r = −0.52 (loneliness)	Designed to assess the perceived availability of social support. Original version available

Table 19.5.9 Instruments measuring *caregiving issues*

Instrument name	Item number (response style)	Factor structure	Reliability	Validity	Comments on utility
Caregiver QOL Scale-Cancer (Weitzner et al., 1999)	35 items (5-point scale)	1. burden 2. disruptiveness 3. positive adaptation 4. financial concerns	α = 0.73–0.90	r = 0.49–0.65 (SF36)	Designed to assess QOL of caregivers
Caregiver Reaction Assessment (CRA) (Given et al., 1992)	24 items (5-point scale)	1. caregiver esteem 2. family support 3. finances 4. schedule 5. personal health	α = 0.80–0.90 on subscales	Good construct validity (CESD, ADL)	Designed to assess reactions to caring for ill elderly patients
Family Appraisal of Caregiving Questionnaire -Palliative Care (FACQ-PC) (Cooper et al., 2006)	25 items (5-point scale)	1. strain 2. positive appraisals 3. distress 4. family well-being	α = 0.73–0.86 on subscales	Well validated (FRI)	Designed to assess caregivers' appraisal of the caregiving process

Table 19.5.10 Instruments measuring *family issues*

Instrument name	Item number (response style)	Factor structure	Reliability	Validity	Comments on utility
FAMCARE Scale (Kristjanson, 1993)	20 items (5-point scale)	1. information giving 2. care availability 3. psychosocial care 4. physical care	α = 0.93; test–retest = 0.91	r = 0.77–0.80 (McCusker Scale)	Designed to assess family satisfaction with advanced cancer care
Family Crisis Oriented Personal Evaluation Scales (F-COPES) (McCubbin et al., 1996)	30 items (5-point scale)	1. social support 2. reframing 3. spiritual support 4. mobilizing family 5. passive appraisal	α = 0.87; 0.62–0.87 on subscales	Well validated	Designed to assess family coping strategies in difficult situations
Family Relationships Index (Edwards and Clarke, 2005)	12 items (true/false)	1. cohesion 2. expressiveness 3. conflict	α = 0.56–0.70 on subscales	Well validated	Designed to assess family dysfunction. Subscale of the Family Environment Scale

Table 19.5.11 Instruments measuring *pediatric aspects* of advanced illness

Instrument name	Item number (response style)	Factor structure	Reliability	Validity	Comments on utility
Childhood Cancer Stressors Inventory (Hockenberry-Eaton et al., 1997)	18 items (true/false and 4-point scale)		α = 0.82	r = −0.63 (CACI)	Designed to assess stressors in children with cancer
Miami Pediatric Quality of Life Scale (Armstrong et al., 1999)	56 items (5-point scale)	1. social competence 2. emotional stability 3. self-competence	α = 0.89	Good discriminant validity	Designed to assess QOL in children with cancer
Multidimensional Anxiety Scale for Children (MASC) (March et al., 1997)	39 items (4-point scale)	1. physical symptoms 2. harm avoidance 3. social anxiety 4. separation anxiety	α = 0.90; 0.74–0.85 on subscales	r = 0.63 (RCMAS)	Designed to assess paediatric anxiety
Pediatric Cancer QOL Inventory (PCQL) (Varni et al., 1998)	32 items (4-point scale)	1. disease 2. physical 3. psychological 4. social 5. cognitive	α = 0.91 patient and 0.92 parent	Good convergent and discriminant validity	Designed to assess global QOL in paediatric cancer patients
Pediatric Inventory for Parents (PIP) (Streisand et al., 2001)	42 items (5-point scale)	1. communication 2. emotional functioning 3. medical care 4. role function	α = 0.80–0.96	Good construct validity	Designed to assess parenting related stress in caring for an ill child

Case–control studies

The case–control study is used generally to test an aetiological hypothesis, by comparing a group with a disease or specific treatment, matched with controls. The methodological challenge is in the selection criteria for the cases to ensure that they are a representative sample and similarly the variables on which matching is achieved, and whether this is by random community selection or paired match. For instance, studies of men with prostate cancer have shown global quality of life to be equivalent to community samples of similarly aged men, but urinary incontinence, impotence, and bowel symptoms to be causally related to the treatments these men have received (Litwin et al., 1995).

Cohort studies

Cohort studies are both observational and analytical in prospectively following groups of patients with key differences to assess outcome. They provide valuable information on the nature of a relationship and whether there is a causal association. Thus, the King's College cohort of women with breast cancer was followed across 15 years of illness to determine the influence of coping style

Table 19.5.12 Instruments measuring *communication* and *satisfaction with care*

Instrument name	Item number (response style)	Factor structure	Reliability	Validity	Comments on utility
Decisional Conflict Scale (O'Connor, 1995)	16 items (5-point scale)	1. uncertainty about alternatives 2. factors of uncertainty 3. decision effectiveness	α = 0.78–0.92; test–retest = 0.81	Well validated	Designed to assess decisional uncertainty in patients facing a medical decision
Decision Regret Scale (Brehaut et al., 2003)	5 items (5-point scale)	1 factor	α = 0.81–0.92	Well validated	Designed to assess decisional regret after making a medical decision
Patient Satisfaction Index (Guyatt et al., 1995)	23 items (7-point scale)	1 factor	α = 0.94; test–retest = 0.86	Well validated	Designed to assess patient satisfaction with treatment
Satisfaction with Decision Scale (SWDS) (Wills and Holmes-Rovner, 2003)	6 items (5-point scale)	1 factor	α = 0.85	r = −0.26 (SF20)	Designed to assess patient satisfaction with medical decisions

Table 19.5.13 Instruments measuring *sexuality* and *intimacy*

Instrument name	Item number (response style)	Factor structure	Reliability	Validity	Comments on utility
Abbreviated Dyadic Adjustment Scale (ADAS) (Spanier, 1976)	32 items (6-point scale)		α = 0.73–0.96	Well validated	Designed to assess the quality of marital relationships
Changes in Sexual Function Questionnaire (CSFQ-14) (Keller et al., 2006)	14 items (5-point scale)	1. pleasure 2. frequency 3. interest 4. arousal 5. orgasm	α = 0.89–0.90	Good concurrent validity	Designed to assess change in sexual activity and satisfaction due to illness
Female Sexual Function Index (FSFI) (Rosen et al., 2000)	19 items (5-point and 6-point scales)	1. desire 2. lubrication 3. orgasm 4. satisfaction 5. pain/discomfort	Test–retest = 0.79–0.80	Well validated	Designed to assess sexual function in women
International Index of Erectile Function (IIEF) (Rosen et al., 1997)	15 items (5-point and 6-point scales)	1. erectile function 2. orgasmic function 3. desire 4. intercourse satisfaction 5. overall satisfaction	α = 0.91	Well validated	Designed to assess erectile function in men with various medical conditions. IIEF-5 available
Relationship Assessment Scale (RAS) (Hendrick, 1988)	7 items (5-point scale)		α = 0.86	r = 0.80 (DAS)	Designed to assess relationship satisfaction in couples

on survival (Greer et al., 1990). Women who were fatalistic, overly anxious, or hopeless/helpless in their cognitions died earlier than those using positive avoidance or fighting spirit. Time available for follow-up is an obvious limitation in palliative medicine.

Clinical case reports

Clinical reports of individual patients have always served an important function in highlighting relevant issues of presentation, diagnosis, or management. One example was a series of patients who sought euthanasia under the Northern Territory of Australia's Rights of the Terminally Ill legislation, which operated for 9 months in 1996 (Kissane et al., 1998). These cases exemplified non-recognition of depression, a poor standard of medical care, and disagreement over the terminal status of patients, highlighting the defective gate-keeper roles set up by the legislation. Building up collections of case reports points to the need for cohort and longitudinal studies as observational evidence is mounted. The corresponding narrative inquiry of the qualitative approach brings an equally worthwhile persepective.

Ethnographic case studies

Longitudinal ethnographic case studies draw on many of the techniques of ethnography to develop an in-depth and detailed case account to explore issues for a cultural or ethnic group.

Table 19.5.14 Instruments measuring *quality of life* and *functional status*

Instrument name	Item number (response style)	Factor structure	Reliability	Validity	Comments on utility
Assessment of Quality of Life at End of Life (Axelsson and Sjoden, 1999)	22 items (10-point scale)	1. physical 2. psychological 3. social 4. existential	Test–retest = 0.52–0.90	Strong correlations with CIPS	Designed to assess QOL in palliative patients.
EORTC-QLQ-C15 Palliative (Groenvold et al., 2006)	15 items (4-point scale)		Based on EORTC-QLQ-C30	C30 well validated; C15 in development	Designed to assess QOL in palliative patients. EORTC-QLQ-C30 available
Hospice Quality of Life Index Revised (McMillan and Weitzner, 1998)	25 items (100 mm VAS)		$\alpha = 0.83–0.87$	Good content validity; further work needed	Designed to assess QOL in hospice patients
McGill Quality of Life Questionnaire (MQOLQ) (Cohen et al., 1995)	16 items (11-point scale)	1. physical 2. psychological 3. existential 4. support	$\alpha = 0.83$	Well validated	Designed to assess QOL in palliative patients
McMaster Quality of Life Scale (Sterkenburg et al., 1996)	32 items (7-point scale)		$\alpha = 0.80$	r = 0.70 (Spitzer QLI)	Designed to assess QOL in palliative patients
Palliative Care Outcomes Scale (Hearn and Higginson, 1999)	12 items (4-point scale)		$\alpha = 0.70$	r = 0.43–0.51 (EORTC-C30)	Designed to assess outcomes in palliative patients and their families
Palliative Care Quality of Life Inventory (Mystakidou et al., 2004)	28 items (3-point and 5-point scales)	1. activity 2. self-care 3. health 4. treatment choice 5. support 6. communication 7. psychological affect	$\alpha = 0.79$	r = 0.44–0.94 (AQEL)	Designed to assess QOL in palliative patients
Quality of End of Life Care and Satisfaction (QUEST) (Sulmasy et al., 2002)	30 items (5-point scale)		$\alpha = 0.88–0.93$	r = 0.38–0.47 (PSI)	Designed to assess QOL and satisfaction with care in palliative patients
Quality of Life at End of Life (Steinhauser et al., 2003)	31 items (5-point scale)	1. life completion 2. provider relationship 3. symptom management 4. preparation 5. social support	$\alpha = 0.68–0.87$	r = 0.62 (FACIT-Sp)	Designed to assess QOL in palliative patients

A study that identified unmet support needs of family caregivers caring for people with AIDS in Southern Thailand (Nilmanat and Street) led to a World Health Organization-funded study to develop policy and models of care to improve the situation. An innovative study exploring the experiences of men with prostate cancer used the technique of photo-novella where the men were asked to provide photos to express their experiences along with the interview texts. Some men chose to photograph themselves, others contributed photos of places or symbols that helped them make meaning from their experiences.

Narrative inquiry

Narratives constructed from research interviews mirror the social life of the person, with language forming the major cultural resource that participants draw on jointly to create meaning (Charmaz, 1999). The seminal work of Kleinman (1988) on illness narratives and Frank's (1995) writings on the wounded storyteller have shaped a narrative tradition designed to offer explanatory models of the world of people experiencing life-limiting illnesses. Recent nursing work has developed individual and group narratives to explore close nurse–patient relationships in palliative care (Aranda and Street, 2001).

Textual and electronic studies

Increasingly researchers are examining ways of researching palliative care practice in ways that are less intrusive to patients and allow them to write or respond at their own convenience in terms

Table 19.5.15 Instrument measuring the *dying process*

Instrument name	Item number (response style)	Factor structure	Reliability	Validity	Comments on utility
Beck Hopelessness Scale (BHS) (Beck et al., 1974)	20 items (true/false)	1. future feelings 2. loss motivation 3. future expectations	α = 0.85–0.93	r = 0.62–0.74 with clinical ratings	Designed to assess suicidality
Life Closure Scale (Dobratz, 2004)	20 items (5-point scale)	1. self-reconciled 2. self-restructuring	α = 0.87	Correlation with ABS	Designed to assess psychological adaptation at the end of life
Needs at End of Life Screening Tool (NEST) (Emanuel et al., 2001)	13 items (11-point scale)	1. financial burden 2. access to care 3. closeness 4. caregiving needs 5. psychological distress 6. spirituality 7. settledness 8. sense of purpose 9. patient clinician relations 10. information	α = 0.63–0.85	Well validated	Designed to assess needs at the end of life
Schedule of Attitudes Towards Hastened Death (SAHD) (Rosenfeld et al., 2000)	20 items (true/false)	1 factor	α = 0.83	r = 0.67 (DDRS)	Designed to assess a patient's interest in a hastened death

of time and place. These include the analysis of public domain texts such as published stories, media texts, and diaries or stories from the Internet. Other electronic sources include the use of online support groups (Høybye et al., 2004). Interviews and supportive therapy interventions conducted by telephone (Sandgren et al., 2000) and web interface are a new direction.

Controlled clinical trials

Preventive or therapeutic interventions are generally tested through controlled studies such as the randomized controlled trial (RCT), which could be double-blinded, placebo-controlled, or cross-over in design.

The place of controlled trials has been much debated in palliative medicine, yet they are vital when outcome is examined as the end point. The study of family-focused grief therapy during palliative care and bereavement delivered to 'high-risk' families selected by screening and thereafter randomized to intervention or control is another example of a carefully designed and methodologically sound study, this time a psychotherapeutic intervention (Kissane et al., 2006).

Methodological difficulties experienced in controlled trials include patient refusers and withdrawals, undeclared confounding treatments, dose variations and fidelity of the treatment applied, defaults in interim assessments, and deaths prior to outcome measurements. Despite such inherent challenges, the quality of evidence achieved necessitates greater utilization of these designs in future research in palliative medicine.

Mixed methods

Increasingly, psychosocial research is being designed utilizing a combined methods approach. Mixed methods can be conducted sequentially where one method leads to another to further explore a construct or phenomena. Triangulation of different data sets can confirm and explain findings more comprehensively. Similarly a study can be designed so that two or more methods complement and inform each other. An excellent recent example of this is found in a study of coping during illness with HIV (Folkman, 2001). Seeking to identify the predictors of coping outcome, Folkman and colleagues began a longitudinal study in 1990 with a cohort of 253 carers of gay men dying from AIDS during the era before triple therapies became available. Bimonthly assessment occurred over 2 years, during which two-thirds became bereaved. The researchers expected to focus on negative affects, but were struck by the interviewees' desire to share positive experiences. Further analysis of 106 narratives revealed that meaning-centred coping increased self-worth, sense of resilience, wisdom, and a perspective that no longer feared death. The importance of meaning-based coping emerged to expand the earlier theory of coping (problem- or emotion-focused processes that regulate distress).

A problem with many mixed method approaches is that one or more methods may not be developed with sufficient rigor to do justice to the method or topic. Development of expertise is equally important for both qualitative and quantitative research and collaboration between such researchers generates a powerful armamentarium.

Characterization of psychological outcome can be through both form and content. Quantitative studies mostly emphasize the content through measurement of specific dimensions, which can be compared to controls over time, but usually at specific points. Qualitative studies add insight into form, with recognition of the pattern of change in outcome over time. Then, repeated measures analysis, with attention to the slope and variability of change

using qualitative techniques, enriches understanding of the evaluation process.

Computer-assisted qualitative data analysis software

Computers have become an integral part of the repertoire of tools for qualitative analysis (Fielding, 2001). There are a number of packages available from the relative simple text retrievers that are useful to sort and manage data into categories of information, to the highly sophisticated new-generation multimedia capacities of interpretive theory building and mapping packages. Some products are free and may be all that is needed for small, straightforward projects. Complex project usually need the facilities of commercial software, preferably with user assistance provided as part of the package. It is important to understand what capabilities are needed for the research process before deciding on a software package (see Table 19.5.16).

Methodological difficulties in psychosocial research in palliative medicine

Psychosocial researchers encounter significant specific difficulties in conducting research with dying people (Glare, 1999; Field et al., 2001). The recruitment of patients, attainment of an adequate sample size (Jordhoy et al., 1999), attrition rates, and the variability of the patient's condition (Kirkham and Abel, 1997) create problems for researchers internationally (Bakitas et al., 2006). Employment of trained data managers, adoption of several recruitment methods, and use of well-thought out inclusion criteria does assist sampling problems (Jordhoy et al., 1999). Moreover, ethical debates exist regarding the impact of research on patients at the end of their lives (de Raeve, 1994), the withholding of treatment in controlled trials (Corner, 1996), and the informed consent process when delirium is present (Karim, 2000). Extensive interviews and use of batteries of questionnaires can be stressful and intrusive at a vulnerable and potentially poignant time in the life cycle (Atkinson and Silverman, 1997). Despite the challenges involved in such psychosocial research, its value is beyond question and critical to our endeavours to improve the care of the dying.

Outcomes in psychosocial research and future directions

The clinical significance or utility of each study merits careful reflection so that standards of care are steadily improved. Quality assurance programmes have highlighted the importance of the feedback loop, which leads to altered practice, innovation, and change (Lawton, 1971). This should be a cyclical activity.

For palliative medicine to grow as a discipline, its research activity must be scholarly and generate the needed evidence that informs purposeful clinical activity. Psychosocial research is a cardinal component of such endeavours. It needs to grow through well thought out national and international collaborations, utilizing integrated methodologies of the highest standards. For too long, clinicians have defensively avoided good science through flawed claims about the unsuitability of palliative patients for research. Fortunately, the specialty is maturing and recognizes the imperative for its future of excellence in research studies.

Psychosocial research in the future needs to embrace RCTs to establish a sound evidence base for its practice. Further, RCTs are needed of pharmacotherapies and particularly meaning-centred therapies to treat existential and spiritual distress. Interpersonal psychotherapy is one manualized and standardized intervention waiting to be applied in palliative care—its emphasis on grief, transitions, roles, and relationships makes it particularly suitable with this population. Interventions need to be both patient- and family-centred.

Suffering remains a cardinal domain for future research activity. Observational studies using mixed methodologies are needed to explore demoralization, dignity, shame, and unworthy dying, incorporating the experience of patients, families and carers, doctors and nurses, and all related support staff to build a complete gestalt of the many intersecting influences on outcome. Over the next decade, such a body of work should guide future intervention studies aimed at further improving the standard of psychosocial care.

Communication studies have developed in oncology over the past decade but remain a vital research domain for palliative medicine. Discussion of prognosis and preparation for death are

some of the most challenging conversations, yet there is a corresponding dearth of systematic research to guide the approach that clinicians take. Promotion of adaptive coping and maintenance of hope alongside acceptance of the reality of impending death constitute a fundamental feature of the effective communication needed in palliative medicine.

