Freud (1917/1957) presented his theory of mourning in a paper entitled 'Mourning and Melancholia' in which he differentiated between healthy and unhealthy mourning. Freud's theory primarily focused on the individual process of mourning. He proposed that individuals develop attachment or love to significant others who are involved in satisfying their needs: the more important the person, the greater the attachment. Love is defined as the cathexis of libidinal (psychic) energy to the love object (the person). When the loved object is lost through death, the survivor's libidinal energy remains connected to the deceased through thoughts and memories. Freud argued that detaching or severing energy from the lost object is necessary. This process, which Freud referred to as hyper-cathexis, is achieved by reviewing all of the person's memories of the deceased. While Freud acknowledged that the process of letting go of the lost object is painful, he saw detachment as critical in order to free the ego so that it can invest in new relationships. Thus, psychoanalytic theory proposed that if hyper-cathexis did not occur, melancholia (i.e. lowered self-esteem caused by the unresolved ambivalence in the relationship with the deceased) or unhealthy mourning would result. Freud's theory referred to the adult experience, but succeeding generations of Freudian practitioners inferred that children and adolescents would be vulnerable to melancholia when a parent died because of their dependence on the parent and their developmental capacity for decathexis or 'grief work'.

Freud's understanding of loss and grief may be challenged because he worked from a psychiatric perspective and most of his theories were based on clinical experiences with depressed people and not on data from normal populations (Payne et al., 1999). Nevertheless, as Payne et al. point out, Freud's concept of grief work and the need to confront grief in order to gain detachment has had a powerful influence on both subsequent theory and clinical practice both in the United States and the United Kingdom.

Pollock (1961) extended Freud's theory of mourning. Pollock suggested that the main purpose of mourning is to facilitate the work of coming to terms with life without the deceased parent. According to Pollock, the process of mourning occurs in stages. The first stage is shock, which is followed by a period in which the work of mourning takes place. The final stage includes a separation reaction in which the presentation of the love object is restructured from present reality to that of memory.

Stages and phases models of grief

Bowlby (1961) originated the theory of attachment and this would seem to underpin the basis for understanding bereavement (Dent, 2005). Bowlby provides an explanation for the common human tendency to develop strong affectionate bonds. He views attachment as a reciprocal relationship that occurs as a result of long-term interactions, starting in infancy between a child and its caregivers. He suggests that grief is an instinctive universal response to separation.

Both Bowlby (1961) and Parkes (1972) were stage theorists. The stage model of grief is a linear progression in which the bereaved person moves through specific stages or phases of grief in order to reach the goal or stage of resolution. The first stage of grief involves denial, shock, and feelings of numbness. The second stage includes acute symptoms of grief such as intense emotional pain, social withdrawal, physical symptoms, and identification with the

deceased. The final stage of grief includes a return to normal functioning and reintegration (entailing a letting go of the loved one). Success or resolution was determined by the extent to which the bereaved was able to give up his or her original attachment with the lost loved one (Wilcox-Rittgers, 1997). Many of the stage theorists such as Parkes (1986) proposed fluidity in this linear model whereby the bereaved may move back and forth between the stages of grieving before moving on to resolution. Kuber-Ross's (1969) stage model of the grief of terminally ill people is often applied to other loss situations such as bereavement.

In the stage model of grief the bereaved person is perceived as being relatively passive in terms of grieving (Holland, 2001). This theoretical perspective has become an established basis for professional training and self-help literature in the field of bereavement (Ribbens McCarthy, 2006). The stage-based model is criticized for having limited empirical evidence to support the existence of such stages in the grieving process (Shuchter and Ziscook, 1993). The early studies that informed these models have also been criticized, particularly for the dominance of young, white, middle-class widows (Payne et al., 1999) and for not accounting for diversity and individuality of reactions and for neglecting resourcefulness (Holland, 2001; Ribbens McCarthy, 2006).

Tasks models of grief

An alternative to stage models is the task model of grief whereby bereavement is seen as a series of tasks to work though rather than just being a series of stages through which the individual has to pass (Worden, 1982, 1991). Here the bereaved person plays an active rather than a passive role in the grieving process. Lindenmann (1944) developed the first task-based model of grief. He isolated three main tasks necessary for successful grief resolution. These tasks included (1) severing ties with the deceased, (2) adjusting to one's new environment without the deceased loved one, (3) and creating new bonds with others. Again, the task of breaking the emotional bonds was considered the ultimate goal of grief work.

Worden (1982) developed a task model of mourning which has been extremely influential and is widely used by those who work with bereaved people. In relation to parentally bereaved children, grief is seen as a set of tasks in terms of normal responses that children need to negotiate (Worden, 1996). Worden discusses the tasks as being: (1) to accept the reality of death, (2) to deal with the emotional impact of the loss, (3) to adjust to the environment in which the deceased is absent, and (4) to emotionally relocate the deceased. In the context of the lives of young people, this approach has been further elaborated by reference to what are theorized as the developmental tasks of adolescence, the aim being to achieve a 'healthy' rather than a 'pathological' outcome; that is, a medical model of grief (Ribbens McCarthy, 2006).

Fox (1988) identified the following tasks for children coping with grief or loss to work through: (1) understand and make sense out of what has happened; (2) identify, validate, and express strong reactions to the loss constructively; (3) commemorate the life that was lived; and (4) learn to go on living and loving. Fox also identified other factors which influence the process of bereavement in children such as their understanding of death, the type of loss, and subsequent life circumstances.

Tasks models have also been criticized for their failure to recognize individual differences and other relevant factors which may trigger upsurges of grief throughout the bereaved person's life (Rando, 1988).

Continuing bonds

An important development in grief theory has been provided by the work of Klass et al (1996), who challenged conventional thinking that the purpose of grieving was the reconstitution of an autonomous individual who could leave the deceased behind and form new attachments, in other words, 'break the bonds' with the deceased. Klass and his colleagues suggest that the purpose of grieving is instead to maintain a continuing bond with the deceased, compatible with other new and continuing relationships.

Dual process model

A more recent and significant advance in our understanding of grief work is the dual process model develop by Stroebe and Schut (1995, 1999). These authors suggest that avoiding grief may be both helpful and detrimental, depending on the circumstances. While previous models centred on loss, the dual process model recognizes that both expressing and controlling feelings are important and introduces a new concept: that of oscillation between coping behaviours.

Within this framework, grief is viewed as a dynamic process in which there is an alternation between focusing on the loss of the person who has died (loss orientation) and avoiding that focus (restoration orientation). The loss orientation encompasses grief work, while the restoration orientation involves dealing with secondary losses as a result of the death (Dent, 2005). For instance, a mother who loses her partner/spouse may have to deal with finances and house maintenance which previously her partner/spouse dealt with. Both the loss orientation and the restoration orientation are necessary for future adjustment, but the degree and emphasis on each approach will depend on the circumstances of the death, personality, gender, and cultural background of each person. The model also posits that by taking time off from the pain of grief, which can be overwhelming, a bereaved person may be more able to cope with their daily life and the secondary changes.

Such an approach is in line with recent discussion of the goal of '*coping*' with bereavement rather than finding a resolution (Corr, 2000). Thompson (2002, p. 7) argues that this dual process model 'alerts us to the complex web of psychological, cultural and socio-political factors which interact to make the loss experience far more complex than traditional approaches would have us believe'. However, a potential problem with extending the adult model to children is that it assumes that their experiences of bereavement are similar (Holland, 2001).

Taking with families and children about death of a parent

Much of the communication literature emphasizes the importance of open and honest communication (Jordan, 1990; Broderick, 1993)—this is seen as the most essential element in grief resolution in a family. Anxiety in children is increased when information is available but no opportunities are provided to allow them to discuss the information (Beale et al., 2004). Providing clear, honest information prevents misunderstandings, which may lead to

frightening fantasies and fears (Saldinger et al., 2004; Turner et al., 2007). Euphemisms and abstractions are not advisable. Telling a young child that the deceased is 'sleeping' could cause the child to fear going to bed (McGuinness, 2011).

The importance and value of age-appropriate, open, honest communication with the child is discussed in Rauch et al. (2003). This information also needs to be timely and in a language appropriate to the child's level of understanding which has been linked to their cognitive development, but it also reflects their experiences of death and dying (Slaughter, 2005). Such factors are acknowledged by more recent understanding of children's concept of learning which has emerged in cognitive developmental research and theorizing in recent years (Slaughter, 2005). This intuitive theory approach of cognitive development emphasizes the role of casual-explanatory models in organizing children's knowledge and driving learning about different domains of experience and recognizes the importance of conceptual change in children's learning (Carey, 1985; Wellman and Geelman, 1992; Gopnick and Meltzoff, 1997; Inagakie and Hatano, 2002).

One of the seminal works in this new tradition analysed the development of young children's conception of the biological world (Carey, 1985). From this perspective, an important factor influencing children's understanding of death is the child's personal experience with people and other living things that have died (Hunter and Smith, 2008). Intuitive theory challenges Piaget's (1976) very influential theory of cognitive development, based on the chronological age of the child. Piaget addressed the ways in which children's thought processes changed over time, regardless of the environment in which they grow. The Piagetian research documenting consistent stages of death established that children's understanding of death is closely tied to cognitive developmental maturation. Within this explanatory framework it is believed that very young children do not have the capacity to understand abstraction such as finality and irreversibility, an understanding that only emerges when the child is capable of operational thinking (Piaget, 1956). Children may in fact see death as reversible. As children grow older, they develop the capacity to understand the abstractions associated with death (Worden, 1996). From this perspective, the development of an understanding of death appears to be most strongly influenced by developing cognitive competency (Slaughter, 2005). Piaget saw these development stages as universal, homogenous, and stable across cultures.

Piaget's model has also been challenged by scholars such as Bluebird-Langer (1989). Bluebird- Langer describes how very young children who are terminally ill or life-threatened have a sophisticated understanding of death through their observation of how adults respond, knowledge of their own symptoms and treatment, and interactions with other dying children. Bluebird-Langer recognizes therefore that although the development of children's understanding of death has been linked to their cognitive development, it also appears to reflect their experience of death and dying.

Research would suggest that younger children are less likely to receive the same amount of information as older children (Christ and Christ, 2006). Beale et al. (2004) delineate that a reason why parents do not share information with their children is because of their belief that the children are not aware of what is happening within the family. This is an important factor in communication and information sharing; younger children are frequently not included because of the belief that they are too young to understand. However, children from a very young age will be acutely aware that something is different within their family life. While they may be unable to comprehend completely what is happening, they will know that things are different and without some age-appropriate explanations it is likely that their assumptive world (Parkes, 1972) will be thrown into confusion and fear. The information given to children also needs to be repeated over time (Worden, 1996). Worden asserts that the repetitive questions that children ask about a death are a way for them to grapple with the reality of the death as well as a test to ensure that the story has not changed.

A recent retrospective study (Ellis et al., 2013) of adults bereaved as children found that those who had not been given timely and accurate information not only felt confused and fearful, they also often felt let down and betrayed by their surviving parent (or surrogate parent). The perception was that this had implications in adulthood, as it often led to trust issues which in turn affected their relationships. According to Herman (1992) one of the most important factors that make childhood loss traumatic is the feeling of having been betrayed by trusted adults.

Children need information not only at the time of the physical death but also when a parent that was known to them in terms of 'mothering /fathering' is lost to them due to illness, as this experience was very distressing for informants as they felt bewildered and confused as they didn't understand what was happening (Ellis et al., 2013). Christ (2000) and Fearnley (2010) reported that regular medical updates about their parent's condition were helpful. In common with Worden (1996), Ellis et al. found that children who are not given accurate information make up a back story to fill in the gaps and this can be more frightening than what actually happened. Ellis et al. also found that while as a mature adult, respondents were able to reflect on their experience and appreciate that it may have been done with the best of intentions (i.e. protectionism), and/or associated with dominant beliefs about parenting at the time, it was still very difficult for them to come to terms with.

The recent cognitive development literature generates specific guidelines for talking about death with children, which acknowledges the importance of children's underlying folk biology to their capacity to conceptualize death. Slaughter states that even when adults provide explanations that appear to be clear and straightforward, such as 'he died because his heart gave out' or 'the doctors did all they could but her body was too weak to keep living' (2005, p. 184), such explanations may not be appropriate for young children if they presuppose a biological conceptualization of the human body. Slaughter goes on to say that even explanations that frame death in terms of a breakdown of the body, while concrete and unambiguous, are likely to be meaningless to a young child who does not recognize that death is characterized and ultimately caused by the cessation of bodily function.

However, the open expression of feelings highly valued in both psychodynamic and stage models of grief, can become destabilizing to a family's negotiated rules for shared emotional stability. Social development theory highlights that in the absence of social resources, such as economic security or social support, bereaved families are forced to rely on interpersonally negotiated emotional controls as strategies for stability. Interpersonal control strategies in response to overwhelming grief, such as interactions suppressing differences in shared experience or restricting destabilizing

change, interfere with the individual and family capacity for open communication, cohesion, and mutual support and may narrow the capacity for flexible coping with future development challenges (Shapiro, 1994, 1996). Shapiro (2001) states that the greater the stressors and discontinuities and the fewer social supports there are, the more likely families will be to rely on interpersonal control strategies that limit their ability to adapt. Such families inhibit their growing children whose maturing cognitive capacities generate new questions about the death and its meaning from exploring the experience of the death and their images of the deceased family member in ways that enhance ongoing development (Shapiro, 1994; Silverman, 2000).

Research undertaken by MacPherson (2005) found that not sharing information and communicating with the children was directly related to the parents' ability to talk together about the illness. It was found that the dying parent influenced the decision whether the children were informed about the prognosis and the well parent followed their example. Fearnley (2010) refers to an interview with a specialist nurse who spoke at length about how in her opinion she had a significant role to facilitate those difficult conversations. She discussed how, by asking the parents questions about what their children knew of the situation and their understanding of it, new communication lines were opened and opportunities created for proactive supportive work to be undertaken. However, she also stressed that the initial discussions were 'very gentle to test out what the children may have been told' and to see what hesitations or beliefs the family may hold that prevented them from talking with their children. It would appear that these initial conversations are imperative so that the channels of communication can be opened.

In common with Hooghe et al. (2011), Ellis et al. (2013) suggest that if the negative consequences of bereavement are to be minimized, it is crucial that rather than unilaterally advocating the promotion of open communication, those working with bereaved families first discuss the complexities of communication with the family members, specifically those concerning talking and keeping silent, and explore the different meanings associated with sharing grief experiences with each other. Such an intervention may help the family as a unit, through interpersonal communication, to integrate experience and adapt to changes with few attempts to control thoughts and feelings in ways that impede shared development (Shapiro, 2008).

However, according to Fearnley (2010), the quality of information exchange is often dependent on the practitioner's professional background. Fearnley reported that a number of families in her study talked about how the focus of support from the nursing teams was medically orientated. Furthermore, it was noted that the nursing staff generally visited the family home during the day, when the children were at school, and therefore their issues were not discussed nor were they party to any information. Fearnley also found that when specialist social care staff were involved there was typically an increase in the amount of information provided to the children. This was provided directly through discussions and therapeutic sessions.

The emerging findings from this study also indicate that some qualified practitioners have difficulties using the words death, dying, and dead. This avoidance of the words and to supplement the conversations with euphemisms (which may lead to misunderstanding of information) were indicative of the individual's personal difficulties and how in general society has a death-denying attitude (Fearnley, 2010). Fearnley reflected about the choice of language and whether this was symptomatic of the notion that the subject is taboo within some cultures. Drawing on the evidence from her research, Fearnley suggests that there is a stigma attached to talking about death and dying and that practitioners find it difficult and embarrassing to discuss such topics. Fearnley asserts that this sequestration leads to a pattern of communicating that avoids any involvement of such unmentionable vocabulary. The metaphor of the elephant in the room is used to delineate how practitioners avoid such discussions and thereby miss opportunities to support children experiencing potentially the most traumatic event they have ever faced. Fearnley suggests that this is related to a lack of training for practitioners both as students and through continual professional development.

Conclusions

In this chapter we have explored the literature that looks at the impact of parental death. We have also outlined some of the dominant models of grief. Most suggest that bereaved people need to engage with their loss and work through it, so that life can be reordered and meaningful again. Worden's tasks of bereavement give a framework to guide the bereaved in their grief work, while the dual process model demonstrates the need to deal with secondary stresses as well as the primary loss, with time away from both. It is also important to recognize that the bereaved do not need to forget and leave the deceased behind, but can integrate them into their future lives by means of a continuing bond. An understanding of the different models of grief together with an understanding of the relationship between age, experience, and manifestations of grief in children are crucial for practitioners to provide effective support. An understanding the family dynamic is also of great importance for those working to enhance communication in identifying possible tensions between members and assessing how members may influence or be influenced by others, as well as understanding what the death means to each member. Each bereaved person is unique and will deal with a significant death in their own way; therefore there is no one right or wrong way to grieve. In many cases, the family is very often the prime provider of socialization, social control, and support. Certain factors either inhibit or enhance a family's grief. Families in which there are fragile relationships, secrets, and divergent beliefs may have more difficulty in adjusting; whereas families who have frequent contact, rituals, and a willingness for each member to share their feelings may find it easier. Those talking to families and children about the death of a parent need to acknowledge the complexities involved. They also need to acknowledge that a family's capacity to communicate and share information with their children is historically driven and mediated by the social, cultural, and economic context in which it resides. If families and children are to be supported at potentially the most traumatic time in their life, practitioners also need to ensure that they have the necessary skills, competencies, and confidence to engage with families in ways that enhance communication and information sharing.

Communication between professionals

Jane deLima Thomas, Katie Fitzgerald Jones, Amanda Moment, and Janet L. Abrahm

Introduction to communication between professionals

Communication between health-care professionals is a core element of palliative care and is increasingly recognized as critical to health-care quality (National Healthcare Quality Report, 2011). The growing complexity of health-care delivery systems worldwide has led to a stronger emphasis on interprofessional communication, resulting in changes in health professional school curricula (McDonough and Bennett, 2006), institution accreditation requirements (Joint Commission Resources, 2009), and standards of interprofessional education (Interprofessional Education Collaborative Expert Panel, 2011). The importance of interprofessional collaboration was underscored in 2010 when the World Health Organization published its *Framework for Action on Interprofessional Education and Collaborative Practice*, emphasizing the need for more integrated and collaborative models of health-care training and delivery.

The focus on interprofessional communication comes, in part, as the result of the growing evidence about the practical consequences of communication successes and failures between health-care providers. The data show that failures in communication may lead to inferior palliative care, including medication errors, delays in treatment, wrong-site surgeries, higher patient mortality rates, longer hospital stays, and worse pain control and functional status (Mills et al., 2008; Martin et al., 2010). Poor communication may also lead to negative consequences for health-care professionals, including higher nursing turnover, negative feedback, and demoralization of colleagues (Health Professions Regulatory Network, 2008). Conversely, successful communication leads to better outcomes for patients and health-care teams including improved understanding by clinicians of patient care goals, improved team morale, higher staff retention, positive feedback from colleagues, and increased productivity (Health Professions Regulatory Network, 2008; Chang et al., 2009).

Palliative care clinicians are often in the position to facilitate communication among various members of the health-care team caring for a patient with a serious illness. First, a palliative care clinician's initial assessment includes an evaluation of the patient's overall clinical status and the roles of and relationships with the providers involved. Second, palliative care clinicians are often consulted for complex patients with difficult to manage symptoms

and emotional suffering, leading to team distress, interpersonal conflict, ethical dilemmas, and lack of clarity about the plan of care. Third, most palliative care clinicians have had some communication skills training, and while their focus of care is patients and their families, many of the same communication techniques are effective with colleagues. Fourth, palliative care clinicians are accustomed to working in interdisciplinary teams (IDTs), where open, respectful communication is the expectation. As a result of these factors, palliative care clinicians can play a key role in pulling together the various providers and ensuring that their points of view are heard, misunderstandings are focu minimized, and a comprehensive plan of care is created that reflects input from all.

Principles of good interprofessional communication

Many clinicians believe that the ability to communicate well is innate, that is, that people are either born to be good communicators or they are not. Evidence, however, shows that communication skills are both teachable and learnable (Back et al., 2007; Krimshtein et al., 2011). This is especially encouraging since health-care professionals' communication skills do not improve reliably with experience alone (Wilkinson et al., 2008; Back et al., 2009a). Health-care providers that participate in communication skills training manifest changes in their behaviour that enhance communication (Reeves et al., 2008, Reeves, 2009), increased confidence as communicators (Back et al., 2007), improved assessment of interprofessional communication (Zwarenstein et al., 2007), and have increased patient satisfaction rates (Back et al., 2007). What's more, communication skills training has been shown to have an impact on participants' skill level even 5 years afterward (Roter and Hall, 2006). While the majority of interventions shown to improve communication in the health-care setting have been geared towards communication with patients, there is growing interest in designing interventions to improve interprofessional communication, too (Norgaard et al., 2012).

The guiding principles of good communication are familiar to many palliative care clinicians and are explored in more depth in Chapter 6.1. We summarize three key points here that are particularly important when considering interprofessional communication.

1. *Good communication begins by adopting an attitude of curiosity*. When starting from a position of curiosity, one is open to

the perspective, rationale, and motivation of the other parties involved (Stone et al., 2010). This attitude minimizes the risk of assuming one knows all the facts, leaping to conclusions prematurely, or alienating the other party. Curiosity relies on active listening (Back and Arnold, 2005): paying close attention, asking facilitating questions, and following up on verbal and non-verbal cues.

2. *Communication happens on many levels simultaneously.* The verbal communication exchanged is only one part of the conversation, which at deeper levels also includes underlying emotions and issues of self-identity for each participant (Stone et al., 2010). Good communicators, therefore, can attend to all of the elements of the conversation, even while maintaining self-awareness about their own communication styles, emotional reactions, and triggers for conflict (Back et al., 2009b).

3. *Good communication requires skill in managing conflict.* While conflict managed poorly can prove destructive to relationships and team function, conflict managed well can be productive and even necessary for healthy interaction between colleagues (Ezziane et al., 2012). Healthy conflict can serve to elucidate and contextualize points of disagreement, promote sharing of new ideas and perspectives, and enhance productivity (Lencioni, 2002; Ezziane et al., 2012).

While palliative care clinicians communicate with other professionals in a wide variety of ways, we have chosen to consider two major categories as prototypes: communication within palliative care IDTs and communication between palliative care consultants and other providers.

Communication within palliative care interdisciplinary teams

Given the complex symptoms, psychosocial issues, and important choices that arise for patients and families facing life-limiting illness, skilful communication among members of the palliative care IDT is essential (Blacker and Deveau 2010). Good communication is a result of—and contributes to—important team attributes. The first attribute that facilitates team communication is having mutual goals and a process for evaluating team function in pursuit of those goals (Dahlin, 2010). When a palliative care team creates shared objectives, usually aimed at the relief of suffering, clinicians become more collaborative and work towards group aspirations rather than individual goals (McPherson et al., 2001). These goals are re-evaluated regularly since they often shift in response to new initiatives, challenging cases, and evolving staff competencies (Lencioni, 2002). Additionally, members of a team that communicates well have a clear understanding of individual responsibilities and roles. Each member of the team should be able to articulate the specific skill and expertise he or she brings to patients and the team (Orchard et al., 2005) and how it differs from that of other team providers. When these areas of knowledge and skill are communicated and respected, the group can function with more cohesion and greater utilization of one another's skill sets (Hall, 2005). What's more, if collaboration is carried out effectively, the clinician's team identity trumps the clinician's discipline identity (e.g. nursing, social work, pharmacy, etc.) and team outcomes supersede those of the individual (Lencioni, 2002). Well-communicating teams also have standards for communication

among providers, including conflict negotiation (Lencioni, 2002). Interprofessional relationships are based on respectful communication, trust in one another's motives, and commitment to accountability when discord arises (Interprofessional Education Collaborative Expert Panel, 2011). A high-functioning palliative care team recognizes the importance of good communication in attaining these three attributes and actively work towards cultivating a culture that supports it.

Barriers to communication in palliative care IDTs

Even teams that acknowledge the importance of communication face many types of barriers that compromise it. First, there are practical and organizational issues such as staffing, geography, and caseloads. Since palliative care is a young and rapidly evolving field clinical teams are often in flux, with staffing models changing according to each institution's demand for palliative care services and the resources allocated to team development (Billings, 2008). Palliative care teams can have any number of part-time or full-time clinicians of different disciplines rotating on and off service, leading to significant communication challenges and variable team cohesion. Moreover, palliative care can be delivered to patients with a wide variety of underlying conditions, leading to geographic spread even within a single institution and creating another obstacle to good communication. Lastly, in rapidly growing programmes caseloads can exceed staffing, leaving little time for the team to ensure that lines of communication are maintained. Teams that have stressful caseloads can abandon interdisciplinary work (where providers work together) for multidisciplinary work (where providers 'divide and conquer') as they struggle to meet the clinical demands. The result is poorer communication and integration of each provider's skill sets and more working in parallel (Hall, 2005).

Second, there are barriers related to information value, hierarchy, and provider insight. In teams that emphasize biomedical information, non-medical providers can feel diminished (Wittenberg-Lyles, 2005). For example, if a social worker has to struggle to make his or her viewpoint heard, even when social or emotional distress is central to the patient's needs, the result can be feelings of disempowerment for the clinician and an incomplete plan of care for the patient. Also, the standard medical hierarchy may lead to barriers in interprofessional communication by causing team members to feel uncomfortable raising concerns (Irvine et al., 2002). For example a floor nurse may have concerns about the safety of a patient's discharge plan but feel unable to voice her worry to the physician who seems sure the patient is ready to go home. Lastly, clinicians can lack of insight about their own communication style and effectiveness. Physicians, in particular, tend to overestimate the efficacy of their communication with other team members (Mills et al., 2008; Chang et al., 2010).

Other hurdles to interdisciplinary communication relate to professional education and identity. Traditionally, skills are taught in 'professional silos' that can foster 'power, competition, and hierarchy not teamwork and collaboration' (Angelini, 2011, p. 175). This can result in limited understanding of or compassion for one another's professional perspectives, priorities, and education (Leipzig et al., 2002). For example, a nurse may view social workers more as 'friendly visitors' than as clinicians who work from a solid clinical or theoretical grounding. In addition to misunderstandings about one another's skill sets, palliative care IDT

members can struggle with overlapping skills. IDT members share both 'ingroup membership (the IDT) and outgroup membership (occupational group)' (Wittenberg-Lyles et al., 2009, pp. 38–39) and clinicians can become protective of their disciplines and specific skill sets, leading to turf wars and interpersonal conflicts (Larson, 2003). For example, a palliative care nurse practitioner who enjoys exploring the psychosocial aspects of his patients' care might worry that the social worker's expertise will relegate him to medical management only.

Strategies for communication in palliative care IDTs

Given the barriers just described, palliative care IDTs must take a purposeful approach to maximize team communication and function. One strategy receiving increasing attention is the use of structured communication tools (Byres et al., 2009; Denver Health, 2012). For example, structured team rounds have been shown to encourage meaningful contributions from all providers involved in patient care (O'Leary et al., 2010) and to increase team satisfaction and interprofessional teamwork (Maeyama et al., 2003). Not surprisingly, team members' satisfaction increases based on the number of team members involved in the care meeting (Maeyama, 2003). Another example of structured communication is the model developed by Michael Leonard in 2002 called SBAR (Situation–Background–Assessment–Recommendation) (Institute for Health Care Improvement, n.d.). In this model, a clinician is encouraged to provide four categories of information when communicating a concern. The first is to describe the situation—the patient's name, location, and cause for concern: 'I am calling about Mrs X in room 14 who is having new episodes of apnoea.' The second is to give a one-line summary of the background: 'She is a 45-year-old woman with end-stage lung cancer who has required increasing doses of morphine in the last 48 hours.' The third is to provide an assessment of what is occurring: 'I believe that the change in her breathing indicates that she is close to death.' The fourth is to offer a recommendation based on that assessment: 'I think we should contact her husband to let him know that time might be short.' A standardized method like this creates a mutual language and process for conveying information no matter who is calling, the nature of the concern, or the level of urgency.

A second strategy to enhance IDT communication is to have designated forums for discussion and feedback. Difficult patient cases should be debriefed either in real time or soon after to help the team grieve, air misgivings, provide support, and assess team process (Salas et al., 2005; Salas et al., 2008). Any member of the team should be able to initiate this for a patient and have the team respond, with time and support from leadership. An example is to hold 'escalating patient care meetings' where the team convenes at the first signs of a difficult patient case to map out a plan, raise concerns, and involve appropriate clinicians. Additionally, team members should have opportunities to provide critical feedback to one another and their leaders by using 360-degree reviews or feedback tools (Lockyer, 2003; Massagli and Carline, 2007). Feedback must be separated from compensation or performance evaluations so that it remains constructive and not punitive (Lencioni, 2002). No matter the method, teams should have mechanisms for providing feedback to one another both in times of high stress and in times of relative calm (Salas et al., 2005; Salas et al., 2008).

A third strategy to maximize IDT communication is taken from the study of high-reliability organizations (HROs) such as air-traffic control systems, nuclear power plants, and aircraft carriers. HROs deliberately create an organizational structure that flattens hierarchy by seeking input from front-line members and acknowledging expertise regardless of rank (O'Leary et al., 2012). In this manner each team member's contribution is sought and valued, leading to empowerment for every team member to participate and voice suggestions and concerns (Hempel et al.2012). If we imagine applying these principles to a palliative care IDT, we can consider a case where a palliative care patient dies suddenly in the hospital and in the ensuing confusion the patient's wife is not informed until she comes in to visit the patient. An HRO approach would include soliciting the perspective of all those involved, including the floor nurse, the administrative staff, the physician, the social worker, and so on. Protocols for notifying family members after the death of a loved one would then be studied and revised based on the input from all team members and communicated clearly back to all. With this approach the tendency to blame particular individuals, especially those in a lower position of power, is minimized, and team trust and communication is enhanced.

A fourth, closely related strategy to enhance IDT communication is to cultivate an open, no-fault culture in addressing medical errors (O'Daniel and Rosenstein, 2008). This requires a shift away from regarding medical errors as individuals' mistakes and instead viewing them as a reflection of systems problems (Berwick and Leape, 1999; Institute of Medicine 1999; Institute of Medicine Committee on Quality of Healthcare in America, 2001). A particular danger arises when organizations focus on correcting mistakes by initiating checklists and safety systems but don't recognize the more insidious problem that occurs when errors are identified through these mechanisms and people are afraid to speak up (Maxfield et al., 2005). In order to minimize this dynamic, organizations must tap into personal motivation and agency, that is, the belief that it is important to speak up and that one has the ability to do so. This is best achieved by interventions such as providing examples of non-threatening language to use when discussing mistakes; setting the expectation that each person is accountable for his or her own behaviour as well as that of colleagues; and encouraging providers to share their experiences of speaking up and empowering others to do the same. The effectiveness of these measures rests on the approach of team leaders, who must create an environment of 'psychological safety that fosters open reporting, active questioning, and frequent sharing' (Edmondson 2004, pp. ii8–ii9).

In this section about IDT communication, a number of themes emerge as important in maximizing good IDT communication and function. Table 6.3.1 integrates and expands on many of these points.

Communication in palliative care consultation

As with communication between members of the palliative care IDT, skilled communication is crucial between palliative care providers and other professionals. First, as noted in the introduction, palliative care clinicians are often consulted for difficult patient cases with complex medical, psychosocial, ethical, and emotional issues. Moreover, since palliative care addresses all of the biopsychosocial and spiritual domains of a patient's care, clinicians collaborate with a wide range of providers of different disciplines across many

Table 6.3.1 Effective interdisciplinary team communication

Characteristic	Description/examples
Team leadership	Facilitate problem-solving
	Create effective systems for conflict resolution
	Communicate performance expectations
	Clarify roles
Mutual performance monitoring	Debrief difficult cases
	Use peer assessment tools (e.g. 360-degree evaluations or multisource feedback)
Supportive teamwork behaviour	Anticipate, communicate, and respond to one another's needs
	Adjust workload distribution
	Accept shared responsibilities
Adaptability	Ability to modify processes as new information arrives
Shared mental model and team process	Acknowledge interdependence
	Agree on team goals and how they will be achieved
	Commit to reaching team goals
Closed-loop communication	Acknowledge information received
	Clarify requests
	Follow up on outcomes
Mutual trust	Discuss mistakes and accept feedback
	Practise constructive (not blaming) communication
Clear and respected boundaries	Communicate roles and responsibilities
	Acknowledge and communicate when boundaries are blurred or crossed
Comfort with conflict and error	Raise concerns freely and openly
	Recognize that conflict is inherent in healthy team process
Standardization of communication	Prioritize frequent face-to-face communication
	Use of structured models for interprofessional collaboration (e.g. team rounds, daily goals-of-care forms and checklists, joint visits)
	Participates in interprofessional education
Accountability	Examine and take responsibility for own actions and those of colleagues.

settings. Furthermore, and perhaps most important, there is huge variability from country to country in access to palliative care services, ranging from no hospice or palliative care presence in some countries to one provider per 158 million people in Pakistan to one provider per 43 000 per people in the UK (Wright et al., 2008). Even in a single country palliative care programmes can vary widely from institution to institution depending on the history, level of development, and make-up of the programme (Goldsmith

et al., 2008). Palliative care clinicians therefore meet varying levels of understanding and acceptance from other clinicians, and must often identify and overcome misperceptions even while trying to provide patient care.

Palliative care consultation rests on the same core principles as consultation by other specialists, including the fundamental importance of good communication. Consultants must remember that a basic principle of consultation etiquette is that the referring clinician is the consultant's primary customer, and not the patient (Goldman et al., 1983). A consultant's recommendations are conveyed to the referring clinician and the consultant does not have control over which—if any—recommendations will be followed (Meier and Beresford, 2007). Studies of physician compliance rates with consultants' recommendations, however, highlight the importance of good communication with referring clinicians, with communication skills comprising ten of the 11 proven factors that increase compliance (the exception being the severity of the illness) (Cohn, 2003):

◆ Response within 24 hours (Pupa et al., 1986)

◆ 5 or fewer recommendations (Sears and Charlson, 1983)

◆ Identification of critical recommendations (versus routine ones) (Pupa et al., 1986)

◆ Focus on central issues (Ballard et al., 1986)

◆ Specific, relevant recommendations (Horwitz et al., 1983)

◆ Definitive language (Klein et al., 1983)

◆ Specificity in drug dosage, route, frequency, duration (Horwitz et al., 1983)

◆ Frequent follow up including progress notes (Mackenzie et al., 1981)

◆ Direct verbal contact (Pupa et al., 1986)

◆ Therapeutic (versus diagnostic) recommendations (Ballard et al., 1986)

◆ Severity of illness (Sears and Charlson, 1983).

Conversely, studies have also shown that if consultants do not follow these guidelines they will be more likely to receive poor feedback and fewer referrals (Goldman et al., 1983).

Communication challenges in palliative care consultation

While all specialist consultation requires effective communication, it can be argued that palliative care consultation carries particular complexity and requires even greater attention to communication. First, providers in other specialties are sometimes uncertain about what palliative care is and which patients might benefit from palliative care consultation (Shipman et al., 2008). Some referring clinicians worry that there is a 'palliative care agenda' to stop aggressive treatments or to encourage patients to sign on to hospice. One survey of 131 clinicians, for example, found there was widespread concern that palliative care

consultants would prematurely discuss end-of-life issues, which led to significant barriers to consultation requests (Rodrigues et al., 2007). Other referring clinicians delay referral to palliative care due to worry that it would alarm patients and families (Smith et al., 2012). Yet other referring clinicians find the name 'palliative care' problematic and would more readily refer patients if the consultation were called 'supportive care' (Ferrell, 2005). In each case, the interaction between palliative care providers and referring clinicians requires thoughtful clarification from the beginning in order to identify concerns or misperceptions before proceeding with the consult.

Second, palliative care consultation usually happens at a time of high emotion, in the context of disease progression leading to considerable symptom burden, psychosocial distress, or a turning point in disease course requiring clarification of the goals of care. Clinicians caring for patients with advanced illness often experience strong emotions themselves, including helplessness, frustration, guilt, and grief (Meier et al., 2001). Palliative care consultants must be able to manage the emotions evoked by the situation, and then communicate clearly in the midst of the turbulence in order to facilitate team health and effectiveness and arrive at the best plan of care (Loscalzo, 2008).

Third, unlike consultants whose specialties are defined by organ system (e.g. cardiology) or disease (e.g. oncology), palliative care addresses the whole patient, including physical, emotional, social, and spiritual aspects. The role of consultant, where the focus of evaluation is limited by the scope of the request, can therefore seem restricting and sometimes lead to internal conflict for the consultant (Meier and Beresford, 2007). Examples include seeing a patient to help with advance care planning who has significant physical symptoms not part of the original consult request; seeing a patient who asks direct questions about topics expressly forbidden by the referrer to discuss; seeing a patient who confides goals or worries not known by the referrer; or seeing a patient whose management the consultant strongly disagrees with (Meier and Beresford, 2007). These situations can be particularly challenging for palliative care clinicians whose aim is to relieve total suffering for patients who may define their needs differently from the referring clinician.

Communication strategies in palliative care consultation

While there is no data supporting the use of a particular strategy in palliative care consultation, we draw from the evidence of medical consultation generally, on the opinions of experts in the field, and on our own clinical experience to recommend an approach that uses five core themes.

1. *Curiosity*: as noted earlier, starting from a position of curiosity leads a palliative care consultant to be non-judgemental and open to the perspective, rationale, and motivation of the other members of the team caring for the patient (Back and Arnold, 2005). Important questions include the following: 'What can we do to be helpful?' 'What do you think this patient or family understands about the disease or prognosis?' 'What have you chosen to talk about and why?' 'What is the current treatment plan and why?' 'What are your hopes and worries for this patient?'

2. *Humility*: when palliative care clinicians are brought into situations with high levels of suffering, the temptation can be to

assume that greater expertise would have prevented the distress. It is important to remember that (a) referring clinicians are acting in what they understand to be the best interests of their patients, (b) the clinician who has cared for a patient over time may have knowledge that the consultant does not have, and (c) certain cases will carry high levels of suffering even when the clinicians involved have considerable expertise (Meier and Beresford, 2007). Acknowledging other clinicians' efforts, expertise, and relationship with the patient can be helpful (Back and Arnold, 2005): 'It sounds like you have gone to great lengths to help this patient and family.' 'Could you explain to me what the risks and benefits of the various treatment options are in a case like this?' 'You have known this patient longer than I have so there may be things I'm missing.'

3. *Transparency*: transparency in a consultant's communication can be helpful in several ways (Back and Arnold, 2005). First, transparency about a consultant's viewpoint and prior experience can help other clinicians understand why the recommendations are being made and consider the rationale when deciding whether to take the recommended course of action. Additionally, transparency in thought processes helps show other clinicians what factors in palliative care are considered important, what assessments are made, and what outcomes are aimed for. Furthermore, a consultant's transparency about biases or areas of uncertainty models an attitude of openness, trust, and mutual respect. An example might be, 'We only have observational studies supporting this recommendation but my own experience is that it can be very helpful in patients like this.'

4. *Clarity*: it is crucial that a palliative care consultant have the ability to distil the many elements of a patient's care—medical data, psychosocial issues, team dynamics, etc.—and provide clear information to facilitate a common understanding of the issues. Ensuring clarity rests on the core principles of consultation outlined above, includes making a careful assessment of the reason and urgency for the consult; obtaining a thorough history from the medical record, patient, and family; keeping the consult recommendations and documentation brief and focused; using specific, definite language in the consult recommendations (e.g. medication dosing); contacting the referring clinician with recommendations; and making specific plans for follow-up, including leaving progress notes and signing off (Cohn, 2003).

5. *Judiciousness*: palliative care consultants must sometimes balance their desire to advocate for their patients with the need to preserve the relationship with the referring clinician and respect the boundaries of consultation etiquette (Weissman and von Gunten, 2012). Many factors can influence how strongly a consultant recommends a certain course of action, including the nature of the relationship between consultant and primary clinician, the risks and benefits of following one course of action or the other, the level of institutional support for palliative care, and the degree of suffering in the patient, family, or other clinicians (Weissman and von Gunten, 2012). Weissman notes that ultimately, palliative care clinicians will be most successful at consultations and collaboration if the provider requesting the consult or stakeholder trusts the consultant to make decisions that benefit the patient and family and preserve the authority of the referring clinician (Weissman, 2007, 2011).

Conclusion

As outlined in the chapter, interprofessional communication is crucial in palliative care, both within palliative care IDTs and between palliative care clinicians and others. Strategies to improve interprofessional communication in palliative care have been named throughout the chapter, but what are the next steps?

Efforts to improve interprofessional communication in health care are happening at many levels. One is the increasing emphasis on integrated care pathways (ICPs), defined as 'multidisciplinary tool[s] to improve the quality and efficacy of evidence based care and communication tool between professionals to manage and standardize the outcome of coordinated care' (Vanhaecht et al., 2006, p. 28). ICPs should if possible be evidence based and act as a guide on how to diagnose, treat, and follow-up the patients and the families. ICPs can also act as standardized communication tools showing promise in improving both clinical outcomes and communication between providers (Mahmoud et al., 2008). Another effort is the convening of expert consensus panels to set standards for interprofessional communication in specific disciplines, fields, or locations, which then can be used by clinicians, administrators, and educators designing clinical or educational programmes (Interprofessional Education Collaborative Expert Panel, 2011). A third effort is the increasing attention from regulatory bodies to tie measures of interprofessional communication to accreditation of clinical and educational institutions (Joint Commission Resources, 2009). A fourth is the development of government health-care policies emphasizing the importance of interprofessional communication and providing guidelines and structures (including funding) for its implementation (The Enhancing Interdisciplinary Collaboration in Primary Health Care Initiative, Nolte, J., 2006). A fifth is continued research to expand the evidence base on interprofessional communication, including outcomes for individuals, programmes, and institutions (Manser, 2009; Martin et al., 2010), as well as efficacy studies for interventions designed to improve it (Baker et al., 2008). A sixth and perhaps most notable effort, however, is the increasing focus on interprofessional education. Clinicians in training (Carpenter, 2009) as well as practising providers (McPherson et al., 2001) are participating in innovative interdisciplinavry educational initiatives, which have been variably studied but have demonstrated efficacy in improving collaborative practice and clinical outcomes (Reeves et al., 2008; Reeves 2009).

Palliative care can clearly benefit from the growing attention on interprofessional communication worldwide and the resulting development of these communication protocols, policies, and curricula. In fact, palliative care as a field is positioned to help lead the way, since clinicians are often experts in both communication and interdisciplinary practice. The task now is to be sure the field keeps current with the evolving scholarship on interprofessional communication and continues to contribute to and apply the emerging wisdom for the benefit of terminally ill patients and the providers who care for them.

6.4

Communications with the public, politicians, and the news media

Barry R. Ashpole

The communications environment

Two universal issues to have emerged in recent years continue to generate a great deal of attention in both the political and public arenas: (1) the future provision and delivery of health care and social services to the population at large; and (2) meeting the needs of the elderly, who are living longer, in greater numbers than in past generations, and with a corresponding increase in the incidence of chronic or long-term illness or disability. Running parallel is the trend in many countries away from institutionalized care to accommodate the preference expressed by many people to receive care and support in their own home in the event of illness or incapacity; the potential economic benefits of which have not escaped policymakers, presenting them with a persuasive argument that suggests a significant shift in the focus and scope of community care in the decades ahead. Against this backdrop is the increasing attention on all fronts given to the quality of care and support—or lack of—for those living with a terminal illness, both patients and their families or loved ones.

In assessing the prevailing communications environment, it is important not to lose sight of the growing evidence in the literature that the philosophy and principles of hospice and palliative care are gaining currency beyond meeting the immediate needs of those living with a shortened life expectancy. The holistic concepts of 'whole-person' care and managing 'total' pain are steadily working their way into family and hospital practice, long-term or extended care, and home care. This emerging trend has served to facilitate discussion about when, during the illness trajectory, should patients be referred to specialized end-of-life care. Almost from its earliest days, however, hospice and palliative care have been associated in the minds of many people—among them health professionals—with dying and death. This has created at times almost insurmountable barriers in the medical decision-making process and in conversations about life's last chapter.

Coverage of end-of-life issues in the news media has tended to be in the context of 'patient choice', which has done much to fuel the highly contentious public debates on assisted or facilitated death, medical futility, and on who has the 'final say' in the medical decision-making process. The protagonists in these debates focus on their respective interpretations of 'dying with dignity', which inevitably encompass the potential cost—both emotionally and financially—of sustaining life. This has resulted in a broad range of initiatives to promote advance care planning. Honouring the principle of patient autonomy and respecting patient wishes,

nonetheless, has become something of an ethical minefield. A residual effect has been the increased support given—ironically on *all* sides in the 'dying with dignity' debate—to the need to improve access to quality end-of-life care.

The communications environment in which to engage in an open dialogue with the public, politicians and policymakers, and the news media, suggests a far more proactive approach to communications than has hitherto been the norm.

The language of end-of-life care

There are differing points of view regarding language usage, particularly with patients, families, or lay people in general. This is not in reference to medical speak or terminology. Discussed here is how people are inclined to *interpret* language. As pointed out, 'hospice' and 'palliative care' are associated in the minds of many people with dying and death and, as a consequence, are taboo subjects or at least exceedingly difficult ones to broach. An important starting point in any dialogue, therefore, is to establish what a patient or family understands of the illness and what they want to know (or not know) in terms of, say, prognosis and likely scenarios as illness progresses—the 'what ifs'. From here, one can begin to gauge expectations with regard to end-of-life care, which can then lead into a discussion of hospice and palliative care. The challenge, however, can be compounded by modern language usage.

As individuals, we may go to extraordinary lengths in our day-to-day lives to avoid being the bearer of 'bad news' in almost any context. We consciously work, it often seems, in overdrive—to 'soften the blow', 'sugar-coat the message', to be 'politically correct' or 'culturally sensitive'. In doing so, we risk living much of our lives evading reality. As an example, 'openness' and 'transparency' have come to replace 'honesty' and 'truth', fundamental principles of hospice and palliative care. Also, is the 'conspiracy of silence' that so often prevails as death approaches—or, for that matter, whenever confronted with crises in our lives—nothing more than a manifestation of a life-long discomfort with the acceptance of the inevitable, of reality—or of truth itself? We live in a society that has, to a greater or lesser degree, devalued or inflated the meaning of words and, as individuals, we often manipulate their use and meaning to serve whatever our individual or collective ends might be. This begs the question: are we losing the ability or capacity to communicate effectively—or to hear what we need to hear—with empathy and without hurt or hurting?

An often overlooked and underappreciated 'component' of language is 'non-verbal' communication. People are not always conscious of how and what they communicate through their body language, facial expressions, or in their tone, no matter whether they are in a one-on-one situation or addressing a large audience or meeting with a small group of people.

Engaging in a dialogue with the public, politicians, and the news media

There is a direct correlation between the quality of care and the quality of communication. The quality of care for the terminally ill patient rests almost entirely on empathetic and meaningful two-way communication among or between all protagonists. It is essential to building a therapeutic relationship, facilitating informed decision-making, and effecting a positive change in the illness experience. The need is to transport this same mindset in reaching out to a far broader audience with the ultimate purpose of improving public understanding, advancing policy development, and building an informed news media. In other words, advocacy, which can be broadly defined as either taking a proactive stance (i.e. capital 'A' advocacy) or taking a reactive stance (i.e. small 'a' advocacy), in other words, acting 'after the fact'. Given the nature of the news media, 'yesterday's news' remains always 'yesterday's news', and opportunities for a meaningful response or redress fade—quickly.

The public

Patient choices tend to be at the forefront of public discussion on many aspects of health care. In the shadow of this discussion is the widespread concern in most countries over the needs of an ageing population. Added to this is the call to improve resource allocation to allow people to remain in their own homes and, if the option is available, to die there. The demands on informal or family caregivers has gained increasing attention also and added yet another dimension to the public discussion on meeting future demand for health-care and social services. Each of these issues should be considered 'avenues' to broaden discussion to encompass the provision and delivery of specialized end-of-life care.

Opportunities for community outreach come in many forms, particularly at the local or regional level, such as participating in public forums, speaking to special or public interest groups . . . and, of course, engaging the news media. Towards this end, a proven strategy has been to establish a pool of local experts, people who can speak with some authority on a given issue. Commonly referred to as a speaker's bureau, this can be an invaluable community resource (for the news media also).

Politicians

National ageing, home care or end-of-life care strategies are lacking in many, if not most, countries. For policymakers, each represents something of a political minefield and the real threat of political 'suicide'. A cautionary note: in countries where there is government funding or resource allocation for hospice or palliative care, there is an ever-present risk when speaking out on end-of-life issues of being seen to 'bite the hand that feeds you'. There can be negative consequences or repercussions if heard or seen to challenge or comment negatively on government action or inaction. This can present health-care professionals with both an ethical and moral dilemma. Understandably, they are guarded in their expressions of concern or criticism, opting to err on the side of caution. This has the potential for neutralizing opposing points of view.

It is important to establish a dialogue with key politicians, at the local, regional, and national level. Policy may emanate at, say, the national, state, or provincial levels of government, but resource allocation may be a shared responsibility with other levels of government, for example, municipal. While politicians are the public face of government, it is important to identify and connect with those individuals who advise or counsel politicians on policy, who are involved in researching and gathering background information on a given issue or topic, and who can help navigate the political system—most importantly at the ministerial level.

The news media

The news media stands as one of the principal arbiters of social attitudes on a broad range of issues; its selection and interpretation shapes public opinion. With this in mind, there is an understandable and widespread scepticism or reluctance on the part of many health professionals to engage with journalists or reporters. It can be a risky business and also a mixed blessing. It is possible, nonetheless, if not imperative to take part in public discussion and, through the news media, give the general public a chance to make up its own mind from a broader set of arguments and different points of view. A prerequisite is to monitor the news media—much in the same way a health professional monitors the literature—to keep abreast of current thinking.

Engaging the news media is a formidable challenge, particularly since it is becoming increasingly more fragmented with each advance in technology. Gone are the days of only a few major news outlets. And, there is a notable change in the calibre of journalists who might be assigned to a 'health story'. Informed medical or policy writers, as examples, are not as commonplace as, say, a decade or two ago. There are, nonetheless, thoughtful elements in the news media, but a health professional may often be faced in an interview with a journalist with less than a general knowledge of the subject matter or issue in question. Brevity is invariably the requirement, most notably in the broadcast media where the ambiguous 'sound bite' seems the overriding order of the day. Inherent in this approach to news reporting is the probability of comments or information taken out of context.

A common technique used by news reporters is to ask a question, rapidly followed by two or three possible answers, in effect 'managing' the interview, for example:

> Why do you think government is not prepared to commit to funding additional free-standing hospices? Is it because it is relying too heavily on the community for financial support . . . or, that the economic case for hospice has yet to be made?

This can flummox the subject being interviewed, who is faced with responding, not to the initial question, but to one or both of the fabricated answers, which are more often than not purely speculative. Lost may be the opportunity for a more accurate or truthful—less provocative—response. Another technique is to ask a 'loaded' question:

> Is it true that as a consequence of government budget cuts, the hospital will reduce the number of desperately needed palliative care beds?

The response may indeed be a simple 'yes' (or, conceivably, 'no'), but the broadcasted or published news item might read:

> Physicians are critical of the government decision to close palliative care beds. Dr X said in an interview that the proposed budget cuts will mean reducing the desperately needed beds for dying patients.

With this in mind, it is critically important not to be diverted from the key points that need to be made. At the outset, stay focused, deliver the 'bottom line' first and then the background or rationale. Keep in mind also that there really is no such thing as 'off the record' and that the journalist you are talking with is not your 'best friend'. Respect that the journalist has a job to do, but do not relax your guard. The watchword should always be preparedness.

The Internet and social media should be considered in the same context as the more conventional print and broadcast news media, with added reservations. While they offer a means of reaching a far wider audience, the Internet and social media function with few conventions or 'rules of engagement'. They might be considered the ultimate in terms of opportunities for freedom of expression. In this technology-fixated age, the Internet and social media fit neatly Marshall McLuhan's theory of 'the medium is the message', by which the medium influences how the message is received. Much is contradictory, distorted or one-sided, emotionally charged, inaccurate, unsubstantiated, or unverifiable. The Internet and social media are something of a 'free for all' in the exchange of information and ideas. Proceed, therefore, with guarded optimism.

A preparedness plan

While the public, politicians, and the news media may be more than familiar, if not personally acquainted, with mainstream medicine, and health-care and social services in general, end-of-life care remains largely unfamiliar territory. For one, it demands dedicating time with a patient or family in a system where time is more often than not at a premium. An example of its complexity is the psychosocial aspects of hospice and palliative care in, say, an ethnically diverse or multicultural society. Dying and death is not something that lends itself easily to a 'tick box' or 'checklist' mentality. Therefore, no matter with whom you are trying to communicate, one needs to develop a preparedness plan for each and every encounter or opportunity.

There are a number of different approaches to formulating such a plan. One that serves the purpose of giving realistic and understandable guidance to effective, empathetic communications asks and answers five key questions: 'Who are we talking to?', 'Where are we now in their minds?', 'Where would we like to be?', 'How do we get there?', and 'How do we know we are right?'

Who are we talking to? (i.e. the 'target' audience)—the term 'target' is used only to characterize those people who are most likely to receive the intended message with sympathetic eyes or ears. Try to describe them demographically and psychographically. If you cannot with reasonable precision, research to find out who and what kind of people they are . . . and, in the case of politicians, what their position or stand is or has been on the issue or subject in question.

Where are we now in their minds? (i.e. perceptions)—this question should be answered in the language of the audience you are trying to reach. It is a summation of what you think the person or people you are trying to reach say or think about the issue you would like to address or discuss. Once again, it may be necessary to conduct research to answer this question with reasonable accuracy. A starting point at this stage of the process is to acknowledge a basic premise of communication: perception is fact.

Where would we like to be? (i.e. communications 'objective')—after your message has been heard or read, what response can realistically be expected from the communication?

How do we get there? (i.e. 'strategy')—if you think of the objective in terms of how you want your audience to respond, then the 'strategy' has to be what it is you say or do to create that response.

How do we know we are right? (i.e. 'support')—whenever possible support the answers to the first four questions. If you have done your homework before starting this exercise, you will constantly refer back to available information as the exercise progresses. If any answer is questionable supposition, decide that it should be checked out or researched. In any event, 'How do we know we are right?' is not a question you ask at the end of the exercise. It is one you ask all the way through: each answer to the four questions requires back-up support, a rationale. A reason why.

Conclusion

Engaging in a dialogue with the public, politicians, or the news media is challenging and requires careful consideration and planning. It demands dedicated time. It can indeed be a harrowing experience navigating the emotional and political terrain that is involved, but, ask yourself, who is better qualified to help shape both opinion and understanding, and policy development, with regard to end-of-life care?

Assessment tools and Informatics

Palliative care needs assessment tools

Afaf Girgis and Amy Waller

Introduction to palliative care needs assessment tools

The delivery of appropriate and equitable care is a challenge facing many areas of health-care, including palliative care. The World Health Organization defines palliative care as 'an approach that improves the quality of life of patients and their families facing the problems associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychological, and spiritual' (World Health Organization, 2013, p. 11). Issues surrounding when and how palliative care should be delivered, as well as to whom, are yet to be resolved. However, inherent in the World Health Organization definition of palliative care is the assessment of needs. In this chapter, we discuss the concept of needs assessment and consider strategies for assessing people's needs and experiences, with a focus on the tools developed specifically for this purpose. Finally, we reiterate the importance of needs assessment tools being implemented as part of routine care to facilitate the right care being offered to people at the time they most need it, by the people or service which is most appropriate to meet identified needs.

Measures to inform clinical care

Patient satisfaction with care, or the extent to which an individual's experience compares with his or her expectations, has been used widely as a proxy measure of disease-related morbidity. Despite its continued popularity, its value in facilitating the process of clinical care is arguably uncertain at best. There are few reports on the reliability of satisfaction surveys (Aharony and Strasser, 1993; Nabati et al., 1998; Bredart et al., 2001). For many decades, patient morbidity has also been studied through assessment of quality of life, or the ramifications of a disease on aspects of life experience (Gustafson, 1991; Lehr and Strosberg, 1991; Gustafson et al., 1993; Skeel, 1993; Akechi et al., 2011; Molassiotis et al., 2011). A wide range of validated measures are available to assess the physical and psychosocial impacts of a disease. More recently, distress has been advocated as the sixth vital sign, alongside temperature, respiration, heart rate, blood pressure, and pain (Bultz and Carlson, 2006; Holland and Bultz, 2007).

Needs assessment has become a more widely utilized measure informing clinical practice since the late 1990s, as it spans both quality of life and quality of care issues (Bonevski et al., 2000).

Richardson et al. (2007) argue that 'from a patient's perspective, the quality of supportive care can be considered to be the extent to which needs are addressed and met, and if they are to be addressed adequately, must first be identified' (Richardson et al., 2007). The relationship between patient needs and other measures, including quality of life and satisfaction, has been the topic of much debate and discussion in the literature (Asadi-Lari et al., 2004; Wen and Gustafson, 2004). There is some evidence demonstrating significant relationships between unmet needs and poor emotional health and dissatisfaction with health services. A recent study evaluating the ability of distress screening to uncover unmet need for psychosocial services in cancer patients concluded that direct assessment of unmet needs was a more efficient strategy for identifying specific need for services (van Scheppingen et al., 2011). Carlson et al. (2012) have argued for a more complementary model, in which screening for distress is augmented usefully by the assessment of meetable unmet needs, with further assessment and empirically supported treatments as needed. The question about 'meetable unmet needs' is clearly complex.

Needs assessment in palliative care

Not all patients for whom death is expected will need specialist palliative care (Palliative Care Australia, 2005a), but for those who do, non-referral, late referral, or crisis referral may affect adversely the quality of care they receive near the end of life. Many factors contribute to non- or late receipt of palliative care. A key factor has been a reliance on prognosis and patient symptoms as the main triggers for specialist palliative care referrals by both generalist and specialist practitioners (Johnson et al., 2008, 2011a, 2011b, 2011c). However, a reliance on prognosis is fraught with problems given evidence of high levels of inaccuracy (systematically optimistic) in doctors' prognoses for terminally ill patients (Glare et al., 2003; Gwilliam et al., 2013). A longer doctor–patient relationship appears to reduce prognostic accuracy further, rather than improve it. The growing and compelling evidence base against prognostication supports the position of international bodies, including Palliative Care Australia and the World Health Organization, which have long advocated for a move away from prognosis and diagnosis-based models to guide delivery of care, to recommending needs-based care (Palliative Care Australia, 2005b; World Health Organization, 2007).

Needs assessment in palliative care inevitably must be guided by the domains of palliative care. These have been well articulated

by the World Health Organization as including pain, physical, psychological, social, cultural, and spiritual needs (World Health Organization, 2013); with a detailed overview of the domains of palliative care, as defined by the Canadian Hospice Palliative Care Association (2002), presented in Fig. 7.1.1.

Needs assessment tools have been developed and tested to assess palliative care and support needs across a variety of settings and diseases. Choosing the most appropriate tool depends on the purpose of the assessment, the target population, and the acceptability and psychometric qualities of the instrument.

DISEASE MANAGEMENT
- Primary diagnosis
- Secondary diagnoses or co-morbities (e.g. dementia, psychiatric diagnoses, substance ues, trauma)
- Prognosis
- Adverse events (eg. side effects/toxicities)
- Allergies

PHYSICAL
- Pain and other symptoms*
- Level of consciousness, cognition
- Function level of safety, aides, falls risk
  - Needs and implications for care
  - Motor (eg. mobility, swallowing, excretion)
  - Senses (e.g. hearing, sight, smell, taste, touch)
- Physiologic (e.g. breathing, circulation, sexual)
- Nutrition and hydration
- Wounds
- Habits (e.g. alcohol, smoking)

PSYCHOLOGICAL
- Personality, strengths, behaviour, motivation.
- Impact of illness on patient and family
- Depression, anxiety
- Emotions (e.g. anger, distress, hopelessness, loneliness)
- Fears (e.g. abandonment, burden, death)
- Control, dignity, independence, self image
- Conflict, Guilt, stress, coping
- Psychological or psychiatry assessment/treatment required

LOSS & BEREAVEMENT
- Loss
- Grief (e.g. acute, chronic, anticipatory)
- Bereavement planning & Referral pathway
- Ongoing support for complicated grief.