More systematic research into decision-making and informed consent in end-of-life care is also needed that provides patient- and family-centred outcomes in terms of quality of care and satisfaction with the process, whilst outcomes that evaluate staff compliance with advance care planning and other decisions are required to provide empirical evidence to inform the otherwise theoretical ethical debate that abounds globally.

Finally, an urgent requirement in many countries of the world is the training of dedicated researchers who can then address many of these problems. Without solid education and experience, the pitfalls appear formidable; skill development in research methodology is crucial to respond to the many challenges emerging in this young discipline.

Ethical issues in palliative care research

David Casarett

Introduction to ethical issues in palliative care research

Recent growth in palliative care research has created a heterogeneous field that encompasses both qualitative and quantitative techniques, and descriptive as well as interventional study designs. Despite the valuable knowledge that has been produced by this research, and the promise of future important advances, its progress has been impeded by a persistent uncertainty about the ethics of these studies (Casarett et al., 2003). For instance, there have been concerns raised about whether patients near the end of life should ever be asked to participate in research (de Raeve, 1994; Annas, 1998) although others have objected to this extreme position (Mount et al., 1995; Casarett and Karlawish, 2000). Nevertheless, the combination of ethical and practical issues can create substantial barriers to palliative care research (Aktas and Walsh, 2011).

This chapter discusses five ethical aspects of palliative care research that investigators and clinicians should consider in designing and conducting palliative care research. These include (1) the study's potential benefits to future patients, (2) the study's potential benefits to subjects, (3) the study's risks to subjects, (4) subjects' decision-making capacity, and (5) the voluntariness of subjects' choices about research participation. Although none of these aspects is unique to palliative care research, palliative care investigators can use these overarching principles to enhance the ethics of palliative care research.

Benefits to future patients: a study's validity and value

Palliative care research should eventually improve care for future patients. These benefits to future patients can be described in terms of validity and value.

Validity

To ensure the ethical foundation of palliative care research, investigators should use valid techniques of design and data analysis, and intend to produce knowledge that is generalizable. Indeed, generalizability is the cornerstone of one definition of research used in the United States: 'a systematic investigation, including research development, testing and evaluation, designed to develop or contribute to generalizable knowledge' (Department of Health

and Human Services, 1991, §46.102(d)). These requirements collectively describe a study's validity (Freedman, 1987). Indeed, it is unethical to expose human subjects to risks in studies that peer reviewers agree cannot adequately answer a research question (Rutstein, 1970).

Value

Above this threshold of validity, palliative care studies may offer more or less importance, or 'value'. Broadly, value can be defined as the likelihood that a study's results will improve the health and well-being of future patients (Casarett et al., 2003). Like validity, value is an important measure of a study design's scientific quality. It is also a measure of its ethical quality, however, because a central goal of research is to produce knowledge that will ultimately be 'important' (Department of Health and Human Services, 1991), 'fruitful' (Brody, 1998, p. 213), or 'valuable' (Freedman, 1990). In fact, one reason that subjects participate in clinical research is to produce knowledge that will benefit others (Advisory Committee on Human Radiation Experiments, 1995; Casarett et al., 2001). Because subjects are willing to accept risks and burdens of research at least in part in order to benefit others, investigators have an ethical responsibility to maximize the probability that a study will be able to do so.

Maximizing validity and value in palliative care research

There are several ways in which investigators can enhance the validity and value of palliative care research. First, a study's sample size should be adequate to answer the research question that is posed. Problems of underpowered studies, and particularly clinical trials, are both widespread and well described (Meinert, 1986). But they are particularly relevant to palliative care research, in which random variation can be quite large (Moore et al., 1998) and recruitment can be difficult (Aktas and Walsh, 2011). To minimize these problems, it can be useful to establish consortia or collaborative groups that can participate in multicentre studies (Kutner et al., 2008). Efforts to integrate data collection into usual care have been promising (Abernethy, 2010), and use of electronic medical record data has allowed large-scale studies at minimal cost (Casarett et al., 2012).

Second, palliative care investigators can increase the generalizability of its results. These steps might include sample size calculations that permit analysis of groups of patients that have

typically not been the focus of investigation, such as patients with non-cancer diagnoses, ethnic minorities, or elderly patients. The generalizability of a study's results might also be enhanced by recruiting subjects outside the usual academic medical settings through outreach to community clinics and hospices.

Benefits to subjects

Palliative care investigators can also enhance the ethical rigor of a study by maximizing the benefits that it will offer to subjects, either during the study or after the study ends. During interventional studies, for example, a treatment could offer the possibility of a meaningful improvement. These potential benefits can be enhanced by choosing an active control design, rather than a placebo. Even if a placebo is used, a study's potential benefits can also be improved by altering the standard 1:1 randomization scheme in a placebo-controlled trial in a way that increases subjects' chances of receiving an active agent (Farrar et al., 1998) or by using a crossover design, if possible. Of course, the potential benefits of study interventions are never certain and a trial is only ethically acceptable only if there is legitimate uncertainty, or equipoise (Freedman, 1987), regarding the relative benefits of an intervention. Therefore, although investigators have an obligation to consider the benefits that a study offers to prospective subjects, this should not be interpreted as a requirement that all interventional studies should offer potential benefits.

Descriptive studies can also offer benefits to subjects who participate. For instance, data gathered during a descriptive study may identify pain that is inadequately treated, dissatisfaction with pain management, or related clinical problems like depression. In anticipation of instances like these, investigators can design standard operating procedures that help to ensure that these problems are identified and triaged appropriately, including communication with the patient's health-care provider if appropriate (Casarett and Karlawish, 2000).

An interventional or descriptive study also might benefit a subject after it is over. Subjects may benefit from learning about a study's aggregate results. For example, if a study comparing two pain medications found that one resulted in fewer side effects, this knowledge may help a subject make a more informed choice among available medications. Others may benefit if the study permits continued access to an intervention after the study ends, often through reduced rate programmes or open-label extension phases. This benefit may be particularly important in palliative care research, if subjects are unlikely to live long enough to see a study medication's approval for clinical use, or to see a study's results published and translated into improved care.

Minimizing risks and burdens

Investigators can also enhance a study's ethical rigor by taking steps to minimize a study's risks (e.g. medication side effects) and burdens (e.g. additional clinic visits or time required for surveys). The criteria by which study risks and burdens are identified and evaluated apply the concept of incremental or 'demarcated' risks imposed by participation in a study (Freedman et al., 1992). For instance, a study that compares two commonly used sustained-release opioids for pain may not present a significantly increased ('demarcated') risk to the patient because treatment with one of the drugs would have occurred off protocol. In

contrast, a study that evaluates a sustained-release opioid in a condition for which it is not typically used (e.g. pruritus) poses risks that must be justified in the study's design. In either case, however, the risks of any medication in a clinical trial should be disclosed in the informed consent process.

Minimizing risks in an interventional trial: the choice of control

Perhaps one of the most contentious and emotional questions in palliative care research (Hardy, 1997; Kirkham and Abel, 1997), and indeed in research generally (Rothman and Michels, 1994; Macklin, 1999; Temple and Ellenberg, 2000), is whether a placebo or sham control arm is ethically appropriate. Broadly, placebos can be defined as interventions that are 'ineffective or not specifically effective' for the symptom or disorder in question (Shapiro and Shapiro, 1998, p. 12). The consensus that all subjects in a clinical trial should have access to the best available standard of care (World Medical Association, 2000) highlights the potential for unethical use of placebo. For example, all subjects with meningitis must have access to an antimicrobial agent that has proven effective; a placebo control in a trial of a new antibiotic would be unethical. In some types of research, however, such as symptom research, the placebo response can be substantial and mimics an active intervention. Moreover, the symptom under study may be transient, such as incident pain. In these situations, a placebo control may be ethically acceptable, particularly if one or more of several other conditions are met. First, placebos are acceptable if subjects receive a placebo in addition to the standard of care, such as a design that randomly assigns patient to receive an opioid plus an adjuvant agent for pain or an opioid plus a placebo. Second, a placebo arm is justified if the symptom under study has no effective treatment. Third, a placebo control is justified if subjects have adequate access to breakthrough, or 'rescue' treatment. This may in turn alter a trial's end points, and may require the inclusion of these doses as a study endpoint (Dhaliwal et al., 1995; Silverman et al., 1993; Broomhead et al., 1997).

Although sham procedures are difficult to define, the term generally is applied to a procedure that is administered in a way that makes it ineffective (Polati et al., 1998). These create ethical concerns because some subjects are exposed to the risks of the procedure without any hope of its benefits (Macklin, 1999). Like placebo controls, though, the use of a sham procedure may be ethical in some studies if the risks to subjects are minimized, some subjects are likely to benefit from non-specific effects, and the research question has high value. For instance, Leonard Cobb's research in the 1950s effectively debunked a widely used cardiac procedure that, if it had been widely disseminated, would eventually have put thousands of patients at risk. Designing a sham-controlled study so that the procedure itself (whether sham or real) poses few if any additional or 'incremental' risks above and beyond usual care also can reduce concerns about ethical acceptability. For example, investigators might insert a sham epidural catheter that would then be used for postoperative analgesia (Haak van der Lely et al., 1994) or a crossover design can be used to ensure that all subjects who bear the risks of the sham procedure also have access to the real procedure's potential benefits. This crossover sham design has been used in other settings (Hahn et al., 1996), and might be appropriate for pain research when the risks or discomforts of the sham procedure are substantial.

Minimizing burdens

For the most part, opportunities to minimize burdens are readily apparent. For instance, it seems reasonable wherever possible to minimize surveys, interviews, and additional study visits (Bruera, 1994). The importance of these actions may be accentuated when study subjects are very ill and an additional appointment or the requirement to complete another measure may increase distressing symptoms, such as fatigue, Investigators who conduct palliative care research should be particularly attuned to strategies that minimize these burdens, such as telephonic data collection.

Palliative care investigators may also need to consider the burdens that a study creates for friends and family members who often take on substantial burdens as caregivers (Steele and Fitch, 1996; Emanuel et al., 1999). By building flexibility into a study design (e.g. use of brief telephone interviews, multiple options for timing of clinic visits), investigators may be able to reduce the burdens of research participation on others.

Ensuring decision-making capacity

Patients who consent to participate in research should have adequate decision-making capacity, which refers to subjects' ability to understand relevant information, appreciate the significance of that information, and reason through to a conclusion that makes sense for them (Grisso and Appelbaum, 1998). Concerns have been raised about capacity in research involving patients with dementia (Marson et al., 1994) and psychiatric illness (Elliott, 1997), and patients in the intensive care setting (Lemaire et al., 1997), among others.

Concerns about the potential for impaired decision-making capacity are reasonable when research involves a population with advanced illness. The prevalence of cognitive impairment is high in this setting (Breitbart et al., 1995; Pereira et al., 1997), occurring in 10–40% of patients in the final months of life and in up to 85% of patients in the last days of life. Cognitive impairment may be difficult to identify because decision-making capacity varies over time (Bruera et al., 1995) and because impairment may result from the experimental or therapeutic medications themselves, such as opioids, benzodiazepines, or corticosteroids (Bruera et al., 1989; Stiefel et al., 1989). Investigators who conduct trials of medications will encounter these challenges even more frequently if trials are designed to evaluate treatments for delirium, for which impairment is an inclusion criterion (Breitbart, 1996).

Concern about impaired capacity also is increased by the potential comorbidity of clinical depression, which occurs in between 5% and 25% of patients near the end of life (Derogatis et al., 1983; Brown, 1986; Kathol et al., 1990; Massie and Holland, 1990). Clinically significant adjustment disorders may be even more common (Derogatis et al., 1983), and it is possible that these disorders may impair either comprehension or decision-making, or both (Elliott, 1997).

Decision-making capacity also can be undermined by severe symptoms, the experience of which may impair comprehension if patients are unable to concentrate on the information offered in the informed consent process (Kristjanson et al., 1994). This concern is particularly relevant in clinical trials that require the presence of one or more poorly-controlled symptom as an inclusion criterion.

The challenges encountered in ensuring decision-making capacity among research subjects may be magnified in longitudinal studies. Even if patients have the capacity to consent at the time of enrolment, they may not retain that capacity throughout the study. Days or weeks after patients give consent to participate, they may be unable to understand changes in their condition clearly enough to withdraw. The result can be a 'Ulysses contract', in which research subjects find it easier to enrol than they do to withdraw (Dresser, 1984).

None of these challenges is easily remedied. Indeed, it is obstacles like these that lead some authors to argue that patients near the end of life should not be allowed to enrol in research (de Raeve, 1994; Annas, 1998). To address the concern and enhance the ethical rigor of palliative care research when decision-making capacity is uncertain, it is important to briefly assess understanding in either open-ended or multiple choice format whenever studies involve subjects who may be near the end of life (Penman et al., 1984; Miller et al., 1996). In some situations, investigators may wish to assess decision-making capacity more formally using validated instruments (Grisso and Appelbaum, 1995). This need not be employed in all studies, but rather considered whenever the prevalence of cognitive impairment is likely to be high and the study design includes risks that must be balanced against benefits (Casarett et al., 2001). For instance, when palliative care research involves only interviews or behavioural interventions that pose minimal risks, informal capacity assessments are generally sufficient. When research poses greater than minimal risks, but offers potential benefits, a structured assessment of understanding may be appropriate. Finally, when a study poses greater than minimal risks but does not offer potential benefits, a formal evaluation of capacity should be considered.

If a patient does not have the capacity to give consent, a legally authorized representative may be able to give consent for research. This approach is justified by the argument that surrogate decision-makers should be allowed to consent to research just as they are allowed to consent to medical therapy, using either a substituted judgement of the patient's preferences or an assessment of what would be in the patient's best interests. If a patient does not have the capacity to consent, but is still able to participate in decisions, investigators should obtain assent from the patient and informed consent from the patient's surrogate (High, 1993; High et al., 1994). This 'dual consent' ensures that patients are as involved in the decision as possible, yet provides the additional protection of a surrogate's consent.

If a patient has decision-making capacity intermittently, or is expected to lose capacity, investigators may obtain advance consent. This innovative approach has been used in a study of treatment for delirium, in which informed consent was obtained from patients while they had decision-making capacity (Breitbart, 1996). Advance consent should be obtained only for specific studies, and should be obtained close to the planned start of research (e.g. at the time of hospitalization or enrolment in a hospice or palliative care programme).

Protecting voluntariness

Another way that investigators can enhance the ethical soundness of a study's design is to examine ways in which subjects' voluntary participation can be protected. In general terms, a choice is voluntary if it is made without significant controlling influences (Faden and Beauchamp, 1986, pp. 241–268; Beauchamp and Childress,

2001, p. 123). Voluntariness can be protected by ensuring that a subject's choice to enrol is made with full knowledge of available alternatives and with the understanding that he or she can withdraw at any time.

Recruitment of subjects from an environment with excellent standards of palliative care enhances the likelihood that decisions about research participation will be voluntary. If patients receive excellent care, they will be best able to make a free and uncoerced choice about research participation. Patients without access to excellent care may view research participation more favourably out of desperation, or may be less willing to withdraw from research because of the perception that effective palliative interventions (e.g. opioids) are not readily available off protocol.

Conclusion

The field of palliative care, and the standard of care that it represents, depends upon rigorous research to provide data that will guide clinical care. Although this research raises ethical questions, these questions need not curtail what promises to be a valuable and highly productive area of research. Ethical questions can be addressed through careful attention to the study's consent process and scientific design. With proper attention to strategies that ensure the ethical conduct of studies, missteps that have produced scandals in other fields will be avoided.

Quality of life in palliative care: principles and practice

Stein Kaasa and Jon Håvard Loge

Introduction to quality of life in palliative care

Quality of life (QOL) is the main goal of palliative care. This is not a new idea; one of the main goals of the health-care system in ancient Greece was to improve what we might now interpret as the patients' quality of life (Aristotle, 1975). Such improvement has therefore been, and will continue to be, an overall goal for palliative care specifically as it is for health care in general.

In a sociological context, QOL is described in theories of human welfare (defined as level of education, and economic and industrial growth). Studies from the 1950s found that economic improvement did not necessarily result in greater levels of happiness, lower levels of worries, or a better outlook (Bradburn, 1969). It was recognized that there was a need for alternative indicators of welfare in addition to the economic and material indicators used at that time. On this background, indicators of human welfare, based upon subjects' perceptions, were developed. Different terminologies have been used by different groups to describe this phenomenon of subjective well-being; subjective indicators, general well-being, or QOL (Andrews and Withey, 1976; Campbell et al., 1976). The common denominators were that the respondents' perceptions were asked for and that the information was collected by means of interviews or questionnaires.

Despite the widespread use of the term QOL as a theoretical concept, in politics and in empirical studies, no precise agreed-upon definition exists. However, in order to simplify the discussion on the content of the term, one may target two general approaches in the understanding of its meanings. Firstly, QOL may be regarded as a broad concept that encompasses 'how is your life, everything taken in consideration' and secondly QOL may be regarded as a more distinct health-oriented concept focusing on specific aspects of health or health care, including symptom levels and functioning. These are not mutually exclusive concepts, but rather a continuum of issues between two extremes allowing an intuitive flexibility in defining quality of life in terms of an overall general phenomenon or as a single sign or symptom, as illustrated in Fig. 19.7.1.

Overall quality of life

In sociological, psychological, and medical contexts, QOL has been used as a broad concept. One major distinction is between QOL as a social phenomenon in which access to health care, education, etc. are seen as indicators of QOL, and QOL as a subjective phenomenon in which the individual's subjective perception is the indicator of QOL. The different definitions of QOL in the latter meaning, all connect psychological, mental, and spiritual domains of a person's life. In the process of finding indicators of these phenomena, satisfaction, happiness, morale, positive and negative affects have been put forward as important components of the quality of life concept. In some of the literature there is an emphasis on normality, viewing QOL as fulfilment of life and the possibilities to live a normal life, while others focus more on mental capacity, to think clearly, to feel well, to love and be loved, to make decisions for oneself, to maintain contact with family and friends, to live at home and/or to be physically active. The ability to make individual decisions has also been emphasized as an important aspect of QOL, including capacity of the individual to realize his life, which includes a perception of personal meaning.

According to these conceptualizations, QOL is strongly linked to normality, including normal function or that a minimum of human needs are met. Such a minimum of needs were also described by Maslow (1970), which is often referred to as 'Maslow's hierarchy of needs', consisting of biological needs, needs for close relationships, needs for meaningful occupation, and need for change. This concept has further been elaborated in a QOL context, viewing quality of life as the level of a person's activity, the ability to relate to others, self-esteem, and a basic mood of happiness (Moum et al., 1988).