PATIENT AND FAMILY

Characteristics

Demographics (e.g. age, gender, race, contact inforamation)

Culture (eg. ethnicity, language, cuisine)

Personal values, beliefs, practices, strengths

Developmental state, education, literacy

Disabilities

SOCIAL
- Cultural values, beliefs, practices
- CALD needs
- Relationships, roles with family, friends, community
- Isolation, abandonment, reconciliation, support systems
- Privacy, intimacy, sexuality
- Routines, rituals, recreation, vocation
- Financial resources, expenses – welfare needs.
- Legal (e.g. powers of attorney for bussiness, for healthcare, advance directives, last will/testament, beneficiaries)
- Family caregiver support
- Guardianship, custody issues
- Special needs - indigenous

END OF LIFE CARE
- Use of Pathways Protocols to guide care
- Preferred place of death
- Anticipation and management of physiological changes in the last hours of life. Education of patient/family/staff.
- Responsive care for patient and family
- Advanced care planning
- Organ donation
- Preparation for expected death
- Information giving and responsive care.
- Rites, rituals
- Pronouncement, certification of death
- Care of family at time of and following death eg. privacy, involvement in care.
- Arrangements for the body eg. mortuary viewing
- Funerals, memorial services.

PRACTIAL
- Comprehensive discharge planning
- Activities of daily living (e.g. personal care, household activities)
- Dependents, pets
- Special needs
- Rural & remote
- Telephone access, transportation

SPIRITUAL
- Meaning, value
- Existential, transcendental issues
- Values, beliefs, practices
- Pastoral and spiritual support
- Rites, rituals, symbols, icons.

* Other common symptoms include, but are not limited to:
Cardio-respiratory: breathlessness, cough, edema, hiccups, apnea, agonal breathing patterns
Gastrointestinal: nausea, vomiting, constipation, obstipation, bowel obstruction, diarrhea, bloating, dysphagia, dyspepsia
Oral conditions: dry mouth, mucositis
Skin conditions: dry skin, nodules, pruritus, rashes
General: agitation, anorexia, cachexia, fatigue, weakness, bleeding, drowsiness, effusions (pleural, peritoneal), fever/chills, incontinence, insomnia, lymphoedema, myoclonus, odor, prolapse, sweats, syncope, vertigo

Selecting the most appropriate assessment tool requires a balance between obtaining the most accurate and comprehensive information possible, while minimizing the burden placed on the patient and clinician. Brief screening tools (1–14 items) (Mitchell, 2010) can provide a quick snapshot of the person's needs and may be most appropriate in busy clinical settings or if the patient has limited functioning. Ideally, this brief screening should be followed up by administering longer assessment tools to ascertain more comprehensive information on the range, severity, and complexity of any identified needs. The choice of assessment tool will be informed by the issues identified through the brief screening. For example, if a patient reports needs in only one domain of a brief tool (e.g. information needs), clinicians may consider using a unidimensional tool to explore that specific area of need in more detail. However, administration of a multidimensional tool which includes items assessing a range of need domains may be more informative when patients identify a number of domains of unmet need in the brief screening tool. For people with advanced disease or who are at the end of life, the mode of administration and participant burden are important considerations for health-care providers when selecting an assessment tool.

Many patients with advanced disease depend upon health-care providers for symptom assessment. However, research examining the extent of agreement between patient and provider symptom assessments (Nekolaichuk et al., 1999a; Laugsand et al., 2010) and patient psychosocial well-being (Newell et al., 1998; Jones et al., 2011a) suggests a need for caution in cases where a total reliance on health-care provider assessments is necessary. For example, a very large cross-sectional study of 1933 cancer patient–health-care provider dyads from 11 European countries revealed an under-estimating of symptoms by health professionals in one in ten cases, with patients with low Karnofsky Performance Status, high Mini Mental State-score, hospitalized, recently diagnosed, or undergoing opioid titration being at significantly increased risk of symptom underestimation by providers (Laugsand et al., 2010).

From a patient care perspective, patient-reported outcomes provide the highest level of accuracy of physical as well as psychosocial assessments (Sprangers and Aaronson, 1992; Nekolaichuk et al., 1999a, 1999b; Sneeuw et al., 2002; Tang and McCorkle, 2002). They may also be least burdensome in terms of financial costs and clinician time (Wen and Gustafson, 2004). The latter is a particularly important consideration for promoting needs-based care, with clinicians often reporting that time is a factor affecting the accurate and timely identification of needs (Pruyn et al., 2004; Waller et al., 2012b). However, the capabilities of the patient at the time of assessment and the clinical setting may necessarily become overriding factors in the choice of assessment mode (Wen and Gustafson, 2004). Caregivers and health professionals have been relied on for proxy assessments, with variable information about the severity and complexity of needs, in populations with advanced disease, where patients may have difficulty completing tools themselves due to the complexity and gravity of their symptoms (Carson et al., 2000). Tools which incorporate both patient and health-care provider input may provide the most detailed information to inform needs-based care.

The following section provides an overview of tools currently available for assessment of needs in a palliative care population, with more detailed information regarding each of these tools in Table 7.1.1. Some of these tools, such as the Palliative care Outcomes Scale (POS), the Needs at the End-of-Life Screening Tool (NEST), and the Sheffield Profile for Assessment and Referral to Care (SPARC-45) do not focus on a particular disease and have been validated in different patient groups. However, much of the work on development and validation of needs assessment tools has focused primarily on the palliative care needs of cancer patients, with fewer tools developed specifically for non-malignant conditions such as heart failure, chronic obstructive pulmonary disease (COPD), dementia, and HIV/AIDs.

Generic needs assessment tools for patients with any chronic disease

Only three generic measures were identified which are suitable for assessment of needs across a range of chronic diseases, two quite brief tools and one comprehensive assessment tool. One of the most established and well-validated tools for use across different patient groups is the POS (Hearn and Higginson, 1999; Bausewein et al., 2011). This 10-item measure assesses physical, practical, family, information, and psychological problems along with quality of life in the previous 3 days, with an additional item for open-ended patient comments. It includes both patient and clinician assessment components and has been used in a variety of clinical settings, including inpatient, home, hospice, and primary care. The POS has been implemented as an assessment tool in a mixture of palliative situations which include cancer, HIV/AIDS, COPD, dementia, heart failure, renal, and neurological populations. A recent systematic review highlights the studies validating or collecting data using the original and adapted versions of the POS, focusing on different patient groups, languages, and cultures (Bausewein et al., 2011).

The NEST is a 13-item measure identifying the subjective experiences and overall care of people at the end of life (Emanuel et al., 2000, 2001; Scandrett et al., 2010) and can be self-completed by the patient or by using a health professional interview. It assesses a wide range of domains of need including caregiver/family, physical, psychological, practical, spiritual, and social problems. Multiple strategies were used to provide evidence of content validity and adequate construct validity and internal consistency are reported. A recent study found that it is a feasible tool for assessing patient needs in the clinical setting (Scandrett et al., 2010); however, further evidence of reliability and responsiveness is needed.

The SPARC-45 (Ahmed et al., 2009) is a longer multidimensional assessment tool consisting of 45 items, developed to assess the palliative and supportive care needs of malignant and non-malignant conditions across general and specialist settings, prompting referrals to palliative care services where necessary. Like the NEST, content validity has been assessed, but there is limited information on other aspects of validity and on the reliability of the tool.

Tools specific to advanced cancer

Given the high representation of cancer patients in palliative populations, most of the published palliative care needs assessment tools have been developed and validated in cancer populations. These range from brief screening tools to longer self-report and interview measures.

The Three Levels of Need Questionnaire (3LNQ) (Johnsen et al., 2011), the Needs Assessment for Progressive Disease-Cancer (NAT: PD-C) (Waller et al., 2008, 2010, 2012a, 2012b) and the Screen for Palliative and End-of-Life Care Needs in the Emergency

Table 7.1.1 Summary of psychometric properties of palliative care needs assessment tools

Measure	Items and domains	Question format	Completion	Population	Psychometrics
Malignant and non-malignant conditions					
NEST Needs near the end-of-life scale	**13 items:** Financial, access to care, social connection, caregiving needs, psychological distress, spirituality, sense of purpose, patient–clinician relationship, clinician communication, personal acceptance	Assesses care needs of people at the end of life Scale ranges from 0 (no need) to 10 (highest need); higher scores indicate higher needs	Patient or health-care provider	Advanced cancer (Emanuel et al., 2000, 2001; Scandrett et al., 2010) Stroke, dementia, liver, renal, pulmonary (Grudzen et al., 2010)	Content validity Internal consistency Construct validity
POS Palliative Outcome Scale (see Bausewein et al. (2011) for a detailed overview))	**10 items:** Pain and other symptoms, patient anxiety, family anxiety, information, level support, life worth, self-worth, waste time, personal affairs Patients also asked open-ended item to identify main problem; staff asked additional performance status item	Assesses problems and quality of life over the last 3 days Scales range from 0 (no problem) to 4 (overwhelming problem); higher scores indicate more problems	Patient and health-care provider Time taken: 10 minutes	Cancer Dementia HIV/AIDS COPD Heart failure Kidney Neurological	Content validity Internal consistency Test–retest reliability Inter-rater reliability Construct validity Responsiveness Translations available
SPARC-45 Sheffield Profile for Assessment and Referral to Care	**45 items:** Communication/information, physical, psychological, religious and spiritual, independence and activity, family and social, treatment	Assesses level of need and desire for help in the last month Need scale ranges from 0 (not at all) to 3 (very much) Desire for help: scale scored as yes or no	Patient	Malignant and non-malignant Cancer (Ahmed et al., 2009; Wilcock et al., 2010) Stroke (Burton et al., 2010)	Validation manuscript in preparation
Malignant only—generic tools (all stages of disease)					
CaNDI Cancer Needs Distress Inventory	**39 items in 7 domains:** Depression, anxiety, emotional, social, health-care, practical, physical	Assess problem intensity and desire for help in past 2 weeks Intensity: scale ranges from 1 'not a problem', to 5 'very severe problem' Desire for help/discussion with health professionals: 'yes' or 'prefer not to'	Patient	Cancer (Lowery et al., 2012)	Content validity Construct validity Internal consistency Test–retest reliability Predictive validity
CARES-SF Cancer Rehabilitation Evaluation System Short Form	**38-57 items in 5 domains:** Physical, psychological, medical interaction, marital, sexual Also Global CARES score	Assesses physical and psychosocial issues affecting cancer patients; and in the clinical version, desire for help Scale ranges from 0 'does not apply' to 4 'applies very much'	Patient (interview follow-up) Time taken: 11 minutes	Cancer (Schag et al., 1991; te Velde et al., 1996)	Content validity Internal consistency Test–retest reliability Construct validity Responsiveness
Palliative Care Screening Tool & NCCN Palliative Care Referral Criteria	**Screening tool 5 items:** Metastatic disease, functional status, serious complications, comorbidities, palliative problems **NCCN 24 items:** Physical, psychological, cognitive, treatment, communication, practical, family, spiritual, social	Identifies patients for whom specialist palliative care referral may be required **5 items:** score range from 0 to 13; higher scores indicate worse functioning; cut-off of 5 indicates need for referral **24 items:** NCCN criteria for referral	Health-care provider	Cancer (Glare et al., 2011)	Content validity

PCM Patient Care Monitor	**80 items in 6 domains:** General physical symptoms, treatment side effects, distress, despair, impaired performance, impaired ambulation. Also a QoL index (54 items)	Assesses symptoms on a scale ranging from 0 to 11; PCM distress score > 65 prompts further assessment by psychosocial	Patient	Cancer (Abernethy et al., 2010)	Content validity Internal consistency Test–retest reliability Concurrent validity
SCNS-SF34 Supportive Care Needs Survey Short Form	**34 items in 5 domains:** Psychological, physical, patient care and support, sexual and health system and information	Assesses level of need for help in the last month Scales range from 1 (no need/not applicable) to 5 (high need)	Patient time taken: 10 minutes	Cancer (Boyes et al., 2009; Schofield et al., 2012)	Content validity Internal consistency Construct validity Responsiveness
SCNS-ST9 Supportive Care Needs Survey Screening Tool	**9 items:** 2 psychological, 2 physical, 2 patient care and support, 1 sexual, and 2 information items	Assesses level of need for help in the last month Scales range from 1 (no need/not applicable) to 5 (high need)	Patient	Cancer (Girgis et al., 2011)	Content validity Construct validity Predictive validity
Malignant: advanced disease only					
3LNQ Three-Levels-of-Needs Questionnaire	**14 items (11 EORTC QLQ-C30 items + 3 additional):** Physical function, role function, social function, psychological (depression, worry), physical symptoms (pain, fatigue, nausea, dyspnoea, appetite), sexuality, feeling burden, loneliness	Assesses problem intensity, problem burden, and felt need in the past week Intensity and burden: scale ranges from 'not at all' to 'very much' Felt need: scale ranges from 'no need'/'met need'/'unmet need'	Patient	Advanced cancer (Johnsen et al., 2011)	Content validity Internal consistency
NA-ACP Needs Assessment of Advanced Cancer Patients	**132 items in 7 domains:** Daily living, physical symptom, psychological, social, spiritual, financial, medical communication & information	Assesses needs and desire for help in past 4 months Scale ranges from 1 (no need/not applicable) to 5 (high need); higher scores indicate higher needs	Patient Time taken: 76 minutes	Advanced cancer (Rainbird et al., 2005)	Content validity Internal consistency Test–retest reliability Construct validity
NAT: PD-C Needs Assessment for Progressive Disease—Cancer	**18 items in 3 domains:** Patient well-being, ability of caregiver/family to care for patients, caregiver/family well-being	Assesses the level of concern and actions taken to address concerns Level of concern ranges from 'none' to 'significant' Provider indicates action taken to manage concern ('directly managed', 'managed by team', or 'referral')	Health-care provider Time taken: 5–10 minutes	Advanced Cancer (Waller et al., 2008, 2010, 2012a, 2012b)	Content validity Inter-rater reliability Concurrent validity
PNPC Problems and Needs in Palliative Care	**132 items in 6 domains:** Physical/daily living, autonomy, psychological, social, spiritual, information, financial	Assesses problems and need for assistance using 2 questions for each item: (1) Is this a problem? (2) Do you want attention?	Patient	Advanced cancer (Osse et al., 2004)	Content validity Construct validity Internal consistency
PNPC-SF Problems and Needs in Palliative Care Short Form	**33 items in 6 domains:** Physical/daily living autonomy, psychological, social, spiritual, information, financial	Assesses problems and need for assistance using 2 questions for each item: (1) Is this a problem? (2) Do you want attention?	Patient Time taken: 5–10 minutes	Advanced cancer (Osse et al., 2007)	Content validity Construct validity Internal consistency

Table 7.1.1 Continued

Measure	Items and domains	Question format	Completion	Population	Psychometrics
SISC Structured Interview of Symptoms and Concerns in Palliative Care	**13 items:** Pain, drowsiness, nausea, weakness, dyspnoea, loss control, loss dignity, burden, anxiety, depression, loss interest, hopelessness and desire death	Assesses common symptoms and concerns; scale ranges from 0 (none) to 6 (extreme) 3 and above as clinical cut-off	Health-care provider Time taken: 28–60 minutes	Advanced cancer (Wilson et al., 2004)	Inter-rater reliability Test–retest reliability Concurrent validity
SPEED Screen for Palliative and End-of-Life Care Needs in the Emergency Department	**13 items in 5 domains:** Social, therapeutic, physical, psychological, spiritual	Assesses the level of need Scale ranges from 0 (not at all) to 10 (a great deal); higher scores indicate higher needs	Health-care provider	Cancer patients in emergency department (Richards et al., 2011)	Content validity Construct validity
Malignant: specific tumour group or domain of need					
NA-ALCP Needs Assessment for Advanced Lung Cancer Patients	**38 items in 7 domains:** Daily living, physical symptom, psychological, social, spiritual, financial, medical communication & information	Assesses needs and desire for help in past 4 months. Scale ranges from 1 (no need/not applicable) to 5 (high need); higher scores indicate higher needs	Patient	Advanced lung cancer (Schofield et al., 2012)	Content validity Internal consistency Construct validity
PAQ Patient Autonomy Questionnaire	**9 items in 3 domains:** Dependency, losing control, limitation of activity	Assesses autonomy needs of cancer patients using 2 questions for each item: (1) Is this a problem? (2) Do you want attention?	Patient	Advanced cancer (Vernooij-Dassen et al., 2005)	Content validity Internal consistency Construct validity
Dementia					
EOLD (3 scales) End of Life in Dementia **SWC-EOLD** Satisfaction care **SM-EOLD** Symptoms **CAD-EOLD** Comfort	**SWC-EOLD 10 items:** Decision-making, communication with providers, understanding condition, medical and nursing care **SM-EOLD 9 items:** Physical (pain, shortness breath, skin); psychological (calm, depression, fear, anxiety, agitation, resistive to care) **CAD-EOLD 14 items:** Discomfort, pain, shortness breath, choking, gurgling, swallowing, fear, anxiety, crying, moaning, serenity, peace, calm	**SCW-EOLD** Assesses satisfaction in last 90 days of life ('strongly disagree' to 'agree'). Scores range from 10 to 40; higher scores indicate higher satisfaction **SM-EOLD** Assesses symptom frequency in last 90 days of life ('never' to 'once a month'). Scores range from 0 to 45; higher scores indicate better symptom control **CAD-EOLD** Assesses frequency in last 7 days life ('not at all' to 'a lot'). Scores range from 14 to 42; higher scores indicate better symptom control	Health-care provider	Dementia (Kiely et al., 2006, 2012; Volicer et al., 2001)	Internal consistency Content validity Construct validity Responsiveness
DCNA John Hopkins Dementia Care Needs Assessment	**86 items in 19 domains:** Safety, management cognitive and neurocognitive symptoms, medical comorbidities, daily activities, caregiver education and support	Assesses degree to which patients and caregiver needs are met Level need: 'unmet', 'partially met', 'met'	Health-care provider	Dementia	Unknown

CANE Camberwell Assessment of Needs for the Elderly	**24 patient items and 2 caregiver items:** Daily living, self-care, physical, psychological, safety, social, financial, medications, behaviour, practical, patient and caregiver information, patient and caregiver distress	Assesses presence of need, level of help from family/friends and services and whether amount of help was adequate Scale ranges from 'no need', 'met/partially met need' 'unmet need' or 'not known'	Patient and health-care provider Time taken: 30 minutes	Dementia (initially developed for mentally ill elderly patients) (Reynolds et al., 2000)	Content validity Inter-rater reliability Test–retest reliability Construct validity Criterion validity
CareNap-D Care Needs Assessment pack for Dementia	**57 items in 7 domains:** Health and mobility, self-care and toileting, social interaction, thinking and memory, behaviour and mental state, house care, community living	Assesses intensity of need and for unmet needs the type action required Scale ranges from 'no need', 'unmet need', 'met need'	Health-care provider	Dementia (McWalter et al., 1998)	Content validity Inter-rater reliability Social validity
Heart failure					
NAT: PD-HF Needs Assessment Progressive Disease—Heart Failure	**18 items in 3 domains:** Patient well-being, ability of caregiver/family to care for patients, caregiver/family well-being	Assesses the level of concern and actions taken to address concerns Level of concern 'none' to 'significant' Provider indicates action to manage concern ('directly managed', 'managed team', 'referral')	Health-care provider Time taken: 5–10 minutes	Heart Failure (Waller et al., 2013)	Content validity Inter-rater reliability Concurrent validity
HFNAQ Heart Failure Needs Assessment Questionnaire	**30 items in 4 domains:** Physical (10 items), psychological (9 items), social (8 items), existential (3 items)	Assesses need for help in the last month Scale ranges from 1 (hardly ever) to 5 (always)	Patient Time taken: 10 minutes	Heart failure (Davidson et al., 2008)	Content validity Internal consistency Construct validity Concurrent validity Discriminant validity
Chronic obstructive pulmonary disease (COPD)					
CCQ Clinical COPD Questionnaire	**10 items in 3 domains:** Symptoms (4 items), functional state (4 items) and mental state (2 items)	Assesses symptom intensity during the past week Scale ranges from 0 (never/asymptomatic) to 6 (almost all of the time/extremely symptomatic)	Patient Time taken: 2 minutes	COPD (van der Molen et al., 2003; Jones et al., 2011)	Content validity Internal consistency Test–retest reliability Construct validity Responsiveness
CAT COPD Assessment Test	**8 items:** Cough, phlegm, chest tightness, breathlessness, activities, confidence in leaving home, sleep and energy	Assesses impact of symptoms on quality of life and well-being Scale ranges from 0 (I am very happy) to 5 (I am very sad)	Patient Time taken: 2 minutes	COPD (Tsiligianni et al., 2012)	Content validity Internal consistency Test–retest reliability Construct validity Responsiveness
SGRQ St George Respiratory Questionnaire	**50 items in 3 domains:** Symptoms (8 items), activity (16 items) and impact on daily life (26 items)	Assess frequency and severity of symptoms, limitation breathlessness on activities and disturbances of social and psychological functioning Scores range from 0 (no impairment) to 100 (maximum impairment)	Patient	COPD (Meguro et al., 2007)	Content validity Construct validity Internal consistency Test–retest validity Responsiveness

Table 7.1.1 Continued

Measure	Items and domains	Question format	Completion	Population	Psychometrics
HIV/AIDS					
ECSQ Events in care Screening Questionnaire	**54 items in 9 domains:** Adherence to medical instructions, medical problems, specialty and inpatient care, preventative health-care and screening, sexual risk behaviour, family planning, psychological symptoms, substance use and life demands	Part 1 of Dynamics of Care assessment Assesses problems in last 3 months Scored as yes or no Dynamics of Care Assessment (interview) assesses need for additional information and whether provider has discussed each need identified	Health-care provider	HIV/AIDS (Patel et al., 2008)	Content validity Construct validity
HOPES HIV Overview if Problems Evaluation System	**106 items in 5 domains:** Physical, psychosocial, sexual functioning, medical interaction and partner relationship	Assesses quality of life and rehabilitation needs Scale ranges from 0 'does not apply' to 4 'applies very much'	Patient	HIV/AIDS (adapted from CARES) (Schag et al., 1992; De Boer et al., 1996)	Content validity Internal consistency Criterion validity Construct validity Responsiveness
MOS-HIV Medical Outcomes Study HIV Health Survey	**35 items in 10 domains:** Health perceptions, pain, physical, role, social and cognitive functioning, mental health, energy, health distress and quality of life	Assesses functional status and well-being Scores range from 0 to 100; higher scores indicate better health	Patient (also interview version) Time taken: 5 minutes	HIV/AIDS (Hughes et al., 1997; Wu et al., 1997; Revicki et al., 1998, Clayson et al., 2006)	Content validity Internal consistency Construct validity Responsiveness

Department (SPEED) (Richards et al., 2011) are all comparatively brief measures (13–18 items) for rapid needs assessment. The 3LNQ (Johnsen et al., 2011) assesses unmet need and desire for help in physical, social, psychological, and sexuality domains, through patients' self-rating of problem intensity, problem burden, and felt need. Preliminary evidence of content validity and internal consistency has been reported. Given its recent development, additional measures of reliability, construct validity or responsiveness are still needed. The NAT: PD-C was developed for completion by a range of health professionals in both generalist and specialist settings. It is the only identified multidimensional tool which assesses the needs of both the patient and caregiver/family concurrently. The reliability and content validity of the NAT: PD-C have been established in both a research and a clinical setting. Concurrent validity is available for some, but not all, subscales of the tool. The SPEED is a tool for health professional assessment of social, therapeutic, physical, psychological and spiritual palliative care needs, specifically for patients seen in the emergency department. It has been tested initially on people with metastatic disease, providing evidence for construct validity. Further work is needed to establish reliability and utility in non-cancer populations.

The Needs Assessment of Advanced Cancer Patients (NA-ACP) (Rainbird et al., 2005), Problems and Needs in Palliative Care (PNPC) (Osse et al., 2004), and Structured Interview of Symptoms and Concerns in Palliative Care (SISC) (Wilson et al., 2004) are longer measures administered by either self-report (NA-ACP, PNPC) or by interview (SSISC). The NA-ACP (Rainbird et al., 2005) is a 132-item multidimensional measure of needs that has undergone rigorous psychometric testing, including content and construct validity, internal consistency and test-retest reliability. The 132-item PNPC (Osse et al., 2004) also assessed the needs of people with advanced cancer across a range of domains, with adequate content and convergent validity as well as internal consistency. A 33-item shorter version of this tool is available, the PNPC-sv (Osse et al., 2007), which covers the same domains as the 132-item PNPC. The short completion time of 5–10 minutes increases the acceptability and clinical utility of this version. Whilst both the PNPC and NA-ACP are acceptable to patients, the time taken to complete these tools may make them less feasible for some palliative patients, particularly toward the end of life.

The SISC (Wilson et al., 2004) is an interview-style assessment covering 13 areas: pain, drowsiness, nausea, weakness, dyspnoea, loss of control, loss of dignity, burden, anxiety, depression, loss of interest, hopelessness, and desire for death. This tool may be useful as a follow-up assessment following initial screening, given the completion time ranging from 28 to 60 minutes.

As indicated in Table 7.1.1, varying levels of psychometric evidence are available for the tools targeting people with advanced cancer specifically. Content validity was established using literature reviews and reviews of existing measures (3LNQ, NAT: PD-C, NA-ACP, PNPC, PNPC-sv, SPEED, SISC) and clinical/expert options (NA-ACP, NAT: PD-C, PNPC, PNPC-sv, SPEED). Construct validity was established using factor analysis (NA-ACP) and correlations with other validated measures (NAT: PD-C, SPEED, PNPC, PNPC-sv). Evidence of inter-rater reliability (NAT: PD-C) and internal consistency (NA-ACP, PNPC, PNPC-sv) was available for some tools; however, all tools require further studies to establish test–retest reliability, predictive validity, and responsiveness.

Cancer-specific tools: across the illness trajectory

Needs assessment tools have been developed for use by cancer patients across the illness trajectory. The Palliative Care Screening Tool & NCCN Palliative Care Referral Criteria (Glare et al., 2011) can be used by health-care providers to identify patients for whom specialist palliative care referral may be required. The 34-item Supportive Care Needs Survey Short Form (SCNS-SF34) (Boyes et al., 2009), the Supportive Care Needs Survey Screening Tool (SCNS-ST9) (Girgis et al., 2012), the Patient Cancer Monitor (PCM) (Abernethy et al., 2010), the Cancer Rehabilitation Evaluation System Short Form (CARES) (Schag et al., 1991; te Velde et al., 1996), and the Cancer Needs Distress Inventory (CaNDI) (Lowery et al., 2012) are also suitable for patients along the cancer continuum and have undergone rigorous psychometric testing. Other tools such as the Needs Assessment for Advanced Lung Cancer Patients (NA-ACLP) (Schofield et al., 2012) and the Patient Autonomy Questionnaire (PAQ) (Vernooij-Dassen et al., 2005) may be useful for assessing particular tumour groups or domains of need.

Dementia

The assessment of needs in people with dementia can be complicated by the patient's limited cognitive functioning and loss of language skills (Schmid et al., 2012). The Camberwell Assessment of Need for the Elderly (CANE) is a structured interview that assesses 24 patient and two caregiver needs (Reynolds et al., 2000). It can be used for research and clinical purposes and performs well on psychometric criteria. Its advantage is that it enables patients, caregivers, and health-care providers to rate level of need, enabling a more comprehensive and accurate assessment of the patient situation. The Care Needs Assessment Pack for Dementia (CarenapD) (McWalter et al., 1998) is a software package assessing the needs of people with dementia living in the community and their carers. This package can be used by multidisciplinary health-care providers and combines patient and caregiver opinions regarding care needs. The End of Life in Dementia (EOLD) scale (Kiely et al., 2006, 2012) is comprised of three scales assessing satisfaction with care, symptoms, and comfort at the end of life. It is completed by the health-care provider and has demonstrated reliability, validity, and sensitivity to change over time. The Tayside Profile for Dementia Planning (Gordon et al., 1997) was developed for clinical use and can be administered as a questionnaire or interview. Unlike the other measures that utilize both patient and caregiver perspectives, the Tayside Profile for Dementia Planning assesses needs from the perspective of the caregiver only. It is also limited in the domains of need assessed (Schmid et al., 2012).

Heart failure

Fewer needs assessment tools are specific to people with heart failure. The Needs Assessment for Progressive Disease—Heart Failure (NAT: PD-HF) (Waller et al., 2013) was adapted from the NAT: PD-C, assessing multidimensional needs for both patients and carers. Preliminary evidence for inter-rater reliability, content and concurrent validity has been established in a clinical heart failure clinic. Similar to the cancer version of this tool, further work is needed to establish reliability, validity, and responsiveness. The Heart Failure Needs Assessment Questionnaire (HFNAQ) is a 30-item measure with adequate content validity,

internal consistency, as well as concurrent and discriminant validity (Davidson et al., 2008). Heart failure-specific tools that have focused on assessment of health-related quality of life, rather than focusing on unmet needs, are the subject of a systematic review (Johansson et al., 2004). The most commonly used include the Minnesota Living with Heart Failure (MLwHF) tool, the Chronic Heart Failure Questionnaire (CHQ), and Quality of Life in Severe Heart Failure (QLQ-SHF) (Johansson et al., 2004).

Chronic obstructive pulmonary disease

The Clinical COPD questionnaire (CCQ) and the COPD Assessment Tool (CAT) are two brief tools that can be used to screen patients for physical symptoms, functional status, and emotional well-being (van der Molen et al., 2003; Jones et al., 2011b). These tools can be completed by the patient and take approximately 2 minutes. Both tools exhibit adequate reliability and validity but a recent study showed patients prefer the CCQ (Tsiligianni et al., 2012). The St George Respiratory Questionnaire (SGRQ), a longer patient-completed measure assessing severity of symptoms and limits on functioning, is used widely in people with respiratory problems. A COPD-specific version has been developed and validated in this population (Meguro et al., 2007).

HIV/AIDS

The Events in Care Screening Questionnaire (ECSQ) (Patel et al., 2008) is the first part of a larger interviewer-administered assessment (Dynamics of Care assessment). The ESCQ can be used as a stand-alone measure to assess needs and concerns, if patients want more information and if the health-care provider had discussed identified needs with the patient in the last 3 months. Construct validity and clinical utility was demonstrated in 628 HIV/AIDs patients. The ESCQ may be a valuable tool for use as an initial screen for patient needs in this population. Further work is needed to establish reliability and validity.

The HIV Overview of Problems Evaluation System (HOPES) (De Boer et al., 1996, Schag et al., 1992) scale was adapted from the cancer version (CARES) to assess the needs of people with HIV/AIDs. Items were derived from the CARES and by expert and clinical opinion, then piloted with 38 HIV patients. This 106-item tool has high internal consistency, convergent, divergent, and construct validity, and is responsive to changes in clinical status over time. While this measure is longer and may be potentially burdensome, the detailed approach allows the health-care provider to obtain more comprehensive information.

Many of the remaining tools available to assess needs in the HIV/AIDS population focus on health-related quality of life rather than unmet needs. Missoula–VITAS Quality of Life index (MVQOLI) (Byock and Merriman, 1998; Schwartz et al., 2005) was developed specifically for palliative care terminal patients. Items were initially identified from a review of the literature and informal interviews of hospice professionals, patients, and their families, then were pilot tested with patients. Convergent, divergent, and concurrent validity have been established; however, further work is needed to assess responsiveness. The tool allows respondents to rate the importance of each dimension and the patient-weighted dimensional sub-scores offer clinical utility.

The Medical Outcomes Study HIV Health Survey (MOS-HIV) is the most widely-used measure in HIV/AIDs (Hughes et al., 1997; Wu et al., 1997; Revicki et al., 1998). It has adequate reliability,

validity, and responsiveness and has been tested in patients at all stages of disease. It has significant advantages including availability in numerous languages and 5-minute administration time via self-report or face-to-face and telephone interviews. However, it has been suggested that the MOS-HIV has limitations including possible ceiling effects associated with scoring; that it may be too general and some aspects of disease may not be assessed; and that it has not been extensively tested in some subgroups of patients (e.g. women, lower socioeconomic status, drug users). A systematic review of quality of life measures recommended the MOS-HIV and the Functional Assessment of HIV Infection (FAHI), but cautioned that these measures have limitations (Clayson et al., 2006).

Integrating needs assessment into routine clinical practice

For a needs-based model of palliative care to demonstrate systematic positive impacts on patient outcomes, it must inevitably involve more than needs assessment. Such a model needs to be well integrated into routine clinical practice, with key components including the following:

◆ Accessibility to people with a life-limiting illness, irrespective of their diagnosis.

◆ Assessment of unmet needs across the spectrum of palliative care domains (see Fig. 7.1.1), systematically and repeatedly to identify changes in needs over time.

◆ Clear care pathways for addressing identified needs by the most appropriate provider or service, including generalist and specialist care providers.

◆ Continuity of care across care settings through efficient communication strategies within and between these care settings.

◆ Training of staff to support the best quality generalist and specialist palliative care to patients and their families.

◆ Rigorous evaluation of outcomes to determine the physical and psychosocial impact on patients and carers of adopting a needs-based model of palliative care, as well as the economic costs and benefits to the health-care system.

Conclusion

◆ Most needs assessment tools have been developed for oncology patients, with validation and other psychometric testing largely being reported for this population. There are fewer tools for other patient groups.

◆ Brief tools, including the POS, NEST, NAT: PD-C, 3LNQ, and SPEED, may be more feasible in routine clinical practice with heavy patient throughput or for patients for whom longer measures may be too burdensome. Longer, more intensive tools can then be administered to provide more comprehensive information for health-care providers.

◆ Other disease-specific tools that have undergone rigorous psychometric testing include the CARES, CaNDI, and SCNS (across cancer trajectory); the NA-ACP (advanced cancer patients); EOLD and CANE (dementia); HFNAQ (heart failure); CCQ and CAT (COPD); and HOPES and MOS-HIV (HIV/AIDs).

◆ Tools such as the POS may be applied to various patient groups and provide information from patient and health-care provider perspectives.

◆ Further evidence of psychometric quality is needed, particularly test–retest reliability, predictive validity, responsiveness, and clinical utility of these tools.

◆ Integration of needs assessment into an overall needs-based model of palliative care will have the greatest likelihood of positive impacts on patients, carers, and health system outcomes.

The measurement of, and tools for, pain and other symptoms

Jane M. Ingham, Helen M. Moore,
Jane L. Phillips, and Russell K. Portenoy

Introduction to measurement tools for pain

For patients with advanced or incurable illnesses, the disease experience is inextricably linked to symptoms, and to the distress that symptoms produce. Symptom assessment is essential in developing and implementing a plan of care intended to reduce illness burden and suffering. The measurement of symptoms is both a key element in this assessment and the means by which therapeutic interventions can be tested in clinical research.

Symptoms are multidimensional and symptom measurement is complex. Addressing this complexity requires consideration of (1) symptom assessment and measurement principles, (2) the clinical and research applications of these principles, (3) measurement instruments for common symptoms, and (4) challenges in the application of symptom measures in palliative care settings.

Symptom assessment and measurement principles

Symptoms—a general definition

The study of symptoms has been hampered to some degree by a lack of consistency in terminology. According to the *Oxford Dictionary of English*, a symptom is 'a physical or mental feature which is regarded as indicating a condition of disease, particularly such a feature that is apparent to the patient' ('Symptom', 2013). Symptoms are inherently *subjective*. They are perceptions, and are usually conveyed by language. Symptom measurement attempts to quantify aspects of this perception in a manner that is valid and reliable.

Symptoms may be distinguished from *signs*, which are objective indicators of disease, and from pathological processes or diagnoses. Although neither symptoms nor signs are diagnoses, some symptoms are used clinically like diagnoses, as a guide to assessment or treatment. For example, 'confusion' is a symptom which, in the context of advanced illness, may imply the existence of cognitive impairment or delirium and lead promptly to a search for reversible causes. A comprehensive evaluation, seeking signs of cognitive disturbance, or change in level of consciousness, is needed, to establish the diagnosis of delirium. It is important to recognize that symptoms by themselves have a differential diagnosis, which may be explored by examination and review of objective data.

Specific symptom descriptors

While languages are enriched by the subtle differences in the meaning of words used to describe human perceptions, the measurement of these perceptions is made more challenging by these nuances. The complexity of measurement is compounded when the symptoms themselves are highly variable and the words used to label them, such as 'pain' or 'fatigue', have a plethora of meanings for patients and a wide range of implications. To address the complexity of pain, for example, the International Association for the Study of Pain (IASP) created a taxonomy that defines pain-related terms, characterizes various dimensions, and links these characterizations to specific diagnoses (IASP, 2011). This work has helped define the parameters of appropriate measurement strategies—what should be measured and how—in relation to varied painful conditions.

In contrast, there is no comparable framework for the meanings, dimensions, and linkages to diseases of other common symptoms, such as 'fatigue', 'confusion', and 'breathlessness'. Fatigue may be interpreted by some patients as sleepiness and by others as muscle weakness or exhaustion. The word 'confusion' may be used variably to refer to impaired concentration, disorganized thinking, forgetfulness, or even hallucinations. The variability of these meanings and the complexity of symptom linguistics are among the many factors that justify the need for formal validation of symptom measurement instruments. Validation determines whether a word or set of words to describe subjective experience has sufficient common meaning to allow accurate determination of characteristics such as presence/absence, intensity, and duration. Without a common meaning, there is the potential for instrument-to-instrument variation in the prevalence of seemingly identical symptoms (Bruera et al., 1991; Cella et al., 1993; Portenoy et al., 1994b; Chang et al., 2000a).

'Dyspnoea' illustrates this complexity. There is no consensus regarding the most appropriate definition for dyspnoea, but it is broadly accepted to be subjective, and hence a symptom. Affirming this view, the American Thoracic Society stresses that self-report is the appropriate means to assess dyspnoea and that dyspnoea is comprised of quantitatively distinct sensations that vary in intensity (American Thoracic Society, 1999). The symptom is not easily described by those who experience it, however. In a study of patients with dyspnoea, 8% answered 'no' to the statement 'I feel

breathless' despite answering 'yes' for numerous other descriptors that are applied to dyspnoea (Elliott et al., 1991). Among healthy individuals, the descriptors applied to breathlessness appear to relate to various physiological mechanisms and not to any specific underlying pathophysiology or disease condition (Mahler et al., 1996). Clusters of descriptors have been found to associate with different diagnostic groups, suggesting that patients are describing qualitatively different experiences of breathlessness (Wilcock et al., 2002).

Another study found similar complexity in the variation across instruments when patients were asked to endorse similar symptoms. Intra-individual variation of about 10% was apparent in the prevalence of 'feeling sad' versus 'depression', and 'feeling nervous' versus 'anxiety' (Chang et al., 2000a). These differences could potentially relate to variation in the meaning of descriptors determined by culture, education, symptom experience (e.g. severity), or attributions specified by the instrument (such as assessment timeframe).

Subjectivity in assessment and measurement

Because symptoms are inherently subjective, patient self-report must be the primary source of information (Slevin et al., 1988; Kahn et al., 1992; Hinton, 1996; National Institutes of Health, 2011a; National Cancer Institute, 2013). This reliance on self-report to measure symptoms resonates well with a broad initiative—most notable in oncology—to validate and promote the use of so-called 'patient-reported outcomes' (PROs) as key metrics in clinical care. The emerging emphasis on PROs reflects increasing consumer demand for patient-centred care, ensuring that the voice of the patient is considered as the plan of care is elaborated.

The National Institutes of Health (NIH) in the United States has supported the development of a Patient-Reported Outcome Measurement Information System (PROMIS®), which aims 'to provide clinicians and researchers access to efficient, precise, valid, and responsive adult- and child-reported measures of health and well-being' (NIH, 2011b). The network advancing the PROMIS® system has developed item banks for measurement of major self-reported health domains that are affected by chronic illness. Item banks are collections of calibrated items from which short-form measures and computer-adaptive tests can be derived. As examples, this network has addressed fatigue, pain, physical function, and emotional distress (Garcia et al., 2007) for cancer clinical trials. The National Cancer Institute (NCI) in the United States has been particularly focused on an expanded role for PROs as outcomes in cancer trials (NIH, 2011a). In the United Kingdom, an example of these efforts is to be found in the Department of Primary Health Care Services, Health Service and Policy Research Group's work on patient-reported measures of outcome and experiences of health-care (PROMs and PREMs) (Department of Primary Care Health Sciences, 2013), and in the palliative care setting, the European Association on Palliative Care has a Task Force working actively on patient-reported outcome measurement (European Association for Palliative Care, 2012).

From a research perspective, direct measurement of PROs is supported by numerous studies that demonstrate poor correlation between observer and patient assessments (Slevin et al., 1988; Grossman et al., 1991; Kahn et al., 1992). There is a poor correlation, for example, between patients' visual analogue scale (VAS) scores for pain and those completed by their health-care

providers, with some evidence that the poorest accuracy may be among patients with the most severe pain (Grossman et al., 1991). Another study that assessed concurrently patients and their spouse caregivers found that, although the spouse caregivers agreed with patients on objective measures with observable referents (e.g. ability to dress independently), they disagreed with subjective aspects of patient functioning (e.g. depression, fear of future, and confidence in treatment) (Clipp and George, 1992). Similarly, evidence from retrospective surveys completed by family members after the patient's death has suggested that assessment by family is better for symptoms that are more observable, such as vomiting (Hinton, 1996), than those that depend more on subjective indicators, such as psychological distress (McPherson and Addington-Hall, 2004) and the impact of events that occur during the dying process (Mularski et al., 2004).

Although the optimal approach to symptom assessment and measurement incorporates patient ratings, it may not be possible to obtain or interpret self-report. This can be the case, for example, in pre-verbal patients and those with cognitive impairment from delirium or dementia. In these groups, symptom measurement can only be done using proxy reports, or determination of pain-related behavioural or physiological changes. These data must be interpreted cautiously when used to quantify symptom distress and quality of life (QOL), particularly towards the end of life (Greer et al., 1986; Morris et al., 1986; Reuben and Mor, 1986; Mor, 1987; Mor and Masterson-Allen, 1990; Higginson and McCarthy, 1994; The Support Principal Investigators, 1995; Kutner et al., 2006). In clinical settings and in studies, the source of the data should always be acknowledged and the self-report and proxy data described separately, if both are acquired (Aaronson, 1990; Kutner et al., 2006).

Symptoms as measurable multidimensional experiences

The effective implementation of therapeutic strategies is contingent on comprehensive symptom assessment. Assessment involves a broad characterization of the nature of the symptom, including measurement of key dimensions (Tables 7.2.1 and 7.2.2) (Foley, 1993; Cherny and Portenoy, 1994; Sui et al., 1994; Ingham and Portenoy, 1996).

Symptom dimensions

Every symptom may be measured in terms of one or more specific dimensions (Dunlop, 1990; Portenoy and Hagen, 1990; Welch

Table 7.2.1 The measurable aspects of symptoms

Specific dimensions	Frequency
	Severity
	Distress
Symptom impact on specific factors	Other physical and psychological symptoms or diagnoses
	Function
	Family, social, financial, spiritual, and existential resources and concerns
Symptom impact on global constructs	Global symptom distress
	Health-related quality of life

Table 7.2.2 Clinical assessment with particular focus on symptom assessment

Assessment: eliciting medical history, examination, investigation review		Formulating a care plan

Identify presenting concerns	*Past history*
	Identification of other intercurrent conditions and previous illnesses and procedures
		Formulate a summary that identifies current:
		◆ Identified medical problems. This should include consideration of the following for each symptom:
		  • Inferred pathophysiology
		  • Relationship to other symptoms. Is symptom—same pathophysiology as other symptom/s, differing pathophysiology from other symptoms, triggering other symptoms, caused by treatment directed at other symptom/s

History of current illness Including therapeutic interventions, e.g. operative procedures, chemo- and radiotherapy. (The detail provided by the patient may serve to provide the clinician with some understanding of the patient's understanding of current extent of disease.)	*Family history* Identification of family illness history. This can also be an opportunity to address experiences relevant to current illness, e.g. carer roles etc. *Social history* Identification of social circumstances. If not addressed already, this can also be another opportunity to explore the impact of disease and symptoms on patient and family and factors that modulate global symptom distress, e.g. coping strategies and family supports	◆ Identified psychosocial problems ◆ Patient concerns, needs, priorities, and goals ◆ Family/carer concerns, needs, priorities, and goals ◆ Anticipated concerns *Formulate an appropriate strategy and 'next steps' in relation to:*

History of each current symptom
Consider addressing:
◆ Chronology, frequency, other clinical characteristics, e.g. location, etc.
◆ Severity
◆ Degree of associated distress or burden
◆ Other factors that alleviate or modulate distress
◆ Impact of each symptom on any other symptoms
◆ Prior treatment modalities and their efficacy
◆ Impact on function
◆ Patient perception of aetiology
◆ Impact of the specific symptom (or constellation of symptoms) on QOL—physical condition, psychological status, social interactions
	Allergies, drug reactions, and medications
	If not addressed already, this can be an opportunity to ensure that the impact of medications on symptoms, barriers to use of medications, and concerns about medications are addressed
	
	Undertake physical examination
	In addition to a full examination in relation to medical problems, particular attention should be paid to identifying findings in physical examination that may relate to symptoms in terms of explaining their pathophysiology, and identifying consequences of symptoms and/or side effects of symptom treatments
		◆ Addressing current and anticipated medical and psycho-social problems, concerns, and needs within context of both patient priorities and goals and medical urgency. This should include addressing specific symptoms considering the role of:
		  • Additional diagnostic tests to assess each symptom's pathophysiology
		  • Therapeutic interventions to address cause of each symptom

Systems review Assessment of other symptoms that the patient may not have raised specifically	*Assess available laboratory and imaging data* In addition to identifying extent of disease, in relation to symptoms particular attention should be paid to identifying findings among data that may relate to symptoms in terms of explaining their pathophysiology, identifying consequences of symptoms and/or treatments, and problems that will be important to consider in developing a therapeutic plan	• Therapeutic interventions to address distress related to each symptom ◆ Informing patient/family/carers about new findings and, as needed, readdressing goals

et al., 1991; Portenoy et al., 1994a, 1994b; Chang et al., 2000b, 2000c; Collins et al., 2002). An early study of adult cancer patients noted that patients can separately measure the frequency, severity, and distress associated with 32 physical and psychological symptoms (Portenoy et al., 1994a). Some of the symptoms were reported to be frequent or severe, but not highly bothersome or distressing, suggesting that the mere report of a symptom does not imply that it is burdensome or in need of treatment. Similar variability in the characteristics of symptoms has been demonstrated in the paediatric setting (Collins et al., 2002).

The temporal dimension of symptoms

Although reference is commonly made to the temporal features of a symptom as if this was one important dimension, there are multiple aspects inherent in the change of symptoms over time. Measurement can focus on onset (abrupt or insidious), duration, trajectory (worsening or improving), and daily pattern

(continuous or intermittent). The occurrence of discrete episodes of worsening symptoms may be relevant as well.

The temporal features of a symptom also can focus on the change over time of other descriptors, such as severity or distress, or various types of symptom impact. Characteristics may change with progression or remission of the disease, or with evolution of perceptions related to the availability of treatment, psychosocial support or adaptation, or the impact of comorbid disorders or symptoms. A key descriptor such as severity may worsen, but associated dimensions, such as distress or impact on QOL, may stay the same or even improve.

Although longitudinal symptom measurement is challenging to accomplish, there is substantial value in doing so. Studies have shown that measurements of symptom distress, functional status and QOL may change dramatically in the months preceding death, but this occurs at different rates and at different points along the disease trajectory (Higginson et al., 2012; Hung et al.,

2013; Sutradhar et al., 2013). When changes in functional status are subtle, findings of changes in symptom distress may be more informative. Clinically, serial measurements and feedback to physicians have been reported to facilitate physician–patient communication and exert a positive impact on QOL and emotional functioning (Velikova et al., 2004). Research in this area is evolving but the overall clinical goal is to ensure the information gathered about symptoms can be applied at multiple points along the trajectory of a disease.

Symptom impact

The impact of symptoms may be described in relation to varied domains of functioning (such as family, social, financial, spiritual, and existential issues) or in terms of global constructs such as overall symptom distress or QOL (Dunlop, 1990; Welch et al., 1991; Portenoy et al., 1994a). Pain provides a useful example of this complexity in the measurement of symptom impact. Unrelieved pain may be associated with depressed or anxious mood, insomnia, anorexia, or interference in the ability to socialize, function physically, or work. Pain may reduce income or lead to role disruption in the family. Although challenging to do, instruments for the valid measurement of each of these domains could be combined to obtain a very broad understanding of the outcomes related to pain.

Given the complexity of multidimensional symptom measurement, the decision usually is made to focus on high-impact concerns. Instruments have been developed with this goal. Again using pain as an example, a commonly used measurement tool—the Brief Pain Inventory (BPI) —focuses on measures of pain severity (0–10 scales) and a validated subscale that assesses pain-related interference with function, mood, relationships, sleep, and enjoyment of life (Daut et al., 1983). The use of an instrument like the BPI (Daut et al., 1983) provides a simple approach to the measurement of multiple domains, but leaves the potential to assess other domains unfulfilled. The online version of this tool is available at: <http://www.mdanderson.org/education-and-research/departments-programs-and-labs/departments-and-divisions/symptom-research/symptom-assessment-tools/brief-pain-inventory.html>.

Symptoms and global constructs

Although the individual measurement of specific symptom dimensions can be highly informative, the value of global constructs to broadly characterize the experience of illness is clear. Fig. 7.2.1 illustrates the impact that a pathophysiological process and various modifying factors may have on the perception of symptom-associated distress and overall QOL. These global constructs can be measured with multidimensional QOL instruments (see Chapter 7.1) or more specific measurements of symptom distress. The multidimensional construct of QOL especially reflects the broad influence of many positive and negative factors on perceived well-being (Aaronson et al., 1988; Moinpour et al., 1989; Aaronson, 1990; Cella and Tulsky, 1990; Moinpour et al., 1990; Aaronson, 1991; Nayfield et al., 1992; Aaronson et al., 1993; Till, 1994).

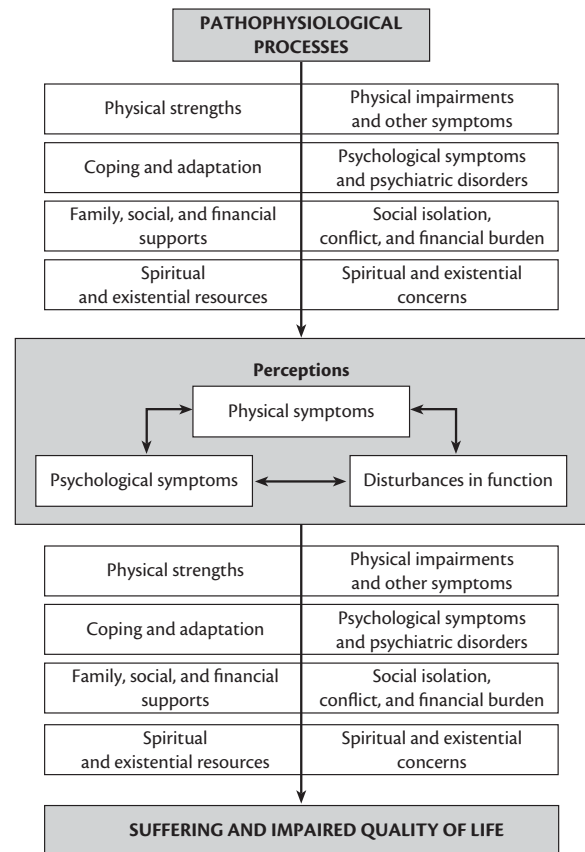
Physical and psychological symptoms, or the distress that they cause, contribute to QOL, but may or may not be the predominant determinants of well-being (Levine et al., 1978; Derogatis et al., 1983; Reuben et al., 1988; Grosvenor et al., 1989; Brescia et al., 1990; Coyle et al., 1990; Dunlop, 1990; Dunphy and


Fig. 7.2.1 Interactions among symptoms, suffering, and quality of life.

Amesbury, 1990; Ventafridda et al., 1990; Curtis et al., 1991; Fainsinger et al., 1991; Portenoy et al., 1994a; Chang et al., 2000c; Collins et al., 2002). A study of symptoms in cancer patients provided empirical evidence that information relating to the impact of symptoms on QOL was maximized by concurrent measurement of other factors, including 'symptom distress' and either frequency or intensity (Portenoy et al., 1994b). Of the three dimensions assessed, distress was the most informative. This observation, which was replicated in another study (Chang et al., 2000c), suggests that distress should be assessed if the goal of the evaluation is to clarify the interaction between symptoms and QOL.

Brief measures of symptom distress have been used as screening tools in clinical practice. The Distress Thermometer, for example, is a simple, self-report, pen and paper measure that asks patients to mark an 'X' on the 'thermometer' scale (0–10) that correlates with their level of distress in the previous week (National Comprehensive Cancer Network (NCCN), 2013b). Given that the score on this unidimensional scale has uncertain diagnostic accuracy, this, and other ultra-short methods, cannot be used alone to diagnose depression, anxiety, or distress in cancer patients (Mitchell, 2007; Thewes et al., 2009). That stated, such instruments may be considered as a first-stage screen to help rule out cases of depression (Mitchell, 2007). Also, the items on associated check lists can be used to identify and triage some 'realms' of concern.

Clinical and research applications of symptom assessment and measurement principles

Historically, symptom measurement has been used in clinical investigations to create primary or secondary treatment outcome variables. In recent decades, however, measurement has been brought more forcefully into clinical practice, where it has been shown to have a use as a part of the routine monitoring of patients (Grossman et al., 1991; Jacox et al., 1994a, 1994b; Foley, 1995; Bookbinder et al., 1996; Gordon et al., 2005).

Symptom measurement in routine clinical management

The clinical use of symptom measurement is evolving. Although it may be accomplished using brief hard-copy questionnaires, such as the Distress Thermometer (NCCN, 2013b) or the Edmonton Symptom Assessment Scale (Bruera et al., 1991), various types of computer-based methods have been developed and promise much greater flexibility in the future (Velikova et al., 1999; Taenzer et al., 2000; Carlson et al., 2001; Cull et al., 2001; Chang et al., 2002; Davis et al., 2007; Velikova et al., 2002; Abernethy et al., 2008, 2009; Mark et al., 2008; Wolpin et al., 2008).

A standardized approach using a validated symptom assessment instrument can serve to give the patient a voice and enable consistent symptom detection, assessment, and documentation. Ideally, assessment should be repeated at intervals. The challenge lies in selecting the right instrument for the patient population and integrating it into clinical practice. The simplest approach—routine screening with a brief instrument—may be best for large populations, notwithstanding the potential lack of diagnostic accuracy noted previously.

Another approach to systematic assessment focuses on single high-impact symptoms, such as pain and this symptom has been given particular attention in the cancer population (Foley, 1995). More broadly, systematic pain assessment has been shown to improve the understanding of health professionals of the pain status of individual hospitalized patients (Au et al., 1994; Gordon et al., 2002), and numerous guidelines now recommend the regular use of pain rating scales in all care settings (ambulatory care, community care, and acute care) (Jacox et al., 1994a; Gordon et al., 2005). In addition, educating people living with pain, and their caregivers, to use assessment tools at home has become a part of a self-management strategy to promote better pain management and continuity across care settings (Koller et al., 2012). An example of a tool for systematic recording of pain observations in the inpatient setting is the tool linked with the National Early Warning Score (NEWS) that has been devised by the Royal College of Physicians in the United Kingdom (Royal College of Physicians, 2012). This early warning score system and linked tool has been designed to trigger a clinical response to acute deterioration. The NEWS tool (Royal College of Physicians, 2012) has capacity to capture various observations such as temperature, pulse, and others, and a place for recording pain observations—indicating that pain should also be regularly recorded and responded to (Royal College of Physicians, 2012).

The experience with pain measurement has encouraged an expansion of routine assessment to the clinical measurement of other symptoms. Simple, face-valid, symptom screening tools developed to explore the spectrum of common physical and psychological symptoms in particular disease states can be helpful in the clinical setting where the screening measurement is complemented by a full clinical evaluation. Several measurement tools have been used routinely in palliative care units for some time (Bruera et al., 1991; Donnelly and Walsh, 1995). More recently, some investigators have explored the utility of symptom and QOL measures in the clinic setting using computer-based touchscreen methodology (Velikova et al., 1999; Taenzer et al., 2000; Carlson et al., 2001; Cull et al., 2001; Chang et al., 2002; Velikova et al., 2002; Davis et al., 2007; Abernethy et al., 2008, 2009). Evidence suggests the computer-based touchscreen methodology is valid, feasible, and acceptable to patients (Abernethy et al., 2008, 2009) and assuming confidentiality is ensured this may be a preferred approach for some patients, in contrast to paper questionnaires.

A number of organizations, including those that accredit hospitals, and national bodies such as the NCCN in the United States, have recommended the implementation of routine screening for pain, and potentially for distress and other symptoms (Holland, 1997; Payne, 1998; Mock et al., 2000; Scottish Intercollegiate Network, 2008; National Comprehensive Cancer Network, 2013a). There is now some evidence that improved outcomes can be achieved when routine symptom measures are augmented with clinical pathway implementation and access to expert consultation. A recent systematic review concluded that there is growing evidence in support of routine collection of symptom measures, as a means to achieve better, patient-centred care in cancer settings, particularly in relation to patient-provider communication and patient satisfaction, and to a lesser extent, in relation to the monitoring of treatment response and the detection of unrecognized problems. In contrast, to date, evidence is weak or non-existent in relation to the impact on changes to patient management and improved health outcomes; changes to patient health behaviour or the effectiveness of quality improvement of organizations; or the transparency, accountability, public reporting activities, and performance of the health-care system (Chen et al., 2013). All of these goals, as well as the goals of focusing staff attention on symptom assessment, reviewing the quality of patient care, and ascertaining the situation-specific barriers to symptom control, are important and warrant further investigation.

The emerging area of implementation and dissemination science will inevitably contribute to the future development of evidence based strategies by which recommendations for 'routine' symptom assessment can be implemented using an array of efficient, user-friendly (for both patients and clinicians), and valid methodologies, including face-to-face patient-physician interviews, pen and paper surveys, and/or computer-based methodology. At this time, and importantly, in implementing screening assessment strategies, clinicians should consider carefully how to optimize the integration of the screening strategy into clinical care. Response strategies should be identified, and consideration given to the development of plans for appropriate and timely response to identified levels of distress that can be feasibly implemented in the particular institution or health system (Seow et al., 2012; Cancer Quality Council of Ontario, 2014). Defined levels of distress for intervention may, for some symptoms, be defined by research-based evidence and for other symptoms, by expert input. As examples at the extreme level, an institution or health system should identify a response pathway for a pain report that

suggests the presence of extreme pain and similarly, for a report of psychological distress that may indicate that a patient is at risk of self-harm. In addition to identifying 'alert' levels, in the clinical setting there is a need to develop institutionally-specific policies and procedures for responses. One approach is to align the responses to symptom distress with existing institutional risk management policies.

Symptom measurement in clinical research

Systematic symptom measurement can provide valid endpoints in clinical research, elucidating both the palliative potential of a treatment and its toxicity profile. Numerous factors must be considered when planning symptom-related research (Table 7.2.3). When observational studies or clinical trials seek detailed information about symptoms, face-valid symptom checklists are not preferred (Miller et al., 1981; Bruera et al., 1991; Burgess et al., 1993; Osoba, 1993; Donnelly and Walsh, 1995). Greater accuracy is achievable with validated measures that address more than one symptom dimension (McCorkle and Quint-Benoliel, 1983; De Haes et al., 1987; de Haes et al., 1990; Portenoy et al., 1994a, 1994b). When symptom related outcomes are secondary endpoints, as they are in most trials of cancer therapy, the use of simpler, standardized toxicity scales, such as those recommended by the World Health Organization and the NCI in the United States (Miller et al., 1981), may be sufficient. The challenge is to capture the relevant concerns as they evolve, using measures that are simple, and brief enough to limit participant burden and encourage compliance (Ingham et al., 1996).

When study aims include evaluation of a number of subjective endpoints, an investigator may decide to combine questionnaires, or alternatively, use a multidimensional measure such as the European Organization for the Research and Treatment of Cancer (EORTC), Quality of Life Questionnaire—Palliative (EORTC QLQ-C15-PAL) (Groenvold et al., 2006) or a short-form version of the EORTC's widely-used cancer-specific QOL measure (EORTC QLQ-C30) (Aaronson et al., 1993). Other instruments include the Functional Living Index-Cancer (FLIC) (Schipper et al., 1984; Morrow et al., 1992), the Functional Assessment of Cancer Therapy (FACT) System (Cella et al., 1993), the Cancer Rehabilitation Evaluation System (Ganz et al., 1992), the SF-36 of the Medical Outcome Study (Stewart et al.,

1988) and others. All of the validated, multidimensional measures of health-related QOL assess a selected group of prevalent symptoms, including pain, fatigue, and anxiety (Schipper et al., 1984; Ganz et al., 1992; Aaronson et al., 1993; Cella et al., 1993). Yet another approach is to use a core instrument with modules that target specific issues, disorders or treatments (Aaronson et al., 1988; Moinpour et al., 1989; Aaronson et al., 1993; Cella et al., 1993).

Although QOL information is important and may be sufficient for many purposes (Carlson et al., 2001; O'Brien et al., 2001; Chang et al., 2002; Millsopp et al., 2006), QOL instruments were not developed as symptom assessment instruments. Neither the prevalence rates nor the characteristics and dimensions of the diverse array of physical and psychological symptoms experienced by patients may be captured adequately by these instruments. Depending on the purpose of the assessment, the aims of the research, the anticipated outcomes and toxicities, and the resources of the investigator, other measures can be added to capture symptom-related information (Aaronson et al., 1988; Moinpour et al., 1989, Aaronson et al., 1993; Cella et al., 1993; Ingham et al., 1996). One way in which this can be accomplished is by the concurrent use of a QOL instrument and a symptom measurement tool.

The utility of a tailored approach to QOL and symptom assessment was demonstrated in a study that explored the importance of specific pain assessments during routine QOL evaluation (Ingham et al., 1996). After clinical observations suggested that the combination of paclitaxel and recombinant human granulocyte-colony stimulating factor for breast cancer was associated with frequent short-lived episodes of pain, supplemental pain measurements were included with QOL measures in a phase II trial. The 'tailored' assessment revealed a marked disparity between the pain data obtained during a routine QOL assessment performed at 3-week intervals and those acquired through the supplemental pain evaluation obtained twice weekly. Despite the interval assessment revealing a marked decline in median pain scores, the supplemental assessment demonstrated transient acute and severe pains in almost half the patients. Clearly, this was important to identify in order to provide information to patients and clinicians on expected transient concerns and management of side effects. Such a tailored approach to measurement may be important in anticipating side effects of treatments, clarifying the usefulness

Table 7.2.3 Methodological considerations for symptom measurement in research setting

Patient-related factors	Factors related to investigator goals and resources	Instrument-related factors
Patient's ability to provide consent and comprehend instruments: Age-related factors Cognitive state Cultural and language barriers Patient's descriptors for symptom Presence of other symptoms	*Study aims and method:* Which symptoms and dimensions of symptoms need to be assessed? When should symptoms be assessed? What methodological controls are needed?	*Validity and reliability:* Validity of instrument for assessment of symptom in general and in particular population Ability of instrument to assess the dimensions and impact of symptom
Patient's willingness to participate in data collection: Patient reluctance to participate in investigation or to report specific symptom	*Data management and statistical analysis:* Available resources for data collection and analysis	*Clinical utility and appropriateness:* Capacity of instrument to assess hypothesis Instrument complexity and respondent burden

of a therapy in symptom palliation, guiding clinical management at the time of treatment, and/or determining the time-dependent effects of therapy on well-being.

In contemplating measurement in any clinical research, consideration must not only be given to the utility of an instrument to measure a subjective effect, but also to whether a reasonable presumption can be made about the extent to which a change in the measured score reflects a 'clinically relevant' change in symptom severity or distress. Statistical significance, particularly in tests of group averages, may or may not indicate that the difference is meaningful in the clinical sense. For example, a clinical trial of an analgesic with a large sample size may show that the group receiving treatment 'A' had an average change in a pain score of 1.0 on a 0–10 scale, whereas the group that received treatment 'B' had an average change of 1.8. This difference may be statistically significant but clinically irrelevant. Moreover, this difference reflects average scores and may hide the fact that some patients had very large changes after a treatment, whereas some did not change at all.

Information about the responsiveness of a questionnaire to clinical changes and the minimal important difference (MID) in scores that depicts a clinically important change (Revicki et al., 2006) are very helpful in determining whether the differences observed during a study actually reflect a clinically meaningful event. There are a number of 'anchor-based' and 'distribution-based' methods to determine MID. Once a MID is determined, data from a trial can be subjected to a responder analysis, which can determine whether the proportion of experimental patients with a clinically meaningful change is statistically different than the proportion in a control group.

The MID may be derived empirically or reflect clinical impression. Analyses of data from a large pain study, for example, suggested that change scores of two or more on a 0–10 scale, or 30% or more on an analogue scale reflect clinically meaningful change (Farrar et al., 2000). Alternatively, it also is widely accepted on clinical grounds that the number of patients who achieve pain relief greater than 50% is a reasonable MID.

Other metrics also can be used to provide a clinical framework for the understanding of scores, or differences in scores, on symptom measures. A common approach is to use the number needed to treat (NNT), which gives the number of people you need to treat with the intervention (compared with the control) to prevent one event (The Cochrane Collaboration, 2002). The number of days on which symptoms reached a level of 'control' also can be employed (Zech et al., 1995). In pain research using the BPI (Daut et al., 1983), an analysis can be applied that first categorizes pain scores into 'mild', 'moderate', or 'severe', and then determines group differences in the proportion of patients who change from one category to another (Daut and Cleeland, 1982; Serlin et al., 1995; Cleeland et al., 1996; Paul et al., 2005).

Additional information about the clinical relevance of a change in symptom scores may be accessible by combining outcomes. In one study of a chemotherapeutic agent, for example, a combination of changes in three variables (reduction in pain by 50%, weight gain of 5%, and improvement in performance status of 20%) along with duration of improvement (4 weeks) was proposed a priori as an indicator of benefit (Rothenberg et al., 1996; Burris et al., 1997; Rothenberg et al., 1998).

Recent work has suggested that severity cut-off points may differ among different symptoms, at least when the object is to relate these cut-offs to physical functioning (Given et al., 2008). In this regard, systematic reviews may offer a method to assess the impact of symptom-related therapies by combining data through meta-analyses. Research has defined MIDs in six PROMIS®-Cancer scales in advanced-stage cancer patients and further work is underway to explore these in relation to other disease states. Of note, these MIDs are applicable to the total scores on 'instruments' made up of items from the PROMIS® item bank, rather than the scores related to specific symptom scales (Yost et al., 2011).

Another recent study provides an example of how investigators explored the MID using a 'well-being' anchor from the Edmonton Symptom Assessment Scale (ESAS) (Bedard et al., 2013). This study found that different changes were relevant for improvement and deterioration; a decrease of 1.2 and 1.1 units in pain and depression scales, respectively, reflected clinically relevant improvement, whereas an increase of at least 1.4, 1.8, 1.1, 1.1, and 1.4 units, respectively, were associated with deterioration in pain, tiredness, depression, anxiety, and appetite loss (Bedard et al., 2013). This work suggests that conclusions about the clinical relevance of changes in symptom scores are best grounded in empirical observations in appropriate clinical populations.

There continue to be many questions to be resolved through future studies. For example, is an improvement from 2 to 1 on an 11-point numeric scale (50% change) as clinically significant as a change from 9 to 4.5 (also a 50% change)? Can the clinical significance of a therapy be evaluated without controlling for side effects, and if not, how should these be measured and indexed? In the complex palliative care setting, how can the clinical relevance of a single symptom be explored fully when most patients experience multiple distressing symptoms concurrently? The latter concern has been raised in studies of symptom clusters that suggest important commonalities across symptoms (Walsh and Rybicki, 2006). If symptom cluster research ultimately demonstrates relevance to assessment, prognostication or treatment, the therapeutic targeting of clusters may have the potential to reduce polypharmacy, lessen drug side effects, and provide pharmacoeconomic benefits (Cheung et al., 2009).

Measurement instruments for common symptoms

Instrument selection for symptom measurement must be guided by an understanding of the goals of assessment and the practicality, applicability, and acceptability of the instrument in the particular patient population. Evidence that the instrument is valid and reliable for the purposes intended should be considered carefully. Concern about the potential burden imposed on patients, clinicians, and investigators, which may justify the use of simple and brief questionnaires, must be balanced against the scientific need to capture complex symptom-related concerns or QOL. If the information is salient and would not be assessed otherwise, the increased burden of the assessment itself may be warranted.

Instruments for the measurement of multiple symptoms

Simple, face-valid checklists may be used to determine the incidence or prevalence of multiple physical and psychological symptoms (Miller et al., 1981; Bruera et al., 1991; Fainsinger et al., 1991;

Donnelly and Walsh, 1995). This approach is limited, however, by the lack of instrument validation and the inability of such checklists to ascertain important dimensions of the symptom experience, such as intensity or distress.

Validated measures can supersede these simple checklists in many clinical situations and many types of studies. A systematic review identified 21 instruments that may be used to measure multiple symptoms in cancer patients (Kirkova et al., 2006). Those that are used commonly vary substantially in design and purpose (Table 7.2.4). Experience in the use of these instruments in non-cancer populations also varies, and the extent to which each has been validated externally or even field tested in other patient groups should be considered when selecting a specific instrument.

Edmonton Symptom Assessment System (ESAS) (Bruera et al., 1991). The ESAS has been used extensively in palliative care research. It evaluates intensity of nine common symptoms of cancer using VASs; a tenth symptom can be added. Patient ratings are preferred but there is extensive experience with proxy ratings. It also has been modified for use in the critically ill (Nelson et al., 2001). One study in an outpatient setting reported a completion rate of 60% for lung cancer patients and almost 40% for all other cancer patients (Dudgeon et al., 2012). Validation in a sample of patients with advanced cancer noted that test–retest validity was better at 2 days than 1 week, and the total score was most reflective of physical well-being (Chang et al., 2000a). This instrument's brevity and established utility in populations with advanced illness are advantageous. In addition, some clinicians have been exploring the use of revised versions of the ESAS (Watanabe et al., 2011).

Memorial Symptom Assessment Scale (MSAS) (Portenoy et al., 1994b). The MSAS is a validated, patient-rated measure that provides multidimensional information about a diverse group of common symptoms (Fig. 7.2.2). The original form characterizes 26 physical and six psychological symptoms in terms of intensity, frequency, and distress. A validated short-form (MSAS-SF), which evaluates these 32 symptoms in terms of a single dimension, has been translated into numerous languages and is widely used in studies of diverse populations (Chang et al., 2000c). A briefer version (the condensed MSAS or CMAS) that depicts 15 symptoms in terms of one dimension (Chang et al., 2004) and paediatric versions (Collins et al., 2002) also have been validated.

Although the MSAS provides ratings for individual symptoms, the tool generally is not used when the research question focuses on one or a small number of symptoms, as it might in an intervention trial. Rather, the MSAS, like other multi-symptom questionnaires, is more valuable as a means to determine the presence or absence of numerous symptoms concurrently and to measure symptom distress. All adult versions of the MSAS have a subscale that measures global symptom distress (Global Distress Index, or MSAS-GDI), and both the MSAS and the MSAS-SF have other subscales that describe physical symptom distress (MSAS-PHYS) and psychological symptom distress (MSAS-PSYCH), respectively. The MSAS-GDI, which is the average of the frequency of four prevalent psychological symptoms and the distress associated with six prevalent physical symptoms, may be the most meaningful clinically, because of its high correlation with measures of QOL and clinical status (Portenoy et al., 1994b).

MD Anderson Symptom Inventory (MDASI) (Cleeland et al., 2000). The MDASI evaluates the presence and severity of 13 core symptoms and has six items that rate the extent to which symptoms interfere with various domains of function. It has been translated into many languages and several supplemental modules have been developed that contain items that augment the core items with disease-specific, disease-site-specific or treatment-specific use. The format of the MDASI is based on the BPI (Daut et al., 1983) and Brief Fatigue Inventory (Mendoza et al., 1999). Studies have demonstrated its utility when administered via interview or an interactive voice response system, and the core-plus-module approach may be advantageous when considering populations with specific symptoms that may be mild but distressing or significantly impacting on function. Examples include the MDASI-BT (brain tumour) (Armstrong et al., 2009) and MDASI-HN (head and neck) (Rosenthal et al., 2007).

Symptom Distress Scale (SDS) (McCorkle and Young, 1978; McCorkle and Quint-Benoliel, 1983). The SDS is a 10-item patient-rated scale that evaluates 10 symptoms, in terms of presence and intensity. The time frame of assessment is 1 day. Although the SDS provides only limited information about specific symptoms, it is a valid measure of global symptom distress. Some have recommended it as a screening instrument for cancer patients in the outpatient (Degner and Sloan, 1995) and community settings (Peruselli et al., 1992). Its potential utility has been suggested in one study of lung cancer patients, which found that the total symptom distress score was a significant predictor of survival (Kukall et al., 1986).

Rotterdam Symptom Checklist (RSCL) (de Haes et al., 1987, 1990). The RSCL is a validated, patient-rated measure that evaluates a spectrum of common symptoms in terms of distress. Thirty physical and psychological symptoms are included and an additional eight items define the impact of symptoms on physical activity and function. The total score assesses global symptom distress and there are subscales that measure physical and psychological symptom distress, respectively. The inability to assess dimensions other than distress, including intensity, and the lack of a general pain item, may be a disadvantage. A validated modified version with the addition of several key physical symptoms has improved its breadth and utility (Stein et al., 2003).

Instruments for the measurement of specific symptoms

Although numerous instruments have been validated for the assessment of some symptoms, such as pain, breathlessness, and depression, there are fewer for other prevalent symptoms, such as anorexia, dry mouth, or change in appearance. Many instruments have been validated in specific populations and may not be valid in others. For example, studies of dyspnoea measures have largely focused on populations with pulmonary or cardiac disease (Stark, 1988; Cockcroft et al., 1989; McCord and Cronin-Stubbs, 1992; Eakin et al., 1993; Mahler et al., 1996; Mahler and Harver, 2000; Mahler, 2006), and these instruments may or may not be valid and reliable when dyspnoea is a result of advanced cancer (Brown et al., 1986; Bruera et al., 1993; Roberts et al., 1993). Recognizing these concerns about generalizability across disease states, there is an emerging focus on the development of instruments for specific disorders (Chen et al., 2007). The development of disease-specific PROs reflects this trend.

To illustrate the range of options available and some of the practical issues that may be important in selecting an instrument, the following discussion focuses on measures for three common symptoms—pain, dyspnoea, and impaired cognition.

Instruments for the assessment of pain

There are many validated instruments for the measurement of pain. Unidimensional scales measure the dimension, usually severity or relief, using a 10-cm line (VAS), numerals (e.g. 0–10), verbal categories (e.g. mild, moderate or severe), or various types of pictures (faces or other pictures). The Memorial Pain Assessment Card (MPAC) (Fishman et al., 1987) is a brief, validated measure that combines several unidimensional scales, including analogue scales to characterize pain intensity, pain relief, and mood, respectively, and an 8-point verbal rating scale (VRS) to further characterize pain intensity.

Multidimensional pain instruments include the McGill Pain Questionnaire (MPQ) (Melzack, 1975; Graham et al., 1980; Melzack, 1987) and the BPI (Daut et al., 1983). The BPI (Daut et al., 1983) has been translated into many languages, repeatedly validated, and used in many studies. It provides information about pain history, intensity, location, and quality (see Daut et al. 1983). It has numeric scales that define pain intensity 'in general', 'at its worst', 'at its least', and 'right now'. A percentage scale quantifies relief from current therapies and body figure allows localization of the pain. Seven questions evaluate the degree to which pain interferes with function, mood, and enjoyment of life.

The MPQ (Melzack, 1975; Graham et al., 1980; Melzack, 1987) evaluates the sensory, affective, and evaluative dimensions of pain, and provides global scores and subscale scores for each of these dimensions. The scores are derived from the adjectival pain descriptors selected by the patient. A 5-point verbal categorical scale characterizes the intensity of pain and a pain drawing localizes the pain. Additional information is collected about the impact of medications and other therapies. To date, the predominant application of the MPQ has been in the assessment of chronic, non-malignant pain and the utility of the subscale scores has not been demonstrated for pain associated with cancer or other medical illnesses (de Conno et al., 1994; Caraceni et al., 2005).

Although self-report is the 'gold standard' for the measurement of pain and other symptoms (Zwakhalen et al., 2006), difficulty exists even for some cognitively intact individuals when completing VASs (Stark et al., 1982; Ganz et al., 1988; Stark, 1988). Since cognitive impairment is prevalent in medically ill populations, this may interfere further with the completion of even unidimensional measures. Much work has been done to develop and validate pain measures that use behavioural indicators of intensity (Gagliese and Melzack, 1997; Gagliese, 2001), particularly for populations with dementia (Herr et al., 2010). For patients with milder cognitive impairment, the Resident's Verbal Brief Pain Inventory, a modification of the BPI (Daut et al., 1983), focuses on the physical and psychosocial elements of pain assessment and is useful, reliable, and valid (Gibson et al., 2004).

Instruments for the assessment of dyspnoea

Breathlessness is highly prevalent and may be associated with underlying disease, concomitant symptoms, psychological well-being and socio-demographic circumstances (Kamal et al., 2011). Like other symptoms, varied dimensions of breathlessness can be assessed (Dudgeon, 2003) and validated instruments are now available (Bausewein et al., 2007).

Unidimensional breathlessness measures include numerical rating scales (NRS) or VASs for the specific dimension under evaluation (e.g. intensity, unpleasantness, or distress), and the modified Borg Scale (Kendrick et al., 2000), which uses a combined numerical and categorical scale to rate the patient's perception of their dyspnoea in relation to a perceived level of exertion. The VAS has good within-subject reproducibility when applied repeatedly in a single session (O'Neill et al., 1986; de Torres et al., 2002), but less reproducibility when the same exercise task is repeated at longer intervals, such as 2 weeks (Wilson and Jones, 1989). Considerable between-subject variation has been demonstrated (Stark et al., 1983). The NRS is highly correlated with the VAS and can be easier for some patients to master (Gift and Narsavage, 1998). Both the NRS and modified Borg Scale have been validated for use over the phone (Bausewein et al., 2008).

The modified Borg Scale has been validated in healthy individuals and in patients with chronic pulmonary disease (Borg, 1982; Kendrick et al., 2000). Although developed to measure dyspnoea in relation to exertion, in addition it now is widely used to rate spontaneous breathlessness. Patients report that the language used in the modified Borg Scale adequately captures their experience of breathlessness (Kendrick et al., 2000) and the scores

MEMORIAL SYMPTOM ASSESSMENT SCALE

NAME :   DATE :

SECTION 1 :

INSTRUCTIONS : We have listed 24 symptoms below. Read each one carefully. If you have had the symptom during this past week, let us know how OFTEN you had it, how SEVERE It was usually and how much if DISTRESSED OR BOTHERED you by circling the appropriate number. If you DID NOT HAVE the symptom, make an "X" in the box marked DID NOT HAVE.

DURING THE PAST WEEK. Did you have any of the following symptoms?	DID NOT HAVE	IF YES How OFTEN did you have it?				IF YES How SEVERE was it usually?				IF YES How much did it DISTRESS or BOTHER you?				
		Rarely	Occasionally	Frequently	Almost Constantly	Slight	Moderate	Severe	Very Severe	Not At All	A little bit	Somewhat	Quite A Bit	Very Much
Difficulty concentrating		1	2	3	4	1	2	3	4	0	1	2	3	4
Pain		1	2	3	4	1	2	3	4	0	1	2	3	4

SECTION 2 :

INSTRUCTIONS : We have listed 8 symptoms below. Read each one carefully. If you have had the symptom during this past week, let us know how SEVERE It was usually and how much if DISTRESSED OR BOTHERED you by circling the appropriate number. If you DID NOT HAVE the symptom, make an "X" in the box marked DID NOT HAVE.

DURING THE PAST WEEK. Did you have any of the following symptoms?	DID NOT HAVE	IF YES How SEVERE was it usually?				IF YES How SEVERE was it usually?			
		Rarely	Occasionally	Frequently	Almost Constantly	Slight	Moderate	Severe	Very Severe
Mouth sores		1	2	3	4	1	2	3	4
Change in the way food tastes		1	2	3	4	1	2	3	4

Fig. 7.2.2 Revised version of the Memorial Symptom Assessment Scale (Portenoy et al., 1994).

Reprinted from *European Journal of Cancer*, Volume 30A, Number 9, Portenoy, R. K., et al., The Memorial Symptom Assessment Scale: An instrument for the evaluation of symptom prevalence, characteristics and distress, pp. 1151–8, Copyright ©1994, with permission from Elsevier, http://www.sciencedirect.com/science/journal/09598049.

appear to be more reproducible than the VAS (Wilson and Jones, 1989). Ceiling effects can be a concern and there continues to be debate about the change needed to equate with 'clinical significance.' Expert opinion (Booth, 2006; Dorman et al., 2009) supports the available evidence (Ries, 2005; Oxberry et al., 2012; Johnson et al., 2013) suggesting that a change of 1 in the modified Borg Scale score or 10 mm in the VAS is the minimal clinically important difference in chronic breathlessness; a larger change in VAS may be needed to be clinically important in acute breathlessness (Karras et al., 2000; Ander et al., 2004).

Another unidimensional scale, the Medical Research Council Dyspnoea Scale (Medical Research Council Committee on the Aetiology of Chronic Bronchitis, 1960), assesses the consequences of breathlessness in relation to limitations on function. It is particularly useful if breathlessness is the only symptom experienced by the patient, but is too insensitive to detect subtle breathlessness changes following an intervention (Mahler, 2006).

Other scales developed to measure dyspnoea are multidimensional. A recent systematic review identified 33 instruments of this type (Bausewein et al., 2007). In selecting one of these instruments clinicians must give careful consideration to the goal of assessment.

The Cancer Dyspnoea Scale (CDS) rates effort, anxiety, and discomfort severity on 5-point Likert scales (Tanaka et al., 2000). It may capture the complex interaction between dyspnoea and anxiety (Smoller et al., 1996). The Chronic Respiratory Disease Questionnaire (CRQ) focuses on the population with chronic obstructive pulmonary disease and measures the impact of dyspnoea on QOL by examining concurrently breathlessness, fatigue, emotional function, and mastery over the disease (Guyatt et al., 1987). With regular use, the instrument requires 10–15 minutes to complete (Moran et al., 2001; Schunemann et al., 2005). Despite limitations in identifying treatment responsiveness for specific clinical interventions (Cullen and Rodak, 2002), instruments like the CRQ that quantify function and health-related QOL have great utility for documenting outcomes.

Dyspnoea also can be measured in terms of exercise tolerance. Several instruments have been validated in advanced disease, namely the Shuttle Walking Test (Booth and Adams, 2001), the Reading Numbers Aloud Test (Wilcock et al., 1999), and the Upper Limb Exercise Test (Wilcock et al., 2005). Unfortunately, the burdensome and time-consuming nature of these tests currently limits their applicability in the clinical setting (Bausewein et al., 2007).

Instruments for the assessment of impaired cognition

Cognitive impairment is a symptom if reported by the patient and a sign if noted by a clinician. Although some data suggest that most patients approach the end of life with cognitive capabilities retained (Seeman, 1992), surveys in populations with advanced cancer indicate a varying prevalence of impaired understanding and communication (Exton-Smith, 1961; Hinton, 1963; Witzel, 1975; Saunders, 1984; Fainsinger et al., 1991), which increases as death approaches (Morita et al., 2003). These findings support the clinical need to evaluate cognitive capability and when doing so, to determine whether patient self-report is possible.

Some assessment instruments have been developed to screen for impairment, or quantify its intensity or impact, and some have been developed to determine the likelihood that the cognitive impairment can be ascribed to a specific diagnosis, such as

delirium, mild cognitive impairment (described as mild neurocognitive disorder in American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5) (American Psychiatric Association, 2013), or dementia.

The most commonly used screening tests for cognitive impairment are the Mini Mental Status Examination (MMSE) (Folstein et al., 1975) and the Blessed Orientation-Memory-Concentration Test (Katzman et al., 1983). These tools are sensitive indicators of cognitive impairment (Bruera et al., 1992; Stiefel et al., 1992; Fainsinger et al., 1993), but are not specific for the diagnosis of delirium or dementia. The MMSE has some noted limitations, namely its length and administration time (approximately 10 minutes), poor sensitivity for frontal lobe dysfunction, and scoring influenced by culture and education levels (Anthony et al., 1982). A rapid cognitive screening approach for clinical practice involves the use of the Clock Drawing Test (CDT) with the Mini-Cognitive Assessment (Mini-Cog). The latter approach has been found to be helpful for detecting gross cognitive impairment, and has been demonstrated to compare well to longer cognitive impairment instruments (Borson et al., 1999; Borson et al., 2000; Ketelaars et al., 2013).

In addition, several instruments have been developed to address some of the MMSE limitations and are increasingly being used. The Rowland Universal Dementia Assessment Scale (RUDAS) is a multicultural cognitive assessment scale that aims to minimize the effects of cultural learning and language diversity (Rowland et al., 2006, Storey et al., 2004) and the Montreal Cognitive Assessment (MoCA) has been demonstrated to be superior to the MMSE at identifying mild cognitive impairment (Nasreddine et al., 2005; Dong et al., 2012; Markwick et al., 2012).

Some instruments aim to improve the detection of delirium, a highly distressing and prevalent condition in medically ill populations (Lipowski, 1987; Levkoff et al., 1992; Lawlor et al., 2000a; Breitbart et al., 2002a; Lam et al., 2003). Given the particularly high prevalence of delirium in inpatient palliative care populations, it has been suggested that routine screening ought to be considered to enable early identification of any reversible cause of the syndrome and to better manage distressing symptoms (Hosie et al., 2013). The DSM-5 (American Psychiatric Association, 2013) and a clinical interview remains the 'gold standard' for diagnosing delirium. Delirium screening or assessment instruments generally attempt to evaluate the key elements identified in this manual (Adamis et al., 2010). Of note, the recent edition has further modified the criteria for diagnosis of delirium (American Psychiatric Association, 2013). A recent review, prior to the publication of the DSM-5 (American Psychiatric Association, 2013), identified 11 instruments that had been developed (Wong et al., 2010), but at this time there is no consensus about the optimal approach for screening (Caraceni and Grassi, 2011). The various measures have been designed for different purposes (Adamis et al., 2010).

The Nursing Delirium Screening Scale (Nu-DESC) is a five-item observational screening tool that can be administered by nurses in the clinical setting in 1 minute. The Nu-DESC has been demonstrated to be psychometrically valid, with sensitivity and specificity similar to the Memorial Delirium Assessment Scale (MDAS) (Gaudreau et al., 2005).

The MDAS (Breitbart et al., 1997) is a widely used ten-item instrument that incorporates both diagnosis and measurement of symptom severity and takes approximately 10 minutes to be completed. It is based on criteria that are included in both the DSM-III-R (American Psychiatric Association, 1987) and the DSM-IV (American Psychiatric Association, 2000) and has been validated in palliative care and advanced cancer populations (Breitbart et al., 1997; Lawlor et al., 2000b). The MDAS is intended for repeated administration over a short time period and is useful for capturing short-term fluctuations in delirium (Breitbart et al., 2002b) and for determining delirium severity (Adamis et al., 2010). This instrument has now been translated into Italian and Japanese (Grassi et al., 2001; Matsuoka et al., 2001), and it has also been used for routine detection of symptoms in a French-speaking palliative care setting (Mancini et al., 2002).

The 16 item Delirium Rating Scale-Revised-98 (DRS-R-98) (Trzepacz et al., 2001), a more comprehensive version of the original Delirium Rating Scale (Trzepacz et al., 1988), also incorporates detection and severity ratings. It was developed based on the DSM-III-R (American Psychiatric Association, 1987) and has been demonstrated to be a useful instrument for diagnosing and rating delirium severity, and for use in longitudinal studies (Wong et al., 2010).

The Confusion Assessment Method (CAM) (Inouye et al., 1990) is a dichotomous scale that can be used by trained clinicians as a screening and diagnostic tool. It is brief, available in multiple languages (Adamis et al., 2010), and widely used in varied populations, including those with advanced illness (Ryan et al., 2009; Wong et al., 2010). It may not be possible to use it in those approaching the end of life (Gagnon et al., 2012) and a four-question version has been developed in an effort to broaden its applicability (Rao et al., 2011).

Challenges in the application of symptom measures in palliative care settings

There are numerous challenges to the systematic measurement of symptoms in both clinical and research settings. These challenges may be attributed to professionals and the systems within which they work, to patients, and to limitations in the instruments used to acquire data.

Professionals may have conceptual and attitudinal barriers to the use of health status measures in patient care and clinical trials (Deyo and Patrick, 1989). These barriers may be relatively more significant in populations with advanced illness. They include scepticism about the validity and importance of self-rated health measures, preferences for physiological and observable disease-related outcomes, and unfamiliarity of health-care providers with the scoring of measures. Knowledge and skills in symptom assessment also may be a problem in some settings (Donovan et al., 1987; Von Roenn et al., 1993). Professional education (Bourbonnais Fothergill et al., 2004) and the routine use of symptom measures in clinical practice (Foley, 1995) may be useful to address these concerns.

There is enormous variation in the health-care systems that provide care to patients with serious illness. Systems vary at every level—from national health services to protocols that guide care in individual units. The ability to measure symptoms systematically, incorporate screening or treatment algorithms, and facilitate quality improvement, is strongly influenced by numerous system-related facilitators and impediments. For example, the Canadian Cancer Quality Council of Ontario has reported that systematic symptom screening had been

incorporated into all 14 regional cancer centres with a steady increase in use—from 51% of cancer patients using the screening tool in 2011 to 59% in 2013 (Cancer Quality Council of Ontario, 2014). That latter group has identified such screening as an important quality indicator. That stated, there is evidence to suggest that further work is needed to identify optimal strategies for systematizing responses to levels of distress, particularly when moderate to severe distress is identified (Seow et al., 2012). Quality improvement methods may be a useful avenue for the development of these approaches.

In some settings, system-related barriers may be addressed through adaptation of the electronic health record. Point-of-care evaluation, decision support, telehealth strategies, and other technological advances may drive improvement in symptom measurement and the management of symptom distress. These changes have begun in many developed countries and will continue to evolve wherever the technological and financial capacity exists.

If professional and system-related barriers to symptom assessment were eliminated, daunting challenges would remain, particularly in populations with serious illness. Patient self-report may be impaired by cognitive impairment or other medical problems associated with progressive illness, or by the highly prevalent symptom of fatigue (Coyle et al., 1990; Dunlop, 1990; Dunphy and Amesbury, 1990; McCarthy, 1990; Ventafridda et al., 1990; Curtis et al., 1991; Portenoy et al., 1994a). For example, one survey demonstrated that patients in a palliative care unit gradually reduced their compliance with twice-daily completion of the ESAS (Fainsinger et al., 1991) from 69% on the day of admission to 8% on the day of death.

Symptom distress or complexity also may be barriers. Severe distress may produce the paradox that those with greatest need of symptom management are least able to provide the information necessary for treatment. This problem highlights the importance of detailed clinical assessment in all instances, particularly in the very ill. The complexity of symptom measurement is evident in the common occurrence of multiple concurrent symptoms (Van Lancker et al., 2014). A study using the MSAS observed that the median number of symptoms per patient was 11.5 and the range was 0–25 (Portenoy et al., 1994a). Instruments that measure global symptom distress may be helpful when multiple symptoms contribute to illness burden but these measures may lack validation in populations other than those with cancer (McCorkle and Quint-Benoliel, 1983; Portenoy et al., 1994a, 1994b).

The realization that time is limited may be a factor in changing the priorities of patients or caregivers, and this shift also may become a challenge in symptom assessment (Perkins et al., 2007). The salience of these changing priorities is uncertain, however. Observational studies suggest that most patients with advanced illness are willing to provide information for research (Cleeland et al., 1994; Cunningham et al., 1995). Some studies indicate that most very ill patients will respond to questions about even highly sensitive topics (Townsend et al., 1990).

When instruments are used to evaluate the medically ill, each item should be considered in terms of its own potential to generate distress. The concern that patients may be relatively disinclined to respond to sensitive questions is especially pertinent to the measurement of some psychological symptoms. One group of investigators, for example, has described observations that some patients find it difficult to address issues such as suicidal ideation,

hopelessness, and emptiness in life, and can experience distress when queried about such items (Wilhelm et al., 2004). The group did not suggest that these important questions should be omitted from clinical assessment but did suggest the use of depression screening instruments that use less contentious questions within the tool, provided those questions can still identify depressed patients. A person to person clinical interaction is important for potentially distressing but nonetheless important questions. This is an important consideration when tools are being used in the absence of a clinician being in the patient's immediate vicinity to provide ongoing assessment and support.

These and other patient-related barriers to symptom measurement may be particularly challenging in several highly vulnerable subpopulations. In addition to those with cognitive impairment, populations of concern include children, minorities, and the imminently dying. Relatively few studies have evaluated symptom screening in sick children and there is no established approach (Dupuis et al., 2012). Validated verbal rating scales or observational scales provide the means to evaluate pain in children of any age (Jay and Elliott, 1984; LeBaron and Zelter, 1984; Elliott et al., 1987; Gauvain-Piquard et al., 1987; Jay et al., 1987; Katz et al., 1987; Kuttner et al., 1988; Manne et al., 1990; Karoly, 1991; Manne and Andersen, 1991; Matthews et al., 1993; Gaffney et al., 2003), and other scales have been developed for the assessment of chemotherapy-related nausea and vomiting (Zeltzer et al., 1988; Tyc et al., 1993). Paediatric versions of the MSAS have been validated (Collins et al., 2002; Hunt, 2006) and can provide information about multiple symptoms concurrently. The development and application of symptom measurement tools for diverse populations of children remain an area in need of further research.

Significant problems in symptom measurement also may be encountered in patients whose culture and language differ from the professionals involved in their care (Waxler-Morrison et al., 1990). Although some instruments have been shown to be reliable and valid across cultures and languages (Cleeland et al., 1988; Cleeland and Ryan, 1994; Grassi et al., 2001), translation and validation of other symptom measures is needed. In the clinical setting, health-care professionals may need to develop simple, face-valid symptom measures to overcome language barriers.

Although most patients will retain the ability to interact at a time very close to death (Seeman, 1992), evaluation of subjective reports may become impossible or very difficult due to cognitive impairment and other concerns (Exton-Smith, 1961; Hinton, 1963; Witzel, 1975; Saunders, 1984; Fainsinger et al., 1991). A transition from verbal rating scales to observational scales, and sometimes to proxy assessments may be necessary to provide data throughout the terminal phase. The validity of this approach, however, remains to be determined.

Yet another group of potential barriers to systematic measurement of symptoms in populations with advanced illness relate to the limitations of the available instruments. Although the increasing availability of validated symptom measures has been an important advance, valid measures are still lacking for some common symptoms, and many tools validated in one population have uncertain generalizability to others. With the exception of selected pain measures, symptom questionnaires have frequently not been tested for validity in patients with cognitive impairment or multiple symptoms (Stark, 1988).

Conclusion

Systematic symptom assessment is a foundation of clinical practice and research. Instruments for the measurement of symptoms have been developed and may facilitate this process. Quantification of symptoms may be able to improve symptom management and further the goal of enhanced QOL. Clinicians and investigators should become familiar with the instruments that are applicable in the population for whom they provide care, and develop methods for their use in routine clinical practice, the research environment, and the palliative care setting.

Informatics and Literature Search

Jennifer J. Tieman and David C. Currow

Introduction to informatics and literature search

Technology has accelerated the ability of individuals and systems to capture, analyse, and distribute data and information. As a result, there is now an unprecedented capacity to access literature and evidence, to improve clinical decision-making and service delivery. Technology has also enabled the development of tools and resources that can enhance clinical care and patient involvement. However, the value of such applications rests upon the quality of the professional knowledge embedded in these applications. The knowledge to support such systems and applications is domain specific. In any field or discipline knowledge builds on, or reacts to, previous research and thought. Therefore, being able to find what has previously been published is critical. While availability and access to literature and evidence is a necessary prerequisite to use, there are still challenges for individuals and systems in retrieving relevant and good quality literature. Finding the right information is not as simple as typing a search term into a database. Indeed, searching for palliative care's literature and evidence is complex and time-consuming, given the way peer-reviewed literature is described and distributed within journals and bibliographic databases.

The role of health informatics

Technology is accelerating the rate at which data can be captured, organized, analysed, distributed, and accessed across the health system and these capabilities are transforming how health-care is conceived and delivered (Australian Health Ministers' Conference, 2008; Mattke et al., 2010; World Health Organization, 2011). This transformation reflects not only the possibilities afforded by technological innovations but the pressures being placed on the health system due to an ageing population, changing patterns of disease burdens, and increasing expectations of health consumers and involvement by health consumers in their care decision-making and management. Ready access to tools, information, and resources is not only driving change but raising expectations. Investment in health information technology (HIT) has been seen to offer many health system benefits, such as point-of-care clinical information, automated patient-record keeping, facilitated access to and exchange of patient data, enhanced coordination of care across settings and providers, and public health interventions for consumers use (Bennett and Glasgow, 2009; Jamal et al., 2009; Kreps and Neuhauser, 2010; Lobach et al., 2012).

Technology is not enough

It is, however, the quality and currency of the information and knowledge embedded in, and transmitted through, HIT that provides its clinical value. The importance of this concept can be seen in the emergence of the field of health informatics with its specific focus on the contribution of the information, rather than the characteristics of the technology alone (Hersch, 2009). This reinforces the importance of domain knowledge and its purpose in assisting professionals in their cognitive tasks and professional responsibilities. The potential links between evidence-based medicine and health informatics are highlighted by the capacity of HIT to make research evidence available to support clinical judgement and to help patients identify and articulate their preferences (Bloomrosen and Detmer, 2010). The definition of medical informatics in Haux's review of the development of this field as 'the systematic processing of data, information and knowledge in medicine and health-care' (Haux, 2010) again recognizes the significance of the knowledge base within HIT. Haux went on in this review to reflect on the forces that are shaping the field: the progress in information and communications technology; the expansion of the knowledge base for health and medicine; and changing expectations of the professions and the society.

For palliative medicine, health informatics and HIT could have many roles to play in supporting clinical decision-making and in enhancing care delivery. Indeed, HIT may be particularly valuable in this field, given palliative medicine is practised in hospices, in-patient wards, residential aged care facilities and other community settings, as well as patients' homes, and given that co-morbidities are common and care needs will change over time, in accordance with the underlying disease. HIT solutions may ease problems in managing a diffuse and multidisciplinary knowledge base and by supporting care within and across multiple settings.

There have already been a number of reviews of e-health and HIT initiatives within palliative care which show that HIT applications are feasible and can provide solutions to a range of practice issues in this field (Kidd et al., 2010; Corn et al., 2011; Demiris et al., 2011; Johnston, 2011; Oliver et al., 2012). There are also completed and in-progress trials and studies looking at diverse HIT applications within palliative care, ranging from community data collection (Abernethy et al., 2011) and palliative telemedicine in the home (Duursma et al., 2011), to symptom assessment in palliative radiotherapy using e-technology (Cox et al., 2011) and Internet-based self-help bereavement interventions (van der Houven et al., 2010). Such investigations ultimately could result in widely available HIT resources.

The challenge is to ensure that HIT resources reflect the best available evidence from research and practice (Banzi et al., 2010; Ketchum et al., 2011). Palliative medicine as a specialty, and palliative care as a discipline and area of professional practice, need to ensure that HIT applications and systems in this field incorporate what is known from palliative care's expanding research base

and from the review of the specialty's current professional practice. Furthermore, HIT applications will need to be monitored, to ensure that they are updated or modified as new evidence emerges and the knowledge base changes.

The literature and evidence base for palliative care

Palliative medicine is a complex specialty drawing on many fields of expertise and academic interest to inform practice. It is a referral-based field of clinical care, not limited by the underlying disease or prognosis. Palliative care physicians can face specific challenges in their clinical practice relating to the changing nature of the knowledge and competencies needed in care delivery. Care is active but not curative in intent, addressing physical symptoms as well as psychosocial needs, and supporting both the patient and the family (World Health Organization, 2011). This reflects an expanding definition of palliative care from terminal care alone to a dynamic responsibility for supportive and palliative care across a time and disease continuum (Currow and Abernethy, 2005). Physicians, therefore, require a knowledge base that enables excellent symptom control as well as identifies emerging factors that could influence the course of the life-limiting illness or active co-morbid illnesses.

Engagement with knowledge and evidence is a critical component of such informed and current practice. However, the ability of palliative care physicians and palliative care as a discipline to use knowledge and evidence in practice depends on the ability to find, retrieve and assimilate this information. Hence, searching and accessing relevant material is a fundamental part of up-to-date and ethically responsible practice. However, finding relevant information can be a complex and time-consuming task yielding suboptimal results.

Size of the evidence base

The technicalities of evidence retrieval are heightened by a rapidly expanding biomedical literature. Each day over 1000 articles are indexed to the Medline database (Straus and Haynes, 2009), and each day reports of 75 clinical trials and 11 systematic reviews are published (Bastian et al., 2010). Such figures challenge the perception that clinicians have the time and ability to remain involved with, and informed by, the biomedical literature.

Concerns about the expanding literature base also apply to palliative care's literature. Research has shown that the absolute number of palliative and hospice care articles indexed on Medline increased in each 5-year period from 1970 to 2005, as did reports of palliative care clinical trials. Over the same time period, the proportion of indexed articles on Medline that were related to palliative and hospice care more than doubled. By 2005, 0.38% of all items indexed on Medline were relevant to palliative and hospice care (Tieman et al., 2008). A related bibliometric analysis not only confirmed that there was a substantial and increasing amount of palliative care literature, but calculated that keeping up to date with the published palliative care literature would mean that health professionals needed to read 19 articles every day (Tieman et al., 2009).

Diffuse nature of palliative care's interests

As a referral-based specialty, information needs in this context can be extensive. Doyle, in his review of the palliative medicine as a subspecialty, noted that the challenge for palliative medicine is:

> To espouse and demonstrate the principles of palliative care ('integral to all good clinical care') whilst at the same time developing the unique skill and knowledge base of specialist palliative care . . . This skill and knowledge base is a big challenge now that patients are being referred with every major pathology. (Doyle, 2005)

Understanding the commonalities and particular care needs of palliative care patients with different disease trajectories has been highlighted, as have the specific palliative care requirements of populations with diagnoses other than cancer. Potentially relevant literature that could inform the palliative care knowledge base will not necessarily be limited to studies in palliative care populations. In particular, it may be necessary to scan other specialist literature for studies of common symptoms and care issues in palliative care such as pain, breathlessness, fatigue, or depression which may be investigated by other medical specialties.

An analysis of the references contained in the 2010 edition of the *Oxford Textbook of Palliative Medicine* demonstrates this crossover in literature. Using a three-term search (palliative.tw. OR hospice.tw. OR terminal.tw.), retrieval rates for each chapter's references were calculated. There was a significant amount of variability between chapters in how many references were retrieved (range: 8–80%), with an overall retrieval of only 26% of the total reference dataset. Chapters which had the lowest rates of retrieval using the three-term search were those looking at the management of common symptoms and disorders, geriatric palliative medicine, issues in neoplastic disease, palliative medicine in non-malignant disease, and complementary therapies in palliative medicine. This suggests that these areas of palliative medicine are using literature that arises from other disciplines and medical specialties (Tieman, 2012).

The diffuse nature of palliative care's interests is likely to be compounded by the issue of scatter in the reporting of research. Hoffmann et al. have shown that the publication of trials and systematic reviews for specialty areas is not confined to specialist journals or even common generalist journals. This means that physicians are likely to miss relevant trials and reviews if they only read specialist journals. The authors noted in their article that:

> Scatter is also likely to be greater in specialties that typically concern patients with a wide variety of conditions. Examples include emergency medicine, primary care, palliative care, and allied health disciplines. (Hoffmann et al., 2012)

Scatter as an issue for palliative care has been reported. In 2005, 6983 palliative care related articles were published in 1985 different journals (Tieman et al., 2009). While most of these articles would not necessarily have been clinical trials or systematic reviews, such spread in palliative care publication suggests that a comprehensive review of the literature is challenging.

Not published, not indexed

Published indexed literature may represent only a portion of the knowledge materials that could be relevant to palliative care clinicians, educators, and researchers. Unpublished reports and documents that have not been indexed form an important part of the knowledge base. Limitations to, and idiosyncrasies of, indexing systems compound further potential losses to the retrieval of literature. Navigating both the formal and informal literature to acquire relevant and significant materials is an important issue for all fields, but may have specific resonance for palliative care, given the diffuse nature of this field.

Research from other fields has shown that material presented at conferences does not always lead to publication. Indeed, the conference conversion rate for biomedical presentations may be as low as 44% (Scherer et al., 2007). According to a 2010 *Heath Technology Assessment* report, positive studies are more likely to be published than negative studies and they are likely to be published more quickly (Song et al., 2010). One study has confirmed similar concerns for this discipline. It demonstrated multiple losses to the effective retrieval of published palliative care literature arising from non-publication of palliative care research, publication in non-indexed journals, and incomplete or idiosyncratic indexing of palliative care articles (Tieman et al., 2010).

Issues in searching the knowledge base

Where literature is held

The size of the literature database is only one source of difficulty in being able to retrieve literature effectively and evidence relevant to palliative care. Understanding where relevant literature is being held, the technical characteristics of individual databases, and the requirements of the different searching interfaces is also important. Each database has its own set of rules for citation referencing, storage, and retrieval, which adds to the complexity of effective searching. Various studies have reported on issues relating to database coverage and technical requirements of searching within different databases (Falagas et al., 2008; Wider and Boddy, 2009; Spreckelsen et al., 2011). Without detailed technical knowledge, seemingly sensible searching decisions can lead to loss of relevant literature. As an example, applying the '*humans*' limit to a search in PubMed will remove items that are not yet indexed or which will never be indexed under this database's rules. This will exclude automatically from retrievals some of the most recent literature that is awaiting indexing but which may already be published online (Sladek et al., 2010).

Unfortunately, not all of palliative care's literature is indexed on Medline. Highly relevant, unique literature is found on other databases including Embase, CINAHL, and PsycINFO. Depending on the specific information needs, this means that a searcher will have to interrogate multiple databases to ensure comprehensive coverage and, therefore, be familiar with the requirements and unique search interfaces of these repositories. Otherwise, the 40% of published palliative care items not indexed on Medline may not be retrieved (Tieman et al., 2009).

Physicians' technical skills in searching

The capacity to access a bibliographic database and construct a search should not be confused with creating an effective search. Information retrieval through searching requires technical expertise as well as content knowledge. The *PRESS: Peer Review of Electronic Search Strategies* report documents the complexities associated with expert searching and demonstrates the many simple errors that can affect retrieval (Sampson et al., 2008). Given that even expert searchers make errors, it is likely that health professionals without formal training will also make errors that will limit what they retrieve.

A recently completed study of palliative care clinicians' search constructions confirms that many clinicians struggled to create useful searches. The analysed searches were often rudimentary with nearly half of the clinical participants using only a single search term to try and retrieve *as many articles as possible that were relevant to palliative care*. The average retrieval in the study of a known set of relevant articles by the searchers was only 25%. Unnecessary limits, incorrect use of Boolean operators and inappropriate narrowing of searches were all common errors in the group (Tieman, 2012).

Although searching competence continues to be identified as an important component of evidence based practice, competence in this skill cannot be assumed. Problems with health professionals abilities in this field have been reported in various systematic reviews (Coumou and Meijman, 2006; Davies, 2007; Masters, 2008; Younger, 2010). There is increasing interest in interventions to support clinicians' use of clinical information retrieval systems, such as Medline. Although these interventions have shown some success in improving searching skills when using electronic bibliographic databases, the overall effectiveness of such training remains uncertain (McGowan et al., 2009; Gagnon et al., 2010).

Using Google

Given the many complexities of accessing and constructing searches in formal bibliographic databases, it is perhaps unsurprising that many health professionals use Google or Google Scholar as a search option. These search engines offer a simple and fast interface with a vast repository of content. However, a variety of concerns have been documented about their effectiveness. Such criticisms relate to a lack of advanced search features to enable the user any control over retrievals, insufficient and unclear indexing, uncertainty about coverage, and a lack of transparency about the embedded search algorithm (Falagas et al., 2008; Anders and Evans, 2010).

Similar concerns have also been raised about the use of Wikipedia as a source of a medical information (Clauson et al., 2008; Munger, 2009), particularly given its impact as a primary retrieval site by search engines (Laurent and Vickers, 2009).

Implications of ineffective searching

Poor searching can have many implications. If a health professional is seeking immediate clinical evidence to inform decision-making, ineffective retrieval may reduce the value of the clinical advice. For those who seek to maintain currency of their professional knowledge by monitoring emerging findings, inefficient retrieval may not only reduce their actual knowledge base, but may increase inappropriately the searcher's self-belief that their knowledge is current. Finally, the clinical authority of health and social guidance is put at risk, as errors in search strategies reduce the value of the retrieved results (Sampson et al., 2008).

Knowledge solutions in palliative care

Dealing with the information flood

Building a comprehensive knowledge base for palliative care practice and research remains an important priority for the discipline. Relying on health professionals to have the appropriate skills to retrieve needed knowledge from such a complex bibliographic environment may be an ineffective response to a fundamental problem. Straus and Haynes have argued that while research-based evidence is being generated at ever faster rates, much of this evidence is not readily available to the clinicians it is intended to support. They highlight a number of potential

approaches to providing better infrastructure in the management of evidence-based knowledge, including better knowledge products and tools that are reliable, relevant, and readable, and more efficient search strategies (Straus and Haynes, 2009).

There is already a range of knowledge resources for palliative care, including specialist journals and journal subsets, web-based evidence repositories, and palliative care segments in major database repositories. Specialist journals such as *Palliative Medicine* and specialist database repositories, such as the pain, palliative and supportive care topic in the Cochrane Library, provide a focus for the publication of research work and its promulgation through the sector. Web resources such as the National End of Life Care Intelligence Network in the United Kingdom, National Hospice and Palliative Care Organization in the United States, the Canadian Virtual Hospice, and the Australian website CareSearch provide national and international access to high-quality evidence resources including guidelines, clinical guidance, and evidence summaries for palliative care specialists, other health professionals, and for palliative care patients and their families and carers. The CareSearch Review Collection provides details on systematic reviews and structured literature reviews relevant to palliative care, offering another approach to synthesized knowledge on palliative care issues. Table 7.3.1 outlines a range of web-based resources for palliative care. Such resources begin to address the need for better knowledge products and tools in this field.

To ensure that all research efforts are captured, academics, researchers, and clinicians involved in research projects need to be encouraged and supported in publishing their findings. This may be particularly important where the results are negative, to reduce publication bias. Clinical trials registration on one of the publicly available registers is an important step in preventing the loss of research. Grey literature repositories of project and research reports may also improve the comprehensiveness of evidence capture. There are some grey literature repositories that include palliative care content including Open Grey at <http://www.opengrey.eu/> and the New York Academy of Medicine's Grey Literature report at <http://www.nyam.org/library/online-resources/grey-literature-report/>. The CareSearch website maintains a grey literature database of 'hard-to-find' Australian materials, including conference presentations, research reports, non-indexed Australian journal articles, and government and organizational reports. Such repositories may be especially important in finding information and evidence relating to the local factors that may influence the relevance or capacity to translate evidence to individual services or specific areas.

Role and contribution of search filters

Different strategies to deal with the searching issues for palliative care are being explored. Search filters represent a brokered informatics-based search solution. A search filter is an experimentally created and tested search strategy that is designed to find particular types of studies or articles dealing with a specific topic, in a particular database and remove material that does not meet these criteria. Effectively, a filter is an evidence-based search for relevant literature. Haynes and colleagues undertook the first work in this field constructing, testing, and validating scientifically a

best performing Medline search strategy to retrieve literature with a particular research study design, using an approach more commonly used to test the performance of new diagnostic tests (Haynes and Wilczynski, 2004; Haynes et al., 2005). This enabled them to measure sensitivity, specificity, and accuracy to assess the performance of each individual search strategy. The resulting study design search filters have been utilized within the National Library of Medicine's PubMed website as the Clinical Queries filters.

Until recently search filter research has focused on methodological filters, that is, search filters designed to find research across any content or topic area but which all use the same study design. The last 5 years has seen increasing interest in developing content filters that look for literature on a particular topic, such as adverse events (Golder and Loke, 2009) or renal information (Iansavichus et al., 2010), regardless of the underlying study design. Importantly, a recent study has shown that the use of search filters improves the efficiency of physician searching (Shariff et al., 2012).

It is worth noting that one of the first content search filters developed in the world was a search filter for palliative care literature (Sladek et al., 2006; Sladek and Tieman, 2008). This search filter was developed using the approach applied by Haynes et al. of testing retrieval in a gold standard set of references identified by hand searching the general biomedical literature. The search filter for palliative care literature comprised nine MeSH terms and three textwords (Sladek et al., 2006). The inclusion of a subset of journals in the search filter followed subsequent research that that showed that not all articles from a set of specialist journals was captured by the search filter (Sladek and Tieman, 2008). The search construction of the current palliative care search filter for use in Ovid Medline can be seen in Table 7.3.2.

Making search filters useful: a PubMed option

A search filter is an extremely valuable health informatics tool as it provides a transparent and reproducible mechanism for

identifying relevant literature within a particular bibliographic database, such as Ovid Medline. Developing or translating a search filter for use in a publicly available database that can be openly accessed through the web, increases dramatically its utility and reach. PubMed is an open access bibliographic database which contains over 19 million biomedical citations. Translating the Ovid Medline palliative care search filter for use in PubMed, means that web users can click on a hyperlink loading the search filter automatically to PubMed and initiating the retrieval of relevant citations. The PubMed translation of the palliative care search filter is detailed in Table 7.3.2.

By combining the palliative care search filter with expert searches on a range of care issues, such as dyspnoea or distress, it is possible to offer a technology-based solution to the problem of individuals' search competence. Visitors to the PubMed Palliative Care Filter page in the CareSearch website have immediate access to PubMed citations filtered by their relevance to palliative care and their specific topic interest. As the PubMed database is updated daily, by providing real-time links, the resulting search is always current. The utility of this searching solution has been enhanced by providing options to refine the search further by limiting to free full text or to randomized controlled trials and systematic reviews only.

The benefits associated with the provision of a PubMed version of the palliative care search filter work have been extended by the introduction of a Heart Failure Search Filter (Damarell et al., 2011) into the CareSearch website in 2010 and a Lung Cancer Search Filter in 2011. A Residential Aged Care Search Filter (Dicker and Hayman, 2014) and a Bereavement Search Filter (Tieman et al., in press) were developed and added to the CareSearch website in 2014.

The future of search

As technological capacities develop, different approaches to search and information retrieval will emerge, to assist in the issues of knowledge management highlighted by Straus and Haynes. There has been substantial work around the possibilities of natural text language analysis (Chung, 2009; Névéol et al., 2009). Another approach looks at the semantic web and semantic wikis, which marry information semantics (or meaning) with the dissemination platforms commonly being accessed by health professionals (Boulos, 2009; Kroeker, 2010). The value of federated searching across personalized web resources is also being explored. Word add-in technology may enable more efficiently tagged literature to be tracked by search engines such as Google (Fink et al., 2010).

There has also been some preliminary research into the role of social media functionalities such as Twitter®, Blogs®, and YouTube® (Fernandez-Luque et al., 2012; Gruzd et al., 2012).

The role of apps for phones in searching remains new territory. The Pew Internet Project has surveyed users and reported on the 'rise of the apps culture' (Purcell et al., 2010). There are already some iPhone apps that can be used to support searching and these applications are likely to grow in the coming years (Kubben, 2010).

Conclusion

HIT provides both a challenge and a solution for the management and activation of palliative care's knowledge base. New technologies are emerging that enable applications to be built that ultimately can enhance care delivery and service provision if taken up

systematically. However, the quality of these applications relies on the quality and currency of the domain knowledge that is embedded within them and distributed through them. The capacity to identify and retrieve palliative care's evidence base is, therefore more critical than ever. Searching, however, remains complex, given an expanding literature base and a diffuse and multidisciplinary set of information needs and information sources. Search strategies, such as the use of search filters that offer validated access to the literature, offer avenues to improve retrieval. Accessibility can also be enhanced by web-based availability to ensure immediate access.

7.4

Validated assessment tools for psychological, spiritual, and family issues

Linda L. Emanuel, Richard A. Powell, George Handzo, Kelly Nichole Michelson, and Lara Dhingra

Introduction to validated assessment tools for psychological, spiritual, and family issues

Palliative care stands out among other medical disciplines for its foundational commitment to the inclusion of psychological, spiritual, and family issues, premised on founding pioneer Dame Cicely Saunders' assertion that 'total pain' involves suffering in the physical, psychological, spiritual, and social domains (Saunders, 1978).

Saunders further contended that suffering in one domain 'migrates' to others. For example, spiritual pain could be somatized or expressed by a person as physical pain. Indeed, research is beginning to identify some of the neurobiological mechanisms for physical expression of pain (García-Campayo et al., 2009; Borkum, 2010). Psychological distress has a reciprocal relationship with social distress, each produced by, and creating, distress in the other. Physical suffering may trigger psychological, spiritual, and social suffering. With the task of the palliative care team being to address suffering in all domains, occasionally resolution of one source will relieve suffering in other domains. Commonly, suffering adopts a life of its own in each domain and needs to be assessed and managed. For instance, an individual in distress who cannot eat due to oesophageal cancer may benefit greatly from palliative surgery. However, the impact of the experience on the individual's psychological and spiritual states, and their relationships with others, may take longer to resolve and entail anticipatory anxieties or concerns that the situation may recur and worsen in the future. If the individual undergoes palliative surgery successfully but these other domains are unaddressed, he/she remains incompletely managed.

Palliative care providers, therefore, should assess all domains competently and understand how suffering 'travels' from one realm to others. The provider must not only assess and address this multi-domain suffering, but measure how well the interventions applied have alleviated it. This applies to the patient and their family, who are considered a unit of care in palliative care, with the provider considering, first and foremost, the patient and then the family.

The patient may experience manifold challenges and losses, starting with the loss of their expectation of health. As each challenge and loss occurs, the patient must absorb the new situation, adapt to it, and reach a new equilibrium (Knight and Emanuel, 2007b). Confronted by serious and rapidly evolving illness, these losses can be overwhelming. Constant reassessment by the provider is essential, as is reconsideration of how to support comprehension, adaptation, and resolution in each of the physical, psychological, spiritual and social domains.

If this were not sufficiently complex, interactions between the patient and their circle of loved ones and community compound it. Understanding how the patient and family impact on one another's experience is a considerable but necessary challenge. Examples are myriad: a patient with depression due to pancreatic cancer transmits the burden of this depression to those who love them; a family unready to accept the terminal nature of their loved one's illness may complicate the patient's acceptance of their own condition and hinder the social tasks of dying that both sides need.

With these interacting dynamics, the provider is greatly assisted by practical assessment approaches and measures of relevant outcomes.

Assessment and measurement

Improving the quality of palliative care is now recognized as a high social priority. Advances in the field's development, however, are impeded by difficulties achieving reliable assessments and management of the 'total pain' domains that matter most in the discipline. These domains are often: (1) subjective, (2) of an impractically large scope, (3) reliant on interviews undertaken at a time when people may be too burdened or ill to answer multiple questions, and (4) difficult to study longitudinally due to the often contracted survival time of this population. Methods to enable measurement of patients' palliative care needs must be adapted to address these challenges. The availability of psychometrically sound and clinically relevant screening, diagnostic, and outcome evaluation tools that optimize patient evaluation, prognostication, and treatment selection, as well as patient satisfaction and quality of life, are essential to high-quality palliative care.

The following sections describe commonly used assessment and outcome measurement tools in a routine clinical setting—some of which are used, often erroneously, interchangeably. These can be

employed in making general patient evaluations across multiple domains, as well as specifically addressing psychological, spiritual, and familial issues. We will discuss their development and, where it exists, validation.

Assessment

Comparing patient-reported symptoms following open-ended questioning versus a structured survey among 265 advanced disease patients in the United States, Homsi et al. (2006) reported that the median number of symptoms found using the latter was tenfold higher than those volunteered, with most non-volunteered symptoms being moderate or severe and distressing. Effective patient management is therefore based on active, systematic health assessments by providers. These evaluations may improve the accuracy of diagnostic and prognostic determinations and the development of individual treatment plans.