Inclusion of normality and biological fulfilment into the global QOL concept is strongly challenged by empirical findings of many patients with major physical and/or psychological limitations reporting a high degree of global QOL (Hjermstad et al., 1999). These empirical findings fit well with another theory, the so-called gap theory of Calman (1984). He described QOL as an inverse relationship of the difference between an individual's expectations and its perception of the given situation: 'the smaller the gap the better quality of life'. According to this gap theory, as illustrated in Fig. 19.7.2, a change in QOL from T0 to T1 can be caused by changes in both expectations and experience, case A and B report the same QOL at T0 and T1, however the underlying causes of the change from T0 to T1 are different in the two individuals.

The gap theory may be used to explain unexpected findings between groups and within groups over time in intervention studies. In other words, one needs to explore the magnitude of all

relevant factors that may contribute to changes. This is especially important to consider in non-controlled intervention studies that use patient-reported outcomes.

Quality of life in medicine

In health-care research, QOL encompasses a range of components that are measurable and related to health, disease, illness, and medical interventions. In health care as well as in other contexts, QOL might have different meanings for different actors and take different meanings according to illness, experience, support, etc. A professional focus may also influence the perception of QOL. For example, a medical oncologist may rate tumour response after delivering combination chemotherapy to a patient with a non-Hodgkin's lymphoma as the most important achievement to improve QOL, while a nurse may focus on patients' ability to deal with daily activities. For a physician in palliative medicine, improvement of QOL for one patient may mean pain control, and for another the establishment of necessary social support. In the context of clinical trials one is rarely interested in QOL as a global concept, but rather as a specific outcome related to the intervention in question, such as improved pain control during night-time by delivery of slow-release morphine at bedtime, or reduced dyspnoea after chest irradiation for a patient with lung cancer. Despite the unresolved issue about how to define QOL, most researchers and clinicians agree that QOL in palliative medicine is related to symptom control, physical function, social functioning, psychological well-being and meaning and fulfilment (existential and spiritual issues). This multidimensional health-oriented concept has been named by many clinicians and researchers as health-related quality of life (HRQOL) (Priestman and Baum, 1976; Bergner et al., 1981; Coates et al., 1983; Goldberg and Williams, 1988; Wade and Collin, 1988). During the last decade, the terms QOL and HRQOL have been challenged by another terminology—'patient-reported outcomes' (PROs). In essence it is a more neutral term which includes all types of measure completed or reported by the patients.

As early as 1947, the World Health Organization (WHO), in its definition of health, described it as multidimensional: 'Health is not only the absence of infirmity and disease, but also a state of complete physical, mental and social well-being' (WHO, 1958). This definition has been identified by several researchers as the beginning of a new era in relation to health and health care. In spite of being highly disputed, the definition includes three dimensions of health that later have been included in the HRQOL concept: physical health, mental health, and social functioning.

Another event that subsequently influenced the development of the QOL concept in health care was proposed by Karnofsky in 1948. He evaluated the palliative effects of nitrogen mustard on various malignant tumours by means of subjective improvement, objective improvement, and performance status (Karnofsky et al., 1948). Performance status was defined according to specific criteria, which have become widely used and known as the Karnofsky Performance Status scale. This simple scale has been shown to be a significant predictor of survival in patients with metastatic disease, as have measurers of HRQOL (Kaasa et al, 1989; Maltoni, 1995; Coates et al., 1997). In a topical review, it was advocated for the use of complementary prognostic factors such as indicators of cachexia, dyspnoea, delirium, and some biological factors (Maltoni, 2005).

During the 1970s, standardized questionnaires were developed in cooperative groups and in academic settings. 'Linear analogue self-assessment scales' (LASAs) were used to capture the QOL of specific cancer groups, such as breast cancer patients. These measures included a variety of subjective domains, such as general well-being, mood, anxiety, activity, pain, and social activity (Priestman and Baum, 1976; Coates et al., 1983). Others developed measures of health status in order to capture patients' general perceptions of health, some examples are the Sickness Impact Profile (Bergner et al., 1981), Nottingham Health Profile (Hunt and McEwen, 1980), Short Form 36 (SF-36) (Ware and Sherbourne, 1992; Ware, 1995), and more physically oriented scales such as the Barthel index (Wade and Collin, 1988). Other measures, which are also classified as QOL measures focus primarily on psychological domains, such as the General Health Questionnaire (GHQ) (Goldberg and Williams, 1988) and Profile of Mood States (McNair et al., 1971).

At the same time a similar development of measures were seen within the area of pain assessment based upon the definition of pain launched by The International Association for the Study of Pain (IASP). IASP defined pain as 'an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage' (IASP Task Force on Taxonomy, 1994). These definitions are conceptually very similar to most definitions of QOL and the WHO definition of health in that the subjective perception of the individual is recognized as the key component of health, pain, and QOL respectively. By looking into the content of the so-called broad measures of QOL, health, and pain, they contain to a large degree the same domains. Recently it is also shown that sleep and psychological distress correlate significantly with pain intensity (Knudsen et al., 2012). Previously pain measurement had involved standardized external stimulants, such as radiant heat, which were used to obtain a psycho-physiological standard to measure clinical pain. A 'language of pain' was developed, which is well illustrated by the McGill Pain Questionnaire (MPQ) (Melzack and Torgerson, 1971). During this development the concept of pain was broadened from previously focusing on pain as a neurobiological entity to a

multidimensional concept like QOL. More simple tools were also used to assess pain intensity in order to simplify the assessment in clinical practice, such as Verbal Rating Scales (VRS), Numerical Rating Scales (NRS), and Visual Analogue Scales (VAS) (Jensen, 1986). A work group in the European Association for Palliative Care (EAPC) has recommended to measure pain intensity on an 11-point NRS using the following anchoring points: 'no pain' and 'pain as bad as you can imagine' (Kaasa et al., 2011).

Assessment methodology

Most of the measurement tools for HRQOL, pain, and other aspects of subjective health are built upon the questionnaire concept, where a standardized paper-based questionnaire is to be completed by the patients. This approach is more or less well suited for palliative care patients. For severely ill patients assessment by means of interviews or standardized observations may be more appropriate. Interviews are flexible and provide detailed information, but are expensive and time-consuming to perform. Further, their usefulness might be limited in multicentre trials where HRQOL is often assessed at several time points (Kaasa, 1992).

Standardized observations of behaviours or functions are alternatives to self-report questionnaires for assessment in specific groups of palliative patients such as pain assessment in cognitively impaired or assessment of functioning such as activities of daily living (ADLs). On a theoretical level one may dispute whether these are assessments of QOL since the observer's and not the patient's perceptions are registered. In cognitively impaired patients, for example, pain is recommended to be measured by observation, which is probably the only valid methodology as of today. On a practical level we do not know the optimal assessment method for a given situation. For example, is physical functioning best assessed by asking the patient or by observing him/her? At what level of cognitive impairment is pain best assessed by standardized observations of behaviour and not by asking the patient? In spite of these and other unresolved issues, assessment of QOL by use of questionnaires has become the far most commonly used approach. The questionnaires have until now mostly existed in paper format, but administration in an electronic format seems to become increasingly popular, especially in research (Velikova et al., 1999).

Patient-reported outcomes and QOL

Another term, PROs, has been launched in order to improve the terminology with regards to measurement of patients' subjective health status. A PRO has been defined as a measurement of any aspect of a patient's health status that comes directly from the patient, without the interpretation of the patient's responses by a physician or anyone else. This implies that the term PRO is an umbrella that covers a wide range of measurements but is used specifically about questionnaires in paper or electronic format that are completed by the patient. QOL is in this context considered a broad concept referring to *all* aspects of a person's well-being. PRO can measure QOL in this broad meaning of the term, but can also focus more narrowly on a single symptom such as pain, or on a function such as physical functioning (Bren, 2006; US Food and Drug Administration, 2009).

The introduction of the term PRO must be understood in the context of manufacturers' claims of treatments' positive effects on patients' QOL. Such claims should be documented by an evaluation of the impact of a given treatment on *all* aspects of a person's well-being since QOL in its broad meaning includes assessment of the physical aspects of disease (i.e. symptoms and function), the person's emotional state, feelings, coping behaviours, self-identity (psychological functioning), and the person's ability to interact with others (social functioning) (US Food and Drug Administration, 2009). In most cases, however, claims by a manufacturer on a treatment's positive effect on QOL have not been based on such a broad assessment. In most cases the claims are based on improvement within specific domains such as reduced levels of pain or less fatigue. A 'Guidance for Industry' on these issues published by the US Food and Drug Administration is a strong support for the relevance of outcomes based on patients' reports but also restricts the use of the term QOL to a more clearly specified situation than has been practised by most until now (US Food and Drug Administration, 2009).

Barriers to the use of patient-reported outcomes in the clinic

Reports indicate that doctors' and health professionals' recognition of subjective symptoms both in general oncology and in palliative care are suboptimal (Cull et al., 1995; Passik et al., 1998; Shuster et al., 1999), and measurement of HRQOL has not become an integral part of clinical practice. These shortcomings have been on the agenda for decades. Recently it was well documented in a study that subjective toxicity, which is a key parameter in the evaluation of cancer treatment and is not consistent across various symptoms, is underestimated by physicians (Gravis et al., 2014). The clinical interpretation is that physicians fail to report symptoms and consequently do not address them in a treatment plan. There are probably several explanations for these shortcomings, such as the content of the measures, that is, many of the scales may not have enough clinical relevance, clinicians do not believe in the importance of assessing subjective experience and/or the impracticalities of using comprehensive measures in daily clinical practice (Chang, 2007). Further, physical functioning is of great importance for palliative patients and thus of high relevance for clinical decisions and clinical studies. Still, it has been demonstrated that adequate measures for use in palliative care is lacking (Jordhøy et al., 2007).

The complexity of HRQOL measures makes them difficult to interpret and they are not easily accessible in the clinical decision-making process. For research purposes there are also needs for improvement of HRQOL measurements: clinical trials often use different measures to assess the same concepts, many measures are unresponsive to changes, many represent a burden on research participants and personnel, many measures have not been validated specifically in the clinical population during the study, and some/many lack sufficient evidence for validity (Garcia et al., 2007).

Computer-based assessment

The progress in information technology has expanded the use of computer systems in the clinic. Presently there is a major shift from paper-based medical records to electronic medical records (EMRs). These can also integrate other clinical electronic information

systems such as digital imaging in radiology and laboratory data. The EMR may in the near future be complemented by clinical computerized support systems. As of today, the configuration and methods of data collection and the data entry varies. Systematic reviews have provided evidence on the effect of computer-based decision systems (Jaspers et al., 2011; Roshanov et al., 2013).

Various research groups in cancer care are in the process of developing computer-based assessment systems for general cancer care (Cella et al., 2010; Petersen et al., 2013). In palliative care, a computer-based tool for assessment of PRO, communication support, and decision support is under development (NTNU Technology Transfer AS, 2014).

Computer systems can also make the communication between patients and health-care providers dynamic as opposed to the static paper-based questionnaire. Furthermore, the computerized form will allow for more flexible ways of administering the tool, including downloading it from the Internet, administration by proxies, and the employment of handheld devices. Scores will be computed immediately and in digital forms. In total, such a development can make integration with other clinical parameters easier, support clinical decision-making, and finally be stored in the EMR.

Plethora of publications and instruments

The enormous increase in publications indexed under the subject heading QOL in MEDLINE reflects the increased focus on patients' QOL during the last 35–40 years. Seven papers were published in the period of 1966–1970 while nearly 40 000 papers were published in 2006–2011. A textbook published in 1996 included more than 200 different measures of quality of life in the broad sense (Spilker, 1996). A database on PRO and QOL instruments established in 2002 (the PROQOLID) now includes 886 instruments (PROQOLID, 2008). The rapidly increasing number of papers and newly developed questionnaires represents a challenge for the researcher and the clinician when they shall select the most appropriate assessment tool for their purpose

This increase in papers and questionnaires also points to a need for collaboration on development of a common nomenclature, as well as standardized and agreed-upon assessment tools. These suggestions have been put forward by several research groups for at least a decade both in HRQOL-assessment in general (Anderson et al., 1993) and in palliative care specifically (Kaasa et al., 2007; Kaasa and Radbruch, 2008). Despite these suggestions it was recently found in the area of pain assessment that new instruments are still being developed and published (Hjermstad et al., 2008). Most of these instruments are rarely used in later empirical studies.

HRQOL in palliative care

The goals of palliative care are acknowledged to include HRQOL as well as spirituality, loss/grief, family involvement, and coping. Many of the most common HRQOL tools have been thought inadequate by researchers for use in palliative care. The instruments have been criticized for being too narrow by only including physical, psychological, and social aspects of a patient's life. Outcome measures require questions that reflect the specific goals of palliative care (Hearn and Higginson, 1997), such as improving the QOL before death, controlling symptoms, and supporting the

---

family (Box 19.7.1). It has been proposed that also meaning should be included, as well as purpose, spirituality, and grief (Cohen and Mount, 1992; Byock and Merriman, 1998; Waldron et al., 1999).

During end-stage disease, patients will often not be able to complete HRQOL instruments and proxies will be the only possible source of collection of information, either by means of interviews (open, semi-structured, or structured) or questionnaires. One possible strategy is to let the health-care provider or a family member complete the HRQOL instrument. However, many studies have shown that assessments by health-care providers or family members differ from the responses obtained from the patients. In some conditions, observers overestimate the psychological burden of disease, while pain and other symptoms are often underestimated.

In summary, HRQOL is the patient's perceptions of their health that are collected directly from the patient without interpretation of others. It is a dynamic phenomenon and different dimensions might be focused on, depending on individual factors, disease factors, symptomatology, coping ability, closeness to death, etc. The content is influenced by the setting, that is, the severity of physical symptoms, general health, spirituality, coping, existentially, etc. Still there is a general agreement to at least include relevant symptoms, physical, psychological, and social domains into the measures, and in many circumstances existential and spiritual domains also seem appropriate to include.

Patient population in palliative care and compliance with QOL assessment tools

There are several issues one must take into account when assessing HRQOL in palliative care. The patients are often sick and frail. Valid and reliable data may therefore be difficult to collect, particularly in the latest stages of life. Patients often have multiple symptoms at the same time and physical symptoms may give raise to psychological problems (and vice versa). These relationships in palliative care in general and specifically in end-of-life care have been discussed and addressed empirically.

What is a palliative care population?

A palliative care population is not a well-defined group of patients. In some programmes most patients are dying while in others the majority of the patients have a longer life expectancy.

Table 19.7.1 Patient population in palliative care—a proposal for classification

	Expected survival	Karnofsky
Combined oncology and palliative care	>12 months	>70
Primary palliation	>6–9 months	60–70
Early palliation	2–3 months	50–60
Late palliation	<1 month	30–40
Imminently dying	<1–2 weeks	<10

Source: Data from David A. Karnofsky et al., The use of the nitrogen mustrads in the palliative treatment of carcinoma—with particular reference to bronchogenic carcinoma, *Cancer*, Volume 1, Issue 4, pp. 34–56, Copyright © 1948 American Cancer Society.

In discussing the use of methodology to collect HRQOL data, the patient population in question should be specified as well as all research questions that are to be answered. Several indicators might be used to describe the population, such as expected survival, type of tumour-directed treatment, do not resuscitate (DNR) status, symptom burden, type of oncological treatment, etc. Recently a research group based on a collaboration within the EAPC has proposed a minimum dataset to use in the description of a palliative care cohort in clinical work as well as in quality assurance and research (Sigurdardottir et al., 2014).

Most patients in trials on palliative chemotherapy have a Karnofsky Performance Status above 60–70 and consequently an expected survival time of more than 6 months with large variations depending on the primary diagnosis. Newer types of chemotherapy, however, such as protein kinase inhibitors and growth factors inhibitors have improved survival substantially in many cancer patients with metastatic disease. Therefore it is argued that palliative care needs to be presented earlier in the disease trajectory (Kaasa, 2013). A second category of patients are those admitted to a palliative care programme, either as inpatients or as outpatients, with an average survival of 1–3 months. A third category may be the imminently dying patients with a Karnofsky Performance Status of 30–40 and lower. This latter category can be further divided into cognitively intact and cognitively impaired patients (Table 19.7.1).

The content of the assessment tools, the number of items in the instrument, and the use of proxy raters are some of the important issues to consider in relation to the patient population being investigated.

Compliance and patient population

Missing data can be defined as data that are anticipated but not returned. There are two main types of missing data: missing items (item non-response) and missing forms (unit non-response). The first relates to uncompleted question(s) within a QOL instrument and the second to a whole QOL assessment missing. Missing data is a potential source of selection bias in cancer research, quality assurance programmes, and in research in palliative medicine (Bernhard et al., 1998). Randomly missing data are not a problem except for some possible loss of power. Usually 1–2% of the responses to a given item within a questionnaire will be missing. However, in most cases missing data are due to a mixture of randomly missing data and data missing not at random (Fielding

et al., 2006). When data are missing for some patients, basic questions arise as to whether these patients differ from those with complete data sets. The patients in poorest health and with the shortest life expectancy are at the highest risk for both types of missing data (Anderson et al., 2000). In order to evaluate a scientific report and to compare cohorts between studies, a standard reporting system of compliance including all available information, should be required. Compliance is often defined as the number of questionnaires completed as a proportion of the number expected. The issue of compliance is described in more detail in textbooks (Fayers and Machin, 2007) and statistical literature (Colton et al., 1998). In this chapter some issues relating to compliance in palliative care will be discussed.

When patients become increasingly ill with progressive disease, they will find it difficult to complete questionnaires. Acceptable compliance can be achieved with HRQOL questionnaires in palliative care, though several patients will need assistance to complete the measures. During end-of-life care, the last 1–2 months of the patient's life, more patients will need help to complete the assessment tools due to physical deterioration, cognitive impairment, severe symptom distress, and/or emotional burdens. Compliance will decrease substantially if help is not provided (Jordhøy et al., 1999) (Fig. 19.7.3). Patients who are immediately dying will experience many distressing symptoms, but if they are excluded from not just research, but quality assurance and in evaluating clinical practice, there is a great risk for lack of empirical knowledge needed for development of systematic treatment procedures for this fragile population (Sneeuw et al., 1997). As of today, HRQOL questionnaires are in a paper-and-pencil format. All patients need to answer all questions in often extensive questionnaires. By using modern information technology systems and developing appropriate software, a custom-made approach can be applied by using systems where patients are only answering relevant questions according to symptoms and conditions in general. (See paragraph on computer-based assessment earlier in this chapter.)

Based on these facts, there are two main strategies in relation to missing data. The first is to reduce the risk of missing data to a minimum. This will include careful consideration of the length of the questionnaire, collection of data by use of optimal procedures for the population at stake, standardized procedures for
Fig. 19.7.3 Number of HRQOL forms completed in proportion to those distributed within various time frames prior to patients' death.

data collection, and careful observation of the data collection, especially towards 'gate-keeping', which implies that the data collector for some reason wants to shield the patient from participation. The ethics are clear on this point, it is the eligible patient's right to choose to participate or not. The second strategy is to carefully analyse for systematic patterns of missing data (both missing forms and missing items) in order to discover a biased data set.