Given its holistic nature, palliative care assessment should include, but extend beyond, traditional medical assessments (Arseven et al., 2005). As suggested by the US-based National Consensus Project for Quality Palliative Care (2013), care plans should involve a comprehensive, timely assessment that is interdisciplinary, coordinated, and include: patient and family interviews; medical record review; discussion with other providers; physical examination and assessment; and relevant laboratory and/or diagnostic tests or procedures. Consultative evaluations should include the patient's current medical status, adequacy of diagnosis and treatment consistent with review of past history, diagnosis, and treatment, and past treatment responses.

Assessment includes documentation of disease status (diagnosis and prognosis); co-morbid medical and psychiatric disorders; physical and psychological symptoms; functional status; and social, cultural, spiritual, and future care planning concerns and preferences. Assessment of children must be conducted with sensitivity to their age and neurocognitive development stage. Patient and family expectations, goals of care and living, understanding of the disease and prognosis, and preferences for the type and site of care, should also be assessed and documented. Regular reassessment and updating are necessary.

Individual clinical assessment approaches have developed organically over time and are often not rigorous, systematic procedures using valid and reliable measurement tools to supplement skilled clinical interviewing. Such instruments exist in abundance, with a systematic literature review by Stiel et al. (2012) identifying 528 different tools (372 targeting patients) for use in palliative care research and clinical practice. Many are not well validated or designed for clinical use and it will likely always remain the case that the clinical interview and some intuitive assessment are essential. Nonetheless, validated instruments should have a role in the clinical setting. The following sections focus on a limited number that have been tested empirically and can facilitate a comprehensive bedside assessment.

Needs at the End-of-Life Screening Tool

The Needs at the End-of-Life Screening Tool (NEST) (Emanuel et al., 2001) is a general assessment tool that uses a holistic approach and 13 questions that are grouped into four thematic dimensions—corresponding, for mnemonic purposes, to each letter of NEST (Needs in the social domain, Existential matters, Symptom management needs, and Therapeutic relationship

matters)—to screen patients for needs of concern. The tool was developed using 15 focus groups and six in-depth interviews among patients, family caregivers, and professionals, followed by a survey of a nationally representative sample of 988 patients (650 at 4–6-month follow-up) with any terminal diagnosis of less than 6 months prognosis, except AIDS. The qualitative work identified areas of importance in end-of-life care, which were tested empirically using factor analysis of patients' survey responses. The tool was assessed further for its feasibility and effectiveness as a screening tool for advanced illness care needs among 451 cancer patients in tertiary care (Scandrett et al., 2010). An adaptation for use in the emergency ward setting is called SPEED (Screen for Palliative and End-of-life needs in the Emergency Department) (Richards et al., 2011).

Measurement

Measuring palliative care outcomes, and the totality of care provided, is an important mechanism by which high-quality health-care systems are developed and maintained (Pasman et al., 2009). Given that health-care costs are a substantial portion of public and private budgetary expenditures, the medical profession is obliged increasingly to generate quantifiable evidence demonstrating the effectiveness, efficacy, appropriateness, and acceptability of services. In some countries, the commissioning of health-care services is dependent upon evidence from patient-reported outcome measures (PROMs) (Bausewein et al., 2011a), where results of importance from the patient perspective play a critical role in care provision, audit, and research.

Outcome measurement

Care is focused on achieving positive clinical and satisfaction outcomes for patients and families by using quality services. Correspondingly, four types of health outcome measurement are patient-, carer-, staff-, and service-based (Jocham et al., 2009). Many measures are part of service assessment rather than direct patient care. However, PROMs can be used routinely in care, patient assessment, and as a continuing measure of progress such as effective pain management. Completed measures can be retained in the patient's medical record to help the clinician monitor change over time.

Identifying good outcome measures, however, is problematic. The utility of a measure is determined by its psychometric properties and how well it relates to its aim. A measure could be referred to as 'good' if it is shown to have validity (face, content, criterion, and construct), reliability (inter-rater, test–retest, and internal consistency), appropriateness and acceptability, responsiveness to change, and interpretable results (Bausewein et al., 2011b). Additionally, in the pressured, time-sensitive environment of the clinical setting, a measure should be easy and relatively quick to administer. These are the benchmarks against which the quality of a measure should be evaluated.

A small number of multidimensional palliative care outcome measures have been developed that meet at least some of the above criteria, including the Palliative care Outcomes Scale (POS).

Palliative care Outcomes Scale

The POS was developed in 1999, for use with patients with advanced disease, and to improve outcome measurement by evaluating essential palliative care components partly from the patients' perspectives (Hearn and Higginson, 1999). There

are currently two versions of the original POS: one for patients to complete, the other for staff. The tool was developed initially across eight palliative care centres across England and Scotland (including inpatient, outpatient, day, home, and primary care settings) among 148 patients for the patient version, and 337 for the staff version. It has since been adapted and validated in multiple regions, from Europe (e.g. Bausewein et al., 2005), to Latin America (Eisenchlas et al., 2008), to Africa (Harding et al., 2010; Powell et al., 2007), and is being adapted for use among children (Downing et al., 2012).

The POS has ten items assessing physical symptoms, emotional, psychological, and spiritual needs and the provision of information and support, with one open question on main problems. Responses are rated on a 5-point Likert-type scale ranging from 0 ('No effect') to 4 ('Overwhelming').

Quality improvement

Quality improvement (QI) is a formal, systematic approach to performance analysis that seeks to measure the status quo and identify and implement ways to initiate improvements. Clinical audit can be the first step in the QI cycle; a method of reviewing existing clinical practice against agreed standards of care to identify areas for improvement, and re-evaluating those care practices after a designated period of time, to assess their outcome compared with baseline data.

Gould et al. (2007) reported a QI collaborative that was conducted to develop capacity among health-care providers in New York City to apply QI methodology—delivering 4-year-long implementation cycles with a total of 82 teams—to palliative care services. They found significant improvements in most team projects and substantial gains made in familiarity with continuous QI techniques and in building palliative care programmes and networks.

Measurements that have been developed for use in outcome assessments and QI exercises, and which focus on the particular health-care domains of the psychological, spiritual and familial, are discussed in the following sections.

Domain-specific tools

Psychological domain

Advanced medical illness and its treatment are associated with high rates of psychological distress in patients and families. The most common psychological problems occurring near the end of life include depression and anxiety (Mitchell et al., 2011). Rates vary widely across studies and are influenced by multiple factors, including the population assessed, the type and severity of disease, and the treatment setting (Mitchell et al., 2011). Depression ranges from 5.1% to 30.1% in populations with advanced illness, such as cancer, AIDS, chronic obstructive pulmonary disease, and congestive heart failure, and up to 15.4% for anxiety (Mitchell et al., 2011).

This section reviews validated screening tools for the assessment of general psychological distress, depression, and anxiety in populations with advanced illness, discussing multiple considerations for assessment and specific tools that may assist providers in timely and appropriate evaluation. For a review of tools that assess other common psychiatric problems—such as adjustment disorders (Akechi et al., 2006) and delirium (Breitbart et al.,

1997)—and family caregiver problems—including bereavement (Zisook et al., 1982) and complicated grief (BrintzenhofeSzoc et al., 1999)—readers may refer to Chapters 17.3, 17.4, 17.6, 17.7 and other published reviews (Stroebe et al., 2007; Thekkumpurath et al., 2008; Grover and Kate, 2012). For diagnosis and management, provide detailed overviews.

Studies show that untreated psychological distress undermines medical decision-making and treatment adherence, which can result in disability and high health-care usage (Colleoni et al., 2000; Prieto et al., 2002). Psychological distress may augment pain perception (Pincus et al., 2002), undermine symptom control (Spiegel and Giese-Davis, 2003), and impair quality of life (Skarstein et al., 2000; Stark et al., 2002). Patients commonly report a perceived loss of meaning or purpose in life, a decrease in engagement in valued activities, and a reduction in pleasure from the social environment (Parker et al., 2003; Hopko et al., 2008). This can impede the ability to cope with the emotional stress of preparing for death and separating from loved ones, and worsen distress in family members (Pessin et al., 2002). Despite effective interventions for psychological distress (Fawzy et al., 1990; Sheard and Maguire, 1999; Donker et al., 2009), it is under-diagnosed (Steinberg et al., 2009; Holland et al., 2010) and screening is rare in practice (Institute of Medicine Committee on Treatment of Posttraumatic Stress Disorder, 2008).

Psychological distress

In the past, one barrier has been the lack of validated tools for screening (Vodermaier et al., 2009). The US National Comprehensive Cancer Network (NCCN) has developed guidelines for regular screening and management (NCCN, 2013). The NCCN defines psychological distress as 'a multifactorial, unpleasant, emotional experience of a psychological (cognitive, behavioural, emotional), social, and/or spiritual nature that may interfere with the ability to cope effectively with cancer, its physical symptoms and its treatment' (NCCN, 2013). The detection of psychological distress often relies on physician assessment and patient-initiated reports; however, they are frequently discordant (Söllner et al., 2001). Consequently, the following tools can assist providers in more accurate identification.

When selecting an appropriate tool, important considerations include the psychometric properties, particularly sensitivity and specificity, treatment setting, and disease severity. Each tool has its own advantages and limitations. Ideally, validated cut-offs provide high sensitivity (i.e. identify all patients in need of support) and specificity (minimize false positives) (Vodermaier et al., 2009). For example, shorter measures are useful clinically (in terms of cost and time), but have fewer domains and, sometimes, limited specificity. In general, tools are classified as ultrashort (one to four items), short (five to 20 items), and long (21–50 items) (Vodermaier et al., 2009).

One ultrashort screening tool recommended by the NCCN is the Distress Thermometer (NCCN, 2013). A single item measures overall psychological distress in the past week on a 0–10 numeric rating scale, with an accompanying Problem List assessing five domains. It has high sensitivity and specificity with the Hospital Anxiety and Depression Scale (HADS) and the Center for Epidemiologic Studies of Depression Scale (CES-D) (Hurria et al., 2009) and good reliability (Hoffman et al., 2004). While a cut-off score of 4 or higher is meaningful (Hurria et al., 2009),

scores of 7 or above may provide optimal sensitivity and specificity (Hegel et al., 2008).

Another ultrashort tool, the four-item Patient Health Questionnaire-4 (PHQ-4) (Kroenke et al., 2009) screens for anxiety and depression. Anxiety items include: 'Feeling nervous, anxious, or on edge' and 'Not being able to stop or control worrying', two diagnostic criteria for Generalized Anxiety Disorder in the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, text revision (DSM-IV-TR). Depressive items include: 'Feeling down, depressed, or hopeless' and 'Little interest or pleasure in doing things'. Responses are rated on a 4-point Likert-type scale ('Not at all' to 'Nearly every day'), with total subscale scores ranging from 0 to 6; cut-offs of 3 or above are clinically significant (Mitchell et al., 2009; Kroenke et al., 2010), with 0–2 (normal), 3–5 (mild), 6–8 (moderate), and 9–12 (severe). Like other tools, it does not diagnose depression or anxiety. However, its predictive ability and reliability (Kroenke et al., 2009) and brevity are advantages.

The short Brief Profile of Mood States Total Mood Disturbance Score (Brief POMS TMDS) includes 11 items evaluating general distress in cancer patients (breast, pancreatic, gastric cancer, and myeloma) (Cella et al., 1987). It reduced the 58-item TMDS with one factor of general distress. Five mood factors include: tension-anxiety, depression-dejection, anger-hostility, fatigue, and confusion-bewilderment. Items are rated on a 5-point Likert-type scale ('Not at all' to 'Extremely'), with total scores ranging from 0 to 44. It is internally consistent and correlated with the long version. Criterion validity discriminates between pancreatic patients, who typically exhibit higher distress scores, and gastric cancer patients. Other strengths include brevity, sensitivity, and true assessment of psychological distress without the 'vigour' mood factor (i.e., measures physical well-being) (McNair et al., 1971; Cella et al. 1987).

Depression

Two widely-used, short screening tools for depression are the HADS (Zigmond and Snaith, 1983) and the CES-D (Radloff, 1977). Both are validated in palliative care populations (Le Fevre et al., 1999; Härter et al., 2006; Vodermaier et al., 2009).

The HADS includes two 14-item subscales measuring depressive and anxiety symptoms (HADS-D) (HADS-A). Items are rated on a 4-point Likert-type scale ('Not at all' to 'Very often'), with subscale scores ranging from 0 to 21 (Zigmond and Snaith, 1983). It is clinically relevant, responsive to treatment (Smarr et al., 2011), validated in multiple languages, including Spanish, Chinese, French, and Italian (Smarr et al., 2011), and reliable (Bjelland et al., 2002). However, the cut-offs vary, ranging from 8 to 22 (total score) and 5 to 11 (subscale scores) (Vodermaier et al., 2009). A cut-off of 8 or more provides optimal sensitivity and specificity (Bjelland et al., 2002), with probable major depression rated as: 8–10 (mild), 11–15 (moderate), and 16 or higher (severe) (Snaith and Zigmond, 1994).

The CES-D (Radloff, 1977) includes 20 items measuring depression and identifying individuals at risk of depression. It assesses mood and level of functioning in the past week, and rates symptom frequency across four domains: positive and negative affect, somatic and interpersonal problems. Items are rated on a 4-point Likert-type scale ('Rarely' to 'Most or all of the time'), with total scores ranging from 0 to 60. Internal consistency is good (Radloff, 1977). Cut-off scores greater than 16 suggest probable clinical

depression (Katz et al., 2004), yielding a sensitivity of 100% and specificity of 85% in cancer patients (Katz et al., 2004). The increased false-positive risk is balanced by brevity, validation in multiple languages, and free use. Shorter five- and ten-item versions (Shrout and Yager, 1989; Irwin et al., 1999) have improved upon response wording.

Anxiety

While tools such as the HADS screen for depression and anxiety, several provide detailed anxiety assessments. The long State-Trait Anxiety Inventory (Spielberger et al., 1983) includes two 40-item subscales assessing State Anxiety (S-Anxiety) and Trait Anxiety (T-Anxiety). S-Anxiety measures current apprehension and tension on a 4-point Likert-type scale ('Not at all' to 'Very much'). T-Anxiety measures anxiety (i.e. discomfort or worry) during typical daily situations (responses range from 'Almost never' to 'Almost always'; Spielberger et al., 1994). Total subscale scores range from 20 to 80. Cut-off scores of 30 and below (no–low anxiety) or higher than 30 (moderate–high anxiety) (Glozman, 2004) and higher than 54 in geriatric populations have been suggested (Kvaal et al., 2005). Advantages include good reliability (Spielberger et al., 1983) and translation into multiple languages, but use requires purchase (Mind Garden, 2013).

The Beck Anxiety Inventory (Beck et al., 1988) includes 21 items assessing cognitive and somatic symptoms. Items are rated on a 4-point Likert-type scale ('Not at all' to 'Severely'), with total scores ranging from 0 to 63. A cut-off score greater than 10 provides high sensitivity and specificity (Hopko et al., 2008), with 0–9 (normal), mild to moderate (10–18), moderate to severe (19–29), and severe (30–63). While brief, easily administered, and validated in oncology populations (Hopko et al., 2008), specific drawbacks include the multitude of somatic symptoms, which can overlap with medical conditions (Julian et al., 2011). Although internally consistent (Fydrich et al. 1992), further validation in palliative populations is suggested (Vodermaier et al., 2009).

The extent of the family carer's burden and impact are becoming better understood and characterized. There are many potential stressors associated with caring, including managing psychological and physical needs, instrumental assistance with a range of practical and medical tasks, such as adherence to medical regimens and decision-making and providing seemingly constant vigilance. Qualitative data reveal common themes in subjective caregiver impact (Dellon et al., 2010; Braithwaite et al., 2011) and several questionnaires report both positive and negative consequences of caregiving (Glajchen et al., 2005). Although carers are often inadequately trained, under-supported, misunderstood, and distressed, there are also positive aspects of providing care to a family member, including satisfaction in caring for a loved one (Glajchen et al., 2012).

Spirituality domain

When confronted by suffering, distress, and mortality across the disease trajectory, patients may articulate spiritual concerns. Despite professional sensitivity regarding the investigation of patients' spiritual distress and the feasibility of addressing issues identified in the typically brief clinical encounter, the spiritual concerns of patients with a life-limiting illness can impact upon treatment choices (Balboni et al., 2013; Peteet and Balboni, 2013). However, research in the spiritual domain remains one of the least

investigated in palliative and hospice care provision, in contrast to the physical-functional aspects.

Whilst instruments to assess religious/spiritual (R/S) issues within the discipline exist—with more being developed due to a growing appreciation of their need (for a more comprehensive list of existing R/S tools, see a review by Büssing (2012))—much of the work has three significant shortcomings: lack of a generally accepted conceptual definition of spirituality (Puchalski et al., 2009), resulting in confusion (la Cour and Götke, 2012); a paucity of tools validated in cross-cultural palliative care populations (Selman et al., 2011); and the dearth, or lack of reporting, of methodologically rigorous supportive validation studies per se, especially for clinical tools (Galek et al., 2011).

Three categories of formal assessment tool in the spiritual domain are screening, history taking, and assessment (Puchalski, 2010). These categories are aligned with normal medical practice and are the best current models for interdisciplinary spiritual care (Puchalski et al., 2009). For a fuller description of this model, see Chapter 4.5.

Spiritual screening

Spiritual screening questions are designed for insertion into routine assessment or screening processes to identify patients with significant spiritual needs. The widely used Distress Thermometer (NCCN, 2012)—a patient-rated tool whose specificity and sensitivity have been demonstrated among bone marrow transplant patients (Ransom et al., 2006) and among a heterogeneous mix of Swedish oncology patients (Thalén-Lindström et al., 2013)—includes 'spiritual/religious concerns' on its problem list. However, no research exists determining what this category means to patients, and therefore what it is measuring.

Some clinicians use the one-question screen 'Are you at peace?', with a 5-point Likert-type scale, that was evaluated by Steinhauser et al. (2006). Although the question was found to provide a brief gateway to assessing spiritual concerns, to date the screen has only been tested with patients with advanced, life-limiting illnesses such as stage IV cancer, congestive heart failure, or chronic obstructive pulmonary disease, despite research indicating such concerns can influence medical decision-making throughout the disease trajectory.

The only multi-question screening instrument supported by a published partial validation study was developed by Fitchett and Risk (2009). The brief screening protocol, subsequently named the Rush Religious Struggle Screening Protocol and used in a QI pilot project among oncology patients (Blanchard et al., 2012) and blood and marrow transplant patients (King et al., 2013), focuses on the identification of patients who may be experiencing R/S struggle—a well-researched concept that has been shown to be related to several significant health outcomes, including mortality (Pargament et al., 2004)—and patents who would like a visit from a chaplain. The triage method consists of three questions that can be administered by anyone on the health-care team without significant training, while the protocol for making referrals to a chaplain is simple and transparent. In a pilot study among non-chaplain health colleagues in an 18-bed, Chicago-based acute medical rehabilitation unit, the protocol identified 7% (n = 12) of patients possibly experiencing R/S struggle, with all but one of these confirmed in need following a chaplain assessment (Fitchett and Risk, 2009).

Spiritual history

Spiritual history questions are recommended for inclusion in the social history section of the routine history. The HOPE tool (sources of Hope, Organized religion, Personal spirituality, Effects on care) (Anandarajah and Hight, 2001), and the SPIRIT tool (Spiritual belief, Personal spirituality, Integration with community, Rituals, Implications for care, Terminal events planning) (Maugens, 1996) are often used.

However, the FICA (Faith, Importance, Community, and address in Care) spiritual history tool (Puchalski, 2006) is the only such instrument partly supported by a validation study (Borneman et al., 2010). Developed in a consensus expert-review process, and then modified based on anecdotal feedback from users, this tool is not intended to be used as a checklist, but rather as a guide to initiate dialogue with patients to explore deeper questions their relationship to spirituality, their spiritual beliefs, and their goals for spiritual health. One of the weaknesses of the limited validation conducted on the tool is the lack of heterogeneity in the R/S preferences of its sample, with over 70% declaring themselves Catholic or Protestant.

Spiritual assessment

Spiritual assessment is, 'A more extensive [in-depth, on-going] process of active listening to a patient's story as it unfolds in a relationship with a professional chaplain and summarizing the needs and resources that emerge in that process (see Chapters 4.5 and 17.1). The summary includes a spiritual care plan with expected outcomes which should be communicated to the rest of the treatment team' (Fitchett and Canada, 2010).

However, although intended, in North America and elsewhere, to guide the work of professional chaplains in detailed discussions with patients about their R/S strengths and issues and how they might affect their care, all existing spiritual assessment tools are unvalidated. Moreover, all require significant training to use and are best reserved for patients whose R/S concerns affect their coping and care planning significantly. Among these unvalidated instruments, the recommended include the following:

- The Guidelines for Pastoral Diagnosis, which provides a diagnostic taxonomy framed in theological language (Pruyser, 1976) across seven dimensions: awareness of the holy, providence, faith, grace or gratefulness, repentance, communion, and sense of vocation.

- The 7X7 model, developed in the mid 1980s, which uses a functional approach to assessment—concerned with how a person finds meaning and purpose in life and with the behaviour, emotions, relationships, and practices associated with that meaning and purpose. It assesses two broad thematic areas comprised of seven *holistic* (medical, psychological, family systems, psycho-social, ethnic, racial, and cultural, social issues and spiritual) and seven *spiritual* domains (beliefs and meaning, vocation and obligations, experience and emotions, courage and growth, rituals and practice, community, and authority and guidance) (Fitchett, 2002).

- Outcome Oriented Chaplaincy, described as, 'the operational paradigm for professional chaplaincy for the twenty-first century' (Peery, 2012, p. 346) that 'emphasizes achieving, describing, measuring, and improving outcomes that result from a chaplain's work' (Peery, 2012, p. 348). It includes an assessment

template as part of an overall system for chaplaincy care based on the mnemonic 'Run In On A Prayer': Reason for Visit, Interventions, Outcomes, Assessment, and Plan.

Spiritual measurement

Like spiritual assessment tools, most spiritual measurement instruments are unvalidated. Two exceptions that have been used widely among physically ill populations are the Brief RCOPE and the Functional Assessment of Chronic Illness Therapy—Spiritual (FACIT-Sp).

The Brief RCOPE (Pargament et al., 2000) features 14 items across two scales: positive religious coping and negative religious coping, recognizing that religion can support or impede coping. It identifies spiritual adjustment; that is, the extent to which conflict, self-blame, or anger at God is present.

The tool was tested initially on a sample of 540 college students coping with a significant negative life event. They were predominantly white (93%), single (99%), female (69%), and Catholic (45%) or Protestant (41%). Factor analysis of the results produced factors largely consistent with the conceptualization and construction of the subscales. Subsequently confirmatory factor analysis of the RCOPE was undertaken in a second sample composed of 551 elderly hospital patients, and found to be moderately supportive of the initial factor structure. Studies have adjusted the tool for individuals with a Buddhist background (Phillips et al., 2009) and adapted the underlying coping concept for use in cancer patients (Zwingmann et al., 2006).

The tool can be very helpful to the clinician or researcher trying to identify patient use of religion in coping and contains a good deal of religious language. As such, it is more appropriate for populations with a theistic and Western, largely Christian, background (Pargament et al., 2011).

The FACIT-Sp (Peterman et al., 2002) focuses on spiritual well-being, another useful concept for clinicians, and is available in several variations aimed at specific populations, such as pain patients. Developed among cancer patients, and avoiding religious language, two subscales, measuring a sense of meaning and peace and the other assessing the role of faith in illness, were determined from the 12-item tool. A total score for spiritual well-being is produced. Based upon two studies, the tool has demonstrated good internal consistency and reliability, a significant association with quality of life, and convergent validity with five other measures of religion and spirituality in a sample of patients with mixed early-stage and metastatic cancer diagnoses. A subsequent study among 240 long-term (average of 10 years post-diagnosis) white, female survivors of cancer supported a three-factor model (meaning, peace, and faith) (Canada et al., 2008). However, this was later found to have less stability as a model across 8805 cancer survivors from a much more ethnically diverse sample, suggesting that items and their constructs might be understood differently across groups (Murphy et al., 2010). Consequently, because the variations of the scale are generally based on specific populations, users should determine whether the version they use is appropriate for their population.

Many of these measurement tools also have been used as spiritual screening tools, in part because of the dearth of validated tools designed explicitly for screening. However, clinicians are cautioned that even the varyingly validated tools have not been validated for clinical screening purposes. Additionally, since these are paper and pencil instruments, they are limited by the language they use. For instance, several use references to 'God' or other higher powers which may be unhelpful to an increasing number of patients, such as in the United States, who perceive themselves as not religious (Pew Research Center's Forum on Religion and Public Life, 2012). Conversely, other instruments use no explicitly religious language, which may not resonate with patients who only express their R/S issues in such terms. Lastly, the terms 'spiritual risk', 'spiritual struggle', and 'spiritual pain' are not well defined or differentiated in the extant literature, although 'risk' is normally understood as a condition which renders the patient susceptible to 'pain' or 'struggle'. Clinicians and investigators should, therefore, be aware of possible ambiguity in the use of these terms.

Family domain

Support for the family is particularly important in palliative care. The needs of family members, many of whom contribute as carers, can shape the patient's experience and ultimately become the focus of bereavement care. Assessment of family members must address their role as carers as well as members of a larger family. While many tools exist, identifying appropriate tools and integrating them into routine clinical management or research is not standard, is poorly tested, and therefore problematic for practical implementation.

The types of caring roles family members adopt stem from diverse patient needs. Family carers can find themselves supporting a patient's physical, psychological, existential, and social needs. An abundant supply of carer burden scales and questionnaires exist that investigate the multidimensional impact on the carer's daily life and well-being. In a review of instruments related to carers in palliative care, the following categories were identified:

◆ satisfaction with service delivery

◆ psychiatric disorders

◆ quality of life

◆ needs

◆ grief and bereavement

◆ burden

◆ preparedness/competence

◆ family functioning

◆ a group of miscellaneous tools (Hudson et al., 2010).

A unitary comprehensive 'gold standard' assessment tool has not emerged, and is unlikely to do so. Although the diversity of existing instruments is potentially valuable—providing the clinician and researcher with choices based upon specific characteristics of a given disease site or caregiving burden domain of interest—the plethora of instruments carries the risk of 'confusing the marketplace' with a multitude of divergent questions, rating scales, and aggregated scores. Despite the wide availability of such instruments, few providers use them in routine practice.

Moreover, challenges exist to using assessment tools that evaluate the family itself and the specific roles of family members of a palliative care patient. There are varying contextual components that impact on the focus of assessment tools. For example, the relationship of a patient to his/her family and family structure can vary considerably depending on whether the patient is an infant, adolescent, adult, or elderly person. Similarly, assessing the

family needs of a household with multiple young children differs from assessing those of a patient and their spouse, or adult child. Categories of existing family assessment tools based on their contextual focus include characteristics of the patient (e.g. spouse vs parent vs child); attention to the family as a unit versus members/caregivers within the family; disease categories, for example, patients with cancer versus those with Alzheimer's disease; location of patient, such as home versus at the hospital; and timing of illness, such as during chronic phases of illness versus end-of-life versus bereavement.

Few existing instruments that focus on families have been evaluated for their utility in guiding clinical practice. Rather, many have been developed based on a particular theoretical framework and validated in specific clinical settings (Neabel et al., 2000). How and when to use such tools clinically, and the mechanisms for implementing interventions based on their results, remain poorly established. While this area is clearly underdeveloped, the following sections discuss tools for assessing and measuring the family unit. (For a more comprehensive list of existing family assessment tools, see a review by Neabel et al. (2000) and of instruments related to family caregivers of palliative care patients by Hudson et al. (2010).)

Family assessment

The Needs Assessment Tool Progressive Disease (NAT-PD, nd) or the Needs Assessment Tool—Progressive Disease Cancer (NAT-PD-C, nd) is recommended by the Centre for Palliative Care's practice guidelines (Hudson et al., 2010) to assess carers' needs. These tools were developed by an expert consensus panel of 66 leaders and key stakeholders in palliative care, based on an extensive literature review. Initially, face and content validity, acceptability, and feasibility were confirmed by health-care professionals who viewed video-recorded, simulated consultations involving actors as patients (Waller et al., 2008). Further testing was undertaken in a clinical setting to determine the inter-rater reliability, validity, and feasibility of the tool (Waller et al., 2010). The impact of using this tool in the clinical setting was assessed for cancer patients and associated with significant reduction in health system, information, patient care, and support needs (Waller et al., 2012). These screening tools include six items to assess the ability of the carer/family to care for the patient across the physical, daily living, psychological, information, financial and legal, and family relationship domains as well as two items to assess the carer's well-being in relation to their own physical, psychological, and bereavement issues.

The Family Crisis Oriented Personal Evaluation Scales (F-COPES) is a 29-item self-report questionnaire intended to identify problem-solving and behavioural strategies used by families during crises (McCubbin et al., 1987). It measures five subscales related to acquiring social support, reframing, seeking spiritual support, mobilizing family to acquire and accept help, and passive appraisal. The tool can help health-care teams identify which families may need additional assistance with managing crises.

Family measurement

Like assessment tools, identifying measurement tools for carers and families requires consideration of the specific contextual components important to the families assessed and the area of interest. For example, some tools are developed specifically for use with cancer patients. Tools measuring the management of carer psychological distress differ from those addressing a family's ability to cope. Moreover, the questions of interest for the health-care teams and organizations will determine which tool to use and how to implement identified tools in the clinical setting. Measuring family needs consecutively over time may be necessary to determine the efficacy of the palliative care team in addressing them. Alternatively, it may be beneficial to measure carer bereavement following the death of their loved one, to consider whether palliative care services are providing long-term outcomes for family members. Needs assessment tools can be useful also for health-care organizations in determining resource allocation. Finally, many measures of families and carers have been developed and studied in non-palliative care settings, meriting a degree of caution if employed in palliative care situations.

Broad categories of relevance for measuring families and carers in palliative care include carer satisfaction with service delivery, carer quality of life, psychological impact, and bereavement. Many tools used to measure psychological domains for patients can also be used for carers.

The Quality of Life in Life-Threatening Illness—Family Carer Version (QOLLTI-F) is a 16-item tool measuring caregiver quality of life and includes the carer's perception of patients' conditions. There are seven subscales: environment, patient state, carer's own state, carer's outlook, quality of care, relationships, and financial worries. It was developed from qualitative research, asking carers what is important to their own quality of life, rather than focusing on the changes or burdens related to caring, with most domains responsive to change (Cohen et al., 2006). All items, the subscale scores and the total score (the mean of the seven subscale scores) have a scoring range from '0' to '10'; to ensure '0' always indicates the worst situation and '10' the best, item numbers 3, 4, 14, 15, and 16 must have their scores transposed.

The Family Appraisal of Caregiving Questionnaire for Palliative Care (FACQ-PC) is a 25-item tool that measures four theoretically derived domains: caregiver strain, positive caregiving appraisals, caregiver distress, and family well-being. Among 160 adult primary carers of a relative with cancer receiving home-based palliative care, it showed acceptable psychometric properties (internal consistency, factorial validity, and convergent and discriminant validity), can be used in clinical assessment, and has potential use in evaluating the effectiveness of palliative care (Cooper et al., 2006). However, one limitation is that the content validation process did not include carers, but rather a small group of professionals (n = 5).

Based upon the FAMCARE scale (Kristjanson, 1993), which was developed using qualitative research to identify indicators of family care satisfaction and their subsequent reduction using *Q*-sort study to the most salient, the FAMCARE-2 was developed among 497 carers from 29 Australian inpatient- and community-based palliative care services. FAMCARE-2 includes 17 items and is measured using a 5-point Likert-like scale (from 1 = 'Very satisfied', to 5 = 'Very dissatisfied') and an additional 'Not relevant to my situation' option.

What we don't know: assessments and measures yet to come

The tools available for the assessment and measurement of psychological, spiritual, and family care issues remain largely inadequate, both in terms of their psychometric validation and applicability in divergent diagnostic, ethnic and age groups, service delivery

settings, and cultural contexts. As understanding of the nature of needs and care in the setting of serious illness deepens, we should expect improvements both in the tools available and how to integrate them into processes of care and QI.

Additional concepts need to be developed and integrated into mainstream palliative care. For instance, work exists on the nature of the state of peace that some attain near the end of life and that many aspire to (Emanuel et al., 2010). Yet, delineation of this state of peace as a construct that can be assessed, measured, and addressed has not developed to the point that tools are integrated into care delivery. Similarly, further understanding of what makes for resilience and successful adaptation are necessary if more patients are to achieve the best death possible for themselves, their families, and society (Knight and Emanuel, 2007a).

All this will be possible only if the culture of palliative care remains seriously committed to the inclusion of psychological, spiritual, and family care within palliative care. While the specialty may still be better at this than other medical disciplines, it is also the case that advances in the clinical sciences of physical symptoms have outpaced other areas. Approaches to address mental health are improving; information on anxiety, depression, delirium, and other psychological suffering encountered in palliative care is increasing, but still there is far to go. Similarly, counselling and psychotherapy for patients and families facing serious illness is a developing area, as are the economics at the household level of palliative care. However, to date there are limited data and clinical guidance available for either. Most striking of all is the sparse empirical knowledge of spiritual care in palliative care. Readers are advised to keep abreast of advances in all of these fields and participate in the culture of palliative care that insists on their importance. If patients are assessed for needs in these areas, and if care outcomes in these areas are measured, increased understanding and improvement will be possible.

SECTION 8

Common symptoms and disorders

Fatigue and asthenia

Sriram Yennurajalingam and Eduardo Bruera

Introduction to fatigue and asthenia

Fatigue is the most frequent and debilitating symptom in patients with advanced-stage cancer, with a prevalence of 60–90% in various studies (Stone et al., 2000; Cella et al., 2001; Servaes et al., 2002; Lawrence et al., 2004). In the palliative care setting, the frequency ranges from 48% to 78% (Stone et al., 2000; Lawrence et al., 2004; Teunissen et al., 2007). Fatigue adversely impacts the physical, functional, and psychological domains of quality of life, resulting in an inability to perform daily activities and affecting mood, social relationships, and work (Wilson and Cleary, 1995; Östlund et al., 2007; Teunissen et al., 2007; Beijer et al., 2008). It may influence patients' decision-making capabilities regarding future treatment and lead to the refusal of potentially curative treatment.

In the past, the term 'asthenia' was used to describe a subjective sensation of tiredness and the term 'fatigue' was used to describe a symptom of tiredness precipitated by effort. However, the terms are currently often used in the same context. In this chapter, we consider the two terms synonymous, and by convention, 'fatigue' is generally used.

Fatigue may include three major features:

1. Easy tiring and reduced capacity to maintain performance.

2. Generalized weakness, defined as the anticipatory sensation of difficulty in initiating a certain activity.

3. Mental fatigue, defined as the presence of impaired mental concentration, loss of memory, and emotional lability.

The National Comprehensive Cancer Network defined cancer-related fatigue as follows: 'Cancer-related fatigue is a distressing persistent, subjective sense of physical, emotional, and/or cognitive tiredness or exhaustion related to cancer or cancer treatment that is not proportional to recent activity and interferes with usual functioning' (Berger et al., 2010).

Fatigue occurs as a result of both cancer and its treatment. The onset of fatigue may precede the diagnosis of cancer or it may occur at any stage in the course of the illness. It may first occur after or be exacerbated by chemotherapy, radiotherapy, or surgery, and may be present for prolonged periods after these treatments. In patients with advanced cancer, fatigue usually coexists with a number of other symptoms, including pain, anorexia, nausea, vomiting, dyspnoea, sleep disturbance, anxiety, and depression (Yennurajalingam et al., 2008).

In recent years, as the management of other symptoms (e.g. pain, dyspnoea, and nausea) has improved, there has been an increased awareness of the importance of recognizing fatigue as a symptom deserving of attention. The management of fatigue is confounded by a limited research base and a lack of data supporting an established therapeutic strategy.

Most of the evidence presented in this chapter relates to studies in cancer patients. However, similar principles can be applied to fatigue in patients with other end-stage diseases such as end-stage AIDS and cardiac conditions.

Pathophysiology

The basic mechanisms by which fatigue is caused are not well understood, and several possible underlying causes of fatigue exist in most patients. Occasionally, one predominant abnormality is present and appears to be the main contributor to the symptom; however, in most cases, several abnormalities and other symptoms are present that may contribute to the genesis of fatigue.

In patients with cancer, complex interactions occur between the tumour and host. Table 8.1.1 outlines mechanisms by which tumours have the potential to directly or indirectly produce fatigue in patients with advanced-stage cancer. Fig. 8.1.1 summarizes contributors to fatigue in cancer patients.

Tumours, host-derived factors, and cytokines

Tumours can produce various by-products, including lipolytic and proteolytic factors and cytokines capable of interfering with the host metabolism and causing fatigue. These factors are believed to also play a role in the development of cancer-related cachexia (Miller et al., 2008; Fearon et al., 2012). The relationship between cachexia and fatigue is discussed later in this chapter.

The evolving literature supports the current hypothesis that the presence of a tumour and/or cancer-related treatment such as radiotherapy and/or chemotherapy induces the dysregulation of pro-inflammatory cytokines such as tumour necrosis factor-alpha (TNF-α), interleukin (IL)-1, and IL-6 (Dantzer and Kelley, 2007; Miller et al., 2008; Seruga et al., 2008). Further, these cytokines have been implicated in the pathophysiology of fatigue by acting on multiple systems, including the brain (hypothalamic–pituitary–adrenal (HPA) axis, sleep, psychological, and dopaminergic alterations), muscles (reductions in mass and strength), immune system (cellular and humoral changes), and metabolism (Dantzer and Kelley, 2007; Seruga et al., 2008; Bower and Lamkin, 2013).

Rats and mice showed increased signs of fatigue when infection and other conditions associated with an increase in pro-inflammatory cytokines were present (Dantzer and Kelley, 2007; Burton et al., 2011). Drugs such as interferon-alpha, IL-2, and TNF-α have been associated with symptoms of fatigue, mood swings, sleep disturbance, and cognitive changes (Dantzer

Table 8.1.1 Mechanisms by which tumours may directly or indirectly cause fatigue

Direct effects	Induced host factors	Accompanying factors
Lipolytic factors	Interleukin-6	Psychological issues
Proteolytic factors	Interleukin-1	Anaemia
Tumour degradation products	Tumour necrosis factor	Cancer-related symptoms: pain, sleep disturbance, dyspnoea, drowsiness
Invasion of brain or pituitary gland by tumour or metastases		Cachexia, hypoxia, and infection; metabolic disorders; dehydration; neurological disorders; endocrine disorders; paraneoplastic syndromes

and Kelley, 2007; Miller et al., 2008; Raison et al., 2010). Cytokine-associated symptoms such as anorexia or cachexia, chronic nausea, fever, depression, pain, and sleep disorders may also contribute to fatigue (Miller et al., 2008).

The proinflammatory cytokines are further regulated by host-related factors such as genetic factors, immune factors, and HPA axis alterations. However, the lack of consensus on the definition of cancer-related fatigue (phenotype), challenges with the methodology used to measure these cytokines, the lack of a standard methodology used for measuring these cytokines, and the limited number of fatigue studies using animal models limit our understanding of the link between inflammation and cancer-related fatigue (Barsevick et al., 2010; Gilbertson-White et al., 2011).

Muscle abnormalities

Impaired muscle function may be one of the main underlying mechanisms of fatigue (Al-Majid and McCarthy, 2001). The fatigue-related muscular abnormalities may be related in part to known abnormalities in cytokine production, but the production of other fatigue-inducing substances by the tumour or the host has been postulated.

Muscle alterations in patients with tumours are well known. Cachexia leads to a loss of muscle and fat, which may partially explain the relationship between cachexia and fatigue (Fearon et al., 2012; Gould et al., 2013). However, patients with tumours can have muscle abnormalities even in the presence of normal caloric intake and a constant body weight and lean body mass. The muscle tissues of cancer patients have been found to contain excessive amounts of lactate (Holroyde et al., 1979). It is unclear whether this lactate is part of the pathogenic mechanism of muscle weakness or a consequence of it. Atrophy of type II muscle fibres has been suggested to be a systemic effect of cancer, even in early or non-metastatic stages (Barron and Heffner, 1978). Tumour-free muscle from tumour-bearing animals shows alterations in the activity of various enzymes, the distribution of isoenzymes, and the synthesis and breakdown of myofibrillar and sarcoplasmic proteins (Fearon et al., 2012). Our group found impaired maximal strength, decreased relaxation velocity, and increased fatigue after electrical stimulation of the abductor pollicis muscle via the ulnar nerve in patients with breast cancer as compared with normal controls (Bruera et al., 1988).

Myopathies can also be caused by medications taken by cancer patients. Corticosteroids can cause loss of muscle mass, and cyclosporin has been implicated as a cause of mitochondrial myopathy (Schäcke et al., 2002).

Interestingly, a recent preliminary study comparing ten advanced-stage cancer patients and 12 healthy volunteers to determine the contribution of muscle fatigue to overall fatigue found no alteration in the muscle contractile property in advanced-stage cancer patients; therefore, the authors of the study suggested that the early motor task failure in cancer-related fatigue was primarily due to a central mechanism (Kisiel-Sajewicz et al., 2012). However, further studies are needed, as more recent studies targeting the fatigue mechanisms involving muscle found no correlation between muscle and fatigue. These studies included supplementation of adenosine triphosphate (Beijer et al., 2008) and L-carnitine (Cruciani et al., 2009).

Deconditioning

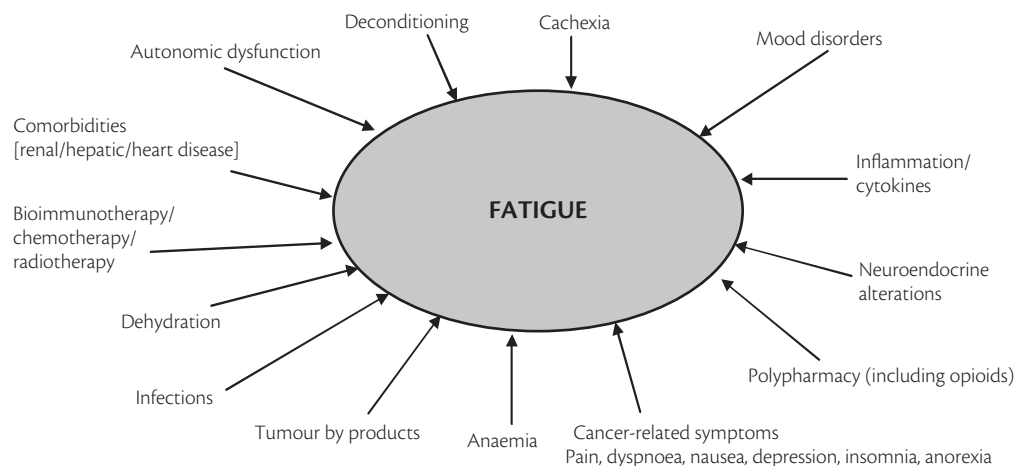
Prolonged bed rest and immobility lead to loss of muscle mass and reduced cardiac output. This deconditioning results in reduced endurance for exercise and activities of daily living and may be compounded by other muscle abnormalities in patients


Fig. 8.1.1 Contributors to fatigue.

with cancer (Berger et al., 2010; Neil et al., 2013). Recent studies have found that endurance exercise training can reduce fatigue and improve physical performance in cancer patients undergoing chemotherapy, cancer survivors, and patients who have undergone bone marrow or autologous stem cell transplantation (Cramp and Byron-Daniel, 2012).

Overexertion

Overexertion is a frequent cause of fatigue in cancer and non-cancer patients (Siegel et al., 2012). It should also be considered in young cancer patients who are receiving aggressive antineoplastic treatment, such as radiotherapy and chemotherapy, and who are trying to maintain their social and professional activities. Research in sports medicine has shown that for prolonged endurance, it is important to provide muscles with adequate substrate (carbohydrate loading). Unfortunately, cancer patients frequently present with abnormalities in muscle metabolism that may not allow adequate use of this substrate (Fearon et al., 2012).

Central nervous system abnormalities

The mechanisms by which fatigue is perceived or induced in the central nervous system (CNS) are poorly understood. Primary or secondary tumours involving the CNS and leading to the invasion of brain tissue (particularly the pituitary gland, with resulting endocrine abnormalities) appear to be possible causes of fatigue in cancer patients.

Disturbed cognitive functioning may be caused by fatigue but may also contribute to fatigue. Brain tumours can cause cognitive dysfunction and other tumours, such as small cell lung cancers, can affect brain function by producing hormones or neurotransmitters (Ronnback and Hansson, 2004; Dantzer and Kelley, 2007; Schagen and Vardy, 2007). Antineoplastic treatments, such as chemotherapy and radiotherapy, and drugs used to treat complications of cancer, such as opioids and corticosteroids, can also affect the CNS (Wood et al., 2006). Research findings suggest that inflammatory cytokines play a role in mental fatigue (Ronnback and Hansson, 2004). However, much more research is needed to improve our understanding of the mechanisms by which fatigue is induced at the CNS level.

Other CNS mechanisms that have been proposed include (a) dysregulation of serotonin and/or its receptors in the brain due to cancer or cancer treatment; (b) circadian rhythm disruptions, which negatively impact arousal and sleep patterns (prior studies suggest that fatigue is positively correlated with decreased daytime activity and restless sleep at night); and (c) dysregulation of the hypothalamic–pituitary axis (Bower et al., 2005). However, there are no trials of patients with advanced-stage cancer to support the hypothesis that any of these CNS-mediated aetiologies is the primary mechanism of cancer-related fatigue (Servaes et al., 2002).

Relationship between fatigue and cachexia

Fatigue and cachexia coexist in the great majority of patients with advanced-stage cancer, and it is likely that malnutrition is a major contributor to fatigue. The loss of muscle mass resulting from progressive cachexia can cause profound weakness and fatigue. As previously discussed, even in the presence of normal protein and caloric intake and normal body weight, structural and biochemical muscle abnormalities are frequently found in cancer patients

(Lawrence et al., 2004; Tisdale, 2009; Barsevick et al., 2010). Similar abnormalities often are used to explain fatigue associated with chronic cardiac and respiratory disease (von Haehling et al., 2009; Briggs et al., 2012).

It is important to recognize, however, that profound fatigue can exist in the absence of significant weight loss. Fatigue is common in patients with breast cancer and lymphomas, which have a low prevalence of cachexia. In non-malignant conditions such as chronic fatigue syndrome and depression, profound fatigue is generally not associated with malnutrition. Our group found no correlation between fatigue and nutritional status or weight in a population of breast cancer patients (Bruera et al., 1989). However, severe malnutrition without fatigue can be observed in patients with anorexia nervosa and in some patient populations with solid tumours. Fig. 8.1.2 illustrates the potential relationship between cachexia and fatigue.

It has been proposed that anorexia and fatigue may be an expression of the major metabolic abnormalities that occur in cancer patients, rather than simply an expression of malnutrition per se (Seruga et al., 2008). This situation would be similar to the occurrence of a catabolic state owing to a viral infection or in the early postoperative period. In these conditions, patients experience anorexia and fatigue that are secondary to the metabolic abnormalities rather than being causes of those abnormalities. Some interventions used to treat cancer cachexia, such as corticosteroid agents, have been found to be effective in the management of fatigue. The mechanisms by which these agents ameliorate cachexia and fatigue, however, are not well understood. Current pharmacological interventions for cachexia are discussed elsewhere in this book.

Infection

Fatigue is frequently associated with infections, particularly those that are recurrent or protracted. It may occur as a prodrome, and it may outlast the infection by weeks or even months (Chrousos, 1995; Rovigatti, 2012). In patients with cancer, immunosuppression due to the cancer itself or to cancer treatment increases the risk of infection and its complications. Chronic infection and cancer induce the same mediators for cachexia, including inflammatory cytokines (Seruga et al., 2008; Bennett et al., 1998). It can be hypothesized that they share similar mediators for fatigue as well.
Fig. 8.1.2 Possible relationship between cachexia and fatigue.

Anaemia

Anaemia is prevalent in cancer patients (see Chapter 8.3). Common causes of anaemia in cancer patients are myelosuppression by chemotherapeutic agents, iron deficiency, bleeding, haemolysis, nutritional deficiencies, and anaemia owing to chronic disease (Grotto, 2008). Severe anaemia (haemoglobin < 8 g/dL) is known to be a cause of profound fatigue. In patients receiving chemotherapy, treating less severe anaemia has been shown to improve energy levels, activity levels, and quality of life. In a prospective, open-label study of epoetin-alpha in 2342 anaemic patients receiving chemotherapy, mean energy levels, activity levels, and quality of life were found to improve with increases in mean haemoglobin levels from approximately 9 g/dL to 11 g/dL (Glaspy et al., 1997; Demetri et al., 1998). The improvements were independent of tumour response and correlated with the increases in haemoglobin levels. Similar findings were reported in a study of 2289 patients receiving chemotherapy: increased haemoglobin was correlated with improvements in energy, activity, and quality of life (Demetri et al., 1998). Although these data suggest an association between anaemia and fatigue, there are limited studies that specifically assess this relationship in populations with advanced illness.

Autonomic dysfunction

Autonomic dysfunction is a common complication of advanced-stage cancer. This syndrome includes malnutrition, delayed gastric emptying, chronic nausea, anorexia, and poor performance status (Bruera et al., 1986; Walsh and Nelson, 2002). Postural hypotension has been documented in patients with a specific type of severe chronic fatigue syndrome (Newton et al., 2009). Autonomic dysfunction may contribute to fatigue as well as to orthostatic hypotension. The association between fatigue and autonomic dysfunction has not been established in cancer patients and should be investigated in future research (Strasser et al., 2006).

Psychological issues

Anxiety, depression, and psychological distress can all contribute to fatigue (Yennurajalingam et al., 2008). However, the nature of these relationships is unclear (Brown and Kroenke, 2009). While some depressive symptoms are frequent in cancer patients, only a minority of patients develop adjustment disorders and only a small percentage present with major depressive or anxiety disorders (Reeve et al., 2008; Rosenstein, 2011). The diagnosis of a major depressive episode in patients with advanced-stage cancer is difficult because the patients frequently present with neurovegetative and somatic symptoms that are part of the disease itself. The diagnosis of major depression thus should rely more on the presence of psychological and cognitive signs and symptoms in these patients than in those without advanced-stage cancer (Chochinov, 2001) (see Chapter 17.3).

Nevertheless, cancer patients presenting with an adjustment disorder or a major depressive disorder can have fatigue as one of the prevalent symptoms. One prospective cohort study of elderly patients with cancer found a significant association between the intensity of fatigue and psychological symptoms such as anxiety and depression (Respini et al., 2003). In a double-blind clinical trial of 94 women with breast cancer, depression was significantly reduced in the 44 patients receiving paroxetine compared to the 50 patients receiving placebo, indicating that a biologically active dose was used; however, the groups did not differ in regard to any measures of fatigue (Roscoe et al., 2005). Thus, the role of psychological factors, including anxiety and depression, in the development of fatigue among cancer patients needs further research.

Metabolic and endocrine disorders

Endocrine disorders (e.g. diabetes mellitus, Addison's disease, and hypothyroidism) and electrolyte disorders (e.g. hyponatremia, hypokalaemia, and hypercalcaemia) are possible causes of fatigue and in many instances have relatively simple and effective treatments.

Interest in hypogonadism as a cause of fatigue and loss of muscle mass has increased in recent years as a result of the prevalence of these symptoms in HIV-infected men. Testosterone deficiency results in the loss of muscle mass, fatigue, reduced libido, and reduced haemoglobin (Basaria et al., 2001). Androgen insufficiency in cancer patients can result from anorexia-cachexia syndrome (Burney et al., 2012). In addition, chemotherapy and radiotherapy can cause hypogonadism. Hormonal ablative therapy has been found to significantly increase the incidence of fatigue in patients with prostate cancer (Storey et al., 2012). In patients with testosterone insufficiency due to HIV disease and other causes, treatment with androgenic anabolic steroids, including testosterone and its derivatives, has been found to increase muscle mass (Grinspoon, 2005), improve energy and libido (Snyder et al., 2000), and increase haemoglobin levels (Snyder et al., 2000). Androgenic anabolic steroids are regularly used for the treatment of hypogonadism in HIV-infected men. A randomized, single-blind, placebo-controlled trial of testosterone replacement in 35 men with mild Leydig cell insufficiency after chemotherapy found that physical fatigue significantly improved in the testosterone-treated group and was associated with a borderline increase in physical activity (Howell et al., 2001). Other variables such as bone mineral density and body composition were not significantly altered. The effects of treating hypogonadism in cancer patients should be researched further.

Abnormalities of the HPA axis concerning corticotrophin-releasing factor have been postulated as another possible endocrine-related cause of fatigue (Tsigos and Chrousos, 2002; Silverman et al., 2010). Corticotrophin-releasing factor levels increase in situations of physical or emotional stress and thus may cause fatigue (Makino et al., 2002; Miller et al., 2008). In addition, the HPA axis is activated by stress; while hyperactivity in this system can lead to depression (Glaspy et al., 1997), reduced HPA activity also has been postulated as a possible cause of chronic fatigue syndrome (Papadopoulos and Cleare, 2012). The proinflammatory cytokines IL-1, IL-6, and TNF-α are central mediators of the inflammatory process that can result in the dysregulation of the HPA axis and the secretion of mediators that induce such symptoms as pain, fatigue, anxiety, and depression, leading to an impaired quality of life (Bruera et al., 1988; Servaes et al., 2002; Bower et al., 2005; Miller et al., 2008). Further research is needed to clarify the role of abnormalities of the HPA axis in the genesis of fatigue.

Paraneoplastic neurological syndromes

Paraneoplastic neurological syndromes are rare but are important to recognize, as many of these syndromes can precede the clinical

Table 8.1.2 Paraneoplastic neurological syndromes associated with fatigue

Syndrome	Characteristics
Progressive multifocal leucoencephalopathy	Leukaemia and lymphoma are the cancers in which this syndrome is most often found
Paraneoplastic encephalomyelitis	70% of cases occur in patients with lung cancer and 30% in patients with other cancers
Amyotrophic lateral sclerosis	
Subacute motor neuropathy	Proximal or distal, often asymmetric (e.g. after radiotherapy for lymphoma)
Subacute necrotic myelopathy	Mainly found in patients with lung cancer
Peripheral paraneoplastic neurological syndrome	Often precedes diagnosis of the primary tumour, similar to Guillain–Barré syndrome
Ascending acute polyneuropathy (Guillain–Barré syndrome)	Mainly found in patients with lymphoma
Neuromuscular paraneoplastic syndromes	
Dermatomyositis, polymyositis	Associated with malignancy in about 50% of cases (onset within 1 year)
Eaton–Lambert syndrome	Strongly associated with small cell lung cancer. Can precede detection of tumour by months. Improves with successful treatment
Myasthenia gravis	30% of cases occur in patients with thymoma, while most of the rest occur in those with lymphoma

presentation of a malignancy. They may be partially reversible with primary treatment of the tumour. Table 8.1.2 summarizes some of the paraneoplastic neurological syndromes associated with fatigue (Darnell and Posner, 2006; Gandhi and Johnson, 2006).

Other cancer-related symptoms

Various correlative studies have shown that fatigue is associated with pain, psychological symptoms such as anxiety and depression, dyspnoea, sleep disturbances, anorexia, and constipation (Echteld et al., 2007; Okuyama et al., 2008; Yennurajalingam et al., 2008). However, the intensity of the individual symptoms in a given patient may determine the symptoms' ultimate contribution to the fatigue (Respini et al., 2003).

Side effects of cancer treatment

Treatments for both cancer and the symptoms and conditions caused by cancer can cause or aggravate fatigue. Worsening of fatigue is common during chemotherapy and radiotherapy (Wang et al., 2010). The mechanisms by which these treatment modalities cause fatigue are not fully understood. Radiotherapy can result in anaemia, diarrhoea, anorexia, and weight loss, and chemotherapy commonly causes anorexia, nausea, vomiting, and anaemia; all these events may contribute to fatigue. In addition, these treatments have secondary effects that may cause or exacerbate fatigue;

> **Box 8.1.1** Cancer therapies and medications that commonly contribute to fatigue
>
> Cytotoxic therapeutic agents
> Radiotherapy
> Biological response modifiers (e.g. interferon)
> Targeted therapy (tyrosine kinase inhibitors)
> Opioids
> Polypharmacy: hypnotics/anxiolytics, anticholinergics, antiepileptics, neuroleptics, opioids, alpha adrenergic blocking agents, diuretics, selective serotonin reuptake inhibitors and tricyclic antidepressants, and benzodiazepines

for instance, fatigue may be a consequence of chronic pain resulting from radiotherapy- or chemotherapy-induced immunosuppression that predisposes patients to infection. Such effects may persist long term. One study found that patients with breast cancer who had undergone adjuvant chemotherapy or autologous bone marrow transplantation appeared to experience fatigue for months to years after the completion of treatment (Cohen et al., 2012; Goldstein et al., 2012).

Biological response-modifying agents have also been implicated in fatigue; for instance, interferon-alpha was shown to cause fatigue in 70% of patients (Jones et al., 1998). In fact, fatigue is the most frequent dose-limiting side effect in patients receiving biological response-modifying treatments for cancer (Aparicio et al., 2011).

Opioids such as morphine have significant effects on the reticular system and are capable of inducing sedation, cognitive changes, and fatigue in some patients. In addition, anxiolytics, hypnotics, and other drugs may cause sedation and fatigue. Box 8.1.1 outlines cancer therapies and drugs that frequently contribute to fatigue in patients with cancer.

Genetics and cancer-related fatigue

There is preliminary evidence that various single nucleotide polymorphisms of proinflammatory cytokine genes (which affect the gene expression levels) are associated with cancer-related fatigue (Barsevick et al., 2010; Bower et al., 2011). Prior studies found overrepresentation of the IL-1B-511 CC alleles among cancer survivors with fatigue (Collado-Hidalgo et al., 2008; Jim et al., 2012). A study by Smith and Humphries found that homozygosity for both the variant C allele and the wild-type G allele of the IL-6-174 polymorphism was overrepresented in patients with fatigue (Collado-Hidalgo et al., 2008; Reyes-Gibby et al., 2008). Another recent study by Miaskowski et al. found a significant association between polymorphisms in the TNF-alpha and IL-6 genes and fatigue (Miaskowski et al., 2010).

In summary, evidence clearly shows that fatigue is a complex, subjective, multidimensional syndrome that can be attributed to multiple causes. It is particularly important to note that not only cancer but also cancer treatments, cancer-related symptoms (e.g. anorexia-cachexia, pain, sleep disturbances, drowsiness, anxiety, depression, cognitive dysfunction, and dyspnoea), metabolic causes, endocrine dysfunction (e.g. HPA axis dysfunction) cytokine dysregulation, and neuromuscular dysfunction may be among those causes, making a comprehensive assessment of paramount importance.

Assessment

Fatigue is one of the most common and complex symptoms in patients receiving palliative care. Due to the lack of consensus on the definition of fatigue and limited understanding of the exact causative mechanisms, its measurement can be challenging (Jean-Pierre et al., 2007; Minton and Stone, 2009; Mortimer et al., 2010; Seyidova-Khoshknabi et al., 2011). Hence there is no 'gold standard' tool that exists for the assessment of fatigue. Its multidimensional nature adds to the complexity of assessment.

The assessment of fatigue routinely should involve the evaluation of the severity of the fatigue; its onset, duration, and level of interference with everyday life; associated psychological or social problems; and possible underlying causes. Table 8.1.3 outlines some assessment tools for fatigue; several others also exist.

Subjective measures of fatigue are generally considered to be the most relevant in clinical practice and in clinical trials. Visual analogue scales, numerical scales, the Functional Assessment of Cancer Therapy–Fatigue (FACIT-F) (Cella et al., 1993), the Piper Fatigue Scale (Piper et al., 1998), and the Brief Fatigue Inventory (Mendoza et al., 1999) have all been validated and can be used in both pharmacological and non-pharmacological studies. In addition to these tools, there are validated functional assessments of fatigue in most frequently applied quality-of-life questionnaires, such as the European Organisation for Research and Treatment of Cancer QLQ-C30 (Knobel et al., 2003) and Functional Assessment of Cancer Therapy-G (Cella et al., 1993). However, there are studies indicating that the short scales within these instruments have certain limitations (Knobel, et al., 2003). The unidimensional scale is useful for the routine assessment of the severity of fatigue in clinical practice, but these tools may only predominantly assess the physical impact of fatigue and not its mental and emotional dimensions.

Multidimensional tools help us to understand various dimensions of fatigue, such as cognitive and emotional dimensions, in addition to the physical dimension. Tools that are multidimensional are generally preferred to those that are not because they give a broader picture of the problem and can highlight both general and specific management approaches that may benefit a specific patient. However, the trade-off is that it requires more time to administer the questionnaire. Examples of multidimensional tools used to assess fatigue include the Fatigue Questionnaire and Multidimensional Fatigue Inventory. For more details, see Chapter 7.1.

Table 8.1.3 Assessment approaches for fatigue

Functional capacity	Task-related fatigue
Treadmill performance (speed, duration)	Visual analogue/numerical rating scale
Number of errors (pilot, driver)	Pearson and Byars Fatigue Feeling Checklist
6-minute walk	
Performance status	**Subjective assessment tools**
Karnofsky Performance Status	Visual analogue/numerical rating scale
European Cooperative Oncology Group criteria	Functional Assessment of Cancer Therapy-Fatigue
Edmonton Functional Assessment Tool	Piper Fatigue Scale
	Brief Fatigue Inventory

Functional capacity tests attempt to objectively determine a patient's ability to perform a standard task, such as walking on a treadmill, riding a bicycle, or driving for a prolonged period (in a simulator). These tests are of very limited value in cancer care and research, as they are very difficult for patients with advanced-stage cancer to perform. A suitable alternative is measuring daily physical activity and fatigue by means of actigraphy (Berger et al., 2007). An actigraph can also be used to record and evaluate sleep quantity and quality, daytime activity levels, and napping. Roscoe et al. (2002) found that actigraph measurements significantly correlated with fatigue in patients with breast cancer. Conversely, Dimsdale and colleagues found no correlation between fatigue expression and actigraph measurements in healthy controls (Dimsdale et al., 2003). Task-related fatigue tests attempt to assess the fatigue induced by standard tasks. The 6-minute walk test, for example, is commonly used to assess physical function (ATS Committee on Proficiency Standards for Clinical Pulmonary Function Laboratories, 2002).

Assessment of performance status is the most commonly used measure of a patient's physical condition in oncology. Two popular tools, the Karnofsky Performance Status score (Karnofsky and Burchenal, 1949) and the European Cooperative Oncology Group score (Zubrod, 1960), rely on a physician's rating of the patient's functional capabilities after a regular medical consult. Another tool used in oncology, the Edmonton Functional Assessment Test (Kaasa et al., 1997), is administered by a physiotherapist and attempts to determine a patient's functional status in addition to identifying obstacles to clinical performance.

Assessment of fatigue also involves the assessment of possible underlying causes, including those factors shown in Fig. 8.1.1. A full assessment therefore involves a careful systems review and psychological assessment, a detailed physical examination, and blood tests that would detect anaemia and electrolyte or endocrine abnormalities. Multiple causes should be suspected in all patients, and the possible impact of various factors should be weighed according to their severity.

Screening for fatigue

Routine screening for fatigue using single-item screening for cancer-related fatigue has become more common in clinical practice as patients seldom report fatigue so as to avoid distracting the treating physician from the management of their disease.

Guidelines of the National Comprehensive Cancer Network Fatigue Practice Guidelines Panel (Berger et al., 2010) recommend that patients be screened for the presence and severity of fatigue at the time of their initial contact with a doctor and that ongoing assessments be made. The guidelines suggest that the screening data be used to designate the fatigue as mild, moderate, or severe (on a 0–10 numerical rating scale, with 1–3 considered mild, 4–6 moderate, and 7–10 severe). A patient diagnosed with mild fatigue would be re-evaluated on an ongoing basis, whereas patients diagnosed with moderate or severe fatigue would undergo more focused assessment and intervention. A recent study found that a fatigue score of 5 or more out of 10 indicated clinically significant fatigue (Butt et al., 2008).

Management

Because fatigue is complex, multifactorial, and multidimensional, it is crucial that an adequate therapeutic approach be used to identify

FATIGUE

General measures

'Non-pharmacological

- Counselling
- Physiotherapy
- Occupational therapy

Pharmacological

- Corticosteroids
- Megestrol acetate
- Psychostimulants
- Investigational agents- (EPA*, thalidomide L-carnitine testosterone, yoga, melatonin and meditation)

Specific measures to address:

- Psychological issues
- Cachexia
- Anaemia
- Infection
- Autonomic failure
- Metabolic and endocrine disorders
- Opioid-induced sedation
- Hypoxia
- Dehydration
- Deconditioning
- Others

and prioritize the different underlying factors (Yennurajalingam and Bruera, 2007; Bruera and Yennurajalingam, 2010). Alterations in fatigue over time may demonstrate a relationship with a particular factor (e.g. fatigue may increase following an increase in tumour size, a change in medication, or a reduction in the haemoglobin concentration). This temporal pattern underscores the importance of continuous assessment and monitoring of symptoms and signs, even in palliative medicine. In planning a therapeutic approach, it is also important to answer the following questions:

1. Is fatigue a symptom of primary concern to this patient?

2. What are the major probable causes?

3. Are there therapeutic measures available that have a reasonable cost/benefit ratio?

An intervention may have the purpose of decreasing the intensity of fatigue, allowing the patient to express a maximal level of functioning with a stable level of fatigue, or both. In palliative care, the satisfactory treatment of a symptom such as fatigue does not mean that the symptom must be eliminated completely. Even minor improvements can be enough to shift fatigue downward on the patient's list of priorities.

In a given patient, it is often impossible to determine with certainty whether or not an identified problem is a major contributor to fatigue or simply coexists with the fatigue. Therefore, it is of great importance to measure the intensity of fatigue and the patient's performance status before and after treating any suspected contributing factor. For example, fatigue should be measured before and after correcting hypercalcaemia or treating anaemia. This can be done in a number of ways, including using a simple numerical scale (e.g. 0 = best, 10 = worst) or a visual analogue scale (e.g. 0 = best, 100 = worst imaginable) or using a patient-reported outcomes measure such as the Patient Reported Outcomes Measurement Information System from the National Institutes of Health (Yost et al., 2011). If the level of fatigue does not improve after correction of an underlying abnormality, it is clear that further treatment of that abnormality will not improve the fatigue in the future.

Fig. 8.1.3 outlines some general and specific measures that may be useful in the management of fatigue in patients with cancer. In many patients, no reversible causes will be identified. Several pharmacological and non-pharmacological approaches may be effective in these patients, however, including those that reduce energy expenditure or levels of fatigue. Specific treatments may also be used to address underlying abnormalities believed to contribute to the fatigue of an individual patient.

Non-pharmacological approaches

Of the various treatment strategies, exercise has the strongest empirical support in patients with early cancer and cancer survivors, with several recent meta-analyses concluding that physical activity has a moderate beneficial effect on cancer-related fatigue (Cramp and Byron-Daniel, 2012). There is also some support for psychological interventions, with a meta-analysis showing a small to moderate beneficial effect (standardized mean difference in the range of 0.10 to 0.30) (Yennurajalingam et al., 2008). The modest effect sizes in the psychological studies may be a result of the fact that many did not include a cancer-related fatigue-related aim or hypothesis (Jacobsen et al., 2007; Yennurajalingam et al., 2008). The few trials that explicitly focused on fatigue, providing education about fatigue and instruction in self-care, coping techniques, and activity management, were more effective than non-specific interventions (Jacobsen et al., 2007).

Physical activity or exercise

A recent Cochrane review confirmed the beneficial effects of exercise in the management of cancer-related fatigue (Cramp and Byron-Daniel, 2012). In a total of 56 studies in which 1461 participants received an exercise intervention and with 1187 control participants, exercise was seen to be statistically more effective than the control intervention (standardized mean difference, −0.27, 95% confidence interval (CI) −0.37 to −0.17). Both aerobic and resistance exercises, such as brisk walking, cycling, swimming, and weight lifting, are helpful; at least one 30-minute episode per day (at least 150 minutes per week) has been shown to reduce fatigue levels. The benefits of exercise for patients with fatigue

were observed for interventions delivered during or after cancer therapy. In relation to diagnosis, they found that exercise benefits patients with fatigue and breast and prostate cancer but not those with haematological malignancies. In addition, they found that aerobic exercise significantly reduced fatigue but that resistance training and alternative forms of exercise failed to reach significance. Further research is necessary to determine the most effective type (aerobic vs resistance), frequency, duration, and intensity of exercise in palliative care patients.

There is limited evidence of beneficial effects of exercise in palliative care patients. In a recent randomized controlled study in advanced-stage cancer patients, 121 patients were referred to exercise and 110 were referred to usual care. After 8 weeks of a standardized 60-minute, twice-a-week intervention, no significant differences were found in the primary outcome of physical fatigue as assessed by a fatigue questionnaire. Statistically significant results were noted in the physical performance measures, including a shuttle walk test and a hand grip strength test; however, this study had a relatively lower adherence rate (69%) and a high drop-out rate (36%) (Oldervoll et al., 2011).

Although no level 1 evidence exists on the efficacy of exercise, exercise should be prescribed for patients with advanced-stage cancer, if appropriate, as exercise may be beneficial to maintain muscle mass and physical strength, which are commonly affected due to cachexia related to progressive cancer (Oldervoll et al., 2011). Exercise may further be beneficial in improving outcomes, including maintaining independence, self-reported physical functioning, well-being, self-esteem, and energy (Segal et al., 2009).

Usually in cases of deconditioning, if appropriate, the physiotherapist can suggest suitable exercises and encourage increased activity, which may have beneficial effects from both physical and psychosocial perspectives. In addition, if the patient is immobile, a physiotherapist can perform passive movements that will help the patient maintain flexibility and decrease painful tendon retraction. Occupational therapists can allow patients to remain safe and increase their activity at home by providing such resources as ramps, wheelchairs and walkers, elevated toilets, safety devices for bathrooms, and hospital beds. In addition, these therapists can give patients and families useful tips that enhance mobility and help prevent further muscle atrophy, tendon retraction, and pressure ulcers.

Counselling

Patient education and cognitive behavioural therapy were found to improve fatigue in patients with advanced-stage cancer (Kwekkeboom et al., 2012). Counselling can be very useful for both patients and families. Patients frequently underestimate the side effect burden at the beginning of chemotherapy. In one study, only 8% of patients expected tiredness but 86% experienced it (Kirsh et al., 2001). This result suggests that many patients undergo treatment without sufficient information to develop realistic expectations about what that treatment entails.

Counselling and informing the patient of the possible causes of fatigue and the types of therapeutic options available may allow the patient the opportunity to develop realistic expectations. As the disease progresses, the patient will be required to adapt to further limitations in physical functioning and activity; similarly, the family will need to have realistic expectations for the patient.

Patients who are empowered by receiving correct and full information and by undergoing counselling, they may combat fatigue by:

1. adapting their activities of daily living by reducing the amount of housework they do or by enlisting the help of others to perform physical duties

2. spending more time in bed or, alternatively, exercising more (the latter if deconditioning is considered to be a contributor to the fatigue)

3. rearranging their schedules within the day, depending on their fatigue patterns

4. requesting changes in medications perceived to be causing a loss of energy

5. avoiding expending energy on unnecessary activities.

Acupuncture

Several studies have been conducted using acupuncture as an intervention for cancer-related fatigue (Garcia et al., 2013). Of these, a recent study by Malossitis et al. (2012) of patients with breast cancer shows the most promise. In this study, 75 patients were randomly assigned to usual care and 227 patients to acupuncture plus usual care. The difference in the mean General Fatigue score of the multidimensional fatigue inventory, which was the primary outcome, between those who received the intervention and those who did not was −3.11 (95% CI, −3.97 to −2.25; $P < 0.001$). The intervention also improved all other fatigue aspects measured by the Multidimensional Fatigue Inventory. The authors concluded that acupuncture is an effective intervention for managing the symptom of cancer-related fatigue and improving patients' quality of life (see Chapter 9.12).

Pharmacological treatments

In patients with fatigue of unknown origin and those for whom specific treatment is not available, several non-specific pharmacological interventions have been proposed. Corticosteroids, megestrol acetate, other anti-cachexia agents, and psychostimulant drugs are the most studied of these interventions. Unfortunately, there is a lack of compelling data to support any of these approaches other than very short term treatment with corticosteroids.

Corticosteroids

Studies have suggested that corticosteroids decrease fatigue in patients with advanced-stage cancer (Moertel et al., 1974; Bruera et al., 1985; Della Cuna et al., 1989; Peuckmann et al., 2010). The mechanism of action by which corticosteroids combat fatigue is unknown. The inhibition of tumour or tumour-induced substances, as well as central euphoriant effects, are potential mechanisms (Moertel et al., 1974). One potential mechanism of improvement of fatigue is by improvement of the physical symptoms commonly associated with cancer and treatment, such as pain, nausea, anorexia, dyspnoea, and drowsiness (Wilcox, 1984; Bruera et al., 1985; Yennurajalingam et al., 2012).

In a preliminary randomized, controlled, double-blind cross-over trial study of 31 patients with advanced-stage cancer, 32 mg/day of methylprednisolone was found to significantly improve subjective fatigue ($P < 0.01$), pain ($P < 0.01$), and appetite ($P < 0.05$) compared with the patients receiving placebo, with no significant differences in side effects between the methylprednisolone and the

placebo groups (Bruera et al., 1985). In a recently concluded randomized, double-blind placebo-controlled study (Yennurajalingam et al., 2012) of 84 patients with advanced-stage cancer, an oral dosage of 8 mg/day of dexamethasone for 14 days was found to be more effective in relieving cancer-related fatigue than the placebo. The mean (standard deviation) improvement in the Functional Assessment of Cancer Therapy–Fatigue subscale at day 15 was significantly higher in the dexamethasone group than in the placebo group (9 (10.3) vs 3.1 (9.59), P = 0.008). However, the numbers of grade 3 and higher adverse effects did not significantly differ between dexamethasone and placebo groups at day 15 (17/62 vs 11/58, P = 0.14). Two other multicenter European trials have confirmed that corticosteroids can improve quality of life and reduce fatigue (Della Cuna et al., 1989; Tisdale, 2009).

Corticosteroid effects usually last only 2–4 weeks. In addition, corticosteroids can cause metabolic abnormalities and serious long-term toxic effects, including osteoporosis, myopathies, and increased risk of infections. Therefore, long-term treatment with corticosteroids should usually be avoided. In addition, the best types and doses of corticosteroids as a treatment for fatigue have not been established. Most studies have used doses equivalent to approximately 40 mg/day of prednisone.

Progestational agents

Preliminary studies involving terminally ill patients have demonstrated rapid (within 10 days) improvement in fatigue and general well-being in patients treated with megestrol acetate at a dose of 160–480 mg/day as compared to patients receiving the placebo, without any significant change in nutritional status (Bruera et al., 1998; De Conno et al., 1998). The mechanism of action by which progestational agents confer these benefits is unclear, although it is believed to be related to glucocorticoid or anabolic activity, as well as effects on cytokine release. A randomized controlled study showed that megestrol improves appetite and fatigue and has a better safety profile than corticosteroids. However a meta-analysis of four clinical studies of progestational agents showed no benefit of progestational agents compared with placebo for treating cancer-related fatigue (Minton et al., 2008).

Other agents of potential benefit in the management of cachexia

Other pharmacological agents that have potential benefit in the management of cachexia, such as thalidomide and omega-3 fatty acids, may also have a beneficial effect on fatigue. Thalidomide was found to preserve performance status in a randomized, double-blind, placebo-controlled study of 28 patients with advanced HIV and cachexia (Reyes-Terán et al., 1996). A pilot study of thalidomide (100 mg/day) in 37 evaluable cancer patients with cachexia found that the patients' sense of well-being had improved after 10 days of treatment (Bruera et al., 1999).

Aspirin and other non-steroidal anti-inflammatory agents have been investigated for the treatment of cancer-related symptoms, more specifically in the management of cachexia (Madeddu et al., 2012). There is evidence that these agents were associated not only with reduction of inflammatory markers associated with the cachexia but also with improvement of function and alleviation of quality of life (Madeddu et al., 2012). However, further studies are needed to determine whether treatment of these agents will result in clinically effective improvement of fatigue.

Psychostimulants

Clinical experience with cancer patients indicates that psychostimulants promote a sense of well-being, decrease fatigue, and alleviate depression. Methylphenidate, a presynaptic norepinephrine (noradrenaline) and dopamine reuptake inhibitor, is the most researched psychostimulant drug used in the treatment of fatigue and other symptoms such as depression and sedation in patients with advanced-stage cancer (Minton et al., 2008).

Methylphenidate has been used to manage opioid-induced sedation and depression in the palliative care setting (Bruera et al., 1992; Homsi et al., 2001; Minton et al., 2011; Kerr et al., 2012). A recent meta-analysis of psychostimulants (Minton et al., 2011) concluded that methylphenidate may be effective for fatigue based on the finding of trends towards benefits for the treatment of fatigue and a lack of a significant difference in side effects between methylphenidate and placebo. However, the authors suggested that perhaps larger trials may be able to detect a significant difference between methylphenidate and placebo. They observed that the under-powering of the studies due to small sample sizes could have resulted in the lack of statistically significant difference between the methylphenidate and placebo.

However, since the publication of the meta-analysis, larger studies using long-acting methylphenidate (Moraska et al., 2010) and short-acting methylphenidate for fatigue (Bruera, 2013; Bruera et al., 2013) have again failed to show any statistically significant benefit of methylphenidate as compared to placebo. On the basis of these findings and preliminary data showing some trends of benefit in fatigued patients with depression or anxiety, the authors concluded that future studies are needed to explore the benefits of psychostimulants in a subset of fatigued patients with a predominance of depressed mood or sedation (Bruera, 2013; Bruera et al., 2013).

Modafinil, whose mechanism of action is postulated to be via enhanced catecholaminergic signalling and decreased gamma aminobutyric acid release, primarily at the anterior hypothalamus, has also been shown to have benefits for the treatment of severe fatigue (Jean-Pierre et al., 2007) and impaired cognition (improved attention and psychomotor speed) (Lundorff et al., 2009). In a study in N-(2-chloroethyl)-N-ethyl-2-bromobenzylamine (DSP-4)-treated mice non-noradrenergic, dopamine-dependent adrenergic signalling was associated with the activation of the wake-promoting mechanism of modafinil (Cooper et al., 2009).

Modafinil is indicated in the treatment of excessive daytime sleepiness in patients with narcolepsy and conditions such as Parkinson's disease and obstructive sleep apnoea (Cooper et al., 2009). It appears to have less potential for abuse than amphetamines (Cooper et al., 2009). This agent also reduces fatigue in healthy individuals during sustained mental work and may have fewer side effects than D-amphetamine (Rammohan et al., 2002; Schwartz et al., 2003). A phase III randomized, placebo-controlled double-blind study of 631 cancer patients receiving chemotherapy showed significant benefit of modafinil treatment in a subset of cancer patients with severe fatigue greater or equal to 7/10 in a 0–10 scale (Jean-Pierre et al., 2007).

Modafinil's role in patients with advanced-stage cancer, however, has not been established, and in general, more research is needed to define the role of psychostimulants in the management of fatigue in patients with advanced-stage cancer.

Treatment/management of underlying factors

As previously discussed, fatigue is often multicausal and may appear as a consequence of other conditions, such as cachexia, infection, or anaemia (Yennurajalingam and Bruera, 2007). Any intervention capable of reversing an underlying contributor should alleviate fatigue. Thus, it is useful to consider all factors that may be contributing to fatigue in any given patient, with the aim of identifying and treating reversible causes. It is also important to remember that reversible causes, such as dehydration, metabolic disorders, or severe anaemia, may coexist with non-reversible causes.

Infection

As infections may cause fatigue, they should be treated appropriately. Factors leading to recurrent infections should be addressed where possible.

Anaemia

In patients with anaemia, determining the underlying cause is important, as it may influence the choice of treatment (see Chapter 8.3). Treatment may also be influenced by the speed at which the anaemia develops. Severe anaemia (haemoglobin < 8 g/dL) is usually treated with blood transfusion. A recent prospective study of 61 patients receiving care in a palliative care unit has shown that blood transfusions in patients with a haemoglobin level of < 8 g/dL improved the patients' fatigue, dyspnoea, and well-being for a period of 15 days; however, further studies are needed (Mercadante et al., 2009; Preston et al., 2012). As noted earlier, there is evidence that patients with less severe anaemia also benefit from increases in haemoglobin levels from the use of an erythropoietic-stimulating agent with chemotherapy (Demetri et al., 1998).

In a study of 4382 anaemic cancer patients receiving chemotherapy, improvement of haemoglobin of 2 g/dL or higher after treatment with an erythropoietic-stimulating agent was significantly associated with improvement of fatigue, with maximum benefit occurring when the patients' haemoglobin level improved to 12 g/dL (Crawford et al., 2002).

The main disadvantages of erythropoietic-stimulating agent include its cost, recent evidence that it may cause increased thrombotic events, suggestions that it may reduce survival times (Fishbane and Jhaveri, 2012), and the delay of 4–8 weeks until an increase of 1–2 g/dL in haemoglobin concentration, with resulting symptomatic improvement, can be observed. These disadvantages are particularly relevant in palliative care patients who have a short life expectancy.

Although treatment of anaemia has been shown to decrease fatigue in patients receiving chemotherapy, the correction of anaemia in patients with advanced-stage cancer at the end of life was found to have a limited impact on the intensity of fatigue (Stone et al., 2000; Munch et al., 2005). This is probably due to the fact that multiple factors contribute to fatigue in these patients, including cachexia, depression, pain, and deconditioning.

Autonomic failure

Autonomic failure in patients with diabetes and neurological disorders has been effectively managed by midodrine, a specific alpha 1-sympathomimetic agent (Low et al., 1997, Singer et al., 2006). Other measures that could be considered to treat such patients include (a) adjusting the dosages of medications that contribute to fatigue or ceasing polypharmacy so as to reduce drug interactions, (b) having the patient exercise, (c) increasing the patient's salt intake or considering mineralocorticoid (fludrocortisone), if indicated, and (d) having the patient avoid triggers of autonomic insufficiency, such as large morning meals, heat (including showers), alcohol intake, and motionless standing.

Psychological factors

Counselling should be considered for patients with adjustment disorders, depression, anxiety, and coping difficulties. Various randomized clinical trials have shown that supportive interventions (group and individual), such as education and stress management groups, coping strategies training, and behavioural interventions, can help cancer patients manage their fatigue (Homsi et al., 2001; Jacobsen et al., 2007). Patients with major depression should be treated with antidepressant medication. As in the general population, the choice of antidepressant in a patient with advanced-stage cancer will depend on other patient factors. Selective serotonin reuptake inhibitors are commonly used and have fewer side effects than tricyclic antidepressants. An alternative is to consider using a psychostimulant, such as methylphenidate or modafinil, to treat the depression. Psychostimulants have been found to be effective antidepressants and are also useful in the treatment of opioid-induced sedation (Parker and Brotchie, 2010). An advantage of psychostimulants is their rapid antidepressant effect, which is usually apparent within a few days. Disadvantages include their neurotoxic side effects and the risk that patients will develop tolerance or dependency.

Sleep disturbances

Daytime sleepiness and sleep disturbances have been reported to influence the cancer related fatigue (Berger and Mitchell, 2008; Liu et al, 2012) (see Chapter 8.6). Hence interventions treating sleep disturbances could improve fatigue. Berger et al., in a study of 219 women with breast cancer receiving chemotherapy, found that a 1-year four-component behavioural therapy (BT) sleep intervention (Individualized Sleep Promotion Plan) compared to healthy living control was associated with no significant improvement in fatigue as measured Piper Fatigue Scale; however, global sleep quality as measured by the Pittsburg Sleep Quality Index was improved in the BT group compared to the control (Berger et al., 2009). In a pilot study of 86 advanced-stage cancer patients, Kwekkeboom et al. found that patient-controlled cognitive behavioural intervention for 2 weeks resulted in improvement of pain, fatigue, and sleep disturbance cluster (P = 0.032) compared to patients on wait-list controlled condition (Kwekkeboom et al., 2012). Further studies are warranted, especially those targeting common underlying mechanisms such as inflammation (Liu et al., 2012).

Metabolic disorders

Metabolic disorders, such as hypercalcaemia, hyponatremia, hypomagnesaemia, and hypokalaemia, should be corrected where possible. Endocrine deficiencies, such as hypothyroidism and Addison's disease, require treatment with hormones. Hypogonadism affects two-thirds of men with advanced-stage

cancer. Low testosterone in men with cancer is associated with fatigue, anorexia, depression, and insomnia. Testosterone replacement therapy can be considered for patients with hypogonadism. A preliminary placebo-controlled study in 26 evaluable patients with hypogonadic advanced-stage cancer (bioavailable testosterone levels of 70–270 ng/dL) showed a trend towards improvement in the fatigue scores after 4 weeks of treatment using intramuscular testosterone (Pulivarthi et al., 2012). Larger prospective studies are needed to look at the effects of testosterone replacement in cancer patients with fatigue and to determine which of these patients are most likely to benefit from treatment.

Dehydration and hypoxia should be managed as appropriate, and the treatment of underlying cardiac or respiratory conditions should be optimized.

Drug induced

The list of prescribed drugs should be monitored regularly to ensure that the fatigue is not an iatrogenic effect. Fatigue is a common complication of cancer-specific therapy including cytotoxic therapy, radiation therapy, hormonal therapy, surgery, and targeted therapy, and this adverse effect may be dose related.

Nutritional deficiencies

Studies have found that the micronutrient carnitine is frequently deficient in patients with advanced-stage cancer, and preliminary studies using escalating doses (250–3000 mg/day) of carnitine supplementation have shown improvements in fatigue. However, a recent randomized controlled study for the treatment of fatigue in 376 cancer patients showed that 2 g/day of L-carnitine did not significantly improve fatigue compared to a placebo (Cruciani et al., 2012).

Nutritional supplements

Various nutritional supplements such as *Ginseng quinquefolius* (American ginseng), *Paullinia cupana* (guarana), co-enzyme Q10, and L-carnitine, have been investigated in cancer patients to manage fatigue with various levels of success.

In a recently published randomized controlled study, Barton et al. found that American ginseng at a dose of 2000 mg daily over an 8-week period improved cancer fatigue significantly compared to placebo (Barton et al., 2013). Three hundred and sixty-four participants were enrolled from 40 institutions in United States. Changes from baseline in the general subscale of the Multidimensional Fatigue Symptom Inventory—Short Form were 14.4 (standard deviation (SD) = 27.1) in the ginseng arm versus 8.2 (SD = 24.8) in the placebo arm at 4 weeks (P = 0.07). A statistically significant difference was seen at 8 weeks with a change score of 20 (SD = 27) for the ginseng group and 10.3 (SD = 26.1) for the placebo group (P = 0.003). Greater benefit was reported in patients receiving active cancer treatment vs those who had completed treatment. Toxicities per self-report and Common Terminology Criteria for Adverse Events (CTCAE) grading did not differ statistically significantly between arms.

In another study by de Oliveira Campos and colleagues, patients with progressive fatigue after their first cycle of chemotherapy were randomized to receive either *Paullinia cupana* (guarana) 50 mg by mouth twice daily (32 patients) or placebo (43 patients) for 21 days (de Oliveira Campos, 2011). After a 7-day washout period, patients

were crossed over to the opposite experimental arm. All patients were evaluated on days 1, 21, and 49. Guarana significantly improved the Functional Assessment of Chronic Illness Therapy—Fatigue (FACIT-F) score compared to placebo on days 21 and 49 (P < 0.01). The Chalder Scale improved significantly on day 21 (P < 0.01) but not on day 49 (P = 0.27). Guarana did not produce any CTCAE grades 2, 3, or 4 toxicities and did not worsen sleep quality or cause anxiety or depression. Lesser and colleagues found that 300 mg coenzyme Q10 supplementation compared to placebo was not significantly associated with improvement of fatigue as measured by FACIT-F scores at the end 24 weeks (37.6 vs 37.6, P = 0.965) (Lesser et al., 2013). However, further studies are needed in palliative care population to determine the effectiveness and safety of standardized nutritional supplements in patients receiving palliative care.

Nutritional support (enteral and/or parenteral)

Studies in patients with advanced cancer suggest that there is limited evidence to suggest that artificial nutrition improves patient survival, performance status, quality of life, treatment toxicity, or psychological well-being. Further studies are needed to determine which subset of palliative patients would benefit from nutritional support so as to improve fatigue and quality of life (Chermesh et al., 2011; Dev et al., 2012).

Multimodal therapy

Symptomatic treatment of fatigue should be considered in cases in which fatigue is not effectively managed by treatment of reversible causes (Yennurajalingam and Bruera, 2007). In these cases, due to the multidimensional nature of fatigue, it is unlikely that fatigue can be effectively treated using a single intervention. A combination of pharmacological and non-pharmacological treatments should be considered on the basis of a predominant pathophysiological mechanism for a given patient (Bruera and Yennurajalingam, 2010). For example, a patient with a significant component of physical fatigue may benefit from a combination of dexamethasone and exercise tailored to the patient's needs. Similarly, various combinations of treatment that have shown preliminary beneficial effects on fatigue in patients with advanced-stage cancer should be considered on an individual basis. These may include interventions such as cognitive behavioural therapy, educational interventions, anti-inflammatory drugs, and exercise. However, further studies using sound research methodology are needed to investigate the efficacy of multimodal intervention in patients with fatigue.

Conclusion

Fatigue in cancer patients is now accepted as a symptom that should be studied in its own right. Unfortunately, few studies have addressed fatigue in palliative cancer populations. Consequently, most of the insight into the complexity of fatigue must be based upon extrapolation from studies performed with patients earlier in the disease trajectory. To improve treatment, we must gain a better understanding of the many aspects of fatigue. Thus, identifying the pathophysiological mechanisms that cause fatigue is important. Assessment and staging tools that are valid and reliable are needed to assist in clinical practice and research. Clinical syndromes of fatigue (cognitive, affective, and physical) also must be better characterized. The roles of nutritional interventions and

commonly used agents, such as corticosteroids, also need to be more thoroughly investigated. The potential of agents such as eicosapentaenoic acid, thalidomide, and anabolic steroids must be explored in studies in which fatigue is a primary endpoint. Finally, the role of psychostimulants should be further researched, and the importance of counselling, rest, and exercise in cancer patients receiving palliative care should be clarified.

Dyspnoea and other respiratory symptoms in palliative care

Kin-Sang Chan, Doris M.W. Tse, and Michael M.K. Sham

Introduction to dyspnoea and other respiratory symptoms in palliative care

A breath is a vital sign of a living creature. When one dies, one expires. A breath, however, serves more than physiological purposes. A sigh often carries unspeakable messages from the inner being. Hence a breath may be filled with physiological, psychological, and spiritual signals.

Breathing, an automatic activity which one undergoes hundreds of millions of cycles throughout one's life, is mostly effortless. Breathlessness serves as a warning signal in responding to the metabolic demand on a person. When the respiratory system is compromised by diseases, every breath may become laborious. Every day, millions of people throughout the world are distressed by breathlessness and other respiratory symptoms. Control of respiratory symptoms remains challenging towards the end of life.

Dyspnoea becomes an important factor predicting the will to live in the terminally ill while approaching death (Chochinov et al., 1999). Relieving distress related to respiratory symptoms is key to addressing suffering.

Definition of dyspnoea

The American Thoracic Society defines dyspnoea as 'a subjective experience of breathing discomfort that consists of qualitatively distinct sensations that vary in intensity' (American Thoracic Society, 1999).The experience is derived from interactions among physiological, psychological, social, and environmental factors, and may induce secondary physiological and behavioural responses. Dyspnoea per se can only be perceived by the person experiencing it. Perception entails conscious recognition and interpretation of sensory stimuli and their meaning (Parshall et al., 2012). Dyspnoea is a term we use for a symptom that patients often describe as breathlessness. In the following text, the two terms are used interchangeably.

Dyspnoea prevalence, pattern, and trajectory

Dyspnoea is common among patients with advanced cancers and non-cancer life-limiting illnesses. The prevalence of dyspnoea varies with the site of primary cancers and the stage of illness. In patients with primary lung cancers, the prevalence of dyspnoea reported ranges from 75% to 87% (Muers and Round, 1993; Smith et al., 2001). In a systematic review comparing the prevalence of 11 symptoms in patients with advanced cancer, AIDS, heart disease, chronic obstructive pulmonary disease (COPD), and renal disease, breathlessness was found in more than 50% of patients (Solano et al., 2006). Dyspnoea was prevalent among 10–70% of patients with cancer, 90–95% of patients with COPD, 60–88% of patients with heart disease, 11–62% of patients with AIDS, and 11–62% of patients with renal disease. In a cohort of 5682 palliative care patients, breathlessness increased from around 50% at 3 months before death to 65% at the time of death, with severe breathlessness increased from less than 10% to 26% at the two time points respectively. Absence of breathlessness between referral and death was only recorded in 11.4% of patients (Currow et al., 2010).

Two patterns of dyspnoea have been reported by cancer patients: the breakthrough-only dyspnoea in 61%, and constant dyspnoea in 39% of patients, among which 20% presented as breakthrough episodes (Reddy et al., 2009). The majority of patients with breakthrough episodes presented with fewer than five episodes daily, with each episode frequently lasting for less than 10 minutes. Simon et al. (2013b) observed two categories of breathlessness among patients with chronic heart failure, COPD, lung cancer, and motor neurone disease: episodic breathlessness that occurs in less than 24 hours (seconds, minutes, or hours) and continuous breathlessness lasting more than 24 hours (days to weeks or months or years). Episodic breathlessness could be triggered by exertion, emotion, or environment; or occur spontaneously without trigger. It could also occur independently or on top of continuous breathlessness. However, episodic breathlessness was only reported as a primary outcome in eight among 27 studies (Simon et al., 2013a).

Dyspnoea along the trajectory of life-limiting illnesses has been evaluated by several longitudinal studies. Bausewein et al. (2010) studied individual and summary trajectories of breathlessness of cancer and COPD patients at baseline and monthly over 6 months or until death. In people with COPD, breathlessness increased over time, on average by one Borg score over 6 months, while in people with cancer, breathlessness increased in the last month of life and towards death. Four breathlessness trajectory patterns have been identified: fluctuating, increasing, stable, and decreasing, with fluctuating breathlessness being most common in people with both severe COPD and advanced cancer (Bausewein et al., 2010).

In a cohort study of 5862 patients by Currow and colleagues, breathlessness as assessed at three time points before death (60–53 days, 30–23 days, and 7–0 days) was compared between cancer and non-cancer patients (heart failure, end-stage pulmonary

disease, and no identifiable cardiopulmonary cause) (Currow et al., 2010). Patients with non-cancer diagnoses had significantly higher levels of breathlessness at all three time points, while cancer patients had less breathlessness initially but increased significantly at day 10 and day 3 before death. In another cohort of over 10,000 cancer patients, the trajectories of performance status and symptom scores during the last 6 months of life were evaluated (Seow et al., 2011). Breathlessness increased in severity over time, particularly in the month before death. With functional decline or towards the end of life, the intensity of dyspnoea progressively increased as Karnofsky Performance Status (KPS) score fell below 60 and peaked between KPS scores of 30 and 20 (Mercadante et al., 2000).

Qualities of dyspnoea and neurophysiology

There are at least three separate qualities of dyspnoea: air hunger or unsatisfied inspiration; work or effort; and tightness (Lansing et al., 2009; Parshall et al., 2012). This classification depends on different perceptual qualities with distinct afferent sources:

1. *Air hunger or unsatisfied inspiration*: this is the conscious perception of the urge to breathe. Patients describe this as 'I cannot get enough air', 'My breaths don't satisfy me', or 'I'm starving for air'. This sense of air hunger can be experimentally induced by hypercapnia, hypoxia, exercise, or acidosis, all leading to increase in respiratory drive. The signal comes from the motor drive of the respiratory centres in the brainstem, and is conveyed to the cerebral cortex as corollary discharge. When this is not matched by an adequate ventilatory response by feedback from afferent receptors throughout the respiratory system, individuals perceive air hunger or unsatisfied inspiration. Afferent information about the pulmonary ventilation achieved from mechanoreceptors in the lungs, airways, and chest wall can relieve or inhibit air hunger or unsatisfied inspiration. Air hunger is positively correlated with automatic drive to breathe (i.e. brainstem motor activity), and negatively correlated with the amount of ventilation.

2. *Work or effort*: this is an uncomfortable sense of respiratory work and effort. Patients describe this as 'It's an effort to breathe', or 'My breathing requires more work'. The perceptions of work and effort probably arise through some combinations of respiratory muscle afferents and perceived cortical motor command or 'corollary discharge' projecting to sensory areas. The sense of work or effort can be produced experimentally by external resistive or elastic load, volitional hyperpnoea, or by weakening of the respiratory muscles.

3. *Tightness*: tightness appears to be specific to bronchoconstriction. Patients describe this as 'My chest feels tight or constricted'. The sensation of tightness arises from pulmonary afferents through the stimulation of airway receptors.

Neuroimaging by positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) has been employed recently for locating the activating areas during dyspnoea. The most consistent and the strongest area of activation is in the right anterior insula (Lansing et al., 2009; Parshall et al., 2012). Other activations can be seen in the left anterior insula, anterior cingulate, supplementary motor area, prefrontal cortex, cerebellum, and amygdala (Parshall et al., 2012). Dyspnoea is associated with activation of cortico-limbic structures, which overlap with that observed in pain (Lansing et al., 2009; Parshall et al., 2012). As demonstrated by fMRI, the unpleasantness of perceived dyspnoea is processed in the right insula and amygdala (von Leupoldt et al., 2008).

Similar to the pain model, it is postulated that dyspnoea consists of multiple dimensions, including the independent component of sensory dimension (sensory intensity and sensory quality), immediate affective stage which trigger immediate behaviour, and a stage of cognitive evaluative and emotional response which affects long-term behaviour (Lansing et al., 2009). Against the traditional neurochemical and neuromuscular model, a neuromatrix-gated model has been proposed to unify multiple factors by recognizing different inputs from afferents at receptor levels and inputs from different areas of the brain (Williams, 2011).

The impact of dyspnoea

Breathlessness correlates with survival and is a predictor of poor prognosis in cancer. In a systematic review of the value of symptom assessment to predict survival in people with advanced cancer, dyspnoea was evaluated in 35 studies involving 9155 patients (out of 44 studies included). Dyspnoea was correlated with survival in 22 studies in univariate analysis, and in ten studies in multivariate analysis. In 23 studies including 6806 patients in the symptom-oriented palliation stage, dyspnoea was also a predictor for survival in multivariate analysis in 30–50% of studies (Trajkovic-Vidakovic et al., 2012). Dyspnoea is one of six parameters used in the Palliative Prognostic Score that predicts 30-day survival of palliative care patients (Pirovano et al., 1999).

Dyspnoea also affects advanced cancer patients through individuals' symptom experience. Previous studies have shown that dyspnoea often brings panic, fear, anxiety, depression, hopelessness, sense of loss of control, and impending death to patients (Gysels et al., 2007). Dyspnoea affects daily and social functions, leading to dependence and loss of role. A more recent study on people with advanced cancer found that dyspnoea was closely associated with fatigue, pain, and depression on multivariate analysis, and interfering with general activities, mood, and enjoyment of life (Reddy et al., 2009). A qualitative study illustrated the meaning of breathlessness experience among patients with cancer, COPD, heart failure, and motor neurone disease (Gysels and Higginson, 2011). For people with cancer, breathlessness, apart from being a signal of cancer, is also a reminder of mortality, despite their optimism with treatment. In people with COPD, breathlessness is perceived as self-inflicted resulting from life-time smoking. People are alarmed by the debilitation caused by breathlessness often in the later stages of disease because of its insidious nature. For people with heart failure, breathlessness is associated with functional limitations and contributes to the negative effects of other symptoms. In people with motor neurone disease, breathlessness makes people realize that the illness affects mechanisms essential for living (Gysels and Higginson, 2011).

Under-recognition of dyspnoea by health-care workers adds to people's helplessness. Each person has to develop their own coping strategies (O'Driscoll et al., 1999).

Clinical assessment of dyspnoea

Clinical assessment of dyspnoea aims at identification of all underlying causes of dyspnoea and assessment of the distress and impact as experienced by patient so as to guide the management

plan. The vehicles for assessment should include detailed history taking and physical examination, carefully selected investigations, and the use of dyspnoea measuring tools appropriate to the clinical context.

History taking

No objective test can replace a patient's own description of the symptom and its experience. Apart from information that helps in elucidating the underlying causes of dyspnoea, a good history from a dyspnoeic patient should include the quality of dyspnoea, its profile (episodic or constant), intensity, associated distress or affective states, impact on the patient's life, and concerns of the patients and caregivers (online Table 8.2.2).

Physical examination

Physical examination is important in evaluating the severity of the clinical situation and the possible underlying causes. Patients with severe dyspnoea may not be able to provide a history, appear exhausted, and have to sit up while breathing rapidly. In such circumstances, initial management plans rely on findings from physical examination and preliminary bedside tests. Warning signs calling for urgent review include the presence of stridor, marked tachypnoea (e.g. respiratory rate > 30 breaths per minute), tachycardia (e.g. heart rate > 130 per minute), marked respiratory distress, and altered level of consciousness (online Table 8.2.3).

Investigations

Investigations, when carefully selected, help to elucidate the underlying cause(s) of dyspnoea and guide the management plan for patients at different stages of illness. The choice of investigations depends on the balance of their benefits and burdens, treatment goals, and patients' preferences. First-line investigations include haemoglobin level, oxygen saturation by oximetry, and, if indicated chest radiograph. The intensity of dyspnoea correlates poorly with degree of hypoxaemia (Bruera et al., 2000) and lung function parameters (Heyse-Moore et al., 2000) and therefore these tests cannot substitute for a patient's own report of dyspnoea. Changes in the chest radiograph including shadows of lung parenchyma, pleura, airway, mediastinum, diaphragm, cardiac silhouette, and pulmonary vessels should be systematically observed.

Specialized investigations are less readily available in palliative care setting. Rarely are arterial blood gases indicated. Lung function tests with a flow volume loop are helpful to look for upper airway obstruction. Maximum inspiratory pressure or nasal sniff inspiratory pressure can detect inspiratory muscle weakness. Echocardiography and Doppler ultrasound may serve diagnostic or guide therapeutic procedures in pericardial or pleural effusion, heart failure, deep vein thrombosis, and pulmonary embolism. D-dimer is raised in cancer and has limited value for diagnosis of pulmonary embolism.

Third-line investigations should be considered in highly selected cases. Computed tomography (CT) may be valuable in delineating conditions including pulmonary embolism, major airway obstruction, superior vena cava obstruction, and lymphangitis carcinomatosis.

Measurement of dyspnoea

For the comprehensive assessment of dyspnoea as a multidimensional symptom, a dyspnoea measuring tool should reflect the subjective sensory experience of individual patients, provide objective measurement of dyspnoea, and serve as an effective means for communication to health-care workers. There are three domains of dyspnoea measurement as proposed by the American Thoracic Society in 2012 (Parshall et al., 2012). They are:

1. *Sensory-perceptual experience*: this includes ratings of symptom intensity, frequency, duration, and the sensory quality. Dyspnoea intensity can be assessed by a visual analogue scale, Borg scale, Likert-type ratings, or numerical rating scale (NRS). Dyspnoea is also among the symptoms assessed in validated multidimensional symptom assessment tools such as the Memorial Symptom Assessment Scale and Edmonton Symptom Assessment Scale. For the sensory quality, Simon and colleagues reported 15 dyspnoea descriptors used by breathless patients in eight clusters (rapid, exhalation, shallow, work, suffocating, hunger, tight, and heavy) (Simon et al., 1990). Simon et al. suggested the possible associations of dyspnoea descriptors with the specific conditions producing dyspnoea (Simon et al., 1990), but a subsequent study by Wilcock et al. (2002) failed to demonstrate the robustness of these descriptors in assisting diagnosis when applied to patients with cancer and cardiopulmonary diseases.

2. *Affective distress*: this may refer to the immediate distress (e.g. unpleasantness) or the cognitive-evaluated distress subsequent to appraisal of its meaning or consequences. Distress or unpleasantness may be rated as a single item as in the case for dyspnoea intensity. Scales with multiple items, such as the Cancer Dyspnoea Scale, assess emotional responses including anxiety (Tanaka et al., 2000).

3. *Symptom impact or burden*: this includes the effect of dyspnoea on behaviour, functions, quality of life (QOL), or health status. The Medical Research Council (MRC) scale provides unidimensional rating of disability (Mahler and Wells, 1988), while the Chronic Respiratory Disease Questionnaire (CRQ) is a multidimensional scale used for assessment of functional abilities (Guyatt et al., 1987). Various QOL scales have been validated for use in cancer or specific for lung cancer and in chronic lung diseases, for example, CRQ (Guyatt et al., 1987), EuroQol 5D (EuroQol Group, 1990), FACT-L (Cella et al., 1995), QLQ-C15-PAL (Groenvold et al., 2006), and QLQ-LC13 (Bergman et al., 1994).

Currently there are over 50 dyspnoea measurements scales readily available to readers (Parshall et al., 2012) covering various domains of dyspnoea and different diseases. However, a unified dyspnoea measurement tool for clinical use in palliative care setting is still lacking. One may consider combining rating of dyspnoea intensity with assessment of the impact of dyspnoea on a patient's QOL (Bausewein et al., 2008b), the NRS, Modified Borg Scale, CRQ- dyspnoea scale, Motor Neurone Disease Rating Scale (modelled on the CRQ), and Cancer Dyspnoea Scale appear most suitable for the palliative care setting (Dorman et al., 2007).

Elucidate the underlying causes of dyspnoea

Multiple underlying causes may coexist in a patient with dyspnoea. Causes of dyspnoea can be classified according to malignant, paramalignant, or non-malignant causes and cardiopulmonary causes versus systemic causes (Table 8.2.1).

Table 8.2.1 Causes of dyspnoea and management of potential treatable causes

Malignant and paramalignant causes	Cardiopulmonary causes	Treatment
	Lung cancer Secondary to lung	Chemotherapy in selected patients Molecular targeted therapy for adenocarcinoma of lung with epidermal growth factor receptor mutation
	Pleural effusion	Repeated thoracentesis Chemical pleurodesis: talc 90% efficacious Thoracoscopic pleurodesis more effective than medical pleurodesis (Shaw and Agarwal, 2004) Indwelling pleural catheter (especially for trap lung) (Davies et al., 2012)
	Superior vena cava obstruction	Stents (95% have relief and faster) (Rowell and Gleeson, 2001) Chemotherapy and radiotherapy (60% in NSCLC) Trial of steroid, diuretics
	Pulmonary embolism	Low-molecular-weight heparin (more efficacious than warfarin)
	Pericardial effusion	Pericardiocentesis, catheter drainage, pericardial window, pericardiotomy
	Major airway obstruction	Radiotherapy, bronchial stent, endobronchial treatment- laser therapy, cryotherapy Trial of steroid
	Lymphangitis carcinomatosis	Trial of steroid
	Radiation-induced pneumonitis	Trial of steroid
	Drug-induced pneumonitis	Trial of steroid
	Chest infection	Antibiotics according to sensitivity
	Systemic causes	
	Cancer cachexia	Prevention of aspiration
	Ascites	Abdominal paracentesis
	Gross hepatomegaly	Prop up position
Non-malignant causes	**Cardiopulmonary causes**	**Treatment**
	COPD	Non-pharmacological therapy, breathing exercise Inhaled short acting bronchodilators, Inhaled long acting bronchodilators (beta$_2$-agonist, anticholinergic), inhaled steroid, theophylline, phosphodiesterase-4 inhibitors
	Bronchiectasis	Airway clearance, antibiotics for infective exacerbation
	Interstitial pulmonary fibrosis	
	Congestive heart failure	Angiotensin converting enzyme inhibitors, beta-blockers/hydralazine + nitrate Angiotensin receptor blockers, spironolactone Digoxin, diuretics
	Arrhythmias	Anti-arrhythmic agents
	Systemic causes	
	Muscle weakness: motor neuron disease, muscular dystrophy	Non-invasive ventilation
	Anaemia	Blood transfusion, erythropoietin
	Acidosis	$NaHCO_3$
	Deconditioning	Exercise
	Respiratory panic attack	Anxiety management, benzodiazepines

Management of dyspnoea

The objectives of dyspnoea are to reduce its frequency and severity, minimize its psychological and spiritual distress, and maximize patients' function and QOL. To achieve these goals, identification of all of the underlying causes of dyspnoea are required, and use of specific or combinations of modalities of management may include the following:

1. Specific disease management

2. Non-pharmacological intervention

3. Pharmacological treatment

4. Palliative non- invasive ventilation

5. Palliative sedation.

Specific disease management

The underlying diseases causing dyspnoea, when reversible or modifiable, should be treated accordingly (Table 8.2.1). Among the diverse causes of dyspnoea, some have the propensity to present with acute, and even life-threatening dyspnoea, including tension pneumothorax, large pleural effusion, asthma attack, COPD exacerbation, fulminant chest infection, acute pulmonary oedema, arrhythmia, major airway obstruction, pulmonary embolism, cardiac tamponade, and metabolic acidosis. Clinicians may face the dilemma of having to decide on the extent of disease-specific and life-sustaining treatments in the presence of a life-limiting illness. Diagnosing the end of life in people with organ failure may be particularly difficult as the disease trajectory is fluctuating and less predictable.

Disease-modifying treatments are often applicable despite the progressive nature of cancer and other chronic debilitating diseases. Emergence of newer chemotherapeutic agents and targeted therapies such as tyrosine kinase inhibitors, monoclonal antibodies, and angiogenesis inhibitors have changed the landscape of cancer treatment with palliative intent, offering opportunity for life prolongation and symptom control. On the other hand, there is evidence that early palliative care integrated with standard oncology care for patients with metastatic non-small cell lung cancer (NSCLC) improves QOL (Temel et al., 2010). A randomized controlled trial (RCT) also showed that metastatic NSCLC patients assigned to early palliative care had a better QOL, less depressive symptoms, longer median survival, received less aggressive chemotherapy, and were more likely to be enrolled in hospice compared to patients receiving standard oncology care (Temel et al., 2010; Greer et al., 2012).

Disease-specific needs of patients with non-cancer diseases should also be recognized. Palliative care has been developing for patients with advanced COPD, chronic heart failure, end-stage renal failure, and neuromuscular and degenerative diseases. A collaborative model involving the palliative care team and other respective specialty teams should be considered to ensure access for patients to disease-specific treatments when indicated.

In both cancer and non-cancer diseases, the palliative care phase may go hand in hand with the disease-modifying phase. As disease progresses, symptom palliation will be more relevant than disease modification as the primary treatment goal. Dyspnoea-based care, such as the Breathlessness Intervention Service at Addenbrooke's Hospital, United Kingdom, has been established recently for management of dyspnoea caused by different diseases (Booth et al., 2011).

Non-pharmacological interventions

'Non-pharmacological interventions' is a broad term referring to any non-drug therapy and its scope for management of dyspnoea is developing. Non-pharmacological interventions for dyspnoea aim at improving the symptom experience and addressing the multidimensional needs of patients that are identified by comprehensive assessment (Booth et al., 2011). Non-pharmacological intervention may be delivered as a single component or as multiple components by health-care professionals including nurses, physiotherapists, occupational therapists, psychologists, and social workers in a multidisciplinary team.

The spectrum of non-pharmacological interventions varies from low-complexity interventions such as positioning to more sophisticated psychological interventions.

The effectiveness of non-pharmacological interventions for breathlessness in patients with advanced malignant and non-malignant diseases (mostly COPD) (Bausewein et al., 2008a), and patients with lung cancer (Rueda et al., 2011), has been reported in two Cochrane reviews. A further review of six systematic reviews of non-pharmacological interventions was recently published (Yates and Zhao, 2012). The following non-pharmacological interventions have been reviewed with different levels of evidence:

Interventions that are supported by good evidence

Breathing training (Bausewein et al., 2008a): as shallow breathing and dynamic hyperinflation increase breathlessness, the following breathing techniques may counteract this mechanism to improve breathing efficiency, including pursed-lipped breathing, diaphragmatic breathing, 'blow-as-you-go', positioning, and pacing technique. Two out of three studies in people with COPD showed positive outcomes. Activity pacing and energy conservation techniques are often taught together with breathing training, but this is less supported by evidence.

Walking aids (Bausewein et al., 2008a): wheeled-walker/rollators are helpful to relieve dyspnoea. Four out of seven studies in people with COPD showed positive results. Walking aids probably exert their effects on breathlessness by increasing the maximal voluntary ventilation as patients brace the arms on the walking aid and lean forward.

Neuromuscular electric stimulation (Bausewein et al., 2008a): muscle deconditioning and wasting can contribute to breathlessness. This modality is particularly useful for patients who are too weak to exercise. Increase in walking distance and decrease in dyspnoea have been reported by three trials performed in people with COPD.

Chest wall vibration (Bausewein et al., 2008a): modifies respiratory sensations by activation of muscle spindles in the intercostal muscles. In the studies of people with motor neurone disease and COPD, there was significant reduction in dyspnoea in four out of five studies.

Exercise (Koelwyn et al., 2012): has been shown to be effective for relieving dyspnoea in COPD but evidence for cancer is conflicting.

Interventions that are supported by some evidence

Handheld fan (Bausewein et al., 2008a): cool air has been shown to reduce the sensation of breathlessness in normal subjects. The effect of handheld fans was demonstrated by a randomized

controlled crossover trial reported by Galbraith et al. (2010). Bausewein et al. compared the fan with a waistband but were unable to demonstrate any benefit over 2 months. However 50% of patients continued to use the fan compared to 20% who used the waistband.

Nurse follow-up programmes (Rueda et al., 2011): three trials on nursing intervention showed benefits in terms of symptom experience, emotional functioning, and performance status.

Acupuncture/ acupressure (Bausewein et al., 2008a): four studies were performed in people with COPD, one study in people with cancer and mixed patients respectively. The results are conflicting.

Interventions that require more evidence

Various interventions including relaxation, music, counselling support, counselling and support with breathing-relaxation training, case management, and psychotherapy are frequently practised (Bausewein et al., 2008a), but require more studies to confirm their effectiveness or the populations who will most benefit from them.

Pharmacological treatment

Unlike pain which has specific pain receptors which can be targeted by pain control treatments, the sensations of dyspnoea are mediated through multiple neurophysiological mechanisms. As the evidence supporting different pharmacological treatments in relieving dyspnoea are emerging, they can be grouped under three categories. A combined modalities approach involving several treatments has not yet been formally evaluated (Clemens et al., 2012).

1. Treatments with clear evidence: oxygen and opioids.

2. Treatments with some evidence: anxiolytics, nebulized furosemide, and Heliox.

3. Treatments with limited evidence: antidepressants, phenothiazines, indomethacin, and inhaled topical anaesthetics.

Pharmacological treatments with clear evidence

Oxygen therapy

Hypoxia triggers the sense of air hunger by stimulation of peripheral chemoreceptor. However, it has been shown that dyspnoea in the terminally ill does not correlate with the degree of hypoxaemia (Bruera et al., 2000). This can be explained by the multiple causes of dyspnoea in cancer. Oxygen therapy has been widely used in acute hypoxaemic conditions, while its long-term use in chronic hypoxaemic COPD to improve survival has been supported by studies. In palliative care settings, oxygen is mainly used for symptom relief of dyspnoea without fulfilling the criteria of long-term oxygen therapy, described by the term 'palliative oxygen therapy'. Palliative oxygen therapy has been studied in the following conditions:

Palliative oxygen for advanced cancer patients

Six RCTs were conducted to compare oxygen with air, with two trials on hypoxaemic patients, combined hypoxaemia, and non-hypoxaemic patients, and non-hypoxaemic patients respectively (Ben-Aharon et al., 2008). In studies on hypoxaemic patients, oxygen therapy was more effective than air in a single advanced-cancer patient by the N-of-1 RCT (Bruera et al., 1992) and in 12 hypoxaemic cancer patients (Bruera et al., 1993),

However, in a meta-analysis of the RCTs on combined hypoxaemia and non-hypoxaemic patients, oxygen was not superior to air in relieving dyspnoea (Uronis et al., 2008).

Palliative oxygen for non-hypoxaemic COPD

In a systematic review of 18 trials on people with COPD (N = 431), oxygen reduced dyspnoea with a standardized mean difference of −0.37 (95% confidence interval (CI) −0.50 to −0.24, p < 0.00001) (Uronis et al., 2011). The reviewers concluded that oxygen can relieve dyspnoea in mildly and non-hypoxaemic COPD patients, who otherwise would not fulfil the criteria for long-term oxygen therapy. Because of the significant heterogenicity among the studies reviewed, use of oxygen in COPD should be evaluated on an individual basis. In another RCT on 143 COPD patients without resting hypoxaemia, ambulatory oxygen, as compared with air, had no benefits in terms of dyspnoea relief, functional improvement, and QOL (Moore et al., 2011).

Palliative oxygen for patients with mixed diagnoses

Palliative oxygen has been evaluated in patients with mixed diagnoses but with no definite benefit proven. A 4-year consecutive cohort from a regional community palliative care service was reviewed to assess the effectiveness of home oxygen therapy on breathlessness (Currow et al., 2009). Out of the 5862 study population, 1239 patients (21.1%) were prescribed oxygen, and 413 patients had before and after data that could be evaluated, among which the majority had cancer (n = 270). There were no significant differences between the mean dyspnoea scores before and after 1 and 2 weeks of home oxygen. Among the 413 patients, about one-third had significant improvement in breathlessness (more than 20% improvement in mean dyspnoea scores), but demographic factors, baseline breathlessness or underlying causes of breathlessness failed to predict these responders.

In a well-designed RCT reported by Abernethy and colleagues, palliative oxygen was compared against room air in 239 patients with life-limiting illnesses. The majority were non-hypoxaemic with a mixed diagnosis of COPD and other lung diseases (73.6%), followed by primary and secondary lung cancer (15.9%) (Abernethy et al., 2010). These patients were non-hypoxaemic but suffered from refractory dyspnoea. Breathlessness and QOL as assessed twice a day at baseline and day 6 showed improvements in both arms, but with no significant difference between oxygen and room air. The authors concluded that oxygen provides no additional symptomatic benefit to room air for relief of refractory dyspnoea in non-hypoxaemic patients with life-limiting illnesses. The effect of air flow in decreasing dyspnoea may account for the effect in the control arm.

Palliative oxygen for patients with chronic heart failure

Three cross-over studies compared the use of oxygen inhalation to air inhalation in adults with stable chronic heart failure for dyspnoea management during exercise testing (Cranston et al., 2008). A systematic review conducted in 2008 failed to demonstrate a consistent beneficial effect of oxygen inhalation over air inhalation (Cranston et al., 2008). More updated studies in this area are lacking. Based on the observation that one-third of people with chronic heart failure have sleep-disordered breathing with intermittent hypoxaemia at night, the value of oxygen for nocturnal hypoxaemia associated with sleep disordered breathing deserves further evaluation.

Based on the above evidence and a systematic review (Davidson and Johnson, 2011), it is recommended that oxygen should only be prescribed to patients with hypoxaemia for its survival effect in COPD and possibly symptomatic benefits in other life-limiting illnesses especially if people are relatively hypoxaemic. For non-hypoxaemic patients with life-limiting illnesses, the effectiveness of palliative oxygen for relieving breathlessness is similar to air and there is no evidence to support its routine use.

Opioids for breathlessness

In a study on 17 COPD patients undergoing treadmill exercise, the level of endogenous opioids released demonstrates the role of opioids in modulating breathlessness (Mahler et al., 2009). The blood beta-endorphin levels increased threefold from rest to end-exercise. Patients received either blinded naloxone or normal saline intravenously before crossing over in a subsequent study. The peak ratings of breathlessness and regression slope of breathlessness as a function of oxygen consumption were significantly higher with naloxone than normal saline. The effectiveness of opioids in relieving dyspnoea has been studied among people with cancer, COPD, and chronic heart failure.

Opioids for breathlessness in cancer patients

There were six RCTs on the use of opioids in cancer patients (Ben-Aharon et al., 2008). Two studies, reported by Mazocatto et al. (1999) and Bruera et al. (1993), compared subcutaneous morphine with placebo, showed improvement of dyspnoea with subcutaneous injection of morphine. Another two studies reported by Davis et al. (1996) and Grimbert et al. (2004) comparing nebulized morphine with placebo showed no significant difference between nebulized morphine and placebo. One study by Bruera et al. (1993) compared subcutaneous morphine with nebulized morphine reported no significant difference between the two routes. Lastly, Allard et al. (1999) studied the morphine dose adjustments for breathlessness control in patients who previously treated with opioid and found no significant difference in dyspnoea with 25% or 50% increments of morphine dosage.