Proxy ratings

Proxies may be considered as an alternative or complementary source of information, especially during end-of-life care (Brunelli et al., 1998). However, there has been a generally negative attitude towards the use of proxy ratings in the HRQOL literature because it has been repetitively demonstrated that assessment directly from the patient is the most valid way of collecting data on subjective health.

Review articles (Sprangers and Aaronson, 1992; Higginson et al., 1994), commentaries (Lampic and Sjoden, 2000; Sprangers and Sneeuw, 2000), and recent studies (To et al., 2012) have addressed the topic of caregivers and significant others as raters. Most of the published articles that address this issue, relate to general cancer populations or those in 'early palliation'. The studies have been criticized because of small sample sizes, major limitations in methodology, and use of unstandardized ad hoc instruments. The findings of the published studies are not totally consistent but can be summarized as follows:

- Health-care providers tend to overestimate patients' anxiety, depression, and general psychological distress.

- Agreement between health-care providers and patients' ratings was better in the absence of distress, than in the presence of distress.

- Pain and other symptoms seem to be underestimated by proxies.

- Proxy rating seems to be more accurate when the domains are concrete and observable.

There are several unanswered questions related to the use of proxy raters (Box 19.7.2): the limitation of proxy data, the content of proxy rating instruments, and the development of a common measure.

Even with these limitations caregivers or health-care providers can be used as proxy raters and it is probably best to use one of the short validated tools in order to compare data between studies and to optimize the clinicians' understanding of the content of the measures. The COOP/WONCA chart (Van Weel, 1993), Edmonton Symptom Assessment Schedule (ESAS) (Bruera et al.,

1991), and EORTC QLQ C-30 (Aaronson et al., 1993) are examples of such instruments. Another alternative is the SF-8 (Ware et al., 2001). However, the SF-8 has not been validated in palliative care populations. The SF-8 is an 8-item version of the SF-36. It yields a comparable 8-dimension health profile and comparable estimates of the physical and mental summary score as the SF-36 (Ware and Sherbourne, 1992).

However, before proxy ratings can be recommended outside a methodological research setting in palliative care, measurement tools and report systems need to be further developed into a user-friendly format and the strengths and limitations of proxy ratings need to be further addressed in research settings.

Choice of questionnaires

In the following, a comprehensive presentation of instruments for use in palliative medicine will not be given; instead some principles with concrete recommendations will be outlined.

The first step of the selection procedure is to specify the overall aim of the project. The overall aim then needs to be followed by an outline of the specific research questions or hypotheses. For each research question a clinical outcome should be decided upon. This will subsequently guide the selection of an assessment tool or even specific scales or items within a tool (Box 19.7.3).

It is generally recommended to assess HRQOL with multidimensional instruments because such measures are more comprehensive than uni-dimensional scales (Osoba, 1994). The HRQOL-measures are commonly divided into *generic, disease-specific*, and *domain-specific*. The *generic* measures are not specific to any population or disease. They are therefore applicable for subjects with more than one condition, and they make comparisons across populations and conditions possible. The *disease-specific* measures are developed for specific groups of patients, for example, such as the EORTC-QLQ-C30 and the FACT-G (Aaronson et al., 1993; Cella et al., 1993) developed for cancer patients or instruments specifically developed for palliative care. Most of the instruments include various aspects of functioning such as physical, role and social functioning and subjective appraisal of symptoms and well-being (Muldoon et al., 1998). Most recent generic and disease-specific instruments also assess positive health; that is, good health and well-being and not merely the absence of problems (Ware, 1995). The *domain-specific* instruments assess specific domains within the overall concept of HRQOL, such as fatigue, pain, or psychological distress.

Assessments of HRQOL will often include combinations of generic, disease-specific, and domain-specific instruments based on the specific purpose of the study. For example, if one wants

---

Box 19.7.2 Limitations of proxy ratings

- Lack of understanding of when and why proxies' ratings and patients' ratings differ

- Lack of short and intuitively understandable assessment tools

- Uncertainty about the instruments' psychometric properties when used by proxies

- Uncertainty about the comparability between patients' and proxies' ratings.

Box 19.7.3 A generic guide for selection of outcomes

- Step 1. Define the overall aim(s) of the project

- Step 2. Define the research question(s) or hypotheses

- Step 3. Agree upon the (clinical) outcome(s) for each recommended question

- Step 4. Select the assessment tool or scales within a tool, guided by the clinical outcome.

to compare the effects of single-fraction irradiation with multiple fractions in a population with painful bone metastasis, a multidimensional disease-specific questionnaire such as the EORTC-QLQ-C30 in combination with a domain-specific questionnaire on pain might be relevant. The number of questionnaires must fit the purpose for the assessment, but must also be balanced against the burden on the respondents and the costs of the data collection. The increased amount of information gained by including domain-specific measures is not always obvious and is clearly dependent on the content, the psychometric properties and the sensitivity of the instruments. For example, if a domain-specific instrument on fatigue does not have better measurement qualities than the fatigue scale within a generic or disease-specific instrument, it is not recommended to include it because of the increased burden to the patient.

Comparative data on different instruments measuring the same constructs are relatively scarce. The cancer-specific instrument EORTC QLQ-C30 and the generic instrument SF-36 were compared in patients with chronic non-malignant pain (Fredheim et al., 2007). Scales assumed to measure the same constructs were highly correlated, and for these scales the SF-36 scales tended to have better internal consistencies. On the other hand, the EORTC QLQ-C30 includes several symptoms that are not assessed by the SF-36.

The researcher might be best off by choosing instruments that are commonly used and found relevant within similar populations and settings. By choosing commonly used instruments, one's findings can more easily be evaluated by other researchers and put in a broader context. The psychometric properties of an instrument might vary across populations, therefore applying a questionnaire for the first time within a 'new population' requires a minimum of testing of some basic psychometric properties of the instrument in that particular population. The downside of this approach is that instruments with sub-optimal measurement qualities are used repetitively due to the costs associated with development and introduction of new and possibly better instruments.

In the following some commonly used instruments are briefly discussed. This does not imply that these instruments are superior to other available instruments.

Generic instruments

The first instruments were published in the 1970s and 1980s, such as the Sickness Impact Profile (SIP) (Bergner et al., 1976) and the Nottingham Health Profile (Hunt and McEwen, 1980). For a more detailed description we refer to other reviews (Bowling, 1995; Ware, 1995; Spilker, 1996). The first generation of instruments was generally lengthy and time-consuming to fill in.

The SF-36 is a second-generation instrument, developed from a larger questionnaire (Ware and Sherbourne, 1992). Eight concepts that were not specific to any disease, age, population, or treatment group were chosen to measure health conceptualized in two main dimensions: physical and mental health. The psychometric properties of the eight scales are generally very good with Cronbach's alphas in the range 0.80–0.93 (Ware, 1996). A revised version (version 2) was published in 2000 (QualityMetric, n.d.). The SF-36 version 2 is licensed and usage is depending upon a signed licence agreement and a fee. SF-36 Version 1 is available for usage without any costs as Rand SF-36 or Rand-36.

The SF-36 physical and mental component summary scales capture about 85% of the reliable variance in the instrument (McHorney et al., 1993). On this background, a shortened questionnaire was constructed. Twelve items from the SF-36 were selected and the instrument labelled SF-12 (Ware and Keller, 1996; QualityMetric, n.d.), and later the even shorter SF-8 (Ware et al., 2001; QualityMetric, n.d.). The SF-12 reproduces the eight-scale profile of the SF-36 but yields less precise scores. A revised version of the SF-12 (version 2) was published in 2002 (QualityMetric, n.d.). The revision followed the same principles as used for the revision of SF-36.

WHOQOL

The World Health Organization has developed the WHO Quality of Life Assessment Instrument (WHOQOL) (1993). The instrument was developed, according to a standardized protocol, simultaneously in several languages and cultures at 15 international centres (Szabo, 1996). The original instrument encompasses five domains measured by 100 items; physical health, psychological health, level of independence, social relationship, spirituality and environment. Each domain includes several facets, in total 24. Each facet contains four items, and the last four items measure overall quality of life and general health. Because of the limitations posed upon the use of the instrument's length, a 26 item abbreviated scale has been published, primarily for use in epidemiological studies (1998).

Disease-specific measures

EORTC QLQ-C30

The development of the cancer-specific questionnaires, the EORTC QLQ-C30 (European Organization for Research and Treatment of Cancer) was finalized in 1993 (Aaronson et al., 1993). Modified versions have been published and the group recommends version 3.0 of the questionnaire (EORTC). The questionnaire covers five functional scales (physical, role, cognitive, emotional and social), general QOL, three symptom scales (fatigue, pain and nausea and vomiting) and six single items. The single items assess common symptoms in cancer patients such as dyspnoea, loss of appetite, insomnia, constipation and diarrhoea.

The timeframe for the assessment is 1 week, which may be of particular relevance in clinical trials. The instrument has good psychometric properties including test/retest reliability (Bjordal and Kaasa, 1992; Hjermstad et al., 1995).

The so-called modular approach adopted by the EORTC Quality of Life Group infers that the core questionnaire can be supplemented with additional questionnaires designed for specific cancer sites (Aaronson et al., 1994). Updates on the latest development of the EORTC questionnaires are found on the website (EORTC, n.d.).

A shortened version containing 15 items intended for use in the palliative care setting, the EORTC QLQ-C15-PAL, was published in 2006 (Groenvold et al., 2006). Pain, physical function, emotional function, fatigue, global health status/QOL, nausea/vomiting, appetite, dyspnoea, constipation, and sleep were retained in the questionnaire. The EORTC QLQ-C15-PAL is a 'core questionnaire' for palliative care. Depending on the research questions or the purpose for use, it may be supplemented by additional items, modules, or questionnaires (Groenvold et al., 2006).

FACT-G

The Functional Assessment of Cancer—General Version (the FACT-G) was first published in 1993. In 1997 it was included as a core questionnaire in a measurement system called Functional Assessment of Chronic Illness Therapy (FACIT) intended for use in chronic diseases. Thus, FACIT is a broader, more encompassing system that includes the FACT questionnaires under its umbrella.

The FACT-G includes 27 items arranged in subscales covering four dimensions: physical well-being, social/family well-being, emotional well-being and functional well-being (Cella et al., 1993). It is considered appropriate for use in patients with any type of cancer. The time frame is 1 week, and the psychometric properties are reported as comparable to the EORTC QLQ C30 (Cella et al., 1993). There seems to be a tendency of the FACT-G being used more frequently in the United States than in Europe, while the EORTC QLQ-C30 is used primarily in Europe.

The FACIT measurement system has also adopted a modular approach with cancer-specific, symptom-specific and treatment-specific subscales. An update on the complete FACIT measurement system is found at the group's website (FACIT, n.d.).

Domain-specific measures

Generic or disease-specific instruments might not be sensitive enough for detection of differences in HRQOL. Questionnaires, also called domain-specific instruments, have been designed to assess specific symptoms, such as pain, fatigue, and anxiety. In some instances these types of instruments might be preferable. For example, in a study of patients with advanced prostate cancer, the EORTC QLQ-C30 fatigue scale did not detect variations in fatigue over time whereas two fatigue-specific instruments captured group differences (Stone et al., 2000). This finding is probably related to the so-called floor- and ceiling-effects. Numerous instruments are available and for a more comprehensive description we refer to relevant textbooks and websites (Bowling, 1995; Spilker, 1996; PROQOLID, 2008; FACIT, n.d.; QualityMetricQualityMetric, n.d.).

Anxiety, depression, and psychological distress

Many frequently used domain-specific instruments for measurement of anxiety and depression are old and can be characterized as first-generation instruments. For example, the Hospital Anxiety and Depression Scale (the HADS) was constructed in 1983 (Zigmond and Snaith, 1983). Other commonly used instruments for measurement of depression such as the Beck Depression Inventory (BDI) and Hamilton Depression Scale (HDS) were first published as early as the 1960s (Hamilton, 1960; Beck et al., 1961). At the time the psychiatric disorders (anxiety and depression) were defined differently than they are in 2014 (American Psychiatric Association, 2013).

When measuring anxiety and depression in palliative care it is important to examine whether the instrument includes somatic items (fatigue, weight loss, loss of appetite, etc.). Such symptoms are valid symptoms of anxiety and depression disorders in psychiatric and healthy populations, and the symptoms are included in the present diagnostic criteria for these disorders (American Psychiatric Association, 2013). However, these symptoms are not valid symptoms of anxiety and depression in palliative care patients because they are strongly affected by the underlying somatic disease.

A review on assessment of depression in palliative care identified 198 papers in which 105 different assessment methods had been used (Wasteson et al., 2009). Just a few studies had used structured interviews which are the 'gold standard' for diagnosing *depression disorders*. Sixty instruments had been used only once, and usage was not based on definition of depression and rather seemed to reflect local traditions. Regional differences were also detected as HADS was most commonly used in Europe but seldom in the United States or Canada.

HADS is one of the most frequently used instruments for measuring anxiety (seven items) and depressive symptoms (seven items) in oncology and palliative medicine. Four of the items constituting the depression subscale are about anhedonia, two items are about mood and one is about retardation. It has been demonstrated that a total score, including both the anxiety and depression subscales is a better predictor of major depression disorder in palliative care patients than the depression subscale (Le Fevre et al., 1999).

In order to bring the PRO on depression more in line with the diagnostic criteria for depression disorder as formulated in the DSM-IV, the Patient Health Questionnaire 9 (PHQ-9) was launched in 1999 (Spitzer et al., 1999). The instrument assesses all the nine depression diagnostic criteria including duration and functional consequences for major depression disorder and has good psychometric properties. A two-item version including the two major diagnostic criteria for depression disorder (lowered mood and anhedonia) has also demonstrated good screening properties (Mitchell, 2008). However, depression screening in cancer patients is debated, and we presently lack documentation that such screening improves depression outcomes compared to routine clinical examinations (Meijer et al., 2011).

Anxiety is more prevalent in palliative care patients than in the general population but has received less attention in the literature than depression. As for depression the term is used both for symptoms and disorders; generalized anxiety disorder (GAD), panic disorder or post-traumatic stress disorder (PTSD) (Roth and Massie, 2007). In a clinical perspective the common co-existence of anxiety symptoms and depression symptoms is of high relevance (Brenne et al., 2013). Assessing both anxiety and depression symptoms is therefore often recommendable. Still, the choice of instruments should reflect what shall be measured (i.e. symptoms or disorders) and the purpose for the assessment. Several PROs on anxiety are available. The HADS is probably the most commonly used instrument in a palliative care setting (Zigmond and Snaith, 1983). The anxiety subscale consists of six items on general anxiety (such as tension and worrying) and one item on panic.

An expert group introduced an alternative term, *distress*, for political reasons in 1997 (National Comprehensive Cancer Network, n.d.). The term was first introduced by one of the pioneers in stress research, H. Selye, who in 1975 defined it as 'persistent stress that is not resolved through coping or adaptation, deemed distress, may lead to anxiety or withdrawal (depression) behavior'. Thus distress implies that the stressor exceeds the individual's coping abilities which effectively handle the so-called good stress (eustress).

The term distress was chosen because it was assumed to be more acceptable/less stigmatizing than psychiatric, emotional or psychosocial, it sounded normal and less embarrassing and it could be measured by self-report (National Comprehensive Cancer Network, n.d.). Distress was conceptualized as a continuum from normal reactions to depression, anxiety and delirium thus mirroring the whole spectre of psychiatric/psychological aspects of palliative care without distinguishing between them.

The introduction of the term distress was rapidly followed by the introduction of an assessment method; the distress thermometer (Roth et al., 1998). The thermometer was a single item with a zero to ten response alternative designed as a thermometer. The instrument has later been supplemented by other items on related phenomena and with the original thermometer as the response alternative.

Instruments for assessing distress are defined differently. One review identified 33 instruments including the HADS (Vodermaier et al., 2009). Another review identified other instruments also assessing psychiatric disorders such as delirium and subscales from HRQOL instruments (Kelly et al., 2006).

Fatigue

Fatigue can be defined as a subjective feeling of tiredness, weakness, or lack of energy (Radbruch et al., 2008). Fatigue is the most frequent symptom in palliative care and is experienced by nearly all patients with advanced disease (Coyle et al., 1990; Stone et al., 1999). In palliative care, as opposed to healthy populations, fatigue relatively weakly correlates with psychological distress and in many cases reflects the subjective experience of being seriously ill (Stone et al., 1999).

Instruments specifically designed for measuring fatigue were first published in the late 1980s. At present several instruments are available (Loge and Kaasa, 1998; Stone et al., 1998; Stone and Minton, 2008), and most of these should be classified as first-generation instruments. A single item with an 11-point NRS for the responses has been proposed for screening purposes (National Comprehensive Cancer Network, n.d.). The Functional Assessment of Cancer Therapy- Fatigue scale is a 13-item free-standing part of the FACT-Anaemia Scale within the FACIT measurement system (Cella et al., 1993). The 13 fatigue items are available as a separate instrument (the FACIT-Fatigue) which is a uni-dimensional measure of physical fatigue (FACIT). However, most researchers agree that fatigue is a multidimensional phenomenon, but the number and types of dimensions is debated. All present fatigue measures include physical fatigue, which corresponds to the subjective feeling of being exhausted and lacking energy. A short (11 items) fatigue-instrument (Fatigue Questionnaire (FQ)) measures fatigue in two dimensions—physical and mental fatigue (Chalder et al., 1993)—and is commonly used in studies of cancer-related fatigue (Stone and Minton, 2008; Minton and Stone, 2009).

A review on instruments to be used in patients with advanced cancer identified more than 40 instruments published between 1985 and 2008 (Seyidova-Khoshknabi et al., 2011). The authors concluded that most instruments were too burdensome for those with advanced cancer. They proposed shorter unidimensional instruments such as the the Brief Fatigue Inventory or the 3-item scale on fatigue in the European Organization for Research and Treatment Quality of Life Questionnaire Fatigue Scale (EORTC QLQ-C30) (Seyidova-Khoshknabi et al., 2011). By this they point to an important aspect in choosing instruments for severely diseased populations. Still, the number of items must be evaluated in a broader context including the purpose of the data collection and the total number of items in the questionnaire package. A short instrument might be feasible if data on fatigue is collected as part of a broad symptom assessment or as a secondary endpoint. On the other hand, a short three-item uni-dimensional scale might lack sensitivity in for example intervention studies.

Pain

Pain is the second most prevalent symptom in palliative care, and for the majority of patients it is the most distressing symptom. It is well documented that pain is underdiagnosed and undertreated (Grond et al., 1996). Pain is the aim for different interventions both clinical and for research purposes in palliative care. In most situations, pain intensity will be the main target for assessments of pain. Additional aspects such as variation of pain over time, pain triggered by physical activity, or breakthrough pain might be of relevance in many situations. In such cases, available instruments must be evaluated for their properties in measuring these aspects of the pain experience.

In general, pain is included as single items or as separate subscales in all existing generic and disease-specific instruments. In these, pain is measured as a uni-dimensional construct (Hølen et al., 2006). However, it is important to underline that pain is a complex and also a controversial area for assessment, although some of the problems are reflecting challenges for HRQOL assessments in general (Hølen et al., 2006). Some major unresolved issues in relation to pain assessments in palliative care are: to what extent shall a pain assessment include assessment of physical and emotional distress caused by pain (Stenseth et al., 2007) (= pain interference)? How should pain be measured in patients receiving analgesics? How to deal with pain thresholds which vary between individuals and with individual access to support? What about differentiating between specific types of pain? How to measure specific cancer pains such as breakthrough pain? How is pain best measured in patients with cognitive impairment who are not able to respond to self-report questionnaires?

Domain-specific tools for measurement of pain such as the McGill Pain Questionnaire measure pain as a multidimensional phenomenon, but it is rather extensive and therefore difficult to apply in debilitated palliative care patients (Melzack, 1975). A shorter version of this instrument has been developed and validated (Melzack, 1987). Others, for example, the BPI (Daut et al., 1983), measure the impact of pain on physical functioning in addition to measuring pain intensity. There is reason to question whether consequences of pain can be validly separated from functional limitations due to other factors (Radbruch et al., 1999). This is of particular concern in palliative care patients due to the complexity of their diseases, the functional limitations they present and their experience of several symptoms at the same time.

An expert working group of the EAPC recommended that selection of tools for pain assessment should be based on the study population and the specific study design (Caraceni et al., 2002). The recommendations of the expert group apply to adults without cognitive impairment. For assessment of changes in pain

intensity, single items with NRS were recommended while the Brief Pain Inventory short form (BPI-sf) were recommended for broader assessments (National Palliative Care Research Center, n.d.). The recommendations were recently updated with a simple algorithm for pain in assessment (Kaasa et al., 2011). The Short Form McGill Pain Questionnaire (SF-MPQ) (Melzack and Katz, 2001) was recommended for studies of pain qualities, such as studies focusing on diagnoses and characterization of pain syndromes. For assessments in cognitively impaired, several instruments are available but not sufficiently tested for explicit recommendations (Zwakhalen et al., 2006).

Use of single items

The use of single items either as self-constructed items or as items borrowed from a complete instrument is generally not recommended. An exception to this is simple questions about facts such as sick leave status where the items assess concretes and not underlying constructs. The validity of self-constructed items is generally uncertain and moving an item from its context might affect the responses.

Cognitive impairment

Cognitive impairment as part of dementia, amnestic disorder or delirium is prevalent in palliative care (Robinson, 1999; Casarett and Inouye, 2001). Among patients with terminal cancers, 20–40% develop delirium or other neuropsychiatric conditions (Pereira et al., 1997). We are not aware of HRQOL studies in cancer patients which have discussed their results in relation to possible cognitive impairment among the subjects. Cognitive impairment might affect completion rates, data quality, and the validity of HRQOL studies in palliative care.

Interviews conducted by health-care providers by means of specific interview guides and observation of behaviour are the appropriate methods for the detection of cognitive impairment (Hjermstad et al., 2004). The subjective experience of cognitive impairment is weakly correlated to neuropsychiatric disturbances but much stronger to psychological distress (Cull et al., 1996). Consequently, cognitive functioning scales within HRQOL questionnaires probably measure mental fatigue rather than cognitive functioning.

The most commonly used interview-based instruments in assessments of cognitive impairment are the Mini Mental State Examination (MMSE) and the Memorial Delirium Assessment Scale (MDAS) (Folstein et al., 1975; Breitbart et al., 1997). Physicians or other health professionals can use these measures without specific preparation, although it is wise to compare first time performances with more experienced personnel as part of the introduction routines into a research project or clinical practice. The MDAS is a brief, reliable tool for assessing delirium severity, while the MMSE is designed for detection of cognitive impairment irrespective of the cause or neuropsychiatric diagnosis. For the MMSE it has been demonstrated that the scores of selected items are equally effective as the sum-score of all the 20 items in identifying cognitive impairment in elderly patients and delirium (Braekhus et al., 1992; Fayers et al., 2005). However, more research is needed before such an abbreviated version can be recommended for general use. The present documentation on the usage of shortened instruments indicates that the standard clinical evaluation of consciousness and orientation are good screeners for detecting cognitive impairment.

Palliative care specific instruments

Several instruments have been developed and validated within palliative care. Most of these instruments are not used extensively in clinical research or in clinical practice today. Clinicians and researchers seem to use either generic instruments such as the SF-36 or disease-specific instruments, the EORTC QLQ-C30, this instrument's shortened version (the EORTC QLQ-C15-PAL) or the FACT-G. These instruments are described earlier in this chapter. The generic instruments may be supplemented by domain-specific measures. Examples are instruments which measure pain, anxiety, depression, fatigue, and aspects at end of life.

HRQOL in the dying

Research on QOL for the dying patient is sparse—probably related to several factors, such as a lack of focus on dying patients and the dying process in general ('the battle is lost—why bother with it'). Furthermore, the dying patient is vulnerable and the ethics related to the research is debated.

There are several methodological challenges related to HRQOL assessment in the dying, including the rapid change in most biological processes and loss of cognition, which is highly relevant for the ability to collect subjective data. As previously pointed out, there are major problems with compliance in this sub-population when using traditional HRQOL questionnaires. In most palliative care programmes the aim is to support the family to care for the dying at home as well as providing specialist professional care. Consequently the team is caring for the patient in a family network. In end-of-life care 12 important aspects of care have been identified; acceptability and continuity, team co-ordination and communication, communication with patients, patient education, inclusion and recognition of family, competence, pain and symptom management, emotional control, personalization, attention to patient values, respect and humanity, and support for patient decision-making (Curtis et al., 2001). Another group involved in the development of assessment tools for patients with life-limiting illness, reached similar conclusions: the outcomes should be patient-focused and family-centred, clinically meaningful, administratively manageable, and psychometrically sound (Teno et al., 1999).

Quality of life assessment is by definition subjective in nature. In the dying patient, who is cognitively impaired, 'subjective data' needs to be collected by observers. There is a lack of validated instruments specifically designed for dying patients; however, there is an increase in literature addressing measurement issues for this patient population, focusing on the development of a conceptual framework (Singer et al., 1999; Stewart et al., 1999). Several attempts have been made to develop observation-based instruments to measure pain in the cognitively impaired (Zwakhalen et al., 2006).

In summary one may say that the patient-focused assessment recommended is very similar to the strategy developed earlier in life, focusing on symptom control and how to relieve the patient burden. However, during end-of-life care, spiritual and existential

issues need to be addressed in more detail in addition to family members' perception of quality of care (Box 19.7.4).

Family satisfaction, HRQOL, grief, and other domains may be used as outcomes of quality of death. A variety of instruments have been used in the published studies to examine different aspects and models of care (Rinck et al., 1997; Hearn and Higginson, 1998; Smeenk et al., 1998; Salisbury et al., 1999), and no consensus on content nor on type of instruments seem to be agreed upon. In several studies a general high level of satisfaction with care has been observed and only minor differences between various palliative care programmes, which may indicate a poor ability of the existing instruments to discriminate between groups when measuring satisfaction with care and HRQOL (Kane et al., 1984; Zimmer et al., 1985; Addington-Hall et al., 1992; Hughes et al., 1992; Jordhøy et al., 2000, 2001).

Practical measurement of HRQOL during end-of-life care

The complexity, length, and content of the existing HRQOL instruments seem inappropriate for use during the dying process. Shorter and simpler instruments are needed here. To our knowledge there is no single instrument widely used for this purpose, but simple NRS have been developed. The Edmonton Symptom Assessment Schedule (ESAS) is a short ten-item instrument (Bruera et al., 1991) that has been extensively used in several scientific reports by the group. Other symptom assessment schedules are also used, such as the Memorial Symptom Assessment Scale Short Form (MSAS-SF), which is one of the several alternatives for symptom assessment (Chang et al., 2000). Still there is a lack of consensus on how to measure HRQOL in the dying patient. New, shorter, and more comprehensive instruments are therefore needed, which ideally could be completed both by the patient and proxy raters in sequence.

Interpretation of data

What is the clinical relevance of a summary score on a single item when comparing groups of patients or individuals? This is one basic question to ask both in daily clinical practice, in interpreting clinical research, and in sample size calculation in the planning process of a clinical trial. The clinical significance is related to the importance of the symptoms or the signs.

In pain assessments a single item on pain intensity rated on a NRS ranging from 0 to 10 is often used as the outcome. When discussing the clinical significance of a pain score, two important questions need to be answered. What is a relevant cut-off point in

order to classify the score of those in need of intervention? What is the minimum difference on a pain score, say on a 0–10 scale, in a randomized trial comparing two different pain medications that is of clinical importance? Some major challenges related to interpretation of HRQOL outcomes are presented in Box 19.7.5.

Change in any clinical variable, independent of the nature of the variable, that is, physiological (blood pressure), psychological (anxiety), and performance (physical function) needs to be interpreted in a clinical framework. It is not a methodological or statistical question whether a change of 20 on a scale from 0 to 100 is of clinical significance. In order to be able to make a valid judgement on the magnitude of a measure in order to regard it as 'clinically significant', the clinician needs at least to understand the nature of the measure, including insight into the content of the composite score, the clinical meaning of the measure, and how it relates to individual patients. The discussion about clinical significance is not unique to QOL assessment. Similar discussions arise, for example, in interpreting the clinical significance of blood pressure medication, interpreting the reduction of tumour size caused by chemotherapy, and the importance of change in median survival in patients with non-small cell lung cancer admitted to a randomized chemotherapy trial.

These are some of the general problems. A more specific problem related to palliative care is the interpretation of change in several QOL estimates in the same study. QOL estimates are by nature multidimensional and each estimate is often based on a summary of responses to several questions. A common metric does not apply between scales and domains (i.e. is 40 on a pain measure similar to 40 on a nausea measure in symptom burden?). In palliative care, where most patients are living with a progressive disease, improvement in overall condition cannot be expected, thus the 'improvement' may actually be nearly 'slowing down' or stabilization of symptom burden. The complexity of human biology may cause an increase in intensity in one symptom when another symptom is relieved. Furthermore, most patients have a mosaic of symptoms, which often needs broad interventions, and consequently one specific outcome may be difficult to identify.

Conclusion

QOL is a term with quite differing meanings, and new terms have been suggested in order to improve the terminology. Presently the term is preferably used in the broad meaning of overall QOL.

The term QOL instruments should not be used unless in the context of overall quality of life. PROs is the common term for all instruments assessing the patient's perspectives.

Multidimensional measures of HRQOL cover physical, psychological, and social aspects of life. In palliative care these measures have been criticized for not covering the existential and spiritual issues sufficiently. A series of measures for use in health care in general (generic instruments) and for use in specific diagnostic groups, such as cancer (cancer specific) and palliative care (palliative care specific), have been developed. A third category of instruments is the domain specific measures. The latter is developed for assessing specific symptoms or signs, such as pain, fatigue, depression, anxiety, physical function, spirituality, etc. The plethora of instruments is a challenge for the users of the instruments, the readers of scientific reports, and for the performance of meta-analyses.

Most instruments have been developed for use in research and may not be suited for use in daily clinical practice. Many instruments for measurement of the same constructs are available and validation has often been insufficient both in relation to the palliative population and on a more general level. However, ongoing efforts include multinational research collaborations in order to develop instruments that are based upon experts' evaluations and input from patients, that are computer based with better measurement capabilities, and that are well suited for use in clinics and research. In the meantime a reasonable strategy is to choose one of the most commonly used HRQOL instruments. Still, the content of a questionnaire always needs to be cautionary investigated to assure that it fits the purpose for the assessment in clinical research, in quality assurance, or in clinical practice.

Health services research in palliative care and end-of-life care

Tinne Smets and Luc Deliens

What is health services research?

In 1979, the Institute of Medicine of the United States stated that the aim of health services research is 'to produce knowledge about the structure, processes, and effects of personal health services' (Institute of Medicine, 1979). A broader definition was offered in 2002 by the American Academy for Health Services Research and Health Policy:

> Health services research is the multidisciplinary field of scientific investigation that studies how social factors, financing systems, organisational structures and processes, health technologies, and personal behaviors affect access to health care, the quality and cost of health care, and ultimately our health and well-being. Its research domains are individuals, families, organizations, institutions, communities, and populations. (Lohr and Steinwachs, 2002)

These definitions emphasize that health services research analyses many aspects of care and is a multidisciplinary field drawing on many disciplines, including biostatistics, epidemiology, health economics, medicine, nursing, psychology, and sociology (Ginzberg, 1991; Institute of Medicine, 1991; Scott and Campbell, 2002). It involves the systematic search for knowledge that will lead to improvements in the delivery of health care (Crombie and Davies, 1996).

Health services research in palliative care and end-of-life care

During the last century, achievements in public health and improved living conditions in developed countries have led to an increase in life expectancy and a significant rise in the proportion of the elderly in the population (Seale, 2000). Death usually occurs from chronic and degenerative diseases, and typically is preceded by a prolonged terminal illness (United Nations Population Division, 2002; Lunney et al., 2003). High illness burden prior to death may be ameliorated by interventions identified as palliative care or delivered by services that provide specialist palliative care. Palliative care could potentially benefit between 50% and 89% of the 50 million people worldwide who die annually (McNamara et al., 2006).

Ensuring equal and adequate access to quality palliative care presents a major public health challenge (Davies and Higginson, 2004). Public health policy is ideally informed by an up-to-date and unbiased evidence base, which can be provided only by health services research. Investigating and interpreting the use of palliative care, including its costs, quality, accessibility, delivery, organization, and outcomes, is important in determining the most effective public health strategies.

During the past two decades, clinical research relevant to the domains of palliative care has increased rapidly. The development of evidence-based guidelines, such as the European Association for Palliative Care (EAPC) recommendations on opioid therapy for cancer pain (Caraceni et al., 2012), exemplifies this trend. At the same time, rapid developments in health services research have generated complementary knowledge about the organizational aspects of palliative care and the experiences of patients and professionals involved in the services. Health services studies have evaluated the caregiving process and the feasibility and effectiveness of one or more particular service or intervention (Steinwachs and Hughes, 2008). Researchers in palliative and end-of-life care have examined topics such as need, access, and quality, and the feasibility, effectiveness and cost of palliative and end-of-life care services and interventions.

Studies of access to palliative care may expose possible disparities. The principle of equitable distribution of health care and the commitment to ensuring equitable access is widely acknowledged (European Union, 2000; Van Doorslaer et al., 2006). Equitable access is often defined as horizontal equity, which means that people with equal needs are treated equally (Wagstaff et al., 1991). Health services research has attempted to identify situations in which patients with specific palliative care needs are denied care on the basis of ethnicity, gender, age, socioeconomic status, educational level, or geographical isolation, or because of inadequate service levels (Scott and Campbell, 2000). For example, a retrospective cohort study in Belgium acquired data from a nationwide sentinel network of general practitioners to analyse end-of-life care in a nationwide representative sample of people who died non-suddenly in 2005–2007, and demonstrated that the less well-educated are disadvantaged in terms of access to specialist palliative care services and contacts with a general practitioner at the end of life compared with the better educated (Bossuyt et al., 2011); while they were no less likely to have a palliative treatment goal, they used multidisciplinary palliative care services less often, moved between care settings less frequently, and had fewer contacts with their general practitioner in the last 3 months of life. These type of data can be used to redress disparities in care through system-level changes.

Evaluation of palliative and end-of-life care services and interventions raises the question of whether the service or

intervention is feasible, achieves its stated goals and objectives, and is cost-effective. Although the development of palliative care services and interventions should be based on evidence that they will increase the likelihood of desired outcomes, clear information on feasibility and effectiveness is often lacking (Kaasa et al., 2006; Costantini and Beccaro, 2009).

Research designs for service evaluation of complex interventions

Palliative care services and interventions are complex and health services research must deal with their complexities (Costantini and Higginson, 2008). Most interventions are not single-component interventions, such as a drug therapy, but rather have several interacting components, such as care by different professionals or coordination in different health-care settings. Patient and family needs also change over time, further complicating the assessment of a range of possible outcomes in the target population (Campbell et al., 2000; Medical Research Council, 2008; Craig et al., 2008).

Practical guidance for developing, evaluating and implementing complex interventions comes from the Medical Research Council (MRC) in the United Kingdom. In 2000, the MRC published a *Framework for the Development and Evaluation of RCTs for Complex Interventions to Improve Health* (MRC, 2000) which was updated in 2008 as *Developing and Evaluating Complex Interventions: New Guidance* (MRC, 2008). According to the MRC framework, interventions should be developed and tested systematically using a phased approach (Campbell et al., 2000). In a preclinical phase, a researcher must identify evidence that the intervention might have the desired effect (Campbell et al., 2000); a review of relevant theory and empirical evidence may provide this. In phase I, the relevant components of the intervention are defined, often through qualitative research such as focus groups or case studies. Qualitative studies can also give insight into the barriers and facilitators to the eventual implementation of the intervention and help explain how it works. In phase II, the exploratory phase, the intervention and study design of the main trial are developed and the feasibility of delivering the intervention, and its acceptability to health-care providers and patients, can be tested. During this phase, the content of the control group also is decided and the outcome measures are piloted. Phase III is the main trial. Experimental designs such as randomized controlled trials (RCTs), cluster RCTs, or stepped wedge designs often are preferred for the evaluation of complex palliative care interventions (MRC, 2008). Phase IV involves examination of its implementation in practice and can explore the rate of uptake of the intervention, its stability, and the possible existence of adverse effects (Campbell et al., 2000). The four phases may not always follow a linear sequence (Craig et al., 2008).

Randomized controlled trials

RCTs are often considered as the gold standard for clinical trials (Cochrane, 1979; Elley et al., 2004; Davis and Mitchell, 2012) and informed consent by an individual patient aware of the random allocation is essential. The elements of this design may be difficult to implement in groups of patients with advanced illness who are receiving palliative care interventions. It may be difficult to obtain informed consent from people who are dying (Hardy, 2000) and random allocation of individuals to a study intervention or a 'usual care' or control group may not be possible when patients are receiving care on the same ward or by the same team. Contamination, that is, the risk that the demonstrated effect of the intervention will be weakened because control group patients unintentionally receive some or all of the intervention, is a significant concern when the intervention is complex (Elley et al., 2004). For example, if the intervention is the introduction of a palliative care service in a hospital or in a specific ward, all patients in the hospital or ward will potentially have contact with the intervention. Contamination can also occur during the delivery of the intervention, especially when it is related to the health-care provider's behaviour or a service's way of working (Elley et al., 2004), for example, when the intervention is aimed at improving patient/health-care provider communication. When random allocation of individuals is not possible or there is substantial concern about contamination, a cluster RCT design may be preferable (MRC, 2002).