Opioids for breathlessness in COPD patients

A systematic review by Jennings and colleagues on the use of opioids in the management of dyspnoea identified nine placebo controlled studies of oral or parenteral opioids and nine studies of nebulized opioids (Jennings et al., 2002). All nine studies on systemic opioids and three out of nine nebulized opioid studies were recruited for meta-analysis. Seven systemic and two nebulized studies were COPD studies. The meta-analysis on the subgroup of COPD studies showed a highly significant result in reducing dyspnoea (p = 0.004) with a standardized mean difference of −0.26. The nebulized opioid group failed to show positive effect (p = 0.31).

The strongest evidence was shown by a double-blind controlled trial by Abernethy et al. with 48 opioid naïve breathless patients (Abernethy et al., 2003). The majority of patients (87.5%) had COPD, who were assigned to receive 20 mg once-daily oral sustained-release morphine or placebo for 4 days, followed by 4 days of cross over. Participants of the morphine arm reported significant improvement in dyspnoea scores and sleep.

Opioids for breathlessness in chronic heart failure patients

There were three RCTs with two yielding positive outcomes and the other recent study with a negative outcome. The first double-blind randomized study was performed in 11 men with chronic heart failure who received either dihydrocodeine or placebo as a single dose (Chua et al., 1997). There was a significant fall in hypoxic and hypercapnic chemosensitivities with dihydrocodeine 1 hour after administration when compared to placebo, together with significant improvement in exercise duration and reduction in dyspnoea.

Another double-blind, cross-over RCT was performed by Johnson in ten patients with chronic heart failure (New York Heart Association (NYHA) class III/IV) (Johnson et al., 2002). Oral morphine 5 mg four times daily was given for 4 days, followed by a 2-day wash out period and then crossed over. There was significant reduction in dyspnoea and five patients were on morphine for 1 year upon follow-up.

A larger-scale RCT on 39 people with chronic heart failure (NYHA class III/IV) was reported (Oxberry et al., 2011). Oral morphine, oral oxycodone, and placebo were given for 4 days each, followed by a 3-day washout and cross over. Breathlessness severity was reduced from baseline with all three interventions, with no statistically significant difference between the two active interventions and placebo. With these conflicting results, the role of opioids for relieving dyspnoea in chronic heart failure requires further study.

Opioids for breathlessness in interstitial lung disease and amyotrophic lateral sclerosis patients

The use of low-dose nebulized morphine (2.5 and 5.0 mg) for relieving dyspnoea in severe interstitial lung disease was not supported by a single RCT with six patients as reported by a Cochrane review (Polosa et al., 2002). A recent RCT reported the effectiveness of nebulized morphine on dyspnoea of mustard gas-exposed bronchiolitis obliterans (Shohrati et al., 2012). A case series reported the effectiveness of 2.5 mg diamorphine in 11 elderly opioid naïve patients with terminal stage of idiopathic pulmonary fibrosis. Follow-up treatment with oral diamorphine remained effective in reducing dyspnoea and no patient showed signs of respiratory depression (Allen et al., 2005).

Morphine was shown to be effective in reducing dyspnoea in a single-arm study of six patients with terminal amyotrophic lateral sclerosis (Clemens and Klaschik, 2008). A significant decrease was seen in both respiratory rate and the intensity of dyspnoea at 120 minutes after morphine administration with no significant respiratory depression.

Opioids for incident or episodic breathlessness

Few RCTs have been performed for episodic breathlessness. A double-blind, cross-over RCT was performed by Charles et al. comparing nebulized hydromorphone, systemic hydromorphone, and nebulized saline in 20 patients (Charles et al., 2008). There were significant improvements in breathlessness before and after each treatment but no difference among three treatments. Oral transmucosal fentanyl has been reported to provide rapid relief of breathlessness in small observational studies (Gauna et al., 2008).

Long-term use of opioids for dyspnoea, opioid safety, and acceptance of opioids

The dosage of opioid and its usage for the long term was reported by a phase II dose increment and pharmacovigilance study by Currow et al. (2011). Sustained-release morphine at a dose of 10 mg daily was administrated to 83 opioid naïve patients with modified MRC dyspnoea scores of 3 or 4, and dosage was increased

in non-responders by 10 mg each week to a maximum of 30 mg daily. The dominant underlying causes of dyspnoea were COPD (54%), cancer (29%), and interstitial lung disease (12%). Sixty-two per cent of participants derived more than 10% benefit. For every 1.6 people commenced on morphine for chronic refractory dyspnoea, one person responded. For every 4.6 people commencing the study, one stopped the medication due to side effects that all reversed with cessation. The dose of morphine was 10 mg daily for 70% of participants, and the benefit was maintained at 3 months in 33% of all patients. There were no episodes of respiratory depression or hospitalizations as a result of the sustained-release morphine. The authors concluded that sustained-release oral morphine 10 mg once daily is safe and effective for most people.

Clemens investigated the effects of opioids on ventilation in two studies. Morphine or hydromorphone were titrated according to dyspnoea intensity in 11 dyspnoeic patients excluding COPD. Opioids produced a significant decrease in dyspnoea intensity at 30 and 90 minutes, but no significant respiratory depression as demonstrated by changes in oxygen saturation and transcutaneous arterial pressure of carbon dioxide ($TcPaCO_2$) (Clemens and Klaschik, 2007). Another prospective, non-randomized study involving 27 patients (25 people with cancer and two with amyotrophic lateral sclerosis) compared opioid-naïve palliative care patients to patients pretreated with strong opioids. No higher risk of respiratory depression or increase in $TcPaCO_2$ was observed in opioid-naïve patients (Clemens et al., 2008). The results of opioid safety from these reports are consistent with the Cochrane review by Jennings and colleagues, which showed that among 11 studies which collected post-opioid blood gases and/or oxygen saturation, there was no report of any significant desaturation, increased $PaCO_2$, and no excess mortality (Jennings et al., 2002).

In a recent qualitative study on use of opioids for dyspnoea involving eight patients, 12 caregivers, and 27 physicians, patients reported a sense of calm and relief from severe dyspnoea and substantial improvement in their QOL (Rocker et al., 2012). Family caregivers felt that opioids helped patients to breathe more 'normally', were effective in relieving patients' anxiety and depression as well as caregivers' own stress, and adverse effects were not a key concern. While all patients and family caregivers preferred to continue opioids, most physicians were reluctant to prescribe opioids for refractory dyspnoea.

Clinical use of opioids

There is clear evidence to support the use of systemic opioids for the control of breathlessness in patients with advanced cancer and COPD without causing excessive respiratory depression. The opioids studied include morphine, diamorphine, and dihydrocodeine. There is limited evidence to support the use of nebulized opioids for controlling breathlessness. The evidence for using opioids for controlling breathlessness in chronic heart failure is conflicting and requires further study. The use of opioids for breathlessness in other life-limiting illnesses such as interstitial lung disease and motor neurone disease are based on anecdotal reports.

There is no universally agreed starting dosage of opioids for the control of breathlessness. Factors to be considered include renal function, hepatic function, severity of pre-existing type II respiratory failure, the patient's frailty, body size, and the availability of nursing monitoring. Sustained-release morphine 10 mg daily has

been most systematically studied. In patients who are already taking opioids for pain control, an increment of 25% of the baseline dosage is supported by one previous study (Allard et al., 1999). Episodic breathlessness can be addressed by morphine given on an 'as needed' basis. The use of fast-acting opioids such as oral transmucosal fentanyl requires further study. Communication with patients and families on the indication and adverse effects of opioids is important for an informed choice and to address myths and concerns.

Pharmacological treatments with some evidence

Anxiolytics

The routine use of benzodiazepines for relief of breathlessness in patients with advanced cancer and COPD has not been supported by the Cochrane review on seven studies and meta-analysis on six studies (Simon et al., 2010). However, there were reports of successful use of benzodiazepines for the control of breathlessness in people with cancer with or without anxiety. One study reported the effective use of subcutaneous midazolam as adjunct therapy to morphine in the alleviation of severe dyspnoea in people in the last hours or days of life (Navigante et al., 2006). These patients had anxiety level correlated with their degree of dyspnoea. In another study, 63 patients were randomized to either oral morphine (starting dose 3 mg) or oral midazolam (starting dose 2 mg) with stepwise titration according to level of dyspnoea in initial in-clinic phase for recent acute onset breathlessness while causes were being investigated. In the subsequent 5 days of ambulatory phase, midazolam was superior to morphine in controlling baseline and breakthrough dyspnoea (Navigante et al., 2010). In another prospective, non-randomized study among people with cancer with dyspnoea associated with anxiety, a combination of morphine with lorazepam was shown to be effective in decreasing respiratory rate and dyspnoea intensity, without causing respiratory depression (Clemens et al., 2008). There may be a role for benzodiazepines for dyspnoea that is associated with anxiety. While the role of benzodiazepines in relieving breathlessness requires further evaluation, benzodiazepines are widely used (Booth et al., 2008).

Inhaled furosemide

Multiple mechanisms are proposed for the effects of inhaled furosemide in relieving breathlessness, including enhanced pulmonary receptor activity, suppression of the pulmonary irritant activity and vasodilation (Newton et al., 2008). The role of inhaled furosemide for relieving breathlessness has been studied in healthy subjects, and in patients with asthma, COPD, and advanced cancer. A systematic review by Newton et al. included 42 studies, of which 39 studies were RCTs (34 studies in asthma, eight studies in healthy subjects, four studies recruited both healthy subjects and asthma, one study in COPD) (Newton et al., 2008). Studies performed in people with cancer included one open clinical trial and one case series. Recently, two more RCTs were reported, one on COPD (Jensen et al., 2008) and one on advanced cancer patients (Wilcock et al., 2008). Overall, three RCTs are relevant to palliative care: two performed in COPD and one in advanced cancer. Both the COPD studies performed by Ong et al. (2004) and Jensen et al. (2008) showed effectiveness of inhaled furosemide in decreasing breathlessness when compared to placebo (Jensen et al., 2008; Newton et al., 2008). One study showed

significant bronchodilatation, and the other showed increase in exercise endurance. For people with advanced cancer, the study by Wilcock et al. showed no difference in breathlessness reduction or isometric arm exercise test in 15 patients (Wilcock et al., 2008). Inhaled furosemide may exert its effect on the airway and be useful in relieving dyspnoea due to airway diseases, but is not proven to be of benefit for breathlessness in cancer which involves multiple mechanisms.

Heliox

Helium has a low density and the potential of reducing the work of breathing and improving alveolar ventilation when nitrogen in air is replaced by helium. A systematic review has shown that Heliox can effectively improve exercise limitation, decrease the work of breathing, and reduce dyspnoea in people with lung cancer and COPD (Laude and Ahmedzai, 2007). In a phase II double-blind, randomized, cross-over, controlled study comparing Heliox28 (72%He/28%O$_2$) with oxygen-enriched air (72%N$_2$/28%O$_2$) on dyspnoea in lung cancer, Heliox28 was shown to be more effective than oxygen-enriched air in improving oxygen saturation, exercise capacity, and dyspnoea scores (Ahmedzai et al., 2004). Since there are individual variations in patients' responses to supplemental oxygen, breathing Heliox with supplemental oxygen may give additional benefits in patients who respond to supplemental oxygen alone. However, its cost and availability will continue to limit its use in clinical practice.

Pharmacological treatments with little evidence

Phenothiazines such as chlorpromazine, promethazine, and levomepromazine have been reported in small studies to provide relief of breathlessness in COPD patients with inconsistent results (Parshall et al., 2012). The management of depression is an important component in managing patients with chronic dyspnoea. However, the evidence of antidepressant in relieving dyspnoea is inadequate. Likewise there is insufficient evidence to support the use of indomethacin and inhaled topical anaesthetics to relief dyspnoea (Parshall et al., 2012).

Palliative non-invasive ventilation (NIV)

There are expanding roles of NIV as a form of palliative ventilatory support. The indication to use NIV for improving survival is well established in patients with acute COPD with type II respiratory failure, hypoxaemic cardiogenic pulmonary oedema, hypoxaemic respiratory failure in the immunocompromised host, and advanced neuromuscular disorders (Elliott, 2004). 'Palliative NIV' (Azoulay et al., 2011) has been used in do-not-intubate (DNI) patients, for dyspnoea palliation, and for prolonging life in terminally ill patients temporarily to meet patients' short-terms goals. In a 5-year follow-up of a 2-year cohort of 38 DNI patients who received NIV, 11 patients survived the hospital stay, four patients (10.5%) were still alive after 5 years (Bulow and Thorsager, 2009). NIV is widely delivered as a ceiling treatment for respiratory failure patients with a DNI order. In a survey on the use of NIV among DNI patients, 75% of physicians and respiratory therapists reported the use of NIV for DNI patients, with more in COPD or heart failure patients than in cancer patients (Sinuff et al., 2008).

Increasing numbers of people with severe respiratory compromise have been put on NIV in clinical practice. Four randomized controlled studies reported the use of NIV in relieving dyspnoea

in acute exacerbation of COPD (Smith et al., 2012). One study yielded negative result, the other three studies showed relief of dyspnoea by NIV but only two studies reported statistically significant relief (Smith et al., 2012). In one RCT, NIV was more effective compared with oxygen in reducing dyspnoea and decreasing the doses of morphine needed in people with end-stage cancer (Nava et al., 2013).

NIV is recommended as a standard of care to be offered to people with motor neurone disease with respiratory insufficiency. In a recent survey on the practice of NIV for motor neurone disease among neurologists in the United Kingdom, 612 patients were referred for NIV over 12 months, and 72.5% were successfully established on NIV (O'Neill et al., 2012). Three-quarters of responding neurologists accessed palliative care service towards patients' end of life. A collaborative approach between respiratory team and palliative care team is essential. NIV is a labour intensive procedure that requires skilled respiratory care, and can be burdensome to patients and their families. In the advanced care planning process with patients and their families, patients' concerns, goals, and overall QOL can be addressed in a holistic manner. The goals of treatment, and the benefits and burdens of NIV, should be constantly reviewed with the option of withdrawal of NIV especially towards the end of life.

Palliative sedation for refractory dyspnoea

Palliative sedation is defined as 'the administration of non-opioid drugs to sedate a terminally ill patient to unconsciousness as an intervention of last resort to treat severe, refractory pain or other clinical symptoms that have not been relieved by aggressive, symptom-specific palliation' (National Ethics Committee and Veterans Health Administration, 2006) (see Chapter 18.2). Agitated delirium, dyspnoea, and pain were the most common indications for palliative sedation. Such sedation has been delivered in inpatient and community settings. In a systematic review on six studies, palliative sedation for people with advanced cancer in the home setting had an incidence of 5–36%, with a mean duration of 1–3.5 days and no association with hastened death.

Cough in palliative care

Prevalence of cough

Cough is prevalent in cancer and in COPD (Kvale, 2006; Chung and Pavord, 2008). Cough was present in 42.9% of general cancer patients at treatment initiation (Molassiotis et al., 2010b) and in more than 65% of lung cancer patients at the time of diagnosis (Kvale, 2006). Prevalence of chronic cough and sputum also increases with age and smoking, and cough is present in 70% of people with COPD (Chung and Pavord, 2008). Cough can cause physical complications including chest wall pain, fracture of ribs, urinary incontinence, sweating, exhaustion, and disturbance of sleep. Patients may also experience psychological impacts, social embarrassment, and isolation (Molassiotis et al., 2011).

Function of cough

Cough comprises of three phases: the inspiratory phase with lengthening of expiratory muscles; the compression phase whereby the glottis is closed with building up of the intrathoracic pressure; and the expiratory phase to expel air at high velocity together with

dynamic compression of the airways, producing the characteristic sound of cough (Chang, 2006). Cough reflex protects the airway by clearing the inhaled materials, accumulated airway mucus secretion, and sputum. The efficiency of cough depends on the optimal function of the three phases of cough, mucus properties, and mucociliary clearance all of which may be affected in cancer or chronic lung diseases. Coughing effort is reduced in respiratory muscle weakness or mechanical disadvantage as in general debility, cachexia, steroid myopathy, gross ascites, or hepatomegaly, and neurological conditions affecting conscious level. Dynamic compression of the airway is affected by vocal cord paralysis, presence of tumour, and stent insertion. Changes in mucus properties occur in chronic inflammation or infection of the lungs and dehydration. In COPD, cystic fibrosis (CF) and chronic smokers, mucociliary action is impaired.

Regulation of cough

Cough reflex is modulated by vagal afferent pathways, including the rapidly adapting receptors (RARs) and the C fibres. The RARs are myelinated fibres activated by cigarette smoke, hypertonic saline, and other stimuli that evoke bronchoconstriction and obstruction (Chung and Pavord, 2008; Canning, 2011). The C fibres are non-myelinated fibres activated by capsaicin, bradykinin, protons (acid pH), but C-fibre dependent cough is prevented by anaesthesia. A new vagal afferent subtype distinct from RAR and C fibre, called the cough receptor, has been identified. Unlike C-fibre dependent cough, the cough receptor-dependent cough is not inhibited by general anaesthesia. It appears to be protective by evoking robust cough efforts in response to touch and acid (Canning, 2011).

The activation of these vagal afferents is dependent on expression of ion channels, the TRP vanilloid 1 (TRPV1) and TRP ankyrin 1 (TRPA1). Both are calcium-permeable, non-selective cationic channels belonging to the family of transient receptor potential (TRP) receptors. TRPV1 receptors are chemosensitive, activated by capsaicin, acid and endogenous inflammatory mediators. The TRPA1 receptors are not activated by capsaicin, but are sensitive to cold temperatures and activated by irritants present in air pollution, vehicle exhaust, cigarette smoke, and endogenous inflammatory mediators (Canning, 2011; Grace et al., 2012).

Afferent sensory nerves converge, interact, and synapse in the tract of the nucleus solitarius (NTS) in the brainstem before being transmitted to the cough centre, which coordinates the efferent cough response (Chung and Pavord, 2008; Canning, 2011). Upregulation and increased expression of TRPV1 are present in airway inflammation. Hypersensitivity and plasticity in brainstem and NTS plays a role in chronic cough. Higher cortical involvement is suggested by the phenomenon that the urge to cough can be voluntarily suppressed and placebo has a profound effect on cough.

Causes of cough in palliative care

Tumours are more likely to cause cough with involvement of airways than the lung parenchyma (Kvale, 2006). Cancer involvement of pleura, pericardium, mediastinum, pulmonary lymphatics, and blood vessels may cause cough, and airway hypersecretion is associated with chest infection or inflammation. People with advanced cancer are predisposed to swallowing problems and aspiration due to various factors, and may present with cough on feeding or at night, aspiration pneumonitis, or pneumonia (Bolser, 2010) (online Box 8.2.1). Conditions with hypersecretion of mucus are associated with cough (see section on airway secretion).

Non-cancer causes of cough in life-limiting diseases include respiratory conditions like COPD, asthma, bronchiectasis, interstitial lung diseases, and non-respiratory conditions like upper airway cough syndrome (UACS) which comprises of a variety of allergic, vasomotor, infectious, and anatomical rhinosinus conditions and gastro-oesophageal reflux disease (GORD) (Chung and Pavord, 2008; De Blasio et al., 2011) (online Table 8.2.4). Cough is significantly more prevalent in smokers.

Assessment of cough in palliative care

Despite the prevalence of cough and its appearance with other symptoms such as dyspnoea, insomnia, and fatigue in symptom clusters (Chen et al., 2011; Molassiotis et al., 2011), cough assessment is under-represented in research. A validated tool for cough for systematic assessment in palliative care is lacking (Molassiotis et al., 2010a; Leconte et al., 2011; Yorke et al., 2012). The clinical approach in cough assessment aims at evaluation of the cough symptom and the possible underlying causes. History, physical examination, and chest radiograph remain the mainstay in elucidating the underlying causes of cough.

The characteristics of cough should be defined from history taking, including associated sputum production, precipitating factors such as smoking, irritants, drugs, feeding, posture, association with timing of the day, and other associated symptoms such as dyspnoea, insomnia, choking, or fatigue. History of previous cancer treatment, smoking, use of angiotensin-converting enzyme (ACE) inhibitors, and concomitant chronic cardiac and lung diseases should be obtained. Visual analogue scale or visual descriptive scale (VDS) may be used for assessing intensity of cough but there are no validation studies. Cough monitors serve to provide objective cough counts. Cough-specific quality of life (EuroQol) questionnaires have been validated for assessing the impact of cough, such as the Leicester Cough Questionnaire, Cough Quality of Life Questionnaire, Burden of Cough Questionnaire, and Lung Cancer Cough Questionnaire (Molassiotis et al., 2010a; Leconte et al., 2011). While cough-specific QOL scores correlated well with cough counts, the relationship between VDS or visual VAS with cough counts or QOL scores are inconsistent (Molassiotis et al., 2010a). A lung function test can help in diagnosis of asthma or COPD. Sputum culture can guide antimicrobial treatment in chest infections. Application of other investigations including a CT scan looking for major airway obstruction has to be carefully considered if it will affect the ultimate management of patient. In patients with suspected aspiration or who fail the bedside swallowing test, referral to a speech therapist for comprehensive assessment should be considered.

Management of cough in palliative care

Evidence for cough treatment in advanced cancer has been disappointing, and the approach to cough in palliative care and lung cancer is formulated based on expert consensus and limited evidence (Molassiotis et al., 2010a; Wee et al., 2012). There is also no evidence to support efficacy of nurse-led management (Yorke et al., 2012). Management of cough in cancer can be categorized to

treatment for specific cancer and non-cancer causes, and modifying cough by enhancing clearance or suppressing cough.

Treatment for cancer related causes

Radiotherapy, chemotherapy, especially with gemcitabine, and endobronchial treatment may palliate cough due to tumours (Kvale, 2006). Thoracic radiotherapy is effective in relieving cough in around 50% of NSCLC, ranging from 20% to 80% (Kepka and Olszyna-Serementa, 2010; Reinfuss et al., 2011). The decision to deliver palliative radiotherapy involves consideration of tumour stage, pulmonary function, symptoms, the patient's performance status, and preference (Rodrigues et al., 2012). Data on cough relief by brachytherapy, laser, or photodynamic therapy are limited (Molassiotis et al., 2010b).

Steroids may be useful in reducing tumour-related oedema, airway obstruction, lymphangitis carcinomatosis, or radiotherapy- or chemotherapy-induced pneumonitis. A steroid trial may be recommended as an early step in the treatment pyramid for cough in lung cancer after considering disease-specific treatments (Molassiotis et al., 2010a).

Antimicrobial treatment is indicated for chest infections but its outcome may be poor in the presence of drug-resistant pathogens and frail patients especially near the end of life. In two recent surveys on antimicrobial prescription in people with advanced cancer near the end of life, empirical broad-spectrum antibiotics were given in 58.7% of patients in one study (Chun et al., 2010), while in another, about one-third of patients were prescribed more than one antibiotic (Abduh Al-Shaqi et al., 2012). There is a call for more careful consideration of antimicrobial use in these patients. Data on efficacy of antimicrobials in relieving cough from chest infection is limited, and in one study, physicians but not patients reported improvement in cough (Mirhosseini et al., 2006).

Treatment for non-cancer causes

ACE inhibitors should be discontinued and irritants of cough should be avoided if possible. When appropriate, considerations should be given to empirical treatment of the most common causes of cough, namely UACS, asthma, and GORD by a trial of first-generation antihistamine or decongestant, bronchodilators, and proton pump inhibitors respectively (Bolser, 2010; Wee et al., 2011). Steroids may be indicated for uncontrolled asthma, non-asthmatic eosinophilic bronchitis, and chronic interstitial lung disease. Antibiotics are indicated for infection precipitating exacerbations in chronic lung diseases.

Suppressing cough by antitussives

Cough suppression aims at symptomatic treatment in cases of dry cough or disturbing cough. Over-the-counter antitussives, often mixed with antihistamines or decongestants, have doubtful efficacy and adverse side effects such as sedation, nausea, and constipation, especially in children under the age of 2 (Ostroff et al., 2011).

Antitussives can be classified as centrally acting and peripherally acting. Most centrally acting antitussives are opioids that suppress cough primarily by the µ-opioid receptors in the central nervous system, while peripherally acting antitussives target the sensory afferents. Among the agents reviewed (Bolser, 2010; Molassiotis et al., 2010a; Wee et al., 2011), hydrocodone, dihydrocodeine, levodropropizine, benzonatate, and sodium cromoglycate have been specifically studied in cancer patients. Only

sodium cromoglycate has been evaluated in a double-blind, placebo controlled RCT.

Centrally acting antitussives

Slow-release morphine has been evaluated in a double-blind placebo-controlled study in patients with chronic persistent cough (Morice et al., 2007). Morphine sulphate given at 5–10 mg twice daily provided a significant improvement of 3.2 points over baseline on the Leicester Cough Questionnaire, and a rapid reduction by 40% in daily cough scores.

Hydrocodone is a codeine derivative with hydromorphone as one of the metabolites. Hydrocodone was studied in an uncontrolled phase II dose titration trial in 20 people with advanced cancer (Homsi et al., 2001). The median best response was a 70% reduction in cough frequency, achieved with a median hydrocodone dose of 10 mg/day. Hydrocodone may be given orally at 5–10 mg every 4–6 hours.

Codeine is a pro-drug that is metabolized by the liver to morphine, norcodeine, normorphine, and hydrocodone. Codeine has been regarded as the gold standard antitussive based on earlier reports, but a recent well-designed RCT did not find it more effective than placebo. Codeine is given at 10–20 mg orally every 4 hours as needed.

Dextromethorphan, a common over-the-counter antitussive, is a non-opioid with fewer side effects and more effect when compared with codeine in suppressing cough. It is administered orally as 10–20 mg every 4–6 hours. Dextromethorphan is metabolized in the liver by the cytochrome P450 isoform CYP2D6 and hence potential drug interaction should be noted.

Peripheral acting antitussives

Sodium cromoglycate, given at two puffs twice daily (total 40 micrograms/day), has been evaluated in a double-blind RCT involving 20 people with lung cancer. It significantly reduced cough when compared with placebo without serious side effects (Moroni et al., 1996). A trial of sodium cromoglycate is recommended by an expert group as a safe choice (Wee et al., 2011).

Levodropropizine, as reviewed for its efficacy for cough in cancer and chronic lung disease, was significantly more effective than placebo and equally effective as dihydrocodeine or moguisteine in reducing cough frequency and severity (Schildmann et al., 2011). Levodropropizine at 75 mg three times daily produces the same efficacy as dihydrocodeine 10 mg three times daily but is associated with less somnolence.

Benzonatate at doses of 100–200 mg three times daily has been reported to be useful for cancer cough in a case series (Doona and Walsh, 1998). The patient should be instructed not to chew the capsule to avoid any local anaesthetic effects in the oropharynx.

Moguisteine has been evaluated in a multicentre, double-blind, parallel group study involving 113 patients with chronic lung diseases and lung cancer (Barnabe et al., 1995). Moguisteine 100 mg three times daily, when compared with codeine 15 and 30 mg, three times daily, was as safe and as effective in suppressing cough (Aversa et al., 1993).

Gabapentin, as evaluated in a RCT for refractory chronic cough, significantly improved Leicester Cough Questionnaire scores as compared with placebo (between-group difference in LCQ score 1.80, 95% CI 0.56–3.04; p = 0.004; NNT of 3.58) (Ryan et al., 2012). Gabapentin is postulated to exert its effect on underlying central sensitization of the cough reflex.

Potential novel antitussives

Agents targeting the primary afferent nerves by inhibiting TRPV1 and TRPA1 have emerged as potential effective novel antitussive drugs. Several selective TRPV1 antagonists have been studied in phase I and phase II clinical trials (Grace et al., 2012).

Airway secretion

Mucociliary clearance (MCC) is a defence mechanism of the airway but may be overwhelmed by mucus hypersecretion. Secretory hyper-responsiveness is a feature of severe chronic lung diseases such as COPD and cancer due to underlying infection and inflammation. There is hypertrophy and hyperplasia of goblet cells and submucosal glands, associated with loss of ciliary function, destruction of surfactant layer, and alteration of mucus properties. Neutrophil-derived DNA and filamentous actin (F-actin), apoptotic cells, and bacteria contribute to purulence (Rogers, 2005). Cough clearance is more effective for higher-viscosity secretion while ciliary clearance is most effective with fairly low viscosity (Balsamo et al., 2010).

Excessive airway secretions can give rise to symptoms of cough, dyspnoea, or noisy breathing as seen in noisy breathing in the terminal phase of life. Mucus hypersecretion is also significantly associated with a more rapid decline in forced expiratory volume in 1 second and increased hospitalization of patients with COPD. Chronic cough and sputum in COPD are associated with poor outcomes (Rogers, 2005; Miravitlles, 2011).

Airway hypersecretion can be managed by treatment of underlying diseases, mucoactive agents, and non-pharmacological airway clearance techniques. Most experiences are derived from chronic lung diseases.

Mucoactive agents

Mucoactive agents act by increasing the ability to expectorate sputum and/or decrease mucus hypersecretion. Categories of mucoactive agents are shown in online Table 8.2.5, but they also overlap in their actions. Variable levels of evidence are provided by studies in people with severe chronic lung diseases (Rogers, 2005; Bhowmik et al., 2009; Bolser, 2010)

Nebulized saline is effective in CF in a dose-dependent manner (Jones and Wallis, 2003), and a lower concentration of 3% saline is safe in COPD (Miravitlles, 2011). Guaifenesin, though commonly available in various oral preparations, lacks an RCT to prove its effectiveness.

Carbocysteine is effective and safe in reducing exacerbations and improving QOL in Chinese COPD patients (Zheng et al., 2008). Beta-adrenergic agonists are used for improving mucus clearance by increasing ciliary activity, but studies give variable results (Rogers, 2005; Balsamo et al., 2010). Macrolides, acting as immuno-modulators of mucin gene expression, are used for hypersecretion, bronchorrhoea and CF. However, data in COPD patients are limited and safety of its long-term use awaits further studies (Martinez et al., 2008).

N-Acetylcysteine based on its mucolytic, antioxidant and anti-inflammatory properties, is a commonly used mucolytic in COPD. Doses used in various studies range from 400 mg/day to 1200 mg/day orally. However, the optimum dose and duration of its use remains to be defined. Mucolytics may produce a small reduction in acute exacerbations without significant adverse effects in COPD, but have little or no effect on lung function and the overall QOL (Poole et al., 2012). Dornase alfa, acting on polymerized DNA and F-actin network, is not effective for COPD but used for CF (Rogers, 2005; Balsamo et al., 2010).

Ambroxol 75 mg has been compared with placebo in an RCT on COPD. Post hoc analysis showed that subjects with more severe symptoms who were treated with ambroxol were more likely to be exacerbation-free through the study period (Malerba et al., 2004).

Airway clearance techniques

Airway clearance therapies (ACTs) include active cycle of breathing technique (ACBT), autogenic drainage, and forced expiration. Passive techniques include postural drainage and percussion. Studies of ACT in COPD have considerable methodological limitations with relatively small sample sizes (Osadnik et al., 2012). ACT use is safe but no significant long-term benefits on the number of exacerbations or hospitalizations, or any short-term beneficial effect on health-related QOL, has been reported (Malerba et al., 2004). A recent randomized controlled equivalence trial on the effectiveness of manual chest physiotherapy techniques on COPD also failed to show any additional benefit when compared with advice on chest clearance alone on QOL at 6 months after an exacerbation of COPD (Cross et al., 2012).

Bronchorrhoea

Bronchorrhoea is defined as production of more than 100 mL of watery sputum daily, well above the average of 25 mL (Lopez-Vidriero et al., 1975). Massive bronchorrhoea may occur in bronchioloalveolar carcinoma, metastatic cancer growing in a bronchioloalveolar pattern, chronic bronchitis, asthma, and bronchiectasis. The sputum in bronchorrhoea is typically mucoid, transparent, and topped by a thick frothy layer. Its property of increased viscosity on standing is distinguished from sputum production without bronchorrhoea and saliva (Lopez-Vidriero et al., 1975). Bronchorrhoea is associated with hypoxia, dyspnoea, exhaustion, chest pain, functional decline, and social limitation. Radiological features include diffuse consolidation, nodules, and solitary or localized lesions. These diagnoses have to be differentiated from pneumonia, pulmonary oedema, haemorrhage, and other lung infiltrates (Polo et al., 2001). Anecdotal reports of treatments include that of palliative radiotherapy, macrolides, anticholinergics, octreotide, steroids, inhaled indomethacin, and epidermal growth factor receptor tyrosine kinase inhibitor (Zylicz, 2010).

Noisy airway secretions in the last hours or day of life (death rattles)

Death rattles occur due to vibration of accumulated pharyngeal and pulmonary secretions in patients who are unconscious or semi-conscious and too weak to expectorate. Death rattles occur in 23–44% of terminal patients (Back et al., 2001; Morita et al., 2004; Wildiers and Menten, 2002), especially associated with lung cancer, pneumonia, and dysphagia. Very severe secretions occur in 4.5%. Death rattle is a strong predictor for death: 76% of patients died within 48h after onset in one study (Wildiers and Menten, 2002).

Previous studies on the use of hyoscine hydrobromide and glycopyrronium did not confirm the superiority of one over

the other (Lawrey, 2005). A systematic review of interventions for noisy breathing at end of life in 2008 failed to identify evidence in supporting the superiority of any anticholinergic agent or non-pharmacological treatment over placebo in a RCT (Wee and Hillier, 2008). Recently, a randomized trial was conducted in 333 terminal patients assigned to 0.5 mg atropine, 20 mg hyoscine butylbromide, or 0.25 mg scopolamine. Results showed no significant difference in effectiveness or survival among the three drugs. The study was not designed to show that this made a difference to the natural history of noisy breathing. For the three drugs, death rattle became non-disturbing or disappeared after 1 hour in 42%, 42%, and 37% of cases, respectively, and further improved to 76%, 60%, and 68%, respectively at 24 hours before levelling off. Treatment appears to be more effective when started at lower initial rattle intensity (Wildiers et al., 2009).

Patients may be positioned on one side. Gentle oral suction may be considered when secretions are in the oropharynx but the distress associated should not be overlooked. Death rattle may have a negative impact on staff, and some doctors and nurses may feel obliged to intervene despite the absence of any evidence that the natural history of noisy breathing is changed by medications (Wee et al., 2008). However, family members of dying patients may not be universally distressed by death rattle (Wee et al., 2006). Individualized treatment is recommended, taking into consideration the potential distress experienced by caregivers.

Haemoptysis

The volume of expectorated blood is often used to define the severity of haemoptysis, but there is no agreed cut-off point (see also Chapter 8.7). Various subjective terms have been used, describing haemoptysis as massive, major, exsanguinating, or life-threatening (Sakr and Dutau, 2010). Massive haemoptysis has been defined as the expectoration of more than 300 mL of blood in a single episode of haemoptysis (Qiu et al., 2009). Massive haemoptysis has also been defined as haemoptysis of over 500 mL within 24 hours, haemoptysis needing volume resuscitation, or haemoptysis causing airway obstruction and asphyxia.

However, the amount of expectorated blood used by other authors to define massive haemoptysis ranged from 100 to 1000 mL/24 hours (Sakr and Dutau, 2010). In untreated massive haemoptysis, 80% of patients may die (Sirajuddin and Mohammed, 2008). In addition to the amount of bleeding, other determinants of morbidity and mortality from haemoptysis include the rate of bleeding, underlying cardiopulmonary conditions, and the patient's ability to maintain patent airways (Sakr and Dutau, 2010).

Causes of haemoptysis, differential diagnoses

The bronchial arterial supply and, to a lesser extent, the non-bronchial systemic arterial supply are responsible for the majority of cases of massive haemoptysis. In a minority, massive haemoptysis may also arise from pulmonary vessels (Sakr and Dutau, 2010). The cause of death is usually asphyxiation.

The causes of haemoptysis include pulmonary infections such as tuberculosis, lung abscess or invasive pulmonary fungal infection, neoplasms, pulmonary conditions such as bronchiectasis and CF, cardiovascular causes, vasculitis, trauma, drugs, coagulopathy, and platelet disorders (Sirajuddin and Mohammed, 2008;

Sakr and Dutau, 2010). Haemoptysis occurs in up to 60% of CF patients over 18 years of age (Efrati et al., 2008). There is a small risk of pulmonary haemorrhage in patients with NSCLC treated by bevacizumab, a humanized monoclonal antibody against vascular endothelial growth factor (Reck et al., 2012). Often, the precipitating factor for haemoptysis is concomitant pulmonary infection, especially with *Pseudomonas aeruginosa* as the causative agent (Efrati et al., 2008). However, the precipitating cause for haemoptysis cannot be found in 15–30% (Sirajuddin and Mohammed, 2008). Fatal haemoptysis could also result from diagnostic or therapeutic procedures, such as transbronchial lung biopsy, lung radiofrequency ablation, or endobronchial high-dose brachytherapy (Carvalho Hde et al., 2005).

Clinical approach

Initial management of haemoptysis includes airway protection and volume resuscitation. The patient should be placed in a lateral decubitus position, with the bleeding side down. A detailed history should then be taken with complete physical examination, followed by laboratory investigations. Differential diagnoses include epistaxis, bleeding from the mouth or pharynx, haematemesis, and false haemoptysis (aspiration of blood) (Andersen, 2006). Baseline investigations include complete blood count, renal and liver function tests, prothrombin time, and activated partial thromboplastin time.

Localization of the site and source of bleeding may define the best treatment for stopping the bleeding. Chest radiograph can identify the site of bleeding in 33–82% of cases of massive haemoptysis, in the form of a mass, pneumonia, atelectasis, or cavitary lesion. Diffuse alveolar haemorrhage typically appears as alveolar infiltrates on chest radiography (Sirajuddin and Mohammed, 2008). Bronchoscopy plays an important role in localization of the anatomical site of bleeding, isolation of the involved airway, control of bleeding and treatment of the underlying cause of haemoptysis. In massive, life-threatening haemoptysis, rigid bronchoscopy, rather than fibreoptic bronchoscopy, is more efficient in ensuring airway patency, and maintaining ventilation and clearance of secretions to improve visualization. A fibreoptic bronchoscope can still be useful, being introduced through the rigid scope to access the upper lobes and peripheral bronchi (Sakr and Dutau, 2010).

CT thorax is comparable to bronchoscopy for detecting the bleeding site, but much more efficient for determining the cause of bleeding (Sakr and Dutau, 2010), such as the presence of bronchiectasis (Efrati et al., 2008). This is because CT can show distal airways beyond the reach of the bronchoscope, and the lung parenchyma (Sirajuddin and Mohammed, 2008). CT-guided transcutaneous biopsy of pulmonary lesions can be used to confirm invasive pulmonary fungal infections (Qiu et al., 2009). Multi-detector CT angiography is useful in evaluation of the integrity of pulmonary, bronchial and non-bronchial systemic arteries. CT, however, may have a limitation in differentiating a blood clot from a tumour.

Management

Management depends on the quantity of bleeding, urgency, and the patient's basic health status. A majority of patients respond well to conservative medical therapy, with or without blood transfusion. The effectiveness of various treatments is only supported by case reports.

Where possible, treatment should be directed at the underlying causes of the haemoptysis, such as oncological treatment, antibiotic, antituberculosis or antifungal therapy, and correction of coagulopathy. In CF, this may be due to malabsorption of vitamin K and liver cirrhosis (Efrati et al., 2008). Drugs such as non-steroidal anti-inflammatory agents or anticoagulant should be withheld.

Systemic treatment includes oxygen, oral or intravenous tranexamic acid (Sakr and Dutau, 2010), aerosolized vasopressin in the dosage of 5 units of orthnithine-8-vasopressin for mild and moderate haemoptysis (Anwar et al., 2005) and recombinant activated factor VII for massive haemoptysis (Lau et al., 2009).

Endobronchial treatment can be applied through the bronchoscope, including cold saline, epinephrine (adrenaline), tranexamic acid, antidiuretic hormone derivatives, such as terlipressin and ornipressin, fibrinogen-thrombin combination, factor XIII, and aprotinin. Endobronchial tamponade could be achieved with balloon, stent (Brandes et al., 2008), spigot, oxidized regenerated cellulose mesh, or biocompatible glue. Endobronchial tumours could be treated with laser photocoagulation, argon plasma coagulation, or electrocautery (Sakr and Dutau, 2010).

Indications for bronchial arterial embolization (BAE) include failure of conservative treatment, massive haemoptysis, recurrent haemoptysis, and poor surgical risk (Sirajuddin and Mohammed, 2008). Immediate control of haemoptysis has been reported in 57–100% of patients (Sakr and Dutau, 2010). Common complications of BAE include chest pain, fever (Efrati et al., 2008), transient dysphagia, groin haematoma, dissection or perforation of arteries (Sakr and Dutau, 2010), and contrast nephropathy (Sirajuddin and Mohammed, 2008). The most dreaded complications are neurological deficits, which could be reduced by cannulation of the target vessel beyond the origin of spinal branches (Sakr and Dutau, 2010). The mortality rate is 7.1–18.2%, considerably less than that of emergency surgery (40%) (Sirajuddin and Mohammed, 2008).

Surgery is reserved for cases of technical failure of arteriography, or when the patient is not fit for transfer to radiological intervention (Sakr and Dutau, 2010). Surgery is also performed when BAE has failed, such as in conditions resistant to embolization, for example, thoracic vascular injury or bronchial adenoma. On the other hand, if the patient is unfit for surgery, BAE may be the only treatment option (Noe et al., 2011). Surgery is also performed as a definitive treatment, to prevent recurrence, as in aspergilloma (Sakr and Dutau, 2010). When the patient is unfit for surgery, percutaneous treatment such as radiofrequency ablation of lung cancer has been used to control severe haemoptysis (Baisi et al., 2010).

Management of fatal haemoptysis

If a patient is at risk of massive haemoptysis, it is essential to establish an action plan in anticipation (see Chapter 8.7). This is a very uncommon way to die. The patient and family need to be informed, psychologically prepared, with possible treatment options discussed. Within the hospital setting, an 'emergency box' with the necessary drugs and towels in the ward will facilitate timely intervention of such crisis. If a massive life-threatening haemoptysis occurs, sedation to relieve the distress should be given as soon as possible. Midazolam 2.5–5.0 mg can be given intravenously as

the subcutaneous route will not provide relief quickly enough. Morphine can also lessen the dyspnoea and distress. A dark towel to cover the patient and dark basin for collecting blood helps to reduce the visual impact. The psychological impact of a patient dying from massive haemoptysis is enormous. Support and attention should be given to the family and people who witness the event. Debriefing and support should be provided to team members after the event.

Anaemia, cytopenias, and thrombosis in palliative medicine

Nancy Y. Zhu and Cynthia Wu

Anaemia and cytopenias

Introduction to anaemia and cytopenias

The illnesses, malignant or benign, that bring patients to a palliative care setting are often complicated by haematological problems such as anaemia, bone marrow failure, disseminated intravascular coagulopathy, and thrombosis. Supportive therapy for these problems can provide gratifying relief of symptoms and improvement in overall quality of life. This chapter emphasizes a practical approach to assessment and therapy intended to maximize quality of life.

Anaemia

Anaemia is present in 77% of men and 68% of women receiving palliative care (Dunn et al., 2003). Typical symptoms associated with a sudden drop in haemoglobin as seen with acute blood loss include tachycardia, orthostatic hypotension, and dyspnoea. If the onset of anaemia is more gradual, compensatory mechanisms can help lessen these symptoms by increasing the cardiac output, increasing plasma volume and shifting the haemoglobin dissociation curve.

Patients can often remain symptom free if mild to moderate anaemia evolves gradually. More commonly, however, a diminished overall well-being is seen manifesting as fatigue, decreased exercise capacity, and decreased appetite. Some patients can also complain of dizziness, headache, syncope, tinnitus, vertigo, and impaired cognitive function. Patients with underlying cardiac disease are more susceptible to anaemic symptoms as they are unable to compensate as readily (Mercadante et al., 2000).

Determining the cause of anaemia in the palliative care setting can be challenging, since the aetiology is often multifactorial. Disease-related causes include bone marrow infiltration, blood loss, haemolysis, and anaemia of chronic disease. Cancer-related treatment can also result in anaemia such as myelosuppression from chemotherapy and treatment-related myelodysplastic syndrome. Concomitant factors such as folate deficiency from malnutrition and gastrointestinal resections can also contribute to anaemia (Mercadante et al., 2000).

Anaemia of chronic disease

Anaemia of chronic disease (ACD) is a hypoproliferative anaemia caused by an immunological reaction to the presence of inflammation and malignancy. It results from the release of multiple cytokines from T cells and monocytes including interferon-gamma (INFγ), tumour necrosis factor α (TNFα), interleukin (IL)-1, IL-6, and IL-10. These cytokines stimulate the uptake into and storage of iron in macrophages and monocytes while also preventing the export of iron out of these cells. Hepcidin, a hepatic peptide stimulated by IL-6 and lipopolysaccharide, contributes to the retention of iron within the reticuloendothelial system. This results in a paradoxical situation of iron-deficient erythropoiesis occurring in a marrow replete with iron. Simultaneously, the cytokines also suppress the ability of the kidneys to produce erythropoietin, enhance red blood cell membrane damage, and prevent the differentiation and proliferation of red cell progenitors in the marrow. Together, erythropoiesis is reduced resulting in anaemia (Weiss and Goodnough, 2005).

The diagnosis of ACD is often based on the exclusion of other forms of anaemia but should always be considered in the palliative care setting. It is present in almost 50% of men and over 70% of women (Dunn et al., 2003). The anaemia is typically normocytic, normochromic, and is usually mild to moderate (80–95 g/L). The reticulocyte count will be low, reflecting a reduced marrow output. Serum iron studies can be helpful in differentiating ACD from iron-deficiency anaemia. Serum iron, total iron binding capacity (transferrin), and iron saturation are all low in ACD while total iron binding capacity is elevated in iron deficiency. Serum ferritin is a reflection of total body iron storage, and since iron stores within the reticuloendothelial system is abundant, ferritin is normal or elevated in ACD (Weiss and Goodnough, 2005).

Acute and chronic haemorrhage

Acute and chronic blood loss is common in a palliative patient, especially in gastrointestinal, head and neck, respiratory, uterine, and urinary cancers. Bulky sarcomas, hepatomas, melanomas, and ovarian cancers can bleed into the malignant masses as well (Mercadante et al., 2000). Even the loss of a few millilitres of blood a day can result in iron deficiency over time. In the early stage of iron deficiency, iron stores are low resulting in a reduced ferritin but normal serum iron, iron saturation, and haemoglobin levels. As iron deficiency worsens, serum iron and iron saturation falls but the haemoglobin is preserved. Anaemia is the end result of severe iron deficiency with the presence of microcytic hypochromic red blood cells. Abnormally shaped cells like target cells and pencil cells are seen as the severity of the iron deficiency advances (Beutler, 2010). In most cases, the chronic blood loss is obvious

from the presence of blood in bodily fluids, but occasionally tests for occult blood or endoscopic examination is necessary to determine the presence and site of the bleeding.

The first step in management of haemorrhage is to control the bleeding lesion if practical (see Chapter 8.7). This may be accomplished surgically, endoscopically, or by radiation of the bleeding lesion (Videtic, 2013). Iron supplementation should be started concomitantly if iron deficiency is present. Treatment can be provided either orally in the form of simple iron salts or parentally as iron–carbohydrate complex. The oral route is preferred as parenteral iron is associated with more severe adverse effects. The dosage for adults should provide 150–200 mg of elemental iron a day. This is ideally taken orally in three or four separate doses 1 hour before meals. Mild gastrointestinal side effects like nausea, heartburn, constipation, or diarrhoea are common. For these patients, changing to another form of iron or reducing the dose initially can be helpful (Beutler, 2010).

Parenteral iron is useful for patients who are intolerant of oral iron, have intestinal malabsorption issues, or may be losing iron more quickly than can be replaced with oral supplementation. The total dose required can be calculated by this formula:

$$\text{Dose of iron (mg)} = \text{whole-blood haemoglobin deficit (g/dL)} \times \text{body weight (lb)}$$

Iron sucrose contains 20 mg of elemental iron per millilitre and is recommended by the manufacturer to be administered at a maximum of 100 mg three times weekly. However, it has been safely given to chronic kidney disease patients at doses of 500 mg over 3 hours on 2 consecutive days. Typical adverse effects include hypotension, cramps, nausea, headache, vomiting, and diarrhoea (Beutler, 2010).

Iron dextran contains 50 mg of elemental iron per millilitre and is recommended by the manufacturer to be administered at a maximum of 100 mg per dose preceded by a 0.5 mL test dose. Larger doses are frequently used and considered safe with an increase in minor adverse effects. Iron dextran can result in a severe anaphylactic reaction occurring in less than 1% of patients. It is not dose dependent so can occur within the first few millilitres of the infusion. Typical presentation includes difficulty breathing, a choking sensation, becoming sweaty and anxious, nausea, and vomiting within the first few minutes of starting the iron dextran infusion. The infusion should be stopped immediately, resuscitation initiated, and epinephrine (adrenaline) be readily available. For patients with severe anaemia, transfusions may be necessary to help boost their haemoglobin. As each millilitre of blood contains 1 mg of elemental iron, blood transfusions will also help boost iron stores as well. Transfusion therapy is discussed later in this chapter in 'Transfusions in the palliative care setting' (Beutler, 2010).

Nutritional deficiencies

Cancer cachexia is seen in about half of all cancer patients, characterized by anorexia and loss of adipose tissue and skeletal muscle mass (Suzuki et al., 2013), leading to progressive nutritional deficiency (Segura, et al., 2005). The incidence of vitamin B_{12} deficiency was similar to that of the general elderly population at 7% but low serum folic acid level was significantly increased at 22%. Folic acid levels have been found to be an insensitive marker of occult folate deficiency, especially in those with weight loss. For example, 58% of patients with major weight loss in the palliative care setting have been found to have features of megaloblastic anaemia with a normal folate level (Dunn et al., 2003).

Folic acid is critical in the metabolism and DNA synthesis of all cells, especially cells that are highly proliferative including haematological cells. Fruits and vegetables are rich in folic acid and the recommended dietary intake for an adult is 0.4 mg. When folic acid intake is reduced to less than 5 micrograms, megaloblastic anaemia ensues in approximately 4 months. Folic acid is absorbed in the duodenum and proximal jejunum so patients with intestinal resections or masses involving this area are at high risk of developing megaloblastic anaemia.

Megaloblastic anaemia results in enlarged megaloblastic bone marrow precursor cells and consequently enlarged red blood cells increasing the red cell volume. Hypersegmented neutrophils with the presence of more than the usual three to five nuclei lobes are classically described in megaloblastic anaemia. All cell lines can be affected resulting in anaemia, thrombocytopenia, and/or neutropenia.

Dietary supplementation can be given orally, usually at a dose of 1 to 5 mg/day. Typically 1 mg a day is adequate to correct anaemia even if malabsorption is present (Green, 2010).

Bone marrow infiltration

While anaemia from metastatic cancer is most commonly related to anaemia of chronic disease, iron deficiency, or other nutritional deficiencies, bone marrow infiltration from metastatic disease can occur. All malignancies can metastasize to the marrow, but the most common are from the lung, breast, and prostate. While not common, the classic clinical picture is that of a leucoerythroblastic blood picture with the presence of immature nucleated red cells, myeloid white cell precursors, and teardrop-shaped red cells. A bone marrow biopsy can help to confirm the diagnosis but since the majority of metastatic malignancies with marrow involvement are incurable, it is oftentimes not clinically necessary (Agarwal and Prchal, 2010).

Mild to moderate marrow infiltration is often times asymptomatic with minimal blood count changes. With more significant marrow involvement, anaemia can be more severe and accompanied by an elevated white blood cell count. Platelets can be low, normal, or elevated. Treatment is focused at managing the underlying disease and symptom control.

Patients with haematological malignancies (Franchini et al., 2013) and bone marrow failure disorders like myelodysplastic syndrome (Foran and Shammo, 2012) have diseased marrows that are unable to produce adequate blood cells, often resulting in pancytopenia. While thrombocytopenia can result in easy bruising, it is unlikely to result in spontaneous bleeding at a platelet count of more than 20×10^9 or in fatal intracranial haemorrhage at a platelet count of more than 5×10^9 (Franchini et al., 2013).

Neutropenia

Neutropenia in the palliative setting is most commonly due to bone marrow failure from myelosuppressive chemotherapy, disease infiltration of the bone marrow, or from intrinsic bone marrow failure. The definition of neutropenia is defined as an absolute neutrophil count (ANC) less than 1500 cells/microlitre with severe neutropenia being ANC less than 500 cells/microlitre. Patients with neutropenia are at high risk of developing severe bacterial and fungal infections. The Infectious Diseases Society of America

defines fevers in neutropenic patients as a single oral temperature of greater than 38.3° Celsius or a sustained temperature of greater than 38.0° Celsius for more than 1 hour (Freifeld et al., 2011).

Patients at highest risk of severe febrile neutropenia are those with ANC less than 500 cells/microlitre for more than 7 days. Those with active comorbidities or significant hepatic or renal dysfunction are also considered to be high risk of severe bacterial infections.

Patients with prolonged neutropenia with ANC less than or equal to 100 cells/microlitre for more than 7 days should be considered for fluoroquinolone prophylaxis with levofloxacin or ciprofloxacin. In patients with fevers and neutropenia, the decision about management is dependent on the patient's values and disease stage. If life prolongation is deemed appropriate, then a discussion about the extent of investigation and management should be discussed on a per case basis.

Standard investigations for febrile neutropenia include complete blood cell (CBC) count with differential leucocyte count and platelet count, serum electrolytes, hepatic enzymes, total bilirubin, and creatinine. At least two sets of blood cultures are recommended, one from each lumen of a central venous catheter and one from a peripheral vein. Cultures from other sites should be taken as appropriate and a chest radiograph should be performed if respiratory findings are present.

High-risk patients with febrile neutropenia should be hospitalized for intravenous empiric antibiotic therapy with an anti-pseudomonal beta-lactam agent such as cefepime, meropenem, imipenem–cilastatin, or piperacillin–tazobactam. Vancomycin should be added for empiric treatment of suspected catheter-related infection, skin or soft-tissue infection, pneumonia, or haemodynamic instability. If fevers persist or new infectious symptoms develop, additional investigations and alterations in the antimicrobials may be necessary. Management should be guided by clinical microbiological data derived from investigations undertaken. Treatment is generally continued until neutrophil recovery (ANC ≥500 cells/microlitre) plus whatever duration is appropriate for the site of infection and organism identified. For patients without neutrophil recovery, antimicrobials should be continued until all signs and symptoms of a documented infection have resolved.

While hematopoietic growth factors such as granulocyte colony-stimulating factor (G-CSF) are frequently used to prevent infections associated with chemotherapy-related neutropenia, it is generally not used to prophylactically raise neutrophil counts in the palliative population. In addition, G-CSF is not recommended for routine use as adjuncts to antimicrobials in febrile neutropenia either. While the days of neutropenia, duration of fever, and length of hospital stay have been minimally reduced in some trials, no survival benefit has been seen.

Disseminated intravascular coagulopathy

Disseminated intravascular coagulopathy (DIC) results from an overproduction of procoagulants, which overwhelms the anticoagulant mechanism resulting in a systemic generation of intravascular microthrombi. Two-thirds of DIC cases are a result of underlying severe infection or malignancy (Levi and Seligsohn, 2010). The incidence of DIC in solid tumours is 7% but is much higher in acute leukaemia, up to 15–20%, which can increase further with chemotherapy treatment. Patients with acute promyelocytic leukaemia have a very high risk of DIC with more than 90% diagnosed at some point in the course of the disease (Levi, 2009). The risk of DIC increases with advanced age, more advanced stages of cancer, and the use of chemotherapy or anti-oestrogen therapy. Triggers for DIC include sepsis, immobilization, and liver metastases (Levi, 2013).

The production of intravascular microthrombi results in multi-organ failure, while the consumption of platelets, fibrinogen, and other coagulation factors increases bleeding. Hence, this results in a contradictory increased risk of both bleeding and clotting. Solid organ tumours are more prone to thrombosis while leukaemia patients are more prone to bleeding. Mucocutaneous bleeding is classic with cutaneous purpura, haemorrhagic bullae, oral and intestinal mucosal bleeding, and bleeding from intravenous sites. Other sites including intracranial haemorrhage, pulmonary haemorrhage, and haemorrhagic necrosis of the adrenals can also be seen. Ischaemic organ failure from microthrombi classically results in renal insufficiency, liver failure, intestinal ischaemia, cutaneous focal necrosis, acral gangrene, and respiratory failure. With severe DIC, cardiovascular shock can ensue (Levi and Seligsohn, 2010).

While DIC from infection and acute leukaemia typically presents very acutely, solid-organ cancer-related DIC can be more subacute and less fulminant with a more chronic presentation (Levi, 2009).

Laboratory findings classically reveal thrombocytopenia and prolonged prothrombin time/international normalized ratio (INR) or activated partial thromboplastin time and a suppressed fibrinogen level. Since fibrinogen acts as an acute-phase reactant and is elevated in the presence of infection or malignancy, it can remain within normal range despite an active DIC process. The most important diagnostic tool is to maintain a high clinical suspicion for DIC in patients with bleeding or clotting symptoms (Levi, 2013).

As the mainstay of treatment for DIC is supportive care while treating the underlying disease, its management becomes very difficult in palliative patients with incurable cancer. Prognosis is poor with a high mortality rate, especially with more severe DIC. Mortality rates range from 31% to 86% depending on the severity of DIC (Levi, 2013).

Supportive care of DIC in palliative cancer patients involve cardiovascular support and replacement of coagulation factors by using blood products. Cryoprecipitate contains large quantities of fibrinogen and factor VIII while fresh-frozen plasma helps replace the remaining coagulation factors. Platelet transfusions are sometimes necessary as well. In patients with clotting as the main presentation, anticoagulation should be initiated cautiously as the risk of bleeding is high (Levi, 2013).

Transfusions in the palliative care setting

The most common indication for blood transfusion in the setting of advanced cancer is fatigue and dyspnoea. Unfortunately, data regarding the relationship between fatigue and dyspnoea and the presence of anaemia remains controversial. In addition, there are currently no randomized controlled trials assessing the effectiveness of blood transfusions in this population. A Cochrane review found a subjective improvement in fatigue and dyspnoea at a rate of 31% to 70% with red blood cell transfusions (Preston et al., 2012).

Blood products are scarce and costly and hence use in the terminally ill evokes ethical discussions involving the principles of autonomy, beneficence, nonmaleficence, and justice. There are currently no guidelines on transfusions for palliative care patients, and each case should be assessed on an individual basis (Smith et al., 2013).

Red cell transfusion rapidly improves tissue oxygenation in the presence of anaemia or acute blood loss. Unfortunately, there is no evidence regarding red cell transfusions in the palliative population. Among non-palliative care patients, a Cochrane review comparing restrictive to liberal transfusion strategies did not find any adverse health outcomes and concluded that in patients without acute coronary artery disease, red cell transfusions is generally not necessary until haemoglobin levels approach 70–80 g/L as long as there is no evidence of bleeding (Carson et al., 2012).

Thrombocytopenia in the palliative setting is most commonly seen in patients with haematological malignancy and bone marrow failure. They can also be seen in advanced liver disease and splenomegaly. Platelet transfusions are scarcer and have a shorter duration of effect in raising the platelet count. They are generally indicated in patients with thrombocytopenia and active bleeding. Extrapolating from surgical patients, a platelet count above 50,000/microlitre should be adequate for bleeding control. Prophylactic platelet transfusions are considered for patients with platelet count less than 10,000/microlitre as they are at higher risk of severe spontaneous bleeding (Kaufman, 2013).

Blood cell transfusions like red cells and platelets have associated with it potential adverse events including transmission of blood-borne viral, bacterial, parasitic, and prion infections as well as transfusion reactions. With improved blood donor screening and blood testing strategies, the associated risks of receiving a transfusion-transmitted infection can been significantly reduced (Katz and Menitove, 2013).

Transfusion reactions range from frequent to rare, and from mild to severe (see Table 8.3.1). The most common are febrile reactions and mild allergic reactions. Febrile non-haemolytic transfusion reactions are likely related to cytokines released in response to antibody–leucocyte or antibody–platelet interactions. Fevers usually respond to antipyretics such as acetaminophen, which does not have the anti-platelet effect of aspirin and non-steroidal anti-inflammatory drugs. Prophylactic antipyretics are not necessary unless there is a history of febrile reactions. Rigor can be ameliorated with a small dose of meperidine, which can stop the symptom almost immediately. In patients with persistent febrile or allergic reactions despite premedication, hydrocortisone 1–2 hours before a transfusion can be used. Leucoreduction of blood products if available can significantly reduce the frequency of febrile reactions as well (Choate et al., 2013).