In some situations, a conventional RCT is possible. For example, Temel et al. (2010) examined the effect of introducing palliative care soon after diagnosis on patient-reported outcomes and end-of-life care among ambulatory patients with newly diagnosed metastatic non-small cell lung cancer. Newly diagnosed patients were randomly assigned to receive either early palliative care integrated into standard oncological care or standard oncological care alone. The study found that those receiving early palliative care had a longer median survival, better quality of life, and fewer depressive symptoms than those receiving standard care. The study concluded that introducing early palliative care for this patient population led to important improvements in quality of life and mood.

Cluster randomized controlled trials

Cluster RCTs are a type of RCT in which clusters or groups of subjects rather than individuals are randomized (MRC, 2002). When randomization occurs at group or cluster level, all participants from the same cluster—for example, hospital ward, hospice, or family practice—are allocated either to the intervention or to the control group. Cluster RCTs are mainly used when delivery of an intervention is at the group level and outcomes are measured at the patient level (Elley et al., 2004).

The main advantage of the cluster RCT design is that randomizing a whole group of individuals reduces the risk of contamination; individuals from the intervention and control groups are less likely to have contact with each other (Elley et al., 2004). Another is that informed consent may be obtained not from the individual patient but for an entire cluster of patients from their 'cluster guardian' who decides whether the cluster as a whole should participate in the trial (MRC, 2002; Fowell et al., 2004, 2006). A 'cluster gatekeeper' takes responsibility for individual patients and can withdraw them from the trial if deemed necessary (Elley et al., 2004). A disadvantage of cluster RCTs is that individuals within the cluster are not independent from each other; for example, patients of the same family practitioner are more likely to share some characteristics and thus to respond to an intervention in a similar way than those who do not share those characteristics. The variation in outcomes between clusters is thus greater than would be expected in RCTs. The resulting loss of power can be avoided by using a larger sample than would be required in an RCT (Campbell et al., 1998; Elley et al., 2004).

One example of the use of a cluster RCT in palliative care is the phase III trial to assess the effectiveness of the Liverpool Care Pathway for the Dying Patient (LCP) performed by Costantini et al. (2011, 2014) in Italy. The LCP was developed in the United Kingdom to improve the quality of care in the last days of life and provides a comprehensive template of evidence-based multidisciplinary care. In this study, pairs of eligible medical wards from different hospitals were randomized to receive the LCP programme or no intervention. The main outcome measure was the difference in the overall quality of end-of-life care provided on the wards that received or did not receive the LCP. The cluster RCT showed that after implementation of the Italian LCP programme, no significant difference was found in the distribution of the overall quality of care toolkit scores between the wards in which the LCP programme was implemented and the control wards (Costantini et al., 2014).

Stepped wedge design

In a stepped wedge design, an intervention is rolled out sequentially to the individuals participating in the trial—as individuals or as clusters of individuals—at different time points (Brown and Lilford, 2006). The order in which the individuals or clusters receive the intervention is determined at random. By the end of the random allocation, all individuals or clusters will have received the intervention. Data are collected at each point when a new group, or step, receives the intervention (Brown and Lilford, 2006). To determine the effectiveness of an intervention, the data points in the control section of the wedge are compared with those in the intervention section (Brown and Lilford, 2006). This design is especially interesting when it is expected that the intervention or service will do more good than harm and denial of the service or intervention to the control group is deemed unethical, which is often the case in palliative care interventions for the dying.

One example of a study using a stepped wedge design is the multicentre, stepped wedge cluster RCT performed by Leontjevas et al. (2013) in the Netherlands. The objective of that study was to estimate the effectiveness of a structural approach to the management of depression in nursing home residents. This structural approach entailed the implementation of a multidisciplinary care programme called Act in Case of Depression (AiD). A network of nursing homes in the Netherlands was asked to enrol one dementia and one somatic ward per nursing home. In the wards, the nursing staff recruited eligible residents. The enrolled nursing home wards were randomly allocated to one of five groups and the intervention was implemented at different time points in each group. The primary outcome measure was the prevalence of depression in the wards using the Cornell scale for depression in dementia. The study found that in the somatic wards the intervention reduced the prevalence of depression but the effect was not significant in the dementia wards.

Observational designs

If an experimental approach is unnecessary, inappropriate, impossible, or inadequate, non-experimental designs, such as observational or before-and-after designs, can be considered (MRC, 2008).

In observational designs the researcher only observes and does not carry out any intervention. Observational designs include cohort studies, prospective as well as retrospective, cross-sectional studies, and case–control studies (Mann, 2003). Cohort studies are used to study incidence, cause, and prognosis. Because they measure events in chronological order, they can be helpful in clarifying cause and effect. Cross-sectional studies are used to determine prevalence. Case–control studies compare groups retrospectively to identify possible predictors of an outcome (Mann, 2003).

An example of an observational study is the phase II study performed by Follwell et al. in Canada, which evaluated the impact of an Oncology Palliative Care Clinic on symptom distress and satisfaction (Follwell et al., 2009). Patients with metastatic cancer who were newly referred to an Oncology Palliative Care Clinic received a consultation by a palliative care team and provided baseline data on the Edmonton Symptom Assessment Scale (ESAS) and the patient-adapted Family Satisfaction with Advanced Cancer Care (FAMCARE) scale. These measures were repeated after 1 week and after 1 month, and comparison of the latter scores to baseline demonstrated improvements in both symptom control and patient satisfaction.

Before-and-after designs can be controlled or uncontrolled. Uncontrolled before-and-after studies measure outcomes before and after some planned event or introduction of an intervention. Observed changes are assumed to be due to the intervention (Eccles et al., 2003). One of the main disadvantages of this design is that trends or changes in practice or in the law governing end-of-life care make it difficult to attribute observed changes to the intervention (Eccles et al., 2003).

In controlled before-and-after designs, a control group with characteristics similar to the group undergoing the planned event or intervention is identified and data are collected from both groups before and after the change. Analysis compares post-intervention performance in the intervention and control groups and observed differences are assumed to be due to the intervention (Eccles et al., 2003).

An example of a study which used an uncontrolled before-and-after design is Veerbeek et al.'s (2008) study of the effect produced by the LCP on the documentation of care, symptom burden, and communication in three health care settings in the Netherlands. During the baseline period, care in the dying phase was provided as usual. During the intervention period, the LCP was used for all patients for whom the multidisciplinary team had evaluated that the dying phase had started. The study demonstrated that the use of the LCP was followed by significantly more comprehensive documentation and lower average total symptom burden.

Challenges in the evaluation of palliative care interventions and services

Trials that enrol patients with advanced illness present unique challenges, both ethical and methodological (Grande and Todd, 2000). Studies that have attempted to do so have revealed problems, including failure to define the intervention, failure to determine appropriate outcome measures, problems with randomization of patients to intervention or control group, problems with achieving recruitment and minimizing attrition, failure to consider the heterogeneity of the patient group, and difficulties with obtaining informed consent (Rinck et al., 1997; Goodwin et al., 2002; Harding and Higginson, 2002; Higginson et al., 2003; Harding et al., 2005; El-Jawahri et al., 2011). Care must be taken to minimize these problems.

Defining the intervention

An intervention refers to 'a set of actions with a coherent objective to bring about change or identifiable outcomes' (Costantini et al., 2008). The experimental intervention and its alternative need to be clearly and precisely defined. This may be difficult with palliative care interventions, as palliative care is by nature holistic, multidisciplinary, and tailored to an individual patient's needs (Grande and Todd, 2000). It is possible that, alongside the intervention, other services with similar characteristics may be delivered to patients from both the intervention and the control group, and these confounding treatments may be difficult or unethical to eliminate or control (Grande and Todd, 2000). Patients who receive home palliative care services as the intervention may, for instance, also receive supportive care from their family physician, making it difficult to define the effect of the intervention. It is advised that clearly defining the intervention and control conditions in trials, and documenting additional care, may improve the quality of trials in palliative care and facilitate the interpretation of results (Rinck et al., 1997).

Determining outcome measures

The outcomes chosen for assessment must be relevant to the intervention or an effect cannot be demonstrated. Additionally, the timing of measures must be such that they pick up the effects of the intervention (Grande and Todd, 2000). It is suggested that the first assessment after baseline should be consistent with the shortest period likely to give a clinically significant effect (Jordhoy et al., 1999). Bad timing may lead to under-recording of the effects of the intervention. In one study (McWhinney et al., 1994), for example, pain was measured at baseline and 1 month later, but the possibility could not be excluded that a patient with no pain at baseline and at 1 month might have had a pain crisis in between that was successfully managed by the palliative care home support team (McWhinney et al., 1994).

The measurement of the outcomes can be difficult in palliative care research. Patients and caregivers may have difficulty completing questionnaires, which can result in a loss of data. For this reason, researchers may rely on proxy measures and retrospective accounts, but the validity of these assessments may be questioned (Jordhoy et al., 1999). Trained interviewers can also be used to collect data (McWhinney et al., 1994) by helping patients and caregivers to interpret the questions and by taking account of cognitive impairment, exhaustion and distress (McWhinney et al., 1994). For palliative care research, it is essential that means are explored to obtain valid outcome measurements; feasibility studies and extensive piloting are necessary.

Randomization

Randomization should always be considered as it is the most robust method of preventing selection bias (Eccles et al., 2003), but trials of palliative care pose particular ethical challenges in terms of randomization of patients. Denial of a service or treatment to the control group may be unethical, and a waiting list control does not solve the problem as palliative care patients are a vulnerable patient group for whom there is often no second opportunity to improve care. For patients who are aware that they are dying, even a short waiting list may be too long (Grande and Todd, 2000). As noted, the use of a cluster RCT design or a stepped wedge design may reduce these concerns by randomizing at a group level before

the patient is identified. In a cluster RCT, access to the service or intervention may be less related to study procedures than to other factors, such as the geographical location of the hospital or general practice, and in the stepped wedge design, all patients eventually receive the intervention.

Achieving recruitment and minimizing attrition

A large enough sample is needed to ensure that differences between the intervention group and the control group can be detected. However, screening and enrolling patients into palliative care trials can be difficult. Many patients understandably choose not to participate and physicians may be reluctant to enrol patients because they may find it hard to accept that cure is no longer possible (Grande and Todd, 2000). As a result, many patients who would otherwise be eligible to be included in a trial are left out. Patients may also die before they can enter the trial or before data can be collected (McWhinney et al., 1994). Furthermore, patients may be lost from the trial due to early death or withdraw due to progressive illness (Jordhoy et al., 1999). Problems with recruitment and attrition may lead to inadequate statistical power. These possible problems should be taken into consideration when calculating sample size.

Heterogeneity of the patient group

Patients requiring or receiving palliative care are a diverse group with different illnesses and different illness courses (Grande and Todd, 2000). In RCTs, it is assumed that the different characteristics of the study population are evenly distributed among the intervention and control group, and outcome differences between the groups result from the intervention. When variation within the study population is very large, however, there is a concern that randomization may not be successful in ensuring equal distribution of important variables among study groups. A possible solution is stratified randomization according to important variables. Particular key variables for stratification are those that the intervention seeks to address such as symptom burden (Grande and Todd, 2000).

Obtaining informed consent

Obtaining informed consent from patients for participation in palliative care trials can be challenging for several reasons (Hardy, 2000; Agar et al., 2013). First, patients may have impaired or fluctuating decision-making capacity. Second, palliative care trials may focus on times in the illness trajectory when consent is impossible to obtain due to concerns about an unethical imposition of requests unrelated to the provision of care; this may occur, for example, when a study focuses on patients perceived to be in the last hours of life. Third, patients may not always have full knowledge of their illness or prognosis, in which case seeking informed consent is a very sensitive issue. Finally, in the advance stages of illness, patients fatigue easily and may find it difficult to concentrate on processes like consent (Hardy, 2000; Agar et al., 2013).

There are several ways in which informed consent for trials in palliative care can be sought (Hardy, 2000; Agar et al., 2013). The gold standard is to ask the patient's informed consent at the time of enrolment in the study. If this is not possible, proxy consent can offer a solution when the patient is unable to give informed consent him or herself. Proxy consent, which has often been

used in dementia research (Karlawish, 2003; National Health and Medical Research Council, 2007), means that another person must be authorized to consent on behalf of the patient to the patient's participation in the research (Agar et al., 2013). When the trial focuses on times in the illness when the patient is unlikely be unable to give informed consent, informed consent can be obtained from the patient in advance, for instance, if the study focuses on symptoms in the last days or hours of life (Hardy, 2000; Agar et al., 2013).

Conclusion

Clear information about the effectiveness of services and interventions is often lacking in palliative care service planning. In order to stimulate growth and quality in palliative care research, good quality studies in health services research are needed. Health services research in palliative care covers topics such as palliative care needs, access to palliative care, quality of care and feasibility, effectiveness, and cost of palliative care services and interventions. Patients needing palliative care often have complex needs and require complex services and interventions; most interventions in palliative care are indeed complex interventions. The MRC framework for developing and evaluating complex interventions offers useful guidance for researchers.

To evaluate complex services and interventions, a wide ranch of study designs, both experimental and non-experimental, can be used. In planning a study of palliative care, researchers should also keep in mind possible difficulties with choosing and measuring appropriate outcomes, with the ethical problems raised by randomization of dying patients, with attrition due to early death or withdrawal of patients due to progressive illness, with obtaining informed consent from dying patients, and with the ethical aspects of imposing on people at the end of their lives.

Clinical audit in palliative medicine

Irene J. Higginson

Quality of care: a worldwide concern?

Quality and value for money in health care is now centre stage in many countries. Whatever the funding system, most developed countries place a high priority on 'consumer' choice and accountability. Scandals related to poor care continue in many countries, higher public expectations, increased health-care spending, and the move towards quality service in many public and private companies have all heightened the desire to introduce quality assurance, clinical audit and evaluation into clinical care (Shaw, 1980a–1980e; Selman and Harding, 2010; Eastman and Martin, 2012) The move from palliative and hospice care from being a concern of primarily the voluntary and charitable sector, to the greater involvement of public and, increasingly, private sector services bring with it a growing need to continuously monitor quality through clinical audits. Audits allow clinicians, managers, and governments to standardize practice and support 'best' possible practice (Shaw, 1988, 1989, 1990). Audit data also can be the foundation for future research—testing methods, identifying potential recruits, or better understanding the focus of research (Currow et al., 2010; Evans et al., 2013; Higginson et al., 2013).

Although many terms in the quality dictionary are new, many of the ideas, such as clinical review, are not. The history of quality improvement and audit can be traced back as far as 1700 BC in Egypt when King Hammurabi (the King who proposed the code of 'eye for an eye') introduced penalties for different degrees of 'surgical incompetence' (Rosser, 1985). This included a proposal that: 'if a doctor operates on a patient and the patient dies, the doctor's hand will be cut off' (Rosser, 1985). In 1518, the Charter of the Royal College of Physicians included: 'to uphold the standards of medicine both for their own honour and public benefit'. The General Nursing Council (GNC) was established in 1919 to 'monitor nurses' practice and conduct'. Florence Nightingale was one of the first clinicians to insist on measuring the outcome of care for her patients, to evaluate treatment. Grand rounds, postgraduate lectures, and clinical presentations all contributed to the review of medical and nursing performance.

References in the medical and nursing literature to quality assurance and clinical audit began in the late 1970s. They continue to rise, although the terms have changed over time (Fig. 19.9.1), including terms such as continuous quality improvement, clinical governance, standards, and preferred practices (Shaw, 1980a, 1988, 1991; Higginson, 1994). The new emphasis on clinical audit, quality improvement, and governance has brought four main differences:

- Explicit criteria for good practice should be applied by all clinicians rather than those in exemplary centres
- All patients in care and all centres should be included in quality monitoring rather than a few 'interesting' cases
- Patients and their families should be able to seek empowerment
- Funding or accreditation may be withheld from those units which do not comply with quality standards or which are found to be ineffective or inefficient (Shaw, 1980a; Higginson, 1994; Higginson and Bruera, 2002).

Why perform clinical audit in palliative medicine?

Palliative care arose out of a desire to improve the quality of care for patients with advancing disease and their families. This was based on evidence that care for people with progressive illness, and care for the imminently dying, was lacking (Higginson and Evans, 2010). Many of the early evaluations of palliative services compared hospice, home, and hospital care (Higginson et al., 2003) and some sought to influence those working in oncology and other professions (Buckingham et al., 1976; Higginson, 1993, 1994; Ling, 2000; Lee et al., 2001). Later, palliative care often led the way in developing ways to examine the quality of care generally and its core precepts were seen to align with public preferences. A recent survey of 9344 citizens across Europe found that respondents highlighted (a) a need for improved quality of end-of-life and palliative care, and access to this care for patients and families and (b) the recognition of the importance of death and dying and holistic care including comfort and support (Daveson et al., 2014).

Palliative and hospice care have grown rapidly such that there are services in all countries of the globe. This growth has been accompanied by the development of many tools and measures to assess and audit the quality of palliative care. The use of these tools is becoming more common and national and international guides for quality are now available (Dudgeon, 2007; Ferrell, 2007). There is now evidence demonstrating the effectiveness of palliative care and hospice services, based on empirical studies in different sites and systematic literature reviews (Higginson et al., 2003; Higginson and Evans, 2010; Gomes et al., 2013a). Although the importance of this

Audit by any other name: combine terms from the table below

work is undeniable, the lack of comparison of different models of care has been criticized (Higginson and Evans, 2010). Practice still varies from one country to another, from one part of a country to another, and from one service to another, even in simple aspects such as staffing levels and mix within a hospice or home care team, the catchment populations, the operational policies and the throughput (Higginson and Evans, 2010). Even today, we need to know which models of care work best and for which types of problems palliative care is most effective. Those providing and those who resource palliative services need to know which interventions and in what combination work best, for what kinds of patients and families, and in which type of localities. Research is important in discovering some of these aspects, but equally audit or quality assessment, is important to identify what works best, for whom and when.

Hospices and palliative services bring new therapies, such as new treatments for symptoms, support and counselling services, or complementary and alternative medicine therapies. These new therapies must be evaluated and audited to determine if and in whom these are useful. Otherwise hospices' resources and the patient's time will be wasted. There is a great danger on concentrating on only current concerns without reviewing previous failings and using those findings to plan improved care in the future.

Clinical audits have been slow to materialize in some settings. Antipathy to the approach is based on various arguments, such as:

- There is no problem, since the high quality of palliative care is evident, as shown by thank you letters

- Palliative care is self-auditing, because staff spend time with patients and families

- The outcomes of palliative care cannot be measured—they are too complicated or intangible

- Measuring more simple outcomes of palliative care, such as pain or symptom control, is not enough, and until we can measure everything, audit should not be attempted

- Resources, information, and time are not available

- Audit looks back at practice which has gone, not the problems which lie ahead.

None of these arguments can be supported by evidence. Numerous audits and quality assessments of palliative care have helped to improve care (Charlton et al., 2002; Cooper and Hewison, 2002; Galvin, 2002; Higginson and Bruera, 2002; Ackroyd, 2003; Burt et al., 2004; Galbraith and Booth, 2004; Hunt et al., 2004; Newbury and Hatherell, 2004; Bausewein et al., 2005; Brandt et al., 2005; Currow and Abernethy, 2005; Harding and Leam, 2005; Morita

et al., 2005; Veerbeek et al., 2006; Godfrey and Poole, 2007; Kaasa et al., 2007; Le and Ashby, 2007; Payne, 2007; Amigo et al., 2008; Currow et al., 2008a, 2008b; Deane et al., 2008; Eisenchlas et al., 2008; Miller and Hopkinson, 2008; Morita et al., 2008; Tsai et al., 2008; Eagar et al., 2010; Harding et al., 2010; Nadimi and Currow, 2011; Benitez-Rosario et al., 2012).

Audit has been recommended in national strategies (Kaasa et al., 2007) and has had major impact in the development of hospice and palliative care in much of Europe, Canada and Australia. The results have been used in the following ways:

- Assisting the development of local and regional palliative care programmes.

- Providing outcomes information that have allowed the programme leaders to advocate for increased funding.

- Demonstrating the effectiveness of different interventions and allowed for increased patient referrals

- Reviewing the quality of work and identification of ways to improve it so that services are planned to ensure future patients and families will not suffer the same failings.

- Identifying areas where care is effective and where it is not; this allows services to be better targeted and will mean that patients and families receive the most up-to-date care.

- Developing procedures for the systematic assessment of patients and families to ensure that key aspects of care are less likely to be overlooked, communication between patients and families and professionals is not overlooked and problems identified by patients and families are brought to the attention of staff, there is a more holistic approach to care, and new staff have a clearer understanding of what should be assessed and how appropriate assessments are done.

- Assisting in the development of predictive models that promote early referral of patients or families who may experience problems.

Audit or clinical governance can help most patients and families receiving palliative care, because it looks at routine practice, rather than at a few 'special' cases. Quite apart from mistakes, suboptimal care may be due to professional or administrative problems which tend to escape anecdotal case reviews. Audit also is important for education and training, because the structured review allows analysis, comparison, and evaluation of individual performance; it promotes adherence to local clinical policies and offers opportunity for publication of results. Educational programmes can be constructed to meet the demonstrated needs of individuals or groups. Increasingly, audit, clinical governance, or quality review are required for the recognition of training posts and for the revalidation of doctors. Royal Colleges and Faculties increasingly seek evidence of formally organized review and could withdraw recognition from departments that do not provide this.

Audit is important for those who resource palliative care, such as commissioners, primary care trusts, and health-care insurance agencies, because it provides tangible evidence that the service is seeking the most effective use of existing clinical resources and aims to improve the quality of care. This is increasingly important when competing for health-care contracts (Clark et al., 1995). Requirements for audit and the implementation of research findings may well be included in such contracts (Clark et al., 1995).

The costs of not auditing are as important as the benefits of auditing (Shaw, 1980a–1980e; Higginson, 1994). In the absence of review, there is a risk that inappropriate treatment may be undertaken, uncontrolled symptoms may cause admission to hospice or hospital, or delay discharge, or unnecessary services may be delivered. All this activity wastes the patients' and families' time and resources, as well as staff time and resources.

Clinical audit takes time and resources (Shaw, 1980a–1980e; Higginson, 1994). These should not be underestimated. Indeed, it may be impossible to undertake audit if a service is struggling, with insufficient numbers of staff to give even basic care such as washing and administering drugs. Perhaps the audit here is to show simply that the service cannot even measure and assess a patient's needs properly. Indeed, simple assessments, such as whether follow-up occurs, can be useful in assessing practice (Selman and Harding, 2010). The resources needed for audit and quality assessment can include:

◆ Time from all staff to prepare for audit, to agree the standards or topic and to review the findings

◆ Time from some staff to carry out the audit and to analyse its results and document the findings and any recommendations

◆ Commitment from *all* staff, managers, nurses, doctors, etc. to consider the results and act upon them

◆ Resources to pay for the staff time involved, plus any other analytical or computing support needed.

Computers are not necessary for audit, but they are increasingly becoming part of routine health care. A number of computer programmes are available for palliative care and other services, many from commercial companies. The audit measures can be included within these programmes, and increasingly application in clinical practice is aided by staff or patients using mobile computing devices. However, if the audit is small or in its early stages, too rigid use of computers by inexperienced staff can be a hindrance, because the need to update the computer delays the evolution of the audit.

The costs of audit mean that it is important to ensure that the audit itself is as effective as possible. What is the purpose of collected audit data if the changes are not acted on? Mechanisms to review the audit and to ensure it is effective are discussed in a later section.

What do we mean by quality?

Quality, as defined in many dictionaries, pertains to 'degree of excellence' or 'general excellence'. But what constitutes excellence in the context of a service, who defines it, and what components should be addressed? For example, should 'excellence' be limited to clinical skills, or should it encompass broader aspects, such as whether the service reaches all those in need? Surely, when measuring quality of a service all the features and characteristics that bear on its ability to satisfy the stated or implied needs of the users of that service should be assessed. Quality in health care is a multidimensional concept, and as such, a multidimensional approach to measurement and assessment of that quality is required (Donabedian, 1966, 1976, 1981a, 1997, 2005).

Numerous authors have identified some of the dimensions that should be included when assessing the quality of a service. For example, Maxwell identifies the following as dimensions of care that need to be measured when monitoring quality (Maxwell, 1984, 1986, 1992):

◆ Effectiveness

◆ Acceptability

◆ Efficiency

◆ Access

◆ Equity

◆ Relevance.

Black agreed with all these, but added a further dimension: humanity, a dimension which would be particularly important for palliative care services (Black, 1990).

So how do we determine whether we are offering a good quality service if we have to consider all these dimensions? One method is to conduct a programme of review and improvement of the service, a process that incorporates clinical audit, quality assurance and quality improvement.

How do we assess the quality of palliative care?

Donabedian and others have translated the assessment of the quality of health care into:

1. Structure/or inputs: resources in terms of manpower, equipment and money

2. Process: how the resources are used (such as domiciliary visits, beds, clinics, drugs or treatments given)

3. Output: productivity or throughput (such as rates of clinic attendance or discharge, throughput—rate that patients are seen)

4. Outcome: change in health status or quality of life that can be attributed to health care (Donabedian, 1978, 1980, 1981b, 1997, 2005).

This model is built on manufacturing industry and, despite limitations discussed below, it has value in that it defines the steps in which health and social care are delivered.

Structural aspects influence the process of care so that its quality can be either diminished or enhanced. Similarly, changes in the process of care, including variations in its quality, will influence the output, and in turn, the effect of care on health status and outcomes. Thus, there are functional relationships (Fig. 19.9.2).

Structure is easiest to measure because its elements are the most stable and identifiable. However, it is an indirect measure of the quality of care and its value depends on the nature of its influence on care. Structure is relevant to quality in that it increases or decreases the probability of a good performance. Process and output are closer to changes in the health status of individuals and their measurement reflects the most immediately discernible attributes of care activities. However, they are only valuable as a measure once the elements of process are known to have a clear relationship

structure → process → output → outcome.

Fig. 19.9.2 Functional relationship.

with the desired changes in health status. Outcome reflects the true change in health status, and thus is the most relevant for patients and society. However, it is difficult to eliminate other causes for change, such as prior care or external events. A useful approach is to focus on the difference between the desired outcome and the actual outcome. Services can then identify whether or not their goals are being achieved and investigate any failings.

Organizational audits usually assess the structure and process of care, whereas clinical audits often measure the process and outcome of care. Although structure is easiest to measure it is furthest from influencing change in the patient and family. Outcome is most difficult to measure but is of direct relevance to the patient and family. Standards of structure or process are most useful when these are of proven effectiveness, or if there is an overwhelming consensus that these are desirable. Structure, process, and outcome measures which have been either used or advocated to assess palliative care are shown in Table 19.9.1.

Stewart et al. have extended the model, subdividing the 'structure' elements into (1) personal and social environment of the patient and family and (2) the structure aspects of care (Stewart et al., 1999). They also subdivided the outcomes into (a) satisfaction and (b) quality and length of life. These subdivisions are consistent with the earlier model of Donabedian, and those proposed for palliative care audit in the United Kingdom. However, Stewart et al.'s differentiation of the personal and social environment is a useful demonstration of how audit results may be different because of different settings, or with a different 'case mix' where patients and families have differing conditions or problems. Casarett et al. have built further on this model, proposing a minimum data set (Casarett et al., 2006).

A rose by any other name would smell as sweet: the evolving terms—audit, quality improvement, governance?

Over the last 30 years, it has been interesting to observe how different terms have come in and out of vogue to describe the evolving approaches to assessing and ensuring the quality of health care. There are also differences among countries. Somewhat disappointingly, the literature in one country tends to ignore audit and quality improvement initiatives in another, thereby reducing the chance to learn. In the United Kingdom and many other European countries, clinical audit (as opposed to financial audit, concerned only with financial matters), became the initial term of choice. Later this was accompanied by quality assurance (which tended to include a programme of several audits, all working together). Such a programme was similar to the development of total (or continuous) quality improvement in the United States and many other countries, which incorporated a cycle called Plan, Do, Study, Act. Some of the widely accepted definitions are shown in Table 19.9.2.

There are elements common to all types of clinical audit or quality review. These include systematic assessment in a cycle that includes the monitoring of care, review of results, and change to improve practice (Fig. 19.9.3). The cycle is repeated and the process should become part of the organization's culture. Practice changes usually are made to be consistent with standards of care that are set locally or nationally, but it is possible to enter the audit cycle at any point; standards can be developed after practices are observed and change is made based on the results.

Table 19.9.1 Aspects of care that could be measured to assess structure, process, output or outcome in palliative care

Type of measure	Examples
Structure	Values or aims of the service
	Financial resources
	Home care/hospital/hospice services
	Day hospice places
	Number of staff or services per cancer patient in the population
	Staffing mix, grades
	Number of staff per patient
	Drugs and equipment available
	Building design
	Physical environment—e.g. safety, pleasantness of surroundings
Process	Number of visits
	Number of admissions
	Procedures followed
	Documentation
	Time taken in a visit
	Policies and procedures for staff training and working
	Mechanism for handling complaints and the documentation of this
	Adherence ethical and legal codes
	Staff support given
Output	Rate of discharge
	Number of completed consultant episodes
	Throughput
	Rate of equipment given out
	Drugs given
	Well-coordinated care—telephone communication etc.
	Supply of medicines after discharge
	Completed patient management plans
	Early arrival of discharge information to GP
	Satisfaction of professionals referring to the service
Outcome	Reduction in distressing symptoms
	Improved mental health of patient and carer
	Patient and carer satisfaction
	Satisfied with place of care
	Open and honest communication as the patient wishes.
	Resolved communication, fears, grief, anger
	Resolved need to plan future events—e.g. funeral or meetings
	Good use of remaining time
	Any spiritual problems resolved or fulfilment
	Reduced carer strain
	Improved carer health
	Resolved grief after death (if appropriate)

Table 19.9.2 Common definitions: audit and quality assurance

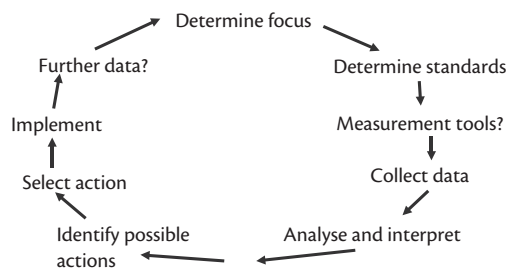
Term	Definition
Medical audit	The systematic critical analysis of the quality of medical care including the procedures used for diagnosis and treatment, the use of resources, and the resulting outcome and quality of life of the patient (Higginson, 1994)
Clinical audit	The systematic critical analysis of the quality of clinical care including the procedures used for diagnosis and treatment, the use of resources, and the resulting outcome and quality of life of the patient
	Clinical audit is like medical audit but involves all professionals and volunteers rather than only doctors
Nursing audit	The methods by nurses compare their actual practice against pre-agreed guidelines and identify areas for improving their care
Prospective audit	The standards and measures are recorded on patients and their families during their care
Retrospective audit	This looks back at the care of patients who have been discharged or have died, and the standards are applied to the information available from case notes or by asking families about the care after the patient has died
Quality assurance	The definition of standards, the measurement of their achievement and the mechanisms to improve performance
	The quality assurance cycle is as for medical audit or clinical audit. However, quality assurance implies a planned programme involving the whole unit or health services. Clinical or medical audit is usually described as one part of a quality assurance programme


Fig. 19.9.3 Cycles of clinical audit, quality improvement, and performance measurement.

Some common distinctions

Clinical audit

Clinical audit is the systematic critical analysis of the quality of clinical care (Higginson, 1994). It may focus on the procedures used for diagnosis and treatment, the use of resources, or the resulting outcome and quality of life for the patient. It can be prospective, where the standards and measures are agreed at the start and are recorded on patients and families during their care, or retrospective, which looks back at the care of patients using either the clinical notes and extracting the information or by asking families. Although early forms of audit involved only single professions—for example, medical or nursing audit (Table 19.9.2)— it is now widely accepted that audit in palliative care should be multiprofessional, to reflect the multiprofessional nature of care.

Organizational audit

The Kings Fund Centre in London originally described organizational audit as the developmental and voluntary stage towards accreditation (Higginson, 1994). Accreditation schemes exist in many countries and usually operate nationally. The audit focuses on the organization and compares specific aspects against agreed standards. These standards usually consider only the structure and process of care, and may try to identify administrative delays, uncoordinated care, poor environment or sign-posting, poor staff training, etc. Organizational standards need to be straightforward enough to be monitored by an external surveyor.

Quality assurance and total quality management programmes

Although there are various definitions for quality assurance, a widely accepted one is the 'definition of standards, the measurement of their achievement and the mechanisms to improve performance'. Clinical audit lies within the frame of quality assurance. Audits may involve the review of the quality of a local clinical practice on a regular basis, for example, through internal 'peer review' by practising clinicians.

Total quality management is a recent term, which has been defined as a strategy to get an organization working to its maximum effectiveness and efficiency. It has been facilitated by closer working relationships between clinicians and managers (Higginson, 1994), builds on the other definitions, and switches the focus from quality practised within professionals to quality within the whole organization. Thus, clinical audit would lie within a total quality management programme. It also introduces the concept of managing the quality process, such as cataloguing reports of local quality initiatives (Higginson, 1994) and using managers to ensure that improvements in quality occur.

Clinical governance

Clinical governance has developed recently because of concerns about variations in clinical practice, particularly assessment, diagnosis, and prescribing. This is of increasing concern in modern medicine because of the rapid development of diagnostic investigations and treatments that may have potentially dangerous effects if not carried out properly. Clinical governance programmes assess what doctors (and most recently nurses) do, and examines both their training and continuing professional development, and all components of their practice. It aims to ensure and develop the practice of all clinicians. Participation in clinical governance is already required of many health-care services, and will soon be required to ensure the revalidation of doctors in many countries (Ferrell et al., 2007).

Who carries out clinical audit and what is measured?

The different approaches to audit and the assessment of quality can be categorized according to two axes. The first is defined by the identity of the auditor. This could be clinicians, managers, or an organization. The second is defined by the object of the audit,
Fig. 19.9.4 Range of activities possible within clinical audit.
Fig. 19.9.5 Effect of activities within clinical audit.

whether it focuses on the care of an individual or a few patients, or on the whole organization or population. Common forms of audit according to these two axes–internal versus external and individual versus organization/population—are shown in Fig. 19.9.4. The type of audit should be determined by the setting and goals. Those focused on improving specific practices often are more oriented towards internal and individual assessment. They are more likely to be educational and voluntary. Those that are external and focused on the overall clinical quality of care are more likely to rely on organizational or environmental standards, determine whether professionals are employing proven high quality treatments, examine structural elements such as staff mix, and note whether quality activities such as a clinical audit programme is in place. These types of audits are more likely to be mandatory and to provide funding or accreditation (see Fig. 19.9.5).

Applying clinical audit to palliative medicine

Clinical audits and other quality activities should be actively embraced by those working in palliative care. Specific steps should be taken to implement the audit processes:

1. Know what we are trying to achieve: goals, standards, and desired outcomes

The definitions of palliative care and palliative medicine provide good guidance on the goals of palliative care, and the appropriate outcomes that might be measured in clinical audit. These include aspects of pain and symptom control, improving the quality of life for the patient, relieving fears and anxiety, and caring for the family members or carers. Therefore, in analysing the goals or standards of care, many have audited their effectiveness in improving outcomes such as control of symptoms, their effect on a patient's quality of life or psychological well-being, or the patient's or family members' satisfaction with care. A European-wide survey of public attitudes recently found that pain, breathlessness, and burden to others were top concerns that needed to be addressed near the end of life (Bausewein et al., 2013).

Specialists in palliative care often focus on end-of-life care and those undertaking clinical audits may choose to evaluate specific concerns encountered in the care of the dying. Kellehear described the features of a modern 'good death' as 'awareness of dying, social adjustments and personal preparations, public preparations (legal, financial, religious, funeral, medical), work or activities reduced, and farewells' (Kellehear, 2000, 2001, 2009) Singer et al. identified five domains of quality end-of-life care: receiving adequate pain and symptom management, avoiding inappropriate prolongation of dying, achieving a sense of control, relieving burden, and strengthening relationships with loved ones (Singer et al., 1999, 2000). Payne et al. identified similar concerns from family members (Payne et al., 1999). These definitions might suggest audit of aspects of patient and family awareness of the illness or their planning of personal and public preparations, and such aspects have been included in some measures, such as the Support Team Assessment Schedule (Higginson et al., 1992; Bausewein et al., 2011a).

In many countries, the role of palliative care in supporting, advising and educating other professions is stressed. For example, family practitioners and hospital clinicians may identify educational needs for symptom control and patient and family support. Therefore, another form of audit could examine the educational and supportive role of palliative care services.

Poor communication is a frequent cause of stress for patients and families. Doctors and nurses need to communicate well with patients and their families rather than withdrawing or appearing hurried or abrupt in their manner. Communication also is needed among professional staff caring for the patient and family member, to ensure liaison and to prevent duplication or delay. Usually patients and family members want to be involved in decision making, and patients want their family members to make decisions when they are not able to, although this wish is not universal (Daveson et al., 2013, 2014). These aspects are also goals suitable for audit.