Mild allergic transfusion reactions are believed to be a result of plasma proteins in the blood products to which the patient has formed antibodies. They are quite common, occurring in approximately 1% of all transfusions. At the onset of pruritus and hives, the transfusion should be stopped and a dose of 25–50 mg of diphenhydramine given. Once the rash improves and the patient fells well without signs of fever, chills, or vasomotor instability, transfusion of the same unit can be re-initiated. In patients with frequent mild allergic transfusion reactions, pre-medication with diphenhydramine can be utilized (Choate et al., 2013).

Table 8.3.1 Types of acute transfusion reactions

Type of reaction	Presentation
Acute intravascular haemolytic	Fever, chills, dyspnoea, hypotension, tachycardia, flushing, vomiting, back pain, haemoglobinuria, haemoglobinaemia, shock
Acute extravascular haemolytic	Fever, indirect hyperbilirubinaemia, post-transfusion haematocrit increment lower than expected
Febrile non-haemolytic	Fever, chills
Allergic (mild)	Urticaria, pruritus, rash
Anaphylactic	Dyspnoea, bronchospasm, hypotension, tachycardia, shock
Transfusion-associated circulatory overload (TACO)	Dyspnoea, tachycardia, hypertension, headache, jugular venous distension
Septic	Fever, chills, hypotension, tachycardia, vomiting, shock
Transfusion-related acute lung injury (TRALI)	Dyspnoea, decreased oxygen saturation, fever, hypotension

Source: data from Choate, J. D. et al., Transfusion Reactions to Blood and Cell Therapy Products, in R. Hoffman et al. (Eds.), *Hematology: Basic Principles and Practice*, Sixth Edition, Elsevier Saunders, Philadelphia, USA, Copyright © 2013.

Transfusion-associated circulatory overload (TACO) results from excess fluid accumulation in the lungs. Transfused blood products rapidly increase a patient's intravascular volume and can exceed the ability of the cardiovascular system to compensate. Patients with pre-existing cardiovascular disease are especially at risk, and transfusing at a rapid rate in the absence of acute haemorrhage is an additional risk factor. Reducing the rate of transfusion in those at risk for fluid overload and the administration of diuretics before a transfusion can be preventative (Choate et al., 2013).

Acute intravascular haemolytic transfusion reactions are a result of the acute haemolysis of ABO incompatible red blood cells in a patient with the corresponding antibody. The reactions are very rapid, occurring within minutes after initiating the transfusion. The transfusion needs to be stopped immediately, cardiorespiratory support initiated, and a crystalloid solution infused to maintain a good urine output (Choate et al., 2013).

Erythropoietin-stimulating agents

Erythropoietin is a hormone naturally produced by the kidney and is an essential growth factor for red cell progenitors in the bone marrow. It is traditionally used to manage anaemia associated with advanced renal disease (Marks et al., 2013) but has become increasingly common in cancer-related anaemia as well. The use of erythropoietin-stimulating agents (ESAs) like epoetin and darbepoetin in patients on myelosuppressive chemotherapy has been shown to reduce the need for red cell transfusions, but can also increase the risk of hypertension, thromboembolic events, and death. There is some suggestion that ESAs may improve quality of life but the data is not definitive. Also controversial is whether ESAs worsen tumour control (Tonia et al., 2012).

The American Society of Hematology/American Society of Clinical Oncology 2010 guideline recommends that ESAs be

considered in patients undergoing myelosuppressive chemotherapy who have a haemoglobin level less than 100 g/L and cautions against ESA use under any other circumstances of cancer-related anaemia. They also recommend using the lowest ESA dose possible and targeting a haemoglobin level to avoid transfusions. If no response is seen after 6–8 weeks, the ESAs should be discontinued (Rizzo et al., 2010).

Venous thrombosis

Introduction to venous thrombosis

Venous thromboembolism (VTE) is a category of disease comprised of deep vein thrombosis (DVT) and pulmonary embolism (PE). Although venous thrombosis can occur in any site, the vast majority of what we know is focused on lower extremity DVT and PE. VTE is associated with significant morbidity and mortality. The link between cancer and thrombosis has long been established and was first described by French internist Armand Trousseau in 1865. Cancer patients experience a higher rate of VTE (Blom et al., 2006). It is estimated that one in 1000 adults per year develop VTE in the general population. About 15% of patients with cancer develop symptomatic VTE, 15–20% of patients with VTE have cancer, and about 10% of patients presenting with idiopathic VTE will develop cancer within a year (Lee, 2004). Cancer is also associated with both a higher rate of anticoagulant failure and a two- to sixfold higher rate of major bleeding (Palareti et al., 2000; Prandoni et al., 2002). Cancer patients with thrombosis also have a shortened life expectancy (Sorensen et al., 2000; Chew et al., 2006).

The pathophysiology of thrombosis in cancer is often complex and multifactorial but can be generally thought of in a simple framework developed in 1856 by the German physician Rudolf Virchow. Together, venous stasis, endothelial injury, and hypercoagulability are now commonly known as Virchow's triad. Large lymphadenopathy or tumours causing local compression, paralysis from spinal cord compression, and hospitalization from complications of cancer can contribute to venous stasis. Many chemotherapeutic agents, surgical interventions, and central venous access can contribute to endothelial injury. Cancer causes various procoagulant changes in the blood, including, for example, an increase in circulating levels of tissue factor, and thrombogenicity often depends on tumour type and stage (Otten et al., 2004; Lee et al., 2006).

VTE continues to be a significant problem throughout a cancer patient's care, from pre-diagnosis to diagnosis to treatment to palliation and death. Older studies carried out in a time when autopsies were done more frequently estimate that up to 50% of patients with cancer have VTE at the time of death. Despite recognizing this link between cancer and thrombosis, there is a paucity of data in the palliative care setting and there still remains the question of how aggressively we should try and prevent, diagnose, and treat thrombosis in the end stages of life.

Goals of VTE treatment

To help answer this question, it is important to understand what treatment of VTE accomplishes for patients. The initial phase is targeted at decreasing symptoms (leg swelling and pain, chest pain, shortness of breath), preventing clot extension, preventing embolic events, preventing early recurrence, and decreasing upfront mortality. Longer-term treatment is targeted at decreasing the risk of recurrent VTE and mitigating post-thrombotic symptoms (Lee, 2004). In most patients, the risk of haemorrhage is outweighed by the thromboembolic risk in the first few weeks to months after a new VTE is diagnosed and, in the absence of major contraindications, prompt investigations and initiation of treatment is usually recommended. Duration of treatment hinges on the fine balance between thrombotic complications and haemorrhagic complications, both of which can change over time (Noble et al., 2008).

Complications of VTE treatment

Treatment of VTE is based largely on anticoagulant therapy. Although new oral anticoagulant agents are being developed, none have currently been studied in the cancer or palliative setting. At present, the mainstay of treatment consists of administering a fast acting agent such as intravenous (IV) unfractionated heparin (UFH) or subcutaneous (SC) low-molecular-weight heparin (LMWH). This is frequently followed by initiation of oral warfarin therapy to target an INR of 2–3 for ongoing maintenance therapy. An overlap of about 5–7 days is required between the parenteral and oral medications as there is a delay in the onset of anticoagulant effect of warfarin.

More recent data has supported the ongoing use of LMWH rather than warfarin in cancer patients, particularly in those receiving active chemotherapy (Lee et al., 2005). Prophylactic anticoagulants for VTE prevention is mostly comprised of low-dose SC UFH or LMWH. All anticoagulants are associated with a risk of major or fatal haemorrhage. IV or SC modalities are additionally cumbersome for patients and may cause discomfort and decrease quality of life. Other considerations for those undergoing anticoagulant therapy include the need for continued monitoring of laboratory parameters including potentially INR, CBC count (to look for thrombocytopenia), and liver and kidney function tests.

Goals of palliative care

The line between active treatment and palliation can often be unclear. Palliative care is targeted at symptom control, maintaining quality of life and psychosocial supports, and decreasing suffering. In the treatment and prevention of VTE, there are many overlapping features. Although anticoagulant therapy is in part used to decrease mortality, much is also used to decrease clot burden and improve symptoms (McLean et al., 2010). Investigation for VTE will often require a hospital visit and potential need for admission. Administration of anticoagulant therapy, as described earlier, is associated with its own challenges (Soto-Cardenas et al., 2008; McLean et al., 2010). Given this, it is prudent to individually tailor treatment plans and care plans for different patients. For example, for a patient who is palliative but still ambulatory and living independently at home, it is very reasonable to consider investigation for and treatment of newly diagnosed VTE, or prophylactic anticoagulation in case of temporary immobilization, as controlling the complications of VTE can help maintain their state of independence.

At the extreme of life, a terminally ill patient who is bedridden and approaching death may benefit more from symptom control only, regardless of aetiology, rather than being subjected to hospital transport for further investigation, uncomfortable

administration of medications with frequent monitoring, and potentially the need for further intervention if complications such as bleeding occur (Tran, 2010).

Conclusions

Haematological complications are common and significant issues in cancer patients and those who eventually require palliative care. The complications of investigation and treatment make devising care decisions for such patients a challenging process. Frank and open discussions with each patient regarding the overall goals of care can help guide management. It is important to remember that a patient's status and thus these very goals will change over time and constant re-evaluation is essential. This will help shape plans that avoid unnecessary testing and intervention, as well as avoid depriving a patient of the compassionate care needed in the end of life.

Genitourinary aspects of palliative care

Olivia T. Lee, Jennifer N. Wu, Frederick J. Meyers, and Christopher P. Evans

Introduction to genitourinary aspects of palliative care

Patients receiving palliative care often face problems related to the genitourinary system, whether their primary disease is of urologic origin or not. Factors contributing to common genitourinary pathology in this setting include advanced and metastatic malignancy, chronic illness, neurodegenerative disease, prior radiation, chemotherapy, or surgery (Doherty and O'Sullivan, 2004; Wu et al., 2011) In particular, this chapter will focus on urinary tract obstruction (upper and lower tract obstruction), intractable bleeding, fistulae, and bladder-associated pain. Management of each process should take into account the patient's symptom severity, performance status, and life expectancy. Treatment options must weigh the benefits of a particular modality against the risks of intervention, with the goal of reducing suffering and improving quality of life. Common genitourinary surgical interventions in the palliative care setting are summarized in Table 8.4.1.

Lower urinary tract obstruction

Lower urinary tract obstruction in the palliative care setting can be due to benign or malignant disease. Primary urologic causes include benign prostatic hyperplasia (BPH), invasive prostate or bladder cancer, urethral stricture, or bladder neck contracture. Non-urologic causes include invasive gynaecological or colorectal malignancies. Symptoms of outlet obstruction include urinary retention, suprapubic pain, frequency, urgency, dysuria, and urinary tract infection. Untreated severe bladder outlet obstruction leads to bladder dysfunction, bladder stones, and kidney injury.

In the work-up of bladder outlet obstruction, a proper history will guide diagnosis and treatment. Prior radical prostatectomy would suggest bladder neck contracture, while prostate radiation therapy (brachytherapy or external beam radiotherapy) suggests urethral stricture. Prior endourologic procedures (transurethral resection of prostate (TURP), bladder tumour, direct vision internal urethrotomy (DVIU), urethral dilation) could suggest urethral stricture disease or BPH recurrence. In women, it is pertinent to know if there is a history of bladder suspension surgery or mid urethral slings. A neurologic history is important to rule out neurogenic causes of urinary retention, such as pelvic plexus injuries (pelvic trauma, abdomino-perineal resection, or low anterior resection) or systemic neurologic disease such as multiple sclerosis, Parkinson's disease, or multiple systems atrophy.

In severe bladder outlet obstruction, physical examination may reveal abdominal or suprapubic distension and tenderness. A digital rectal examination is appropriate to evaluate BPH, invasive and recurrent prostate cancer, or rectal masses. In women, a pelvic examination could reveal a vaginal, uterine, or adnexal mass. A urinalysis and urine culture will detect infection or microscopic haematuria. Performing a bladder scan to determine a post-void residual volume allows one to assess incomplete emptying and the amount of retention. A post-void residual volume greater than 90–100 mL is concerning for outlet obstruction. Formal urodynamic studies will provide more accurate information about bladder pressure, capacity, compliance, and risks of upper tract injury. Renal ultrasound may detect hydronephrosis and parenchymal thinning if obstruction is severe. Further imaging with computed tomography (CT) or magnetic resonance imaging (MRI) can aid in diagnosis of a pelvic or abdominal disease process or evaluate progression of a known disease. If one suspects concomitant neurogenic bladder dysfunction with outlet obstruction, urodynamic testing will help in deciphering the primary cause for incomplete emptying. Cystoscopy would aid in diagnosing a bladder mass or prostatic invasion. Prior to performing invasive diagnostic procedures, however, one must assess the utility of each in its role in guiding palliation of symptoms. For example, if a man has progression of known prostate cancer and evidence of incomplete emptying with a large volume post-void residual, then one could forego additional studies and proceed with catheter drainage. Lastly, in the setting of bladder outlet obstruction, one should rule out constipation or faecal impaction causing obstruction, as it is common in the palliative care population and is possible to treat.

Management of bladder outlet obstruction varies from pharmacologic therapy to catheterization (urethral or suprapubic), endoscopy, or major open surgery. Each approach depends on the source and aetiology of the obstruction. In the case of BPH, patients who have lower urinary tract symptoms that include frequency, urgency, weakened force of stream, sensation of incomplete emptying, dysuria, and evidence of retained urine, one would start an alpha-blocker, a 5-alpha reductase inhibitor, or both to improve emptying. The 5-alpha reductase inhibitors have minimal benefit improving obstruction from prostate cancer. In an acute episode of complete urinary retention, an indwelling urethral catheter or

Table 8.4.1 Palliative urologic procedures

Procedure	Indication	Anaesthesia
Suprapubic catheterization	Bladder outlet obstruction	General or spinal anaesthesia
Ureteral stents	Ureteral stricture Malignant extrinsic compression Retroperitoneal fibrosis	General anaesthesia
Percutaneous nephrostomy tube placement with or without ureteral occlusion	Ureteral obstruction or fistula Bladder haemorrhage	Conscious sedation or general anaesthesia
Intravesical instillation of formalin	Intractable haemorrhagic cystitis	General anaesthesia
Transurethral resection of prostate (TURP)	Bladder outlet obstruction from BPH or invasive prostate cancer	General or spinal anaesthesia
Direct vision internal urethrotomy (DVIU)	Urethral stricture	General or spinal anaesthesia
Cystourethroscopy, transurethral resection of bladder tumour (TURBT), fulguration, clot evacuation	Bleeding from bladder tumour	General or spinal anaesthesia
Urethral stent placement	Urethral stricture, non-healing urethra	General or spinal anaesthesia
Selective angioembolization	Intractable haemorrhage or urovascular fistula	Conscious sedation or general anaesthesia
Diverting ileal conduit	Pelvic malignancy obstructing bladder	General anaesthesia
Palliative cystectomy/palliative cystoprostatectomy	Intractable bleeding Invasive pelvic malignancy obstructing urine Chronic bladder pain	General anaesthesia
Palliative nephrectomy	Bleeding Pain from mass Recurrent infection	General anaesthesia
Fistula repair	Uroenteric or urovaginal/uterine fistulae	General anaesthesia

suprapubic catheter is required, followed by close monitoring of serum electrolytes and water losses due to post-obstructive diuresis. While post-obstructive diuresis (defined as > 200 cc/hour urine output) is most often self-limiting, in the patient who is unable to replace water losses enterally either due to altered mental status or physical barriers, support with isotonic intravenous fluids is required. After the acute episode of urinary retention, the goal is to transition the indwelling catheter to clean intermittent catheterization (CIC) if the patient is physically and mentally able and willing.

If patients continue to suffer from outlet symptoms despite medications or cannot tolerate catheter diversion, then surgical approaches should be considered. The common surgical intervention for BPH is TURP. For invasive prostate cancer, a 'channel TURP' is appropriate, in which a more limited resection is performed to avoid incontinence. If prior prostate radiation with external beam or brachytherapy was performed, endoscopic treatment with TURP or DVIU risks urinary incontinence and tissue non-healing and therefore should be carefully considered.

For urethral stricture disease, conservative measures include urethral dilation and indwelling urethral catheter or diversion using a suprapubic catheter. Endoscopic options include DVIU or placement of urethral stents. The role of urethral stents is limited to the bulbar urethra and remains controversial due to the high complication rate of urethral ingrowth, stent migration, encrustation, infection, and irritative voiding symptoms (De Vocht et al., 2003). Primary anastomotic or substitution urethroplasty should

have no role in the palliative care setting as urethral reconstruction is very involved and often requires multistage repair in a patient population with potentially compromised wound healing. Surgical treatment should be reserved for select patients who can tolerate an intervention and have a prognostic time course that would benefit from surgery. It is important to note that recurrence of obstruction is not uncommon, for cancer regrowth or stricture disease. Furthermore, complications from invasive procedures such as bladder or urethral injury, problematic bleeding, and electrolyte disturbances can occur. Thus, a thorough discussion must be held with the patient and family before proceeding and should only be considered if a patient cannot be managed with an indwelling urethral catheter, intermittent catheterization, routine urethral dilation, or suprapubic catheterization. In the setting of invasive pelvic masses that compress or invade the bladder outlet, pelvic irradiation or palliative surgery with urinary diversion using a bowel segment conduit with or without cystectomy/pelvic exenteration may be appropriate.

Urinary catheters and catheter-associated urinary tract infections

In choosing catheter type and technique, infection risk and the patient's functional capacity are important considerations (Cespedes and Gerboc, 2012; Niel-Weise et al., 2012). An indwelling urethral catheter is the most common method of relieving bladder outlet obstruction. When used chronically, however, indwelling catheters cause recurrent urinary infections, urethral

erosion, and irritative bladder symptoms. If given the choice, CIC is preferred over an indwelling urethral catheter; however, it requires patient compliance, mental capacity and physical dexterity, or it requires attentive nursing staff. If CIC is not a viable option, then indwelling suprapubic catheter is an alternative to urethral catheters. Suprapubic catheters reduce the risks of infection, urethral erosion, periurethral abscess, epididymitis, and urethral trauma (National Institute for Health and Clinical Excellence, 2003; Cottenden, 2009). It does, however, require surgery to place a suprapubic catheter and in the process, carries the risk of an anaesthetic, and injuring surrounding structures such as bowel. Again, a global assessment of the patient's clinical and psychosocial situation is necessary to decide whether a urethral catheter, intermittent catheterization, or suprapubic catheter will serve the patient best, while avoiding unnecessary risk.

The major risk of chronic indwelling catheters is urinary infection (Schaeffer and Schaeffer, 2012). Catheter-associated bacteriuria risk increases by 10% for each indwelling catheter day. This is in contrast to a 1–3% risk for each sterile or CIC (Warren et al., 1999). Note that asymptomatic bacteriuria associated with chronic catheters does not need treatment and routine urine culture is not necessary in patients with chronic catheters. Only symptomatic catheter-associated urinary tract infections (CAUTIs) require treatment with appropriate antibiotics. Symptoms such as fever, urgency, frequency, dysuria, and urine culture with at least 10^5 colony-forming units of no greater than two species of organisms warrant an infectious work-up (Centers for Disease Control and Prevention, 2012). Proper sterile technique with catheter placement and routine 3–4-week exchanges of indwelling catheters and clean technique for intermittent catheterization should be followed. In patients who develop recurrent, symptomatic CAUTIs, low-dose prophylactic antibiotics may be appropriate (Petronella et al., 2012). For patients who have problematic encrustation due to a chronic catheter, consider more frequent exchange of catheters or genitourinary irrigation using sterile saline or neomycin-polymyxin solution daily or twice daily, as needed.

Selection of catheter material is also important in the setting of chronic indwelling catheters, as infection, encrustation, allergy, and comfort vary. Among them, latex rubber and silicone are the most common materials. Silicone catheters (100% or silicone coated) are preferable for long-term use because they reduce the risk of encrustation and 100% silicone catheters are safe for patients who have latex allergy (Jahn et al., 2007; Cottenden, 2009; Gould et al., 2010). Silicone-coated latex catheters are softer than 100% silicone catheters and cause less discomfort. Silver alloy-coated and antibiotic-impregnated catheters are also available and have been found to reduce the risk of catheter-associated bacteria only in the short term (1-week) duration of use (Schumm and Lam, 2008; Tenke et al., 2008). In the long term (> 14 days), the silver alloy- or antibiotic-impregnated catheters have not shown benefit in reducing infection (Geng et al., 2012). Similarly, nitrofurazone impregnated catheters were found to reduce *Escherichia coli* and *Enterococcus faecalis* adherence to catheters; however, this effect was lost beyond 5 and 3 days of incubation, respectively (Desai et al., 2010).

Upper urinary tract obstruction

Upper tract obstruction involves the renal collecting system and ureters. Intraluminal sources of obstruction include masses (transitional cell carcinoma, fibroepithelial polyps), stricture, or stones. Extraluminal sources include pelvic or retroperitoneal malignancy, fibrosis, or prior radiation. Patients may present with flank pain, nausea, or vomiting. If untreated, ureteral obstruction can cause loss of unilateral or bilateral renal function, end-stage renal disease, pyelonephritis, or urosepsis.

If ureteral obstruction is suspected, preliminary studies should include urinalysis, renal ultrasound, and serum creatinine or an estimated glomerular filtration rate. If hydronephrosis is present and the source is known (i.e. progressive retroperitoneal or pelvic mass), then further diagnostic tests may not be necessary, and percutaneous nephrostomy tube can be placed to relieve obstructive pain and renal insufficiency. If the source is unclear and if a ureteral stent is considered, then additional imaging with CT urogram will help characterize the location and source of the ureteral obstruction. Further, nuclear renal function studies may be considered only if it will help guide treatment.

In the acute setting of obstructive uropathy, the patient's and family's wishes in regard to relief of obstructive pain and improvement of renal function must be addressed. If the patient and family wish to accept renal failure, then symptom relief with analgesics may be sufficient for palliation. In order to treat obstructive nephropathy, endoscopic procedures with a nephrostomy tube placed percutaneously or a ureteral stent placed transurethrally are common approaches. Benefits of a nephrostomy tube include sparing the patient an anaesthetic by having an interventional radiologist place it under conscious sedation and diverting the urine proximal to the source of obstruction. These tubes and stents require exchange every 3 months or calcifications and encrustation can become problematic. The placement risks include bleeding in patients with coagulopathy, vascular injury, perinephric hematoma, discomfort, and social stigma associated with an external drainage bag.

Ureteral stents also alleviate obstruction but have a higher failure rate due to inability to traverse the site of blockage, and if successful, external malignant compression leads to eventual obstruction despite a ureteral stent (Docimo and Dewolf, 1989; Chung et al., 2004; Kamiyama et al., 2011). Metallic stents have shown success in keeping ureters patent in the setting of malignant compression (Borin et al., 2006; Liatsikos et al., 2010). If a ureteral stent fails, then a percutaneous nephrostomy tube is required (Gasparini et al., 1991; Wilson et al., 2005; Allen et al., 2010). Stent placement requires a patient that is fit for general anaesthesia routinely every 3–4 months for exchanges and is associated with the risks of genitourinary trauma, bleeding, urinary extravasation, and infection. Ureteral stents are appealing because they are internal and not visible; however, patients and families should be counselled on the effects of colicky pain, frequency, dysuria, and pelvic pressure. Alternatives to urinary diversion in the face of malignant extrinsic obstruction include reducing the obstructive mass with appropriate chemotherapy, radiation, or debulking surgery.

Benign causes of ureteral obstruction, including stones, stricture, or retroperitoneal fibrosis can be managed similarly with ureteral stents or nephrostomy tubes. Attempts to definitively treat the source of obstruction in such scenarios will depend on the patient's competing comorbidities, life expectancy, and ability to tolerate the risks associated with intervention. In the case of obstructing ureteral stones, one could discuss treatment with shockwave lithotripsy or ureteroscopy and laser lithotripsy. In the

case of stricture, balloon dilation or laser endoureterotomy are reasonable options (Banner and Pollack, 1984). Ureterectomy and further reconstruction (i.e. ureteroneocystostomy, ureteroureter-ostomy) has an unlikely role in this setting due to the invasive nature and risk involved. Similarly, ureterolysis for retroperito-neal fibrosis is unlikely.

Intractable haematuria

Intractable haematuria in the palliative care patient can be difficult to control and may be life-threatening (see also Chapter 8.7). Depending on the source of bleeding, symptoms can be painful or painless, accompanied by lower urinary tract symptoms, clot retention, or infection. If untreated, patients will continue to have anaemia requiring frequent transfusions, clot retention, and secondary obstructive uropathy, and eventually haemorrhagic shock and death. Risk factors in this population include bleeding diatheses due to impaired synthetic function, anticoagulant medication, and poor wound-healing ability. Management depends on the aetiology and location within the upper or lower urinary tract (Garber and Wein, 1989).

For upper urinary tract bleeding involving the kidneys or ureters, sources include renal cell carcinoma, urothelial carcinoma, arteriovenous malformation, angiomyolipoma, haemorrhagic cysts, or metastatic disease. While rare, upper urinary tract communications with nearby vessels (ureterovascular, pyelovascular, and renovascular fistulae) can cause brisk bleeding and require quick intervention with transfusion, and angioembolization. Ureterovascular fistulae, although rare, occur with risk factors that are more common in the palliative care population, such as chronic ureteral stents, vascular stents, significant atherosclerosis, arterial aneurysms, or history of radiation. Renovascular or pyelovascular fistulae are usually iatrogenic after percutaneous kidney surgery (i.e. percutaneous nephrolithotomy). The clinician must have a high level of suspicion in order to detect this pathology, as presentation and diagnostic studies can be elusive.

General work-up of gross haematuria includes cystourethroscopy and upper urinary tract imaging with a CT urogram or retrograde pyelography. If the bleeding source is localized to a lesion in the collecting system, then ureteroscopy and endoscopic fulguration with or without excision is a reasonable approach. If bleeding recurs despite endoscopic treatment or if the source of bleeding is not amenable to endoscopic fulguration, then selective arterial embolization is recommended. In the setting of life-threatening haemorrhage, haemodynamic stabilization and blood transfusion should be followed quickly by angiography with selective arterial embolization. Any anticoagulants should be held until bleeding is controlled. Surgical exploration to control bleeding is an option if endovascular embolization is not possible. For bleeding renal masses that cannot be managed endoscopically or endovascularly, palliative nephrectomy or nephroureterectomy could be considered in very select patients.

For ureterovascular fistulae, control of the communicating vessel can be achieved by endovascular stenting, open reconstruction, embolizing, or ligating with or without arterial bypass (Rovner, 2012). Consideration must be taken for infection due to urine contamination, and treated as needed. Control of the urinary tract can be achieved via urinary diversion, least invasive of which would be placement of a nephrostomy tube with ureteral coiling. More involved and less feasible in this population includes open reconstruction to perform a uretero-ureterostomy, transuretero-ureterostomy, or cutaneous ureterostomy.

Lower urinary tract sources of haematuria include bladder tumour (urothelial or non-urothelial origin), haemorrhagic cystitis secondary to chemotherapy (cyclophosphamide and ifosfamide) or radiation, bleeding prostatic varices, or urethral trauma. First, anticoagulant medications should be held if possible, coagulopathies should be corrected, and blood transfusion should be performed in anaemic patients.

Initial management includes hand irrigation and continuous saline bladder irrigation with a large-calibre Foley catheter. For prostatic bleeding, gentle Foley catheter traction can help tamponade the source. Medical management with 5-alpha reductase (finasteride) or androgen deprivation can reduce prostatic bleeding in the long term (Sieber et al., 1998). Persistent prostatic or bladder bleeding refractory to conservative measures will require operative intervention to fulgurate sites of bleeding, resect bladder or prostatic tumour, and evacuate clots.

For persistent bladder bleeding from malignancy, radiation, or cyclophosphamide-induced haemorrhagic cystitis, epsilon aminocaproic acid (Amicar®) may be used in intravenous, oral, or intravesical form, to aid in clot formation (Stefanini et al., 1990). Patients on Amicar® should be monitored for rhabdomyolysis, a rare but serious adverse event reported in the literature. Those patients who are on therapy for greater than 24 hours should have routine tests for myoglobinuria, myoglobinaemia, creatine kinase, lactate dehydrogenase, aspartate aminotransferase, decreased muscle strength, and myalgia (Seymour and Rubinger, 1997). If bleeding is ongoing, then bladder irrigation with 1–2% alum (potassium or ammonium aluminium sulphate) or 1% silver nitrate can be effective (Goel et al., 1985). If renal insufficiency is present or bladder lesions allow a significant amount of alum to enter the vascular system, then serum aluminium levels should be monitored. Patients can typically tolerate these intravesical treatments and anaesthesia is not usually required.

For haematuria refractory to the above-mentioned agents, formalin instillation is very effective but carries a high toxicity risk, including severe lower urinary tract symptoms, incontinence, small capacity bladder, fibrosis, and perforation (Donahue and Frank, 1989; Ghahestani and Shakhssalim, 2009). Formalin at 2.5–4% concentration is instilled passively until half the bladder capacity is reached and then left in for 20–30 minutes. Then the bladder is irrigated continuously with normal saline. Since this procedure is very painful, general or regional anaesthesia is required. Prior to formalin instillation, vesicoureteral reflux must first be ruled out with an intraoperative cystogram. If reflux is present, balloon catheters should be inserted into the lower ureters and the patient placed in reverse Trendelenburg position to prevent formalin reflux and subsequent upper tract damage (Sarnak et al., 1999). The effect of intravesical instillations can be maximized with urinary diversion (percutaneous nephrostomy tubes and ureteral occlusion) in order to minimize the effects of urokinase, a clot inhibitor present in urine (Sneiders and Pryor, 1993; Zagoria et al., 1993; Russo, 2000).

An alternative to intravesical agents in the treatment of haematuria from a malignant source includes radiation therapy. In one study, up to 59% of patients with advanced bladder cancer had resolution of haematuria and 73% had pain reduction after
Fig. 8.4.1 Simplified palliative treatment algorithm for bleeding and pain of bladder origin, including malignant and benign conditions. All of the treatment steps are not required. Some treatments will be bypassed depending on the severity of the symptoms.

treatment (Srinivasan et al., 1994). In another study, complete palliation of locally advanced bladder cancer was found in 43% of patients (Salminen, 1992). Although bladder and bowel complications are possible, radiation therapy is generally well tolerated. Chemotherapy has not been as well studied for palliation of pain or bleeding in advanced bladder cancer.

If conservative methods fail, embolization or surgical ligation of hypogastric arteries may be required. Palliative cystectomy with urinary diversion such as an ileal conduit should only be considered if all other options have failed or are not feasible, as it is the most invasive treatment associated with the greatest morbidity. The various treatments and recommended algorithm for intractable haematuria are depicted in Fig. 8.4.1.

Urinary tract fistulae

Risk factors that contribute to vesicoenteric and vesicovaginal fistulae (VVF) are common to the palliative care patient, such as advanced malignancy, prior pelvic surgery, radiation, poor nutrition, poor wound-healing ability, and infection (Rovner, 2012). Common causes specific to vesicoenteric fistulae are colon malignancies, diverticulitis, and Crohn's disease. Similarly, gynaecologic malignancies and pelvic inflammatory disease contribute to VVF. Symptoms of fistulae involving the urinary tract include pneumaturia, urinary tract infection, suprapubic pain, and incontinence. Faecaluria, diarrhoea, and tenesmus are associated with vesicoenteric fistulae. Vaginal leakage can be significant in VVF. Untreated, these symptoms lead to rash, skin breakdown, ulcers, chronic infection, and sepsis.

Diagnostic studies include pelvic examination, urinalysis, contrast imaging with a CT cystogram, CT urogram (to detect ureterovaginal or ureteroenteric fistula), CT scan with rectal contrast, or MRI. Endoscopy with cystoscopy and colonoscopy may also help confirm the diagnosis. Goals of palliative management of urinary fistulas include symptom management and containment of urinary leakage. Spontaneous closure is rare. These goals can be achieved conservatively with diversion of urine using a Foley or suprapubic catheter or bilateral nephrostomy tubes with or without permanent ureteral occlusion (Gupta et al., 2009). Surgical diversion with an ileal conduit or formal fistula repair are more involved and only appropriate in select patients. For vesicoenteric fistulas, a diverting colostomy or the use of rectal stents may temporize symptoms (Harford et al., 2008). Depending on the severity of the fistulae, conservative measures may or may not alleviate symptoms.

Pelvic and bladder pain

Pelvic and bladder pain can cause significant distress with symptoms of suprapubic pressure, urgency, or dysuria. The aetiology of bladder and pelvic pain will dictate the treatment approach. Diagnostic work-up includes drawing a urinalysis and culture, pelvic exam, imaging with X-ray and ultrasound to evaluate for obstructing urolithiasis or bladder stones. A CT scan or MRI is indicated to better identify abdominal or pelvic masses. Cystoscopy can be performed to identify an intravesical mass, bladder stone, or fistula. If the patient has a known malignancy as the source of pelvic pain, extensive work-up may be unnecessary.

Invasive pelvic masses cause pain due to the loss of bladder capacity and compliance, leading to high filling pressure, urgency, frequency, incontinence, and infection. Extrinsic compression on the bladder can cause similar lower urinary tract symptoms. Initial treatment includes placement of a urethral catheter to facilitate drainage. Ongoing bladder pressure and spasms despite drainage could be treated with analgesics, antimuscarinic medication, or belladonna and opium suppository. Urinary diversion with nephrostomy tubes could further alleviate symptoms of voiding dysfunction; however, it *may not* address pain from mass effect.

Neuropathic pain caused by mass compression onto the lumbosacral plexus can be treated medically with analgesics, antidepressants, or antiepileptics (Jaeckle et al., 1985; Rigor, 2000).

Radiation, chemotherapy, or surgery is appropriate in very select patients, to reduce the size of the mass. Transurethral resection of invasive prostatic or bladder malignancy could be considered as well. Alternative treatment of pain from cystitis includes oral pentosan polysulphate sodium (Elmiron®). Intravesical agents include dimethyl sulphoxide, heparin, and hyaluronic acid, which have variable success. Management of haematuria related to radiation cystitis is addressed earlier in this chapter.

Conclusion

Genitourinary problems are not uncommon in the palliative care setting and can become more severe as a patient's disease state progresses. Diagnostic tests and management approaches need to be tailored to each patient's clinical and social situation. Selection of tests and treatment modalities should be based on using the least invasive means to achieve the most relief in suffering. Some genitourinary conditions in this setting are potentially fatal, such as urinary tract haemorrhage and renal failure, and in the acute or subacute setting, require re-evaluation of the end-of-life goals and wishes of the patient and family.

Oral care

Andrew N. Davies

Introduction to oral care

Epidemiology

Oral symptoms are common in patients with advanced cancer (see below) (Davies and Epstein, 2010). Most patients have at least one symptom, and many patients have several symptoms. Oral symptoms are also common relative to other symptoms in patients with advanced cancer (Davies and Epstein, 2010). Indeed, xerostomia (dry mouth) is consistently ranked as one of the five most common symptoms in this group of patients.

Investigators have found disparities between the recorded prevalence of certain oral symptoms and the true prevalence of these oral symptoms in patients with advanced cancer (Shah and Davies, 2001). These disparities probably relate to service-related factors (e.g. inadequate oral assessment procedures), professional-related factors (e.g. perception that these symptoms are unimportant), and patient-related factors (e.g. perception that other symptoms are more important).

Oral problems are also common in other groups of patients with life-limiting illnesses (and more generally in patients with chronic illness) (Davies and Finlay, 2005). For example, the reported prevalence of oral problems in a study of patients with Parkinson's disease was as follows: xerostomia—55%; loose dentures—31%; sore gums—23%; ulcers—17%; bleeding gums—12%, burning sensation—10%; loose teeth—8%; sore teeth—5% (Clifford and Finnerty, 1995). Similarly, the reported prevalence of oral problems in a study of patients with multiple sclerosis was as follows: orofacial paraesthesia—37%; orofacial pain—30%; taste disturbance—23%; orofacial muscle spasm/palsy—17%; difficulty chewing—8% (Fabiano, 1983).

Aetiology

Oral problems may be related to:

- Direct ('anatomical') effect of the primary disease
- Indirect ('physiological') effect of the primary disease
- Treatment of the primary disease
- Direct/indirect effect of a coexisting disease
- Treatment of the coexisting disease
- Combinations of the above factors.

One of the most important causes of oral problems is the indirect ('physiological') effects of the primary disease. Thus, patients often develop physical problems (e.g. fatigue), which impedes their ability to undertake oral hygiene measures. Moreover, patients often develop psychological problems (e.g. depression), which further affects their ability/motivation to undertake oral hygiene measures (Friedlander and Mahler, 2001).

Clinical features

Oral problems are a significant direct cause of morbidity in palliative care patients. Table 8.5.1 shows the severity of oral symptoms, whilst Table 8.5.2 shows the distress caused by oral symptoms, in an advanced cancer population (Davies, 2000b). Moreover, oral problems can lead to a more generalized deterioration in a patient's physical state, and also in their psychological state (Rydholm and Strang, 2002). Oral problems are also an indirect cause of mortality in palliative care patients (i.e. oral colonization/infection leading to systemic infection) (Mandel, 2004).

Assessment

The assessment of oral problems is essentially similar to the assessment of other medical problems. It involves taking a history, performing an examination, and the use of appropriate investigations (Birnbaum and Dunne, 2000). Many of the oral assessment tools that are used in palliative care are not validated for use in this clinical setting (and indeed are not appropriate for use in this clinical setting) (Davies, 2005).

A wide range of investigations are used in everyday clinical practice (Birnbaum and Dunne, 2000), but only some of these investigations will be relevant in patients with advanced cancer (e.g. microbiological testing). The decision to perform an investigation will depend on the nature of the problem (important or not), the nature of the investigation (invasive or not), the likely outcome of the investigation (management altered or not), and the condition/prognosis of the patient (Davies, 2005).

Management: general principles

The successful management of oral problems involves adequate assessment, appropriate treatment, and adequate re-assessment. The aims of assessment are to determine the nature of the problem, and factors that may influence the choice of treatment: inadequate assessment may result in the use of ineffective or inappropriate interventions. The aims of re-assessment are to determine the response to the treatment (i.e. efficacy of treatment, tolerability of treatment): inadequate re-assessment may result in the continued use of ineffective or inappropriate interventions (and ongoing morbidity from the oral problem).

The treatment of oral problems may involve definitive management of the problem ('cure'), symptomatic management of the

Table 8.5.1 Severity of oral symptoms in patients with advanced cancer (Davies, 2000)

Symptom (N = 120)	'Slight'	'Moderate'	'Severe'	'Very severe'
Dry mouth (n = 93)	14%	37%	33%	16%
Mouth discomfort (n = 55)	40%	29%	22%	9%
Change in the way food tastes (n = 53)	30%	45%	19%	6%
Difficulty speaking (n = 37)	40%	30%	19%	11%
Difficulty swallowing (n = 28)	46%	29%	14%	11%
Difficulty chewing (n = 27)	41%	41%	11%	7%
Mouth sores (n = 17)	59%	35%	6%	0%

problem ('palliation'), management of the cause of the problem, and/or management of the complications of the problem. Whilst there may be a range of options for management in everyday practice, there may be fewer options for management in patients with advanced cancer. The decision to undertake a treatment depends on a number of factors, including the nature of the problem, the nature of the treatment, the availability of the treatment, the general health/condition of the patient, and, particularly, the wishes of the patient.

In some cases the most appropriate treatment for a patient with advanced cancer is the same treatment that would be given to a patient with early cancer (or no cancer). Thus, intensive treatment of the oral problem often results in the best palliation of the oral problem. It is not justified to withhold treatment on the grounds that the patient has advanced cancer. However, it may be justified to amend treatment (when appropriate). For example, the standard treatment for a poorly fitting denture involves fabrication of a new denture. However, in patients with a poor performance status, an alternative treatment for a poorly fitting denture would involve re-lining of the old denture (Walls, 2005).

Management: multidisciplinary working

Oral care/problems should be the concern of all clinical members of the core palliative care multidisciplinary team (MDT). Dental professionals are important members of the extended palliative care MDT (i.e. dentists, dental hygienists). They have a number of key roles, including (a) training of other members of the MDT, (b) management of specific oral problems (e.g. dental caries), and (c) management of complex oral problems (in combination with other members of the MDT). Many dental procedures can be performed in the home or hospice setting, although such 'domiciliary dentistry' requires specialized skills and appropriate equipment (Walls, 2005).

Other members of the MDT team will, of course, have a major role in the management of certain oral problems (e.g. speech and language therapists, dieticians).

Management: evidence-based practice

Oral care in palliative care is frequently based on historical anecdote, rather than on available research evidence. Hence, many patients continue to receive relatively ineffective treatments for their oral problems (e.g. ice cubes for xerostomia), whilst some patients continue to receive entirely inappropriate treatments for their oral problems (e.g. vitamin C tablets for 'dirty mouth'). However, there is a wealth of evidence for the efficacy of various interventions in the non-palliative care population, and increasingly in the palliative care population (Davies and Finlay, 2005; Davies and Epstein, 2010).

Oral hygiene

Maintenance of good oral hygiene is important for the maintenance of good quality of life in patients with cancer and other life-limiting illnesses (Sweeney and Davies, 2010).

Dental care

Toothbrushing

The single most important oral hygiene measure is toothbrushing, which should be undertaken at least twice daily (Sweeney and Davies, 2010).

A wide range of toothbrushes is available, including powered ('electric') toothbrushes. It is recommended that a small-headed brush, which has soft-to-medium texture bristles is used. 'Ultra-soft' toothbrushes can be used for patients whose mouths are sore; such toothbrushes include baby brushes and specialist brushes, for example, TePe® Special Care toothbrush. Powered toothbrushes with a rotation-oscillation action appear to be better at removing dental plaque than manual toothbrushes (and other types of powered toothbrushes) (Robinson et al., 2005).

The recommended life span of a toothbrush is about 3 months, but it should be replaced sooner if the filaments of the brush become softened and/or misshapen. (At this stage the brush is no longer effective at removing dental plaque). Toothbrushes should be replaced sooner if the patient is immunosuppressed or receiving chemotherapy. Furthermore, toothbrushes should be immediately replaced if the patient has experienced any type of oral infection.

Patients should use toothpaste containing at least 1000 ppm fluoride. Most toothpaste contains a foaming agent, which may prove problematic for those patients who have difficulty swallowing (and who are at risk of aspiration). In these cases, a non-foaming alternative should be used (e.g. Biotene® toothpaste, chlorhexidine gel). If patients cannot tolerate the use of toothpaste (due to oral discomfort), then they can simply use water during toothbrushing.

Interdental cleaning

Interdental aids are designed to remove dental plaque from the areas between teeth that cannot be reached by a toothbrush. Ideally, some form of interdental cleaning should be used on a daily basis (Sweeney and Davies, 2010), although this may not be achievable or appropriate for some patients. The types of cleaning aids available include dental floss, dental tape, wood sticks, and interdental brushes.

Chemical plaque control

For some patients, mechanical control of dental plaque is extremely difficult because of their level of debilitation and/or the presence of oral pathology. In such cases chemical control of dental plaque may be considered for maintenance of oral hygiene (Sweeney and Davies, 2010).

Currently the most effective anti-plaque agent is chlorhexidine (Jones, 1997). The chlorhexidine molecule has a positive charge at either end, and binds readily to negatively charged sites on the dental enamel pellicle, mucosal cells, and bacterial cells. Chlorhexidine is slowly released from such surfaces, so maintaining its antimicrobial activity (a property known as substantivity).

Chlorhexidine is used most commonly as a 0.12–0.2 % mouthwash (10–15 mL twice a day), although it is also available as a 1% gel and a 0.2% spray in certain countries. Indeed, there are no indications for using chlorhexidine more than twice a day (see earlier). It is important to realize that chlorhexidine will not remove established dental plaque—this must be physically removed by a dentist or dental hygienist.

The most common side effect associated with long-term use of chlorhexidine is staining of the teeth and the dorsal surface of the tongue. The tooth staining can easily be removed by a dentist or dental hygienist. Other problems include the taste of the mouthwash, and the alcohol content of some mouthwashes (which may cause mucosal discomfort). These problems may be overcome by diluting the mouthwash with up to an equivalent volume of water (Axelsson and Lindhe, 1987).

Denture care

Denture hygiene must be carried out regularly and should be incorporated into a daily oral care routine (Sweeney and Davies, 2010). It should is done at least once per day (preferably at night). All dentures must be cleaned outside the mouth, and the soft tissues of the mouth cleaned separately (see below).

The denture should first be held under running water to remove debris, and then be brushed thoroughly with a large toothbrush, denture brush, or personal nailbrush to dislodge any remaining debris or plaque. Commercial products are available for cleaning dentures, but soap and water, or water on its own, is usually satisfactory. Ordinary toothpaste should not be used, because they are quite abrasive and may damage the polished surface of the denture. The denture should be rinsed well before placing it back in the patient's mouth.

Dentures should ideally be rinsed under running water after every meal, and the lining of the mouth checked for food debris before re-inserting the dentures. Calculus ('tartar') may form on the smooth surfaces of a denture as a result of deposition of calcium from the saliva. Calculus may irritate/damage the underlying oral mucosa, and should be professionally removed as soon as it is noticed.

In order to maintain a healthy oral mucosa, it is advisable to leave dentures out of the mouth overnight. Plastic dentures should be soaked in a dilute solution of sodium hypochlorite (1 part Milton® sterilizing fluid to 80 parts water). This allows disinfection of the denture, and reduces the likelihood of denture stomatitis. Dentures with metal parts should be soaked in chlorhexidine (0.12–0.2% solution), since sodium hypochlorite can potentially damage the metal parts.

Care of the oral mucosa

The oral mucosa should be cleaned three to four times per day, ideally after each meal (Sweeney and Davies, 2010). For those patients who are able, rinsing the mouth with water is adequate to remove any debris. For those who are unable to rinse, the mucosa should be cleaned mechanically with a water-moistened gauze or foam stick.

Salivary gland dysfunction

Xerostomia is 'the subjective sensation of dryness of the mouth', whilst salivary gland hypofunction is 'any objectively demonstrable reduction in either whole and/or individual gland flow rates' (Davies, 2010a). Salivary gland dysfunction (SGD) has been defined as 'any alteration in the qualitative or quantitative output of saliva caused by an increase (hyperfunction) or decrease (hypofunction) in salivary output', although SGD is more often used as an umbrella term to describe patients with xerostomia and/or salivary gland hypofunction (Davies, 2010a).

Epidemiology

The prevalence of xerostomia is 22–26% in the general population (Davies, 2010a), whereas the prevalence of xerostomia is 78–82% in patients with advanced cancer (Davies et al., 2001; Tranmer et al., 2003). Similarly, the prevalence of salivary gland

hypofunction has been reported to be 82–83% in patients with advanced cancer (Chaushu et al., 2000; Davies et al., 2002b). SGD is common in patients with other life-limiting conditions, and indeed in patients with many chronic conditions (Davies and Finlay, 2006)

Aetiology

There are numerous causes of SGD in the oncology population, with the most common cause being drug treatment (Davies et al., 2001). SGD is a side effect of many of the drugs used in day-to-day practice, including many of the drugs used in supportive and palliative care (e.g. analgesics, antiemetics) (Sreebny and Schwartz, 1997). Other causes of SGD include: (a) cancer related, for example, tumour infiltration, paraneoplastic syndrome; (b) cancer treatment-related, for example, radiotherapy, graft-versus-host disease; and (c) other causes, for example, dehydration, malnutrition, anxiety, and depression (Davies, 2010a).

Xerostomia is usually the result of a decrease in the volume of saliva secreted (i.e. salivary gland hypofunction). However, xerostomia may also result from a change in the composition of the saliva secreted.

Clinical features

The clinical features of SGD are very variable, and reflect the differing functions of saliva (Davies, 2010a). SGD is associated with a number of oral problems, but is also associated with more generalized problems. Indeed, SGD is associated with a significant negative impact on quality of life (Rydholm and Strang, 2002):

◆ General problems—oral discomfort, lip discomfort, cracking of lips

◆ Eating-related problems—anorexia, taste disturbance, difficulty chewing, difficulty swallowing, decreased intake of nutrition

◆ Speech-related problems—difficulty speaking

◆ Oral hygiene—poor oral hygiene, halitosis

◆ Oral infections—oral candidosis, dental caries, periodontal disease, salivary gland infections

◆ Systemic infections—secondary to oral infection (e.g. pneumonia, septicaemia)

◆ Dental/denture prosthesis problems—dental erosion (leading to dental sensitivity/trauma to oral mucosa)

◆ Psychosocial problems—embarrassment, anxiety, depression, social isolation

◆ Miscellaneous problems—sleep disturbance, difficulty using oral transmucosal medication (i.e. sublingual/buccal medication), oesophagitis, urinary frequency (secondary to increased intake of fluid).

It is important to emphasize that there may be a discrepancy between the symptoms experienced by patients and the signs identified by health-care professionals. The classic signs of salivary gland hypofunction include dryness of the oral mucosa, dryness of the lips, absence of a pool of saliva in the floor of the mouth, fissuring of the oral mucosa (especially of the tongue), and cracking of the lips. However, patients with xerostomia, and some patients with salivary gland hypofunction, may have no obvious abnormalities on examination.

Assessment

A wide range of investigations may be employed in the management of SGD in the general population (Davies, 2010a). Some of these investigations are used to diagnose SGD (e.g. measurement of salivary flow rates), whilst other investigations are used to determine the cause of the SGD (e.g. detection of auto-antibodies). However, most of these investigations are not indicated in the assessment of SGD in the oncology population. Indeed, a diagnosis of SGD can invariably be made on the basis of routine clinical skills, that is, taking a history and performing an examination (Navazesh et al., 1992).

Management

SGD is a heterogeneous condition, and so requires individualized management (Davies, 2010a). The management of SGD depends on a variety of different factors, including the aetiology/pathophysiology of the SGD, the clinical features of the SGD, the general condition of the patient, the dental status of the patient, the treatment preferences of the patient, the availability of specific interventions, and the affordability of specific interventions. The management of SGD involves a number of different strategies, including (a) treatment of the cause of SGD, (b) symptomatic treatment of SGD, and (c) the treatment of the complications of SGD.

The symptomatic treatment of SGD involves the use of saliva stimulants (agents that promote saliva secretion) and saliva substitutes (agents that replace missing saliva) (Davies, 2010a). There are good reasons for prescribing saliva stimulants rather than saliva substitutes. Thus, saliva stimulants increase the secretion of 'normal' saliva, and so will ameliorate xerostomia and the other clinical features of SGD. In contrast, saliva substitutes, which are very different from normal saliva (i.e. physically, chemically), will usually only ameliorate xerostomia. Moreover, in studies that have compared saliva stimulants with saliva substitutes, patients have generally expressed a preference for the saliva stimulants (Bjornstrom et al., 1990; Stewart et al., 1998). Nevertheless, some patients do not respond to treatment with saliva stimulants, and so will require treatment with saliva substitutes (e.g. some patients with radiation-induced SGD).

Saliva stimulants

Chewing gum

Chewing gum increases salivary flow by two mechanisms; approximately 85% of the increase is related to stimulation of chemoreceptors within the oral cavity (i.e. taste effect), whilst approximately 15% of the increase is related to stimulation of mechanoreceptors in and around the oral cavity (i.e. chewing effect).

Chewing gum has been reported to be effective in the management of xerostomia in various groups of patients, including advanced cancer patients with drug-induced SGD (Davies, 2000a). Moreover, chewing gum has been reported to be more effective than organic acids and artificial saliva in studies involving mixed groups of patients with SGD (Bjornstrom et al., 1990; Stewart et al., 1998). Patients with SGD should use 'sugar-free' chewing gum, and patients with dental prostheses should use 'low-tack' (less sticky) chewing gum.

Chewing gum is generally well tolerated. However, side effects can occur, and may be related to (a) chewing, for example, jaw discomfort, headache; (b) inappropriate ingestion, for

example, respiratory tract obstruction, gastrointestinal obstruction; (c) non-allergic reactions to additives, for example, oral discomfort, flatulence; and (d) allergic reactions to additives, for example, stomatitis, perioral dermatitis. Chewing gum is an acceptable form of treatment for most patients, including most elderly patients (Davies, 2000a).

Organic acids

Various organic acids have been used as saliva stimulants, including ascorbic acid (vitamin C), citric acid (the acid in citrus fruits), and malic acid (the acid in apples and pears). Organic acids increase salivary flow through stimulation of chemoreceptors within the oral cavity.

Ascorbic acid has been reported to be relatively ineffective in a study involving a mixed group of patients with SGD (Bjornstrom et al., 1990). Thus, only 33% of the patients rated ascorbic acid as either 'good' or 'very good', and only 23% of patients wanted to continue with it after the study.

Studies suggest that citric acid can provide symptomatic improvement for some groups of patients with SGD, although not patients with radiation-induced SGD. However, in the study by Stewart et al., only 24% patients expressed a preference for the citric acid product, compared with 46% for the chewing gum and 30% for the artificial saliva (Stewart et al., 1998).

Malic acid has been reported to be relatively more effective in a study involving a mixed group of patients with SGD (Bjornstrom et al., 1990). Thus, 51% of the patients rated malic acid as either 'good' or 'very good', and 44% of patients wanted to continue with it after the study.

The use of organic acids is associated with the development of oral discomfort. Thus, organic acids should not be used in patients with dry mucosae, cracked mucosae, stomatitis, and/or mucositis. Moreover, the use of organic acids may be associated with the exacerbation of certain pH-related complications of SGD (i.e. demineralization of the teeth, dental caries, oral candidosis). Thus, organic acids should not be used in patients with teeth, and should be used with caution in patients with dental prostheses.

Parasympathomimetic drugs

Parasympathomimetic drugs stimulate the part of the autonomic nervous system responsible for the secretion of saliva from the salivary glands. The parasympathomimetic drugs include choline esters (e.g. pilocarpine, cevimeline) that have a direct effect, and cholinesterase inhibitors (e.g. distigmine, pyridostigmine) that have an indirect effect by inhibiting the metabolism of endogenous acetylcholine.

Pilocarpine has been reported to be effective in the management of SGD due to salivary gland disease (e.g. Sjögren's syndrome), drug treatment (Davies et al., 1998), radiotherapy (Davies and Shorthose, 2007), and graft-versus-host disease. Indeed, it has been reported to be more effective than artificial saliva in the management of SGD secondary to drug treatment (Davies et al., 1998), and radiotherapy (Davies and Singer, 1994).

The side effects of pilocarpine are usually related to generalized parasympathetic stimulation, and include sweating, headache, urinary frequency, and vasodilatation. The incidence of side effects is dose related, that is, the higher the dose of pilocarpine, the higher the incidence of side effects. A systematic review found that few (6%) patients with radiotherapy-related SGD discontinue

pilocarpine due to side effects at the standard dose of 5 mg three times daily (Davies and Shorthose, 2007).

The other choline esters that have been used in clinical practice include bethanechol, carbacholine, and cevimeline (Davies, 2010a). Bethanechol has been reported to be effective in the management of drug-induced SGD, and of radiotherapy-induced SGD. Similarly, cevimeline has been reported to be effective in the management of Sjögren's syndrome, radiotherapy-induced SGD, and graft-versus-host disease. The cholinesterase inhibitors that have been used in practice include distigmine and pyridostigmine (Davies, 2010a).

Acupuncture

Acupuncture has been reported to be useful in the management of SGD secondary to benign salivary gland disease, drug treatment, and radiotherapy, Nevertheless, a recent systematic review concluded that (at present) 'there is no evidence for the efficacy of acupuncture in the management of xerostomia', and stated that 'there is a need for future high quality randomized controlled trials' (Jedel, 2005).

Saliva substitutes

Water

Patients often use water to treat dryness of the mouth. However, in studies, patients have reported that water is less effective than 'artificial saliva'. Moreover, in one study, patients reported that the mean duration of improvement of dryness of the mouth was only 12 minutes (range 4–29 minutes) (Olsson and Axell, 1991).

In spite of this, many patients choose to use water rather than other saliva substitutes. The reasons for this phenomenon include familiarity, efficacy (moderate), tolerability, availability, and affordability. The use of water is not associated with side effects per se, although polydipsia is inevitably associated with polyuria (and nocturia).

It should be noted that there is no scientific rationale, and indeed no research evidence, to support the use of chilled or frozen water (i.e. ice chips, ice cubes).

'Artificial saliva'

It is common practice for health-care professionals to prescribe 'artificial saliva' for the treatment of SGD. A number of commercial products have been developed, which differ in formulation (e.g. spray, gel, lozenge), lubricant (e.g. carboxymethylcellulose, hydroxyethylcellulose, mucin), and additives (e.g. flavourings, fluoride, antimicrobial factors).

The 'ideal' artificial saliva should be easy to use, pleasant to use, effective, and well tolerated (Davies, 2010a). Moreover, it should have a neutral pH (to prevent demineralization of the teeth), and contain fluoride (to enhance remineralization of the teeth). Unfortunately, some commercial products have an acidic pH, and these should definitely not be prescribed in dentate patients, and should probably not be prescribed in any patient with SGD.

It should be noted that most of these commercial products have not been formally tested in any group of patients with SGD. However, there are positive studies in the literature involving patients with advanced cancer of a specific mucin-based artificial saliva (Sweeney et al., 1997; Davies et al., 1998; Davies, 2000a).

Artificial saliva is generally well tolerated, although some patients report local problems (e.g. oral irritation, taste

disturbance), whilst some patients even report systemic problems (e.g. nausea, diarrhoea). The duration of effect of artificial saliva is invariably short, which necessitates the repeated use of these products during the day and night. Indeed, the short duration of effect is one of the main reasons why patients do not continue to use artificial saliva. In an attempt to overcome this problem, a number of investigators have developed intra-oral artificial saliva reservoirs. Reservoirs can be incorporated into new (purpose-built) dental prostheses, or into existing (standard) dental prostheses. Moreover, reservoirs can be incorporated into bite guards that may be worn throughout the day, or simply at night-time.

Sialorrhoea

Sialorrhoea has been defined as 'an excessive secretion of saliva' (Davies, 2010b). Sialorrhoea is not synonymous with drooling, although patients with sialorrhoea may also experience drooling. The symptomatic management of sialorrhoea is similar to the symptomatic management of drooling (see 'Drooling') (Davies, 2010b).

Drooling

Drooling has been defined as 'abnormal spillage of saliva from the mouth on to the lips, chin and clothing' (Davies, 2010b). Drooling is usually not related to sialorrhoea, but is related to difficulty in retaining saliva within the mouth (secondary to facial weakness/deformity) and/or removing saliva from the mouth (secondary to dysphagia). Indeed, many patients with drooling have salivary gland hypofunction rather than sialorrhoea. The symptomatic management of drooling includes anticholinergic drugs (e.g. oral or nebulized glycopyrronium bromide, transdermal or nebulized hyoscine hydrobromide), botulinum toxin A, parasympathetic nerve ablation, and salivary gland duct relocation (Davies, 2010b).

Tenacious saliva

The strategies used to manage tenacious saliva include treatment of any SGD (see earlier), treatment of any dehydration (and encouragement of drinking), oral rinsing (e.g. soda water, sodium bicarbonate), humidification, and dietary manipulation (e.g. avoidance of milk, avoidance of caffeine) (British Columbia Cancer Agency, n.d.). Other strategies have been reported to be effective in patients with non-malignant diseases, include drinking of fruit juices (e.g. dark grape, pineapple) (Anonymous, 2000), and treatment with beta blockers (Newall et al., 1996).

Taste disturbance

Taste disturbance occurs as a result of a reduction in taste sensation (hypogeusia), an absence of taste sensation (ageusia), or a distortion of normal taste sensation (dysgeusia) (Ripamonti and Fulfaro, 2010). The prevalence of taste disturbance has been reported to be 44–50% in patients with advanced cancer (Shorthose and Davies, 2003; Tranmer et al., 2003). Taste disturbance is relatively common in patients with cancers of the head and neck region, and extremely common in patients that have received radiotherapy to the head and neck region.

There are a variety of different causes of taste disturbance in patients with cancer (Ripamonti and Fulfaro 2010): (a) cancer related, for example, damage to taste buds, damage cranial nerves, damage to central nervous system (CNS); (b) cancer treatment related, for example, local surgery, local radiotherapy, systemic chemotherapy; (c) oral problems, for example, SGD, poor oral hygiene, oral infections; (d) neurological problems, for example, damage cranial nerves, damage to CNS; (e) metabolic problems, for example, malnutrition, zinc deficiency, renal dysfunction; (e) miscellaneous, for example, ageing, menopause, drug treatment.