Total pain has been described as including physical, emotional, social, and spiritual components. Although the earlier discussions have covered the emotional and physical aspects of palliative care, it is also important to consider audit of the social and spiritual aspects. Social aspects might include whether the patient and family have sufficient practical and financial support to remain at home, or whether they have been cared for in their place of choice, usually home (Gomes et al., 2013b). Spiritual audit might consider whether patients are able to raise aspects of spiritual

concern to them and find a mechanism to relieve problems, or whether patients are in any form of spiritual crisis. Guidelines for spiritual practice have been developed, and several of the more recent measures that can be used for audit include spiritual aspects, measuring items such as peace and feeling good about self (Selman et al., 2010, 2011).

There are also simple goals, such as place of death, or meeting other patient or family preferences, or access to services by certain patient groups (such as those from ethnic minorities, or non-cancer conditions) that might be suitable for audit. In auditing the processes and outcomes associated with these goals, clinicians must recognize and accommodate variation. For example, although around 70% of patients would prefer to die at home, increasingly patients choose hospice as a second choice, wishes are very individual, are little understood in some sections of society and are altered by experience (Gomes et al., 2013b). Thus this indicator, like other process indicators, needs to be reviewed cautiously.

How can these goals be turned into standards? Any goal or standard which is set must be measurable, sufficiently challenging but achievable. It would be unrealistic to set a goal or standard that all patients would be free from pain, but it would be reasonable to set a goal of what proportion of patients' pains might be controlled and in what circumstances pain might be uncontrolled. A baseline could be established from current practice. Standards of action when pain is uncontrolled could be audited. Such an approach has been used in developing audit programmes in many countries, including Africa (Harding et al., 2010; Selman and Harding, 2010).

When standards are ill-defined, achievement of goals can be compared across services. This approach has been used successfully by the Australian Palliative Care Outcomes Collaborative, which has compared data on the assessment of symptoms and concerns using the Palliative care Outcome Scale (Eagar et al., 2010).

2. Have a way of assessing and re-assessing the quality of care

For all of the above aspects, measurement tools or indicators are needed. There are now a number of these available in palliative care which have been validated to different degrees. The Association for Palliative Medicine of the United Kingdom established a working party to review these and subsequently published a 'which tool' guide (Clinical Effectiveness Working Group et al., 2002). The group carried out a MEDLINE search to identify potential measures and to check whether they had been used in more than one centre. Then the group provided a preliminary guide as to whether they would recommend the tools in research or clinical audit palliative care.

More recently, a Europe-wide project PRISMA surveyed clinicians internationally on outcome measures used in clinical audit, clinical practice and research, and examined the barriers to using outcomes in routine clinical practice and for audit (Bausewein et al., 2011b; Harding et al., 2011). Key findings were that:

◆ There was disharmony in the tools used. Of the 311 participants who completed a survey, 99 tools in clinical care and audit, and 94 in research, were cited by fewer than ten participants (Harding et al., 2011).

◆ Time constraints, burden, and lack of training and guidance were the main reasons for not using outcome measures in practice. Participants expressed the need for more guidance and training in the use of outcome measures in clinical practice and audit (Bausewein et al., 2011b).

◆ In clinical care and audit, assessment of the patient's situation, monitoring changes, and evaluation of services were the main reasons for use of outcome measures (Bausewein et al., 2011b).

◆ The most common outcome measures used in clinical practice were, in order of frequency of use:

• the Karnofsky Performance Status or Palliative Performance Scale (both measures of functional activity/consciousness)

• the Edmonton Symptom Assessment System (ESAS)

• the Palliative care Outcome Scale (POS)

• the Symptom Distress Scale (SDS)

• the Support Team Assessment Schedule (a precursor to POS).

Some measures used in clinical audit have been validated in many languages and settings. Table 19.9.3 shows examples of these. The two most common multidimensional measures used in clinical audit, the ESAS (Bruera et al., 1991; Amigo et al., 2008; Richardson and Jones, 2009; Bergh et al., 2011; Carvajal et al., 2011; Selby et al., 2011; Watanabe et al., 2012a; Hui and Bruera, 2013) and the POS (see Box 19.9.1 for an example of one item in this measure, pain) (Hearn and Higginson, 1999; Bausewein et al., 2005; Brandt et al., 2005; Stevens et al., 2005; Siegert et al., 2010; Higginson et al., 2012) (see also <http://www.pos-pal.org>) have both had extensive research into their validity, reliability, and factor structures, as well as translations and cultural adaptations in many languages. This includes determining factor structures, clinically important differences, and use for screening for depression and other symptoms (Siegert et al., 2010; Bergh et al., 2011; Selby et al., 2011; Zimmermann et al., 2011; Harding et al., 2013; Watanabe et al., 2012b; Hui and Bruera, 2013; Saleem et al., 2013). POS builds on an earlier widely used measure, the Support Team Assessment Schedule (STAS) (Box 19.9.2) but was designed for use by patients as well as staff and families.

An alternative to multidimensional assessment is audit of single symptoms or other problems, for example, constipation, communication, or access to care. This is called topic review. Other approaches are also possible, although seldom used. Box 19.9.3 reviews these.

In contrast to the use of these measures to perform internal audits of individual patient care issues, other strategies often are used for organizational audits or peer review systems. These have tended to employ indicators that can be used in inspections of services, and concentrate on the structure and process of care, such as:

◆ Service values—a statement of service values and objectives related to the palliative care service guides the organization and delivery of high-quality care

◆ Organization and management—the palliative care service or Organization is managed efficiently to ensure patients and families receive suitable and effective multidisciplinary care

◆ Organizational and operational policy—Organizational and operational policies reflect current knowledge and principles and are consistent with the requirements of statutory bodies, purchasing authorities and service objectives

◆ Physical environment for care—the physical environment is safe and accommodates individual and shared needs

Table 19.9.3 Common outcome measures used in clinical audit

Measure, scale or tool	Used in . . .	Strengths	Limitations	Useful for: Clinical—☆ Research—▲
Karnofsky Performance Status (KPS) Scale	All settings	Quick and widely used	Assesses only function	☆▲
Edmonton Symptom Assessment Scale (Aaronson et al., 1993)	All settings	Simple and short, can be used either by patient or with nurse assistance, widely used and validated	Potential bias introduced by change in the person recording the answers as care continues. Patient may have wider concerns than those included	☆▲
POS—Palliative care Outcome Scale (POS) (Higginson et al. 1999; Hughes et al. 2001)	All settings	Simple and short—has patient completion, family completion and staff completion versions; tested for validity and reliability, has items for individual patient generation	Patient may have wider concerns than those included	☆▲
Support Team Assessment Schedule (STAS) (Cartwright 1990; McGee et al., 1991; Finlay, and Dunlop 1994; Hearn and Higginson 1999)	Used by community palliative care teams, hospital teams, day care, inpatient units and hospital at home services	A wide ranging checklist looking at clinical and communication issues; available in other languages and has been modified with additional specific items	Teams need to actively use this questioning each section, not just ticking boxes; professional completion. Now often replaced by shorter POS, although not all aspects included in POS	☆▲
PACA—Palliative Care Assessment (Hearn and Higginson 1999)	Hospital palliative care team and outpatient	Short and relatively simple to use	Professional completion. Not so widely used	☆
EORTC—European Organisation for Research into Treatment of Cancer—QLQ C30 (Cella, and Tulsky 1990; Cella 2004)	Developed for chemotherapeutic cancer trials—lung cancer patients; work of palliative module underway	Reliable and valid in research settings, broad ranging	Functional questions may cause distress if asked repeatedly	▲
FACT, Functional Assessment of Cancer Therapies	General cancer settings in United States, especially research studies—has a palliative module	Major validation programme	Use in palliative care not yet widely reported	▲
McGill Quality of Life Questionnaire (Cohen et al. 1995, 1997; Ellershaw et al. 1995)	Advanced cancer and HIV patients at home or in-patient palliative care unit	Includes an existential domain, as well as symptoms and psychological issues	Not been widely tested in UK settings	▲
Symptom Distress Scale	Life-threatening cancer and heart disease	Some validation; looks at symptoms and mood in relation to quality of life	Patient completion in presence of interviewer	▲
Other possible audit measures—usually more orientated to process of care				
Proportion who die at home	Used by health authorities to monitor overall care	Quick and easy to measure and aggregate. Easy to make comparisons	Home death may not have been patient choice. May be distorted by lack of appropriate inpatient provision	
Proportion who die in their place of choice	Used by some palliative home care and primary care teams.	Reflects patient choice and individual wishes	Difficult to get information in some circumstances, choice may change over time	
Proportion of final weeks spent at home	A proxy measure that can give some indication of the availability of community support services	Quick and easy to measure and aggregate. Clear operational definitions allow valid comparisons between districts	May be distorted by lack of appropriate inpatient provision	

◆ Self-determination and climate for care—the caring environment for patients and families is conducive to independence, self-esteem and participation in daily life

◆ Direct patient and family care—professional staff manage to ensure that patient and family needs are assessed, planned, implemented and evaluated on an individual basis

◆ Multidisciplinary working and team work—a range of skills is available to meet service goals, and specific contributions are identified and integrated

◆ Staffing and skill mix—good employment practices are in place and staffing levels are systematically determined in order to meet service needs

Box 19.9.1 Definition and ratings of Palliative care Outcome Scale (POS) item 'pain control'

Over the past *3 days**, have you been affected by pain?

0—Not at all, no effect

1—Slightly—but not bothered to be rid of it

2—Moderately—pain limits some activity

3—Severely—activities or concentration markedly affected

4—Overwhelmingly—unable to think of anything else

* Note—the time period can be varied.

Box 19.9.3 Types of audit: an appraisal of their uses in palliative care

Key indicators

These can be based on the structure or process of care, as in organizational audit or can be based on clinical indicators, such as in clinical audit. In organizational audit the indicators are reviewed by inspection, in clinical audit they are reviewed by the clinical team (see Fig. 19.9.3 and Fig. 19.9.4).

Routinely collected data, such as throughput, visits, or re-admission rates can be used in some areas of health care, but in palliative care these may not be appropriate and the clinical record may have to be amended to include relevant items. In clinical audit, a few key indicators are chosen and recorded prospectively and examined after a period of care. In organizational audit or peer review the survey team ask for information about the indicators and then seek evidence of these. In clinical audit, measures such as those shown in Table 19.9.3 are used.

Topic review

A topic is chosen and reviewed prospectively or retrospectively. Although the latter often revels inadequacies in the clinical records it is often valuable in providing a baseline for later comparison. Examples of topics are medical records and letters, referral or admission procedures, control of a particular symptom, prescribing practice, or the diagnostic procedures used.

Random case review

Here notes are selected at random and critically reviewed by doctors not involved in that person's care. This method may lose direction if the aims and criteria for quality are not clear. One way to focus the audit is to develop a previously agreed checklist for use in the critical review. The method can be linked with key indicators—a random sample of notes are examined for the key indicators.

Patient or family satisfaction

The simplest method is to analyse patient and family complaints. However, in palliative care patients may die before they are able to complain. Surveys of patients' or families' views may be included in the overall quality improvement plan of a hospice or hospital, see Table 19.9.3 for examples of how this may be used.

Adverse patient events

This systematically identifies events during a patient's treatment which may indicate some lapse in the quality of care. Patients' clinical records are reviewed retrospectively by a health professional or a ward clerk for examples of agreed adverse events. This method is of value in specialities such as surgery, where adverse events (e.g. death or postoperative infection) are usually recorded in the patient's records. However, in palliative care the method is awkward, because adverse palliative events are more difficult to identify routinely and may not be included in the patient's records unless these are standardized.

◆ Education, training, and staff development—staff have access to education and training programmes, which reflect the different levels of activity and practice necessary to meet service goals, provide appropriate care and respond to change

◆ Staff support—staff support systems are in place as an integral part of the Organization and a healthy working environment is promoted, which recognizes the possible physical and emotional effects of work on staff

◆ Ethics and law—there is guidance and support for staff to comply with statutory requirements and use a systematic approach to decision-making where ethical and legal status issues are involved.

3. Change practice to improve care and/or ensure that any deficiencies are corrected

Ideally, the audit cycle should include a period to implement change to improve quality based on the findings of the audit. Data should be discussed with the whole team to determine what changes might be appropriate. Decisions also may involve a review of the literature or consulting with other individuals to determine whether they have solutions to particular problems. For example, in London we identified that our control of breathlessness in the last weeks of life was not reaching our targets: this was the most severe symptom in patients (Higginson and McCarthy, 1989). To decide what change was needed we had to consult chest physicians, physiotherapists, and other colleagues about what treatment might be appropriate in the home, review the literature on effective treatment, and examine the possible causes of breathlessness. This led us to substantially change our practice and it also has probably led to further research into the management of breathlessness.

In larger specialist palliative care services, difficulties in implementing the change have been described (Higginson et al., 1996). These include the following:

◆ Inadequate cascading of the information from those present at the audit meetings to other staff

◆ Difficulties in ensuring that those with hands-on patient contact but at the end of the cascade, such as auxiliary nurses, feel ownership of any changes and therefore are willing to take part in them

◆ Difficulties if the main communicator is a resistor to change. Many healthcare professionals have inane conservatism to resist the change of long cherished views. This may be partly from fear of their deficits being revealed.

The change management process is a vital component of clinical audit but is often neglected. Continuing education is important and can be targeted to ensure that those to be educated feel part of the teaching or learning process. A systematic review by Antunes et al. shows how the process of introducing routine outcome measurement into practice requires leadership, facilitation, education, and ongoing support, including attitude change in staff (Antunes et al., 2014).

Audit in developing countries

It is appropriate to ask whether audit is yet relevant in developing as well as developed countries? Palliative care programmes in these countries have relatively few health-care professionals, and these have varied levels of training. In addition, some patients and families have high levels of illiteracy, making self-completion of assessment forms impossible. The burden of illness and symptom distress in patients dying of AIDS, tuberculosis, malaria, and even cancer-related syndromes may be different, just as belief systems vary, and therefore assessment tools may need to be adjusted in these populations (Higginson and Bruera, 2002).

Nonetheless, the professionals who deliver health care in the developing world document the results of interventions and use them to guide future direction in a manner not different than professionals in developed countries. Symptom control, information needs, and physical, emotional, spiritual, and social support for patients and families are important, just as in Europe, Australia, and North America (Selman et al., 2009). It can be argued that the limited resources make it even more imperative to ensure that, as the programmes evolve, they are capable of serving the largest possible number of patients and families in the most effective possible way. Audit is one way to minimize the risk of failure, and to learn, at an early stage, about potential problems and to identify success. A good example of a successful adaptation are the programmes of clinical audit now well established in Africa, with culturally adapted and validated forms of existing measures, in particular the African APCA POS (see Fig. 19.9.6). The tool is used to aid assessment, conduct clinical audit and in research (Harding et al., 2010). Considerable progress has now been made in Africa with audits using this measure to identify successes and shortcomings and ways to improve care (Harding et al., 2013).

Conclusion

Audit approaches and methods are now well advanced in palliative care, especially in clinical audit. We have a choice of possible and already tried methods and measures which we can adapt for our own needs, rather than having to undertake much of the development ourselves. Practical tools for clinical audit may use multidimensional measures, such as the Support Team Assessment Schedule, the new shorter Palliative care Outcome Scale, or the Edmonton Symptom Assessment Scale, or specific measures for topic audits. Clinical audits which use satisfaction surveys or surveys after bereavement are probably more costly, but are still possible. Apart from completing the audit cycle, clinical audit can look to developing clinical protocols for treatment, or algorithms to predict patient problems and the need for specialized care. Organizational audit and peer review is also now well established, and different systems are available.

Audit, or the various alternative terms that describe this assessment of the quality of care, is here to stay, and is now widely accepted. But it requires resources, and so it must be sure to benefit patients and families, be kept as simple and efficient as possible, and have a strong educational component. Further work is needed to evaluate the impact of different audit approaches and methods on improving care, so that we know which approach is most cost-effective. In addition, there is a need to develop and test methods of audit in developing countries. If palliative approaches extend backwards to include patients earlier in care, rather than those just near to death, then the audit could become a means for clinical dialogue and education between specialties. Palliative medicine could take the lead in encouraging this, promoting

APCA AFRICAN POS

PATIENT ID _____   **Staff name**_____

Date _____   **POS no**   1st☐   2nd☐   3rd☐   4th☐   5th☐   6th☐

ASK THE PATIENT	POSSIBLE RESPONSES
Q1. Please rate your pain (from 0 = no pain to 5 = worst/overwhelming pain) during the last 3 days	**0 (no pain)- 5 (worst/overwhelming pain)** 0 ☐ 1 ☐ 2 ☐ 3 ☐ 4 ☐ 5 ☐
Q2. Have any other symptoms (e.g. nausea, coughing or constipation) been affecting how you feel in the last 3 days?	**0 (not at all)- 5 (overwhelmingly)** 0 ☐ 1 ☐ 2 ☐ 3 ☐ 4 ☐ 5 ☐
Q3. Have you been feeling worried about your illness in the past 3 days?	**0 (not at all)- 5 (overwhelming worry)** 0 ☐ 1 ☐ 2 ☐ 3 ☐ 4 ☐ 5 ☐
Q4. Over the past 3 days, have you been able to share how you are feeling with your family or friends?	**0 (not at all)- 5 (yes, I've talked freely)** 0 ☐ 1 ☐ 2 ☐ 3 ☐ 4 ☐ 5 ☐
Q5. Over the past 3 days have you felt that life was worthwhile?	**0 (no, not at all)- 5 (yes, all the time)** 0 ☐ 1 ☐ 2 ☐ 3 ☐ 4 ☐ 5 ☐
Q6. Over the past 3 days, have you felt at peace?	**0 (no, not at all)- 5 (yes, all the time)** 0 ☐ 1 ☐ 2 ☐ 3 ☐ 4 ☐ 5 ☐
Q7. Have you had enough help and advice for your family to plan for the future?	**0 (not at all)- 5 (as much as wanted)** 0 ☐ 1 ☐ 2 ☐ 3 ☐ 4 ☐ 5 ☐
ASK THE FAMILY CARER	
Q8. How much information have you and your family been given?	**0 (none)- 5 (as much as wanted)** **N/A ☐** 0 ☐ 1 ☐ 2 ☐ 3 ☐ 4 ☐ 5 ☐
Q9. How confident does the family feel caring for _____?	**0 (not at all)- 5 (very confident)** **N/A ☐** 0 ☐ 1 ☐ 2 ☐ 3 ☐ 4 ☐ 5 ☐
Q10. Has the family been feeling worried about the Client over the last 3 days?	**0 (not at all)- 5 (severe worry)** **N/A ☐** 0 ☐ 1 ☐ 2 ☐ 3 ☐ 4 ☐ 5 ☐