Patients may complain of a single taste problem (e.g. ageusia for all foods), or a combination of taste problems (e.g. hypogeusia for some foods, dysgeusia for other foods). For example, in a study involving patients with advanced cancer and taste disturbance, 40% reported ageusia, 31% reported hypogeusia, and 53% reported dysgeusia (Davies and Kaur, 1998). Patients with dysgeusia may report a variety of different sensations, but invariably report that food tastes unpleasant. Taste disturbance can lead to other physical, psychological, and social problems, which, in turn, can lead to a further deterioration in quality of life (Rydholm and Strang, 2002; Hutton et al., 2007). For, example, impairment of taste may be associated with anorexia, decreased nutritional intake, and weight loss.

The assessment of taste disturbance involves taking a history, performing an examination, and undertaking appropriate investigations. However, it is usually not necessary to undertake an objective assessment of the taste disturbance (i.e. measure taste acuity). The management of taste disturbance involves treatment of the underlying cause, dietary intervention, zinc therapy, and/or other (anecdotal) therapies (Ripamonti and Fulfaro 2010). In some cases it may be possible to treat the underlying cause of the taste disturbance, for example, SGD. Indeed, studies have shown that saliva stimulants improve both the xerostomia, and the associated taste disturbance (Davies and Singer, 1994). Nevertheless, in many cases, it is not possible to identify and/or treat the underlying cause of the taste disturbance.

Dietary intervention involves (a) utilization of foods that taste 'good'; (b) avoidance of foods that taste 'bad'; (c) enhancing the taste of the food (using salt, sugar, and other flavourings); and (d) addressing the presentation, smell, consistency and temperature of the food (Twycross and Lack, 1986; Komurcu et al., 2001). Ideally, a dietician should review all patients with taste disturbance, since dietary intervention requires an individualized approach. Studies of zinc therapy in various patient groups have produced conflicting results (Ripamonti and Fulfaro, 2010). Thus, it may be that zinc is effective for some, but not all, causes of taste disturbance. Oral zinc supplements are generally well tolerated, although they can cause dyspepsia, and abdominal pain. Hence, it seems reasonable to offer patients with taste disturbance a trial of an oral zinc supplement (in the absence of other treatment options).

Oral infections

Oral infections are common in patients with advanced cancer. A number of studies have assessed oral candidosis in this group of patients (see 'Oral candidosis' section), and there appears to be an association between the presence of oral candidosis and poor performance status (Davies et al., 2006, 2008). In contrast, few studies have assessed other oral infections in this group of patients. Nevertheless, dental caries has been reported in 20–35%

of patients (Aldred et al., 1991; Jobbins et al., 1992), and gingivitis in 36% of patients (Gordon et al., 1985). Oral herpes simplex virus infections are also relatively common in patients with advanced cancer (Sweeney and Bagg, 2000).

Oral candidosis

A variety of different fungi have been reported to cause oral infections. However, *Candida* species are responsible for almost all oral fungal infections. This chapter will confine itself to a discussion of infection caused by *Candida* and related species, that is, oral candidosis.

Epidemiology

Certain *Candida* species are considered to be commensal organisms within the oral cavity. Indeed, the median reported prevalence of oral yeast carriage in the general population is 34%. Oral yeast carriage is very common in patients with advanced cancer, with a reported prevalence of between 47% and 87% (Davies et al., 2002a). Similarly, oral candidosis is very common in patients with advanced cancer, with a reported prevalence of between 8% and 83% (Davies et al., 2008).

Aetiology

Candida albicans is the most common species isolated from the oral cavity, although other species are being increasingly isolated from the oral cavity for example, *C. glabrata*, and *C. dubliniensis* (Finlay and Davies, 2005). The main explanation for the increasing frequency of non-*C. albicans* species is the increasing use of antifungal drugs. The main consequence of the increasing frequency of non-*C. albicans* species is the increasing occurrence of antifungal drug resistance.

Candida species are relatively non-pathogenic organisms. Hence, oral candidosis usually occurs as a result of changes in host and/or intraoral factors. Oral candidosis is very common in immunocompromised patients. It is widely believed that systemic corticosteroids cause oral candidosis. However, most studies involving patients with advanced cancer have failed to identify such an association (Finlay and Davies, 2005). Moreover, a review of the literature concluded that, 'the relationship between systemic steroid therapy and oral candidal carriage or infection is not clear' (Samaranayake, 1990). Similarly, it is widely believed that systemic antibiotics cause oral candidosis. However, studies involving patients with advanced cancer have again failed to identify such an association (Finlay and Davies, 2005). Moreover, a review of the literature concluded that, 'the relationship between antibiotic therapy and candidosis is far from unequivocally proven' (Odds, 1979). However, there is a strong association between oral candidosis and the use of topical antibiotics and topical corticosteroids. Oral candidosis is very common in patients with SGD, and common in patients with a denture, particularly an upper denture (Finlay and Davies, 2005).

Clinical features

Oral candidosis can present in different clinical forms, with several forms sometimes being found in one patient. Patients with oral candidosis may, or may not, have oral symptoms. Moreover, these symptoms may be due to the infection, or the underlying cause of the infection (e.g. SGD). Indeed, many patients continue to have oral symptoms, even after they have been treated for oral candidosis (Finlay, 1986).

Pseudomembranous candidosis is the most common type of oral candidosis (Finlay and Davies, 2005). It is generally asymptomatic. Pseudomembranous candidosis is characterized by the presence of off-white spots/plaques on the buccal mucosa, or elsewhere in the oral cavity: the lesions can be easily removed. Erythematous candidosis is relatively common. Patients often complain of localized discomfort/pain. Erythematous candidosis usually involves the tongue or the buccal mucosa, and presents as an area of inflamed (reddened) mucosa.

Denture stomatitis is a very common type of oral candidosis in patients with dentures (Finlay and Davies, 2005). It is generally asymptomatic, although some patients complain of palatal discomfort. Denture stomatitis is characterized by varying degrees of inflammation of the hard palate: the lesion may consist of patchy inflammation, confluent inflammation, and/or areas of hyperplasia. Angular cheilitis is relatively common, particularly in edentulous patients. Patients often complain of localized discomfort, and the lesions may 'weep' or bleed. Angular cheilitis invariably involves both angles of the mouth, and presents as cracking/inflammation of the mucosa and skin. (The lesions may be covered with a crust/clot.) Denture stomatitis is often associated with angular cheilitis.

The other types of oral candidosis are relatively uncommon (e.g. median rhomboid glossitis) (Finlay and Davies, 2005). Oesophageal candidosis is a frequent complication of oral candidosis (Samonis et al., 1998). The clinical features of oesophageal candidosis include odynophagia (pain on swallowing), and dysphagia (difficulty swallowing). The diagnosis can be confirmed by performing an oesophagoscopy, or a barium swallow. The appearance on barium swallow is typical, with 'fluffy', punched-out lesions along the length of the oesophagus. Candidaemia/systemic candidosis are less frequent complications of oral candidosis.

Assessment

A diagnosis of oral candidosis should be based on a combination of clinical features and microbiological investigations (Finlay and Davies, 2005).

The clinical features of oral candidosis are relatively non-specific. For example, white patches on the oral mucosa (akin to pseudomembranous candidosis) can also occur in bacterial infections (Tyldesley et al., 1977). Similarly, erythematous patches on the oral mucosa (akin to erythematous candidosis) can also occur in a number of other conditions, for example, chemotherapy-induced mucositis.

As discussed above, it is common to isolate yeasts from the mouths of patients. Thus, a diagnosis of oral candidosis should only be made if there is heavy growth from targeted microbiological swabs. (A light growth would indicate oral yeast carriage, rather than oral candidosis.) Other microbiological tests are warranted if a patient suffers from persistent/recurrent oral candidosis (e.g. species typing, sensitivity testing).

Management

The management of oral candidosis involves:

◆ Treatment of the infection

◆ Treatment of the cause of the infection

◆ Symptom management.

A variety of different topical and systemic treatments are available for treating oral candidosis (Table 8.5.3 and 8.5.4) (Pappas et al., 2009; Anonymous, 2012). A recent Cochrane systematic review concluded that drugs absorbed from the gastrointestinal tract appeared to be more effective than drugs not absorbed from the gastrointestinal tract (Worthington et al., 2010). It should be noted, however, that the evidence for the effectiveness of individual antifungal drugs in treating cancer patients is somewhat limited (Worthington et al., 2010).

The choice of treatment depends on a number of factors (Finlay and Davies, 2005):

1. Extent of disease: topical agents are appropriate for treating localized disease, whilst systemic agents are more appropriate for treating multifocal/generalized disease.

2. Immunocompetence: systemic agents are more appropriate for treating immunosuppressed patients than topical agents.

3. Drug resistance: resistance to the polyenes is uncommon, although resistance to the azoles is becoming increasingly common.

4. Concomitant disease: the azoles have a number of relative/absolute contraindications, which may limit their usage.

5. Concomitant drug treatment: the azoles have a number of drug interactions, which may limit their usage.

6. Patient preference for medication.

7. Patient adherence with medication: topical agents are associated with greater non adherence than systemic agents.

8. Availability/affordability of different treatments.

In view of the problem of antifungal drug resistance, it is recommended that antifungal drugs, particularly azoles, should usually only be prescribed for microbiologically proven cases of oral candidosis. Furthermore, antifungal drug should be prescribed for short periods, since longer courses promote the development of resistance (White et al., 1998). However, 'single-dose' treatments are invariably ineffective in the management of oral candidosis (as opposed to vaginal candidosis). Similarly, antifungal drug should be prescribed in high doses, since lower doses also promote the development of resistance (White et al., 1998).

Many patients suffer with recurrent episodes of oral candidosis. The reason for this phenomenon is that although the infection is adequately treated, the underlying cause of the infection is not treated. For example, patients with oral candidosis secondary to SGD will usually respond to antifungal drugs, but will often relapse on withdrawal of the antifungal drugs. However, studies have shown that treatment of SGD significantly reduces the subsequent prevalence of oral candidosis (Rhodus et al., 1998).

The successful management of denture stomatitis and/or angular cheilitis depends on a combination of antifungal drug treatment, and disinfection of the denture (see earlier) (Finlay and Davies, 2005). Moreover, maintenance of denture hygiene is essential to prevent recurrence of these infections.

Denture-related problems

Denture-related problems are again common in patients with advanced cancer. The reported prevalence of subjective problems is 45–86% (Gordon et al., 1985; Aldred et al., 1991; Jobbins et al., 1992), and of objective problems is 57–83%, in published studies of

Table 8.5.3 Topical antifungal agents for managing oral candidosis (i.e. localized infections in non-immunosuppressed patients)

Drug group	Drug	Recommended regimen	Comments
Polyene group	Nystatin	1–5 mL suspension (100,000 U/mL) four times a day or 1–2 pastilles (200,000 U/pastille) four times a day 7–14-day course: continue drug for 48 hours after lesions resolved	Drug needs to be kept in contact with lesions. (Larger volumes of suspension may be used with diffuse lesions.) Suitable for treating pseudomembranous candidosis Chlorhexidine may inactivate nystatin—it is advisable not to use chlorhexidine immediately before/after using nystatin Resistance uncommon
	Amphotericin B	1 lozenge (10 mg) four times a day or 1 mL suspension (100 mg/mL) four times a day 10–15-day course	Drug needs to be kept in contact with lesions Resistance uncommon
Azole group (imidazoles)	Miconazole	5–10 mL oral gel (20 mg/g) four times a day or 1 mucoadhesive buccal tablet (50 mg) once a day 7–14-day course: continue drug for 48 hours after lesions resolved	Drug needs to be kept in contact with lesions. Some systemic effect. (Smaller volumes of gel may be used with localized lesions). Suitable for treating pseudomembranous candidosis, denture stomatitis and angular cheilitis Miconazole is also active against staphylococci, which may be present in some cases of angular cheilitis
	Clotrimazole	1 troche (10 mg) five times a day 7–14-day course	Drug needs to be kept in contact with lesions. Some systemic effect. Suitable for treating pseudomembranous candidosis
Other topical agents	Chlorhexidine		Mainly used as an adjunctive agent
	Gentian violet		Successfully used to treat oral candidosis in HIV patients
	Tea tree oil		Successfully used to treat oral candidosis in HIV patients

Table 8.5.4 Systemic antifungal agents available to treat oral candidosis (i.e. generalized infections in non-immunosuppressed patients, persistent/recurrent infections in non-immunosuppressed patients, infections in immunosuppressed patients)

Drug group	Drug	Recommended regimen	Comments
Azole group (tiazoles)	Fluconazole	50–200 mg once a day (capsule/oral suspension) 7–14-day course	Considered first-line systemic treatment Inhibits cytochrome P450 leading to certain drug interactions Resistance becoming a problem
	Itraconazole	100–200 mg per day (capsule/oral liquid) 7–14-day course	Indicated for fluconazole resistant/refractory disease Not recommended for routine use in patients with/at risk of cardiac failure Capsule absorption dependent on low pH within stomach Inhibits cytochrome P450 leading to certain drug interactions Resistance becoming a problem
	Posoconazole		Option for managing refractory disease
	Voriconazole		Option for managing refractory disease

patients with advanced cancer (Gordon et al., 1985; Aldred et al., 1991; Jobbins et al., 1992). Most problems relate to poor fitting of the dentures (e.g. oral discomfort, oral ulceration, food getting stuck under denture). Denture-related fungal infections are also common in patients with advanced cancer (i.e. denture stomatitis, angular cheilitis). The reported prevalence of denture stomatitis is 12.5%, of angular cheilitis is 5%, and of combined denture stomatitis and angular cheilitis is 3.5% in a published study of patients with advanced cancer (Davies et al., 2006).

Oral care in terminal phase

Oral care often takes prominence during the terminal phase of the illness. Indeed, oral care is a major component of so-called integrated care pathways ('care of the dying' pathways). However, the oral care protocols in these pathways are not evidence based, and are reported to produce somewhat disappointing outcomes (Fowell et al., 2002).

Certain authors recommend 1–2-hourly oral care patients in the terminal phase (Anonymous, 1996). This is very obtrusive for patients (and families), and very time consuming for health-care professionals. Some patients may require this frequency of care, although many patients require much less frequent care, to maintain oral comfort. Thus, the frequency of oral care should be determined on an individual basis, rather than on the basis of a protocol.

Oral care is often delegated to families in the terminal phases. Some family members relish this task, whilst others find it difficult and/or distressing. It is important, if appropriate, that families are given the opportunity to provide oral care. Equally, it is important that families are not coerced into providing oral care. Furthermore, health-care professionals must provide adequate instructions, and ongoing support and supervision, for families that do undertake this task.

One of the most common problems amongst unconscious patients is the presence of a desiccated oral mucosa. Family members (and health-care professionals) often perceive this as a source of discomfort, although this is unlikely to be the case in an unconscious patient. Oral care protocols often recommend the regular application of water. However, this strategy is largely ineffective, since the water rapidly dissipates as a result of swallowing and/or evaporation. A more effective intervention involves the regular application of a suitable water-based moisturizing gel (e.g. K-Y® jelly, Oral Balance® gel).

The philosophy of care in the terminal phase should be the maintenance of patient comfort (Sweeney, 2005). It is relatively easy to determine the merits of oral care in conscious patients. Thus, health-care professionals should always ask patients about their experiences of oral care, that is, whether the oral care makes them feel better, whether the oral care causes any problems. Nevertheless, it is much less easy to determine the merits of oral care in unconscious patients. However, if an intervention causes or appears to cause distress, then that intervention should be discontinued.

Sleep disorders

Kyriaki Mystakidou, Irene Panagiotou,
Efi Parpa, and Eleni Tsilika

Introduction to sleep disorders

Sleep disturbances can present independently or concomitantly with other medical and/or psychiatric disorders, such as chronic pain and depression. Insomnia is the most prevalent sleep disorder and can become a persistent problem for patients with serious or life-threatening illnesses. The burden of chronic sleep disturbances is heavy for patients, caregivers, and health-care providers and its impact can affect physical, psychological, occupational, and economic well-being (Morin and Benca, 2012). Assessment and management of sleep disorders is necessary when treating chronically ill patients.

Sleep physiology

Sleep is a state that shows alternating patterns of neural activity controlled by homeostatic and circadian mechanisms interacting in complex ways. The sleep–wake cycle is a highly regulated process that involves two distinct types of sleep: (1) rapid eye movement (REM) sleep, which is the active phase of sleep defined by faster electroencephalography (EEG) activity, rapid horizontal eye movements seen on electrooculography, vital sign instability, and occurrence of skeletal muscle hypotonia, as well as dreams; and (2) non-REM sleep (Kryger et al., 2000).

The major characteristics of normal sleep architecture include the generalized slowing of EEG activity that characterizes the transition from drowsiness to light sleep (stage one), the emergence of sleep spindles and K-complex waveforms that accompany the onset of deeper sleep (stage two), and the desynchronized slow (delta) waves of slow-wave sleep (SWS) (stages three and four) (Kryger et al., 2000). Sleep occurs in a circadian pattern, with most deep sleep (SWS, delta sleep) occurring during the first half of the night, and the most REM sleep occurring during the second half of the night. During an average night, individuals experience five cycles of non-REM and REM sleep that last for approximately 70–90 minutes each. Sleep normally progresses slowly from stage one to stage four of non-REM sleep. Periods of non-REM sleep constitute approximately 80% of total sleep time and non-REM reaches its greatest depth during SWS. After a period of SWS, the individual enters an episode of REM sleep, followed by re-progression through stages one to four of non-REM sleep (Kryger et al., 2000). Sleep architecture varies widely from person to person in terms of the amount of time spent in each sleep stage, the number of cycles, and the amount of interruption by waking. There are individuals who, because of their circadian rhythm patterns and chronotype, prefer early bed times and wake times and there are those who prefer later bed times and wake times.

Sleep is generated by two opposing processes that interact together to strengthen sleep: the homeostatic drive for sleep and the circadian system that regulates wakefulness (Borbely and Achermann, 1999;Kryger et al., 2000). The homeostatic drive for sleep involves mutually inhibitory interactions between sleep- and arousal-promoting systems and increases with the length of time that an individual has been awake. Non-REM sleep and SWS appear to be primarily controlled by this homeostatic process.

The circadian system plays an important role in the control of the timing of sleep onset, the timing of sleep offset, and the distribution of REM sleep. The circadian system is known as the wake-promoting system because it determines the timing of sleep propensity and wakefulness (Borbely and Achermann, 1999). Individuals who sleep in phase with their circadian rhythm obtain a better quality of sleep, with minimal time to fall asleep and fewer awakenings, than those who sleep outside of their circadian chronotype (i.e. shift workers, jet-lagged pilots and airline attendants). The central pacemaker of the circadian system for all physiological processes (including the modulation of sleep and wakefulness) is located in the suprachiasmatic nucleus of the hypothalamus. Retinal light input synchronizes the pacemaker to the external light–dark cycle via a direct retinal hypothalamic tract. A complicated neural pathway links the suprachiasmatic nucleus to the pineal gland, where melatonin is secreted in a circadian pattern with onset of the secretion in the early evening, peak levels occurring in the middle of the night, and very low or non-existent melatonin levels during the day. In the mammalian circadian system, melatonin serves as a chemical messenger of the circadian pacemaker. Central melatonin receptors are concentrated primarily in the suprachiasmatic nucleus, where melatonin functions in a feedback loop (Borbely and Achermann, 1999).

Prevalence of sleep disorders

The reported prevalence of sleep disturbances depends on the definitions used and the underlying pathology (Roth, 2007). A general consensus has emerged from population-based studies that approximately 30% of adults report one or more of the symptoms of insomnia: difficulty initiating sleep, difficulty maintaining sleep, waking up too early, and, in some cases, non-restorative or poor quality sleep (Roth, 2007). Rates of insomnia with associated daytime dysfunction in attendees of general medical practices

range from 10% to as high as 34% (Sateia and D' Nowell, 2004). This high prevalence of chronic insomnia is supplemented by an additional 25% to 35% who experience transient or occasional insomnia (Sateia and D' Nowell, 2004; Morin and Benca, 2012). It has been estimated that approximately 6–10% of adults meet the criteria for an insomnia disorder (Sateia and D' Nowell, 2004; Morin and Benca, 2012).

Given the prevalence of sleep problems, it is remarkable that sleep disturbance is seldom considered to be a primary cause of patients' distress. Often, it is perceived to be important only in the context of other symptoms. Clinicians caring for patients with serious illness should have a stronger foundation in at least those disorders for which medically ill patients often seek care—insomnia, excessive daytime sleepiness, obstructive sleep apnoea syndrome, and restless legs syndrome.

Classification of sleep disorders

Sleep disorders are classified according to the International Classification of Sleep Disorders of the American Sleep Disorders Association (Freedom, 2011). This system categorizes sleep disorders into two large categories: primary sleep disorders, such as dysomnias and parasomnias (Kryger et al., 2000; Morin and Benca, 2012), and secondary sleep disorders due to medical or psychiatric conditions (Borbely and Achermann, 1999).

Primary insomnia and hypersomnia, narcolepsy, breathing-related sleep disorders such as sleep apnoea, and circadian rhythm sleep disorders are all classified in the dysomnia category. These disorders may disturb sleep quality, quantity, or timing of nocturnal sleep, or may cause excessive daytime sleepiness. Parasomnias are unusual experiences or behaviours that occur during sleep; they include sleep terror disorder and sleepwalking, as well as nightmare disorder (Freedom, 2011).

This classification is largely based on phenomenology. Although research may ultimately identify measurable physiological disturbances that allow classification based on test results, diagnosis now relies mainly on patient reports. This may pose diagnostic challenges, particularly given the heterogeneity that exists in medically ill populations. These challenges are exemplified by several of the more common disorders, such as insomnia, excessive daytime sleepiness, and circadian rhythm sleep disorders.

Insomnia

In clinical practice, insomnia can be defined as the patient's subjective report of difficulty initiating or maintaining sleep, despite adequate opportunity and circumstance to sleep. The predominant complaint is dissatisfaction with sleep quality or quantity. Additional components may include early awakening and interrupted or non-restorative sleep, along with nightmares (Sateia and D' Nowell, 2004; Roth, 2007; Morin and Benca, 2012). Daytime tiredness or poor functioning; fatigue or malaise; naps during daytime; disturbances in concentration, memory, and mood; tension headaches; or gastrointestinal symptoms, along with impairment of quality of life, represent additional criteria for the diagnosis of acute and chronic insomnia (Morin and Benca, 2012).

Acute or adjustment insomnia is often associated with life events or unscheduled sleep changes, usually remits when the precipitating event has subsided, and lasts no more than 3 months. The criteria for chronic insomnia, which may be primary or secondary to a medical and/or psychiatric condition, includes sleep disturbance for at least 3 nights/week that persists for more than 3 months, although night-to-night variability in sleep is often reported and there may be an occasional good night sleep intertwined with periods of disrupted sleep (Sateia and D' Nowell, 2004; Morin and Benca, 2012).

Excessive daytime sleepiness

Excessive daytime sleepiness is a common symptom, particularly among patients with serious medical illness. It may be secondary to neurological dysfunction caused by the disease itself, to a disease-modifying or symptomatic treatment, or to a factor unrelated to the disease or its treatment. For example, excessive daytime sleepiness may result from cancer involvement of brain or leptomeninges, or as a result of chemotherapy or cranial radiotherapy (Davidson et al., 2002; (Phillips et al., 2012). Because sleepiness renders patients 'calmer', caregivers (including medical staff) do not always identify sleepiness as a problem. While some degree of sedation during the day may be beneficial for the terminally ill patient, excessive somnolence can potentially be quite disabling and compromise physical functioning and social interactions of patients, which might be extremely important even in the final weeks of life (Regestein, 1977).

Patients with primary or secondary forms of insomnia may experience excessive daytime sleepiness. In this situation, patients or their families may report recurrent episodes of drowsiness or involuntary dozing that arise mainly in sedentary situations (Sateia and D' Nowell, 2004). This phenomenon, which should not be confused with fatigue or tiredness, is very common among patients receiving palliative care services. Paradoxically, some patients with primary insomnia report excessive daytime sleepiness but demonstrate findings indicative of normal or even increased daytime alertness (Bonnet and Arand, 1996). As a result, subjects with primary insomnia who additionally manifest convincing evidence of excessive daytime sleepiness should be assessed for other potential causes of sleepiness, such as sleep apnoea or periodic limb movement (Regestein, 1977).

Circadian rhythm sleep disorders

Maintenance of a normal sleep pattern is dependent on adherence to a well-established schedule of sleep and wakefulness. Patients with serious illnesses are particularly prone to disturbances of the sleep–wake schedule: when night sleep has been poor, there is an inclination to delay the hour of rising and/or to engage in lengthy daytime naps. Disorders of the circadian sleep rhythm, such as complete disappearance of the normal sleep pattern, delayed sleep, and advanced sleep phase syndromes, all may occur in these patients (Dagan, 2002).

The delayed sleep phase syndrome consists of a problematic sleep onset, with further delay in rising and increased napping. With difficulty in falling asleep until the early morning hours, sleeping till the early afternoon may occur and further promote the vicious cycle of problematic sleep onset during bedtime (Dagan, 2002). In other cases, fatigue and sedation associated with major medical illness may result in advancement of the normal sleep–wake schedule, resulting in early morning awakening (advanced sleep phase syndrome). The disappearance of the normal circadian rhythm results in a pattern of multiple shorter sleep periods, which are interspersed with wakefulness throughout the 24-hour

cycle (Dagan, 2002). As a result, the patient is able to sleep at other times, but unable to sleep at the desired time.

Causes of primary sleep disorders

Primary sleep disorders presumably result from varied neurological diseases, and given the variation in presentation, there are likely to be multiple pathophysiological processes that initiate or sustain these disturbances. An increased vulnerability to sleep disturbances has been associated with a positive family history of insomnia and, possibly, genetic factors, such as the presence of the short allele of the serotonin transporter gene (Morin and Benca, 2012). A rare and fatal familiar insomnia is autosomal dominant and characterized by severe autonomic disturbances, hallucinations, dementia, and severe progressive insomnia (Montagna et al., 1994).

Some primary sleep disturbances are thought to be a disorder of hyperarousal; this may be experienced throughout the entire day and manifests as hypervigilance during the day and difficulty in initiating and maintaining sleep during the night (Roth, 2007). This state has been demonstrated through measurements of the whole-body metabolic rate, heart rate variability, neuroendocrine measures, and functional neuroimaging. For example, a pattern of hyperarousal in patients with primary sleep disorders was shown by raised body temperature, increased 24-hour metabolic rate, heart rate, and electromyographic activity (Bonnet and Arand, 2012). Hypothalamic–pituitary–adrenal axis dysfunction has been confirmed through plasma and urinary measures of norepinephrine (noradrenaline), cortisol, and adrenocorticotropic hormone—all of which appear to have higher levels in subjects with primary sleep disturbances (Bonnet and Arand, 2012).

Using quantitative electroencephalogram analysis, subjects with primary sleep disturbance also have been shown to have an increase in beta and gamma frequencies at sleep onset and during non-REM sleep; these are thought to be associated with increased cognitive activity, as well as greater cerebral glucose metabolism during waking and non-REM sleep states (Nofzinger et al., 2004). In imaging studies, reduced grey matter volume in the left orbitofrontal cortex and hippocampus also has been reported (Altena et al., 2010).

Secondary sleep disorders and contributing factors

Sleep disorders have been associated with a very large number of potential causes. One or more of these may be the main driver for disturbed sleep, or may contribute to another primary cause. Patients with serious medical illnesses often have more than one. In those with advanced cancer, for example, sleep disturbance may be related to neoplastic involvement of the central nervous system, various treatments for the cancer, or to symptoms such as pain, nausea or constipation (Regestein, 1977; Katz and McHorney, 1998; Davidson et al., 2002; Roth, 2007; Palesh et al., 2010; Phillips et al., 2012). Advanced illness also may be associated with other conditions, such as nutritional deficiency, respiratory disorders, or nocturia, which are strongly linked to sleep disturbances (Regestein, 1977; Crisp, 1980).

Many specific medical conditions, such as chronic pain, hypertension, pulmonary and/or heart diseases, and prostatism, have been associated with sleep disturbances (Regestein, 1977; Crisp, 1980; Katz and McHorney, 1998). Substance abuse also may contribute, as can any cause of delirium, a movement disorder, or any primary disease of the central nervous system (Regestein, 1977; Crisp, 1980; Katz and McHorney, 1998). Delirium is especially common among terminally ill patients (Regestein, 1977; Crisp, 1980; Katz and McHorney, 1998) and is associated with a distorted sleep–wake cycle: wakefulness during daytime is typically reduced, while night-time brings increased alertness and agitation (Dagan, 2002). As a result, the circadian rhythm is severely reversed or disrupted. Sleep deprivation itself may also predispose to the development of delirium.

Dementia also is associated with sleep disruption. Sleep studies of dementia patients reveal increased sleep latencies, lighter sleep, reduced REM sleep, and increased awakening after sleep (Klink et al., 1992; Katz and McHorney, 1998).

Sleep-disordered breathing is a particularly common cause of disturbed sleep and can be an important comorbidity in populations with life-limiting illnesses. Central sleep apnoea is the absence of airflow for more than 10 seconds with an absence of ventilatory effort. Obstructive sleep apnoea is associated with continued ventilatory effort. One review noted that 29–67% of older adults with insomnia had obstructive sleep apnoea, with the apnoea–hypopnea index greater than five (Luyster et al., 2010). Obstructive sleep apnoea is associated primarily with heavy snoring and excessive daytime sleepiness although some patients report frequent nocturnal wakening, morning headaches, choking or gasping, nocturia, and fatigue (Regestein, 1977; Crisp, 1980; Chilcott and Shapiro, 1996; Morin and Benca, 2012). The syndrome is associated with obesity, male sex, older age, short neck, and redundant pharyngeal tissues.

Patients with serious illnesses also can develop periodic limb movement in sleep (Regestein, 1977; Katz and McHorney, 1998). This disorder consists of repetitive stereotyped leg and/or arm movements which occur at intervals of 20–40 seconds, typically in clusters throughout the night. It can be secondary to sedative-hypnotic withdrawal, tricyclic medication, anaemia, uraemia, leukaemia, diabetes mellitus, or peripheral neuropathy. In some cases, it might also be associated with restless legs syndrome (Regestein, 1977; Katz and McHorney, 1998), which interferes with sleep onset. This syndrome is characterized by an uncomfortable sensation, localized to the lower legs, producing an urge to move the lower extremities. The sensation is usually worst at night and is relieved by movement. As a result, both disorders can lead to great difficulty falling and staying asleep (Morin and Benca, 2012).

Environmental factors and/or poor sleep hygiene, such as a sleeping environment not conducive to sleep, snoring, and/or restless bed partner, also have been included among the psychophysiological conditions that precipitate insomnia or predispose to it (Crisp, 1980; Klink et al., 1992; Chilcott and Shapiro, 1996; Katz and McHorney, 1998). Hospital admission, for example, has been associated with marked sleep disruption (Klink et al., 1992; Katz and McHorney, 1998). The more common complaints include difficulty falling asleep, frequent awakenings, somnolence, and poor sleep quality (Klink et al., 1992; Katz and McHorney, 1998).

Although an increasing rate of insomnia has been noted in older people, debate exists as to whether increasing age is associated with sleep disturbances (Ohayon et al., 2001). Investigators

suggest that progressive inactivity, dissatisfaction with social life, and presence of comorbid illnesses (both physical and psychological) can induce insomnia in older people (Sateia et al., 2000; Ohayon et al., 2001). Insomnia also is more common in women, and in individuals who are less educated or are unemployed, separated, or divorced (Sateia et al., 2000). In chronically ill non-cancer patients, age and gender were the most clearly identified demographic factors associated with insomnia, with an increased prevalence in women and older adults (Roth, 2007; Morin and Benca, 2012). On the contrary, younger age increases the risk of sleep disturbances in the cancer population.

Common psychiatric disorders and sleep disturbance

Numerous psychosocial and psychiatric conditions have been linked to sleep disturbance. An anxiety-prone personality with hyperarousability, unrealistic sleep expectations, incorrect perceptions about sleep difficulties, as well as misconceptions about causes of insomnia, represent common perpetuating factors (Chilcott and Shapiro, 1996; Weissman et al., 1997; Katz and McHorney, 1998; Ohayon et al., 2001). Psychiatric disorders linked to the onset and persistence of a life-threatening illness may lead to disturbances of sleep (Pasacreta and Pickett, 1998; Verhaak et al., 1998; Bower, 2008; Du-Quiton et al., 2010; Ewertz and Jensen, 2011). Negative cognitions, such as uncertainty about the disease and its treatment, fear of death, and concerns about disease progression and diminished quality of life, can contribute (Bailey et al., 2007; Mishel et al., 2009). Although the linkages between specific psychiatric disorders and sleep disturbances are complex, their elucidation may lead to innovative insomnia treatments focused on psychological and/or pharmacological interventions (Van't Spijker et al., 1997).

Moderate to severe depression is common in medical illness, occurring for example in 25–50% of cancer patients, and insomnia may be considered an important diagnostic marker for depression in populations with serious illness (Palliative Care Notes, 2000). Indeed, the most robust correlate of insomnia in cancer patients is depressed mood (Davidson et al., 2002) and 90% or more of depressed patients experience abnormal sleep patterns. Supporting the salience of this relationship is evidence linking depression to disturbances in the continuity of sleep, decreased latency to the first REM sleep period, and diminished SWS (stages three and four) (Reynolds, 1987). These associations underscore the importance of assessing mood in patients with sleep disorders and sleep in those with mood disorders.

This relationship between insomnia and depression is not simple, however. Uncertainty exists regarding the use of a somatic symptom, like sleep, in establishing the diagnosis of depression, since such symptoms may be a result of the illness. There also is no specific evidence regarding the efficacy of antidepressant medications in the treatment of insomnia associated with depression in the terminally ill.

Sleep disturbances also are associated with anxiety. In one study, 63% of cancer patients with anxiety had insomnia, the multifactorial causes of which included nightmares (Palliative Care Notes, 2000). Many situational factors can drive anxieties, including fear of illness progression, forthcoming procedures, or family or financial distress. For terminally ill patients, sleep-associated anxiety may be related to a fear of death.

The subjective experience of anxiety may occur with overactivation of stress response systems, notably the hypothalamic–pituitary–adrenal axis; this phenomenon is associated with insomnia (Roth, 2007). Some have argued that chronic activation of these physiological systems may explain why insomnia is an independent risk factor for medical conditions such as coronary artery disease (Mallon et al., 2002).

Chronic pain and sleep disturbance

Chronic pain also is highly associated with disturbed sleep (Klink et al., 1992; Verhaak et al., 1998; Roehrs et al., 2006; Kundermann and Lautenbachter, 2007). It is estimated that 50–90% of patients with chronic pain report poor sleep quality (Menefee et al., 2000; Lavigne et al., 2005; Breivik et al., 2006). The sleep disturbances that may accompany pain include difficulty falling and staying asleep, lack of restful sleep, frequent awakening, and daytime somnolence (Klink et al., 1992; Menefee et al., 2000; Okura et al,. 2008). Chronic pain from musculoskeletal diseases has been found to affect sleep architecture (Mahowald et al., 1989; Branco et al., 1994), abnormalities in REM sleep architecture have been noted in patients with fibromyalgia (Branco et al., 1994), and decreased SWS and increased alpha sleep changes have been associated with both fibromyalgia and rheumatoid arthritis (Mahowald et al., 1989; Branco et al., 1994).

Pain and sleep disorders also can have a reciprocal relationship. Just as poorly controlled pain can disrupt sleep, chronic sleep deprivation may increase pain (Smith and Perlis, 2004; Lavigne et al., 2005; Roehrs et al., 2006). Indeed, it has been reported that sleep quality can predict the levels of pain the following day and that the number of hours of sleep reported the previous night represents a highly significant predictor of pain during the next day (Edwards et al., 2008). It has been suggested that the relationship is so close that even healthy subjects can suffer from hyperalgesia due to sleep deprivation (Roehrs et al., 2006; Kundermann and Lautenbachter, 2007). If untreated, the conjunction of these two processes can have drastic consequences; the combination of high pain intensity and insomnia has been shown to increase the already-doubled suicide risk found in patients suffering from chronic pain (Smith and Perlis, 2004).

Opioid therapy and sleep disturbance

Opioids have a variety of effects on sleep and can cause sleep disturbances even in the absence of pain (Lydic and Baghdoyan, 2007). It has been shown that increased opioid medication during the day can represent a significant predictor of poor sleep during the following night and a night of poor sleep can be followed by higher levels of opioid intake the following day (Mystakidou et al., 2011). These phenomena have not been directly linked to the sedative effects of these drugs, to which tolerance usually develops (Benyamin et al., 2008). If sedation is severe or persistent, however, it can disrupt daytime arousal and lead secondarily to sleep problems. Opioid-induced daytime somnolence may be manageable with opioid dose reduction, opioid rotation, or the use of a psychostimulant (Mystakidou et al., 2011).

Opioids also are associated with sleep-disordered breathing (Mahowald et al., 1989; Lydic and Baghdoyan, 2007; Panagiotou and Mystakidou, 2012). Both central and obstructive sleep apnoea have been associated with chronic opioid treatment (Walker et al., 2007; Webster et al., 2008; Walker and Farney, 2009; Luyster et al., 2010; Mystakidou et al., 2011; Panagiotou and Mystakidou, 2012).

Sleep disturbances in the palliative care setting

Sleep disorders in the cancer population

As noted, cancer patients may experience sleep disturbances as a direct effect of the neoplasm; as a consequence of cancer surgery, chemotherapy, and/or radiation therapy (Davidson et al., 2002; Phillips et al., 2012); or as a correlate of pain or other symptoms, related disorders such as delirium, treatment with opioids or other medications, or varied psychological or psychiatric conditions (Davidson et al., 2002; Palesh et al., 2010). Sleep and fatigue have been reported as important components of a symptom cluster in cancer and a longitudinal study suggested that fatigue in breast cancer patients undergoing chemotherapy was significantly associated with subjective reports of poor sleep and objective measures of daytime sleepiness (Liu et al., 2012).

The prevalence and characteristics of sleep disturbances vary within the cancer population. Breast and lung cancer patients have the highest rates of sleep disturbances and insomnia symptoms are more likely to be reported by younger patients (Davidson et al., 2002; Palesh et al., 2010). There are no reported sex differences (Palesh et al., 2010). Phillips et al. (2012) reported that poorer overall sleep in cancer patients was predicted by less education, more medical comorbidities, and previous radiotherapy, while depression and fatigue were significantly related to problematic sleep.

The few studies that have recorded objective data from cancer patients with sleep disturbances suggest a complex relationship between subjective events and neural processes. For example, there is evidence that self-report of sleep duration and latency correlates poorly with polysomnographic or actigraphic sleep data (Roscoe et al., 2011; Liu et al., 2012). The relationship between self-reported sleep disturbance and cancer-related fatigue was not confirmed in actigraphic studies (Roscoe et al., 2011; Liu et al., 2012), and sleep architecture was not affected by cancer treatment. Another study found no relationship between fatigue and insomnia in men with prostate cancer (Savard et al., 2004).

Insomnia also is a serious concern among cancer survivors, including children and adolescents (Kaleyias et al., 2012). Children with brain tumours have the highest prevalence of long-term morbidities. The most prevalent sleep disorders included insomnia, excessive daytime fatigue and sleepiness, as well as restless legs syndrome.

Sleep disorders in other chronic diseases

Sleep disorders are common other serious or life-threatening illnesses. In populations with HIV/AIDS, fatigue, daytime sleepiness, and difficulties initiating and maintaining sleep have been reported (Norman et al., 1990; Moeller et al., 1991). The severity of sleep disturbance and associated daytime dysfunction is correlated with progression of the disease (Moeller et al., 1991). The presence of depression, anxiety, and cerebral involvement, particularly in HIV-dementia complex (Norman et al., 1990), is likely to have major impact on the sleep of these patients. Sleep disturbances may represent early changes in the central nervous system associated with the infection or an adaptation to bolster immune response (Norman et al., 1990). Studies have shown that sleep alterations of asymptomatic HIV-infected males include increased SWS in the second half of the night, while, on the contrary, a decreased percentage of SWS has been reported in patients with diagnosed cerebral disease (Norman et al., 1990). Sleep disturbances have also been described in association with treatment for HIV infection (Moeller et al., 1991).

Patients with chronic obstructive pulmonary disease have been traditionally reported as poor sleepers. Severe daytime hypoxia and/or hypercapnia, as well as dyspnoea, chronic cough, and sadness/anxiety may play an important role in the increased prevalence of sleep disturbances (Budhiraja et al., 2012; McSharry et al., 2012). Insomnia, shorter sleep time, increased light sleep with multiple arousals, lower sleep efficiency, and increased daytime sleepiness have all been reported (Budhiraja et al., 2012; McSharry et al., 2012). Furthermore, altered sleep architecture with decreased REM sleep was found as a criterion of impaired sleep efficiency (McSharry et al., 2012). These abnormalities were reported separate and distinct from the obstructive sleep apnoea syndrome, which can impose an additional significant burden in such patient cohort.

Liver diseases also have been associated with sleep disturbances (De Cruz et al., 2012). Relatively high rates of insomnia, daytime sleepiness, daytime napping, and nocturnal awakenings occur in patients with cirrhosis, even in the absence of hepatic encephalopathy. Derangements in sleep patterns include circadian rhythms disorders, restless leg syndrome, and a progressive decrease in total wake time, with an increase in total SWS and REM (De Cruz et al., 2012). Patients with primary biliary cirrhosis suffer from profound fatigue and excessive daytime somnolence, resulting in poor night sleep. Sleep disruption in hepatitis C is mainly due to neurological disturbances involving both the peripheral and central nervous system, comorbid psychiatric disorders (both mood disorders and psychosis), and fatigue due to interferon therapy. Polysomnographic studies confirm decrease in SWS and sleep efficiency, and an increase in REM latency, stage two sleep, and awakenings after sleep onset (De Cruz et al., 2012). Patients with Wilson's disease may experience disorders of REM sleep, reduced total sleep time, and hypersomnia; several cases with significant increases in REM-related disturbances (cataplexy and sleep paralysis) have been reported (De Cruz et al., 2012). A dysfunctional suprachiasmatic nucleus has been suggested to contribute to a circadian rhythm disturbance in patients with Wilson's disease, and some patients have a dopaminergic deficit that leads to secondary Parkinsonism, which itself may be associated with REM sleep disturbances, especially REM behaviour disorder (De Cruz et al., 2012). Degenerative brain diseases, such as Alzheimer's disease, also can produce chronic insomnia and related disturbances of the sleep–wake cycle (Morin and Benca, 2012).

Diagnosis and evaluation of sleep disorders

Clinical assessment

The diagnosis of sleep disturbances requires a comprehensive history (Sateia and D'Nowell, 2004; Morin and Benca, 2012). In view of the high prevalence and substantial morbidities in palliative care setting, patients should routinely be evaluated for sleep problems. Evaluation includes careful analysis of the sleep–wake cycle and identification of all sleep-related symptoms, as follows:

- Identify the type of primary complaint (dysomnia, parasomnia) by evaluating difficulty initiating/maintaining sleep, early awakening, non-restorative sleep, and daytime consequences.

◆ Characterize the complaint by assessing its onset, severity, course, and duration (e.g. gradual or abrupt, frequency, and intensity).

◆ Document the sleep–wake cycle by noting sleep schedule, naps, activities, medications, pre-sleep activities, wake-up time and time out of bed, and regularity of schedules.

◆ Document cognitions such as negative expectations (e.g. 'I will never get to sleep'), distortions (e.g. 'Should I stay in bed and rest if I cannot sleep?') and catastrophization (e.g., 'If I cannot sleep I cannot work', 'I cannot function'; 'My life is falling apart').

◆ Evaluate daytime function, as well as the patient's particular sleep requirements; patients may be short/average/long sleepers, and the absence of daytime consequences suggests clinical insignificance or short sleepers.

◆ Identify possible precipitants, perpetuating factors, and causative factors, and record ameliorating or exacerbating factors, including substance use (medications, alcohol or other drugs, caffeine, and nicotine).

◆ Identify medical and neuropsychiatric (personal/family) history, along with other sleep-related symptoms.

◆ Assess previous treatments response and attitudes.

◆ Complement the information from the history with data from a sleep log or diary, if possible; this should cover at least 2 weeks.

Findings from a physical examination and laboratory data also may be important in establishing the significance of factors that could cause or contribute to a sleep disorder. Objective sleep studies, including polysomnography or actigraphy, may be helpful in selected cases. Polysomnography is considered the 'gold standard' and generally is not indicated for the routine assessment of insomnia (Sateia and D' Nowell, 2004; Morin and Benca, 2012). Nonetheless, it may provide definitive information in cases of suspected sleep apnoea or sleep-related movement disorders, when violent or potentially self-injurious behaviour occurs during sleep, or when patients are treatment resistant (Littner et al., 2003). Actigraphy is an indirect measure of the sleep–wake cycle, which is inferred by means of movement recording. It, too, can be a helpful adjunct in some patients, although it is not indicated in clinical practice (Littner et al., 2003).

Questionnaires

'Sleep quality' includes quantitative aspects (such as sleep duration, sleep latency, and number of arousals) and subjective aspects (such as 'depth' or 'restfulness' of sleep) (Beck et al., 2004). Self-report measures, including sleep diaries, sleep logs, and questionnaires, have been developed to aid the assessment of these features (Davidson et al., 2001).

Daily sleep diaries can record timing of retiring and rising, sleep onset latency, number and duration of awakenings, time and duration of naps, use of hypnotic medications, and overall ratings of feeling rested and sleep quality. Sleep logs can be used to give a day-to-day account of sleep activities 24 hours per day over a period of time (Davidson et al., 2001).

Other types of self-report questionnaires also have been developed. The Pittsburgh Sleep Quality Index (PSQI) represents one of the most useful (Beck et al., 2004; Mystakidou et al., 2007, 2009).

It may be used as a simple screening measure to identify cases and controls, or 'good' and 'bad' sleepers. It is self-administered and collects data on multiple facets of sleep quality. It takes only 5–10 minutes to complete, and has a possible range of 0–21 points. The Global Sleep Quality Index (GSQI) is obtained from the sum of seven components: subjective sleep quality, sleep latency, sleep duration (hours of actual sleep at night), habitual sleep efficiency, sleep disturbances, use of sleeping medication, and daytime dysfunction (Beck et al., 2004). A higher score indicates poorer sleep quality. Studies suggest that a cut-off score of equal or more than 5 can be used to identify poor sleepers (Beck et al., 2004).

Other self-report instruments used to measure the perceived severity of sleep problems include the Insomnia Severity Index (Morin, 1993; Savard et al., 2005) and the Epworth Sleepiness Scale (ESS) (Johns, 1991). The latter tool is widely used and is a subjective measure of daytime sleepiness. It is brief and self-administered, and asks the subject to rate his or her likelihood of sleeping in eight specific situations that are commonly encountered in daily life. The items are each scored on a 0–3-point scale, which are added to give an overall total score of 0–24. The results represent the subjects' average sleep propensity across these situations of daily life. Higher scores indicate more sleepiness. An ESS score of 2–10 is considered 'normal' and more than 10 is indicative of pathological sleepiness (Johns, 1991).

Another important tool for the clinical assessment of sleep disturbances is the Medical Outcomes Study (MOS) Sleep Scale (Sprintzer and Hays, 2003). This scale quantifies the effects of sleep problems on individuals. It uses 12 questions to assess the effects of sleep problems through several individual dimensions of sleep including sleep disturbance, snoring, sleep adequacy, headache, somnolence, and respiratory impairments with sleep. Similar to the PSQI, it allows calculation of a 'global sleep problems index'. It is scored from 0 to 100; for sleep adequacy, a high score indicates better sleep ('more adequate'), and for the remaining parameters, a high score indicates more pathology (Sprintzer and Hays, 2003).

Treatment of sleep disorders

When sleep disorders are secondary to medical and/or psychiatric conditions, or are exacerbated by these factors, treatment directed at the cause should be undertaken if possible. Symptomatic drug therapy may be needed concurrently, typically with a sedative-hypnotic or an antidepressant. Factors that affect drug choice may include nature of insomnia symptoms, the medical and psychological status of the patient, age, and response to previous treatments. Once treatment is begun, continuous re-evaluation is warranted to determine efficacy and complications, and to adjust dosage or type of medication accordingly. If possible, drug therapy should be used on an intermittent basis, rather than continuously, with the theoretical appeal of preserving effectiveness over time (Schuman and Attarian, 2012).

According to recent guidelines, the treatment of insomnia should be initiated with either a short-acting or intermediate-acting benzodiazepine-receptor agonist or with ramelteon, unless the patient has a depressive disorder, in which case a sedating antidepressant should be used (Morin and Benca, 2012; Schuman and Attarian, 2012) (Table 8.6.1). An antidepressant also should be considered if the first-line drug is ineffective. A benzodiazepine with a longer half-life may be chosen if the hypnotic's duration of

Table 8.6.1 Pharmacotherapy of sleep disturbances

Drug name	Dose (mg) [dose recommended in elderly and medically ill (mg)]	Metabolism	Half-life (hours) and peak plasma concentration (hours after administration)	Adverse effects
Benzodiazepine hypnotic drugs (benzodiazepine receptor agonists)				
Alprazolam	0.5–1	Hepatic via CYP3A4	11.2	Abnormal coordination, depression, drowsiness
Diazepam	5–10	Hepatic	20–50	Agitation, amnesia, anxiety, ataxia, confusion, depression, drowsiness, dizziness
Estazolam	1–2 [0.5]	Hepatic	10–24, 2	As for diazepam
Flurazepam	15–30 [15]	Hepatic	47–100, 2	As for estazolam
Quazepam	7.5–15 [7.5]	Hepatic	25–41, 1.5	As for estazolam
Temazepam	7.5–30 [7.5]	Hepatic	6–16, 1	As for estazolam
Triazolam	0.25–0.50 [0.125–0.250]	Hepatic	1.5–5.5, 2	As for estazolam
Non-benzodiazepine hypnotic drugs (benzodiazepine receptor agonists)				
Zaleplon	10–20 [5–10]	Extensive, primarily via aldehyde oxidase	1, 1	Chest pain, peripheral oedema, amnesia, anxiety, depersonalization, depression, gastrointestinal symptoms
Zolpidem	5–10 [5]	Hepatic, primarily via CY3A4	2.5–2.8, 1.6	Dizziness, headache, somnolence
Zopiclone	3.75–7.5 [7.5]	Extensively hepatic	5–7, > 2	Palpitations, agitation, anterograde amnesia, asthenia, gastrointestinal symptoms
Antidepressant drugs				
Amitriptyline	25–100 [20]	Hepatic to nortriptyline (active)	9–27, 4–8	Restlessness, dizziness, insomnia, sedation, fatigue, anxiety, impaired cognitive function, blurred vision, dry mouth, arrhythmias, orthostatic hypotension
Mirtazapine	15–45 [7.5–15]	Extensively hepatic via CYP1A2, CYP2C9, CYP2D6, CYP3A4, and via demethylation and hydroxylation	20–40, 2	Somnolence, constipation, xerostomia, increased appetite, weight gain
Doxepin	75–100 [25–50]	Hepatic	8–24, 2–3	As for amitriptyline
Trazodone	150–400 [150]	Hepatic	7, 1	As for amitriptyline
Non-prescription medications				
Melatonin	0.5–6	–		No known toxicity or serious side effects
Alternative agents				
Ramelteon	8 (30 min before bedtime)	Extensive first-pass effect; oxidative metabolism primarily through CYP1A2 and to a lesser extent through CYP2C and CYP3A4		Central nervous system depression, reproductive hormonal regulation disturbances

Table 8.6.1 Continued

Drug name	Dose (mg) [dose recommended in elderly and medically ill (mg)]	Metabolism	Half-life (hours) and peak plasma concentration (hours after administration)	Adverse effects
Anticonvulsants				
Gabapentin	300–600 [300]	Hepatic, renal	5–7, 2–4	Drowsiness, dizziness, ataxia, tremor, diplopia, nystagmus, myalgia, peripheral oedema
Clonazepam	0.25–0.50 [0.25]	Hepatic	30–40, 1–4	Drowsiness, dizziness, ataxia, nervousness
Tiagabine	4–8 [4]	Hepatic	7–9, 0–75	Drowsiness, dizziness, ataxia, tremor, new onset of seizures in patients without epilepsy, asthenia, gastrointestinal disturbances
Antipsychotics				
Olanzapine	5–10, 5	Hepatic	21–54, 6	Drowsiness, dizziness, ataxia, tremor, extrapyramidal symptoms, new-onset diabetes mellitus
Quetiapine	25–200, 25	Hepatic	6, 15	As for olanzapine

effect is insufficient. Although evidence of efficacy for sleep disturbances is lacking, other drugs are considered in refractory cases or when a specific disorder is identified. For example, a neuroleptic may be appropriate when sleep disruption occurs in association with an organic brain syndrome.

Benzodiazepine receptor agonists

Zolpidem, zaleplon, and zopiclone are currently the medications of choice in the treatment of short-term or transient insomnia. Although their use in chronic insomnia remains unclear due to uncertainty about long-term effectiveness, they are used for various types of chronic insomnia (Sateia and D' Nowell, 2004). These drugs reduce sleep latency and wake time after sleep onset. Side effects are usually minimal. There is a very small chance of abuse, dependence, and tolerance, and no withdrawal or rebound insomnia is observed after long-term use (Schuman and Attarian, 2012).

Although generally considered safe, the use of the benzodiazepine receptor agonists in populations with advanced illness must be undertaken cautiously. The rate of drug metabolism may be significantly slower in medically ill and geriatric patients, predisposing to greater drug accumulation and daytime carry-over effects. Studies suggest that the use of sedative-hypnotics in the elderly is associated with increased risk of falls, hip fracture due to motor incoordination, and cognitive impairment (Sateia and D' Nowell, 2004). Perhaps the most common undesirable side effects are those of daytime sedation, nocturnal confusion, and performance decrement (Sateia and D' Nowell, 2004).

Other sleep medications

Sedative antidepressants have also assumed an important role in the treatment of chronic insomnia and non-restorative sleep (Sateia and D' Nowell, 2004). The tricyclic compounds, amitriptyline and doxepin, can be administered at lower dosages than those typically required for the treatment of major depression (Schuman and Attarian, 2012). Although usually safe with cautious dosing,

the risk of toxicity related to excessive sedation, orthostatic hypotension, cardiotoxicity, and anticholinergic effects (including delirium from central effects) must be recognized (Sateia and D' Nowell, 2004). In some countries, mirtazapine and trazodone are used for their potential effects on sleep. Clinicians must always have in mind that the metabolism of antidepressants may be substantially slower in chronically medically ill patients and the elderly.

Melatonin is a hormone produced by the pineal gland that contributes to reinforcement of circadian and seasonal rhythms (Morin and Benca, 2012). It has received widespread attention for treating chronic insomnia and other sleep disorders, particularly sleep–wake cycle disturbances, Recent evidence suggests that it can be used in elderly patients, since melatonin is normally reduced as part of ageing. Ramelteon, a melatonin receptor agonist, reduces latency to sleep, but does not increase total sleep time; it has been reported that it might help promote circadian rhythm entrainment at lower doses (Morin and Benca, 2012; Schuman and Attarian, 2012).

Other drugs are sometimes tried when insomnia has been refractory to routine therapies. Antihistamines used as sleep-inducing agents include diphenhydramine and doxylamine succinate. An herbal preparation, valerian, has been shown to bind to gamma-aminobutyric acid type A receptors and to improve subjective improvement in sleep quality without improvement in quantitative measures (Morin and Benca, 2012). Some anticonvulsants, such as tiagabine hydrochloride and pregabalin, have been reported to increase SWS, as well as to decrease wakefulness after sleep onset and decrease sleep latency (Morin and Benca, 2012). Pregabalin has been reported to decrease insomnia and anxiety in patients with comorbid generalized anxiety and insomnia (Montgomery et al., 2009), and to reduce insomnia and pain in patients with fibromyalgia (Russell et al., 2009). Finally, atypical antipsychotics, quetiapine and olanzapine in particular, are occasionally used for insomnia, particularly if there are associated

signs of organicity (Morin and Benca, 2012). All of these drugs must be used very cautiously in the medically ill due to concerns about daytime sedation, dizziness, cognitive impairment, and falls (Morin and Benca, 2012).

Non-pharmacological interventions

The management of sleep disorders in the medically ill should aim to improve the quality and quantity of sleep, mitigate the impact of contributing comorbid disorders, and improve quality of life (Schutte-Rodin et al., 2008; National Cancer Institute, 2010). From this perspective, cognitive and behavioural therapies may have advantages for some patients (Lindley et al., 1998; Smith et al., 2005; Irwin et al., 2006; Page et al., 2006; Kozachik and Bandeen-Roche 2008; Harsora and Kessman, 2009; Harvey, 2010). Some studies suggest that a large majority of patients with chronic diseases can benefit from cognitive behavioural therapy (CBT) (Belanger et al., 2006), notwithstanding the potential for limited effectiveness in some populations, such as the elderly (Irwin et al., 2006).

CBT is an integration of cognitive therapy and behavioural modification techniques. In the 1950s, Skinner, Pavlov, and Wolpe developed behaviour therapy from learning theories derived from their experiments in classical conditioning, operant conditioning, and desensitization. Behavioural therapy focuses on observable behaviours that can be modified in the present; the patient gradually is taught to replace maladaptive learned responses with healthier behaviours, through positive, and negative reinforcement (O'Donohue and Krasner, 1995; Belanger et al., 2006). The advantages of behavioural therapy for sleep disorders is the durability and the lack of dependency or rebound insomnia; the disadvantages are that the technique requires regular practice and the effect may take 2 weeks or longer to appear (Morin et al., 1999).

Cognitive therapy, which was initially developed in the 1960s by Beck, helps patients to evaluate and change negative thoughts or cognitive distortions, a process known as cognitive restructuring (Belanger et al., 2006). Patients can be educated to identify dysfunctional beliefs related to sleep or the consequences of insomnia, interventions that aim to reduce anticipatory anxiety (fear of insomnia). They also may learn specific techniques to reduce symptoms and enhance self-efficacy.

CBT is goal-oriented and requires active participation by the patient (Belanger et al., 2006; Reeve and Bailes, 2010). It is predicated on an understanding of insomnia as a problem that has transitioned from acute to chronic as a result, at least in part, of maladaptive compensatory strategies and behavioural contingencies separate from medical or psychiatric causes (Buysse et al., 1994). To address these issues, patients who are able to participate in this therapy can be taught specific cognitive and behavioural strategies to improve sleep hygiene, correct misconceptions about sleep, and manage symptoms and distress (Turner and Asher, 1979; Smith et al., 2005).

In CBT, patients may learn specific techniques, such as relaxation training, guided imagery, diaphragmatic breathing, meditation, autogenic training, and biofeedback (McCurry et al., 2007). Hypnosis can reduce the frequency and severity of hot flashes and may also improve sleep quality in breast cancer patients. (Becker, 1993; Elkins et al., 2008; Jensen et al., 2012). Relaxation training, usually progressive relaxation, is probably the most frequently employed technique, and is based on procedures developed by

Jacobson in the early twentieth century (Jacobson, 1938; McCurry et al., 2007). The approach involves progressively tensing and then relaxing each muscle group while concentrating on and contrasting sensations of tension and relaxation.

Studies suggest that CBT may improve time to fall asleep and nocturnal wake time, as well as inducing other benefits, such as improved pain management and reduced anxiety (Smith et al., 2005; Espie et al., 2008). Compared to the control group, a group of 30 cancer patients with chronic sleep-onset insomnia who underwent three sessions of progressive muscle relaxation training, with instructions to practise twice per day for 9 days, achieved a significant, 83-minute differential reduction in latency to sleep onset, which was maintained at a 3-month follow-up (Cannici et al., 1983). In another study, 12 cancer patients benefited from stimulus control, relaxation techniques, sleep hygiene, and cognitive approaches to decrease worry and emotional arousal during pre-sleep intervals (Schutte-Rodin et al., 2008). Stimulus control in this model was based on the principles of classical conditioning and attempted to associate the bed with sleep in an effort to re-associate the bedroom with a rapid onset of sleep and to establish a set wake-up time that stabilises the sleep–wake rhythm. Patients experienced significant improvements by the end of treatment, as well as a post-treatment reduction in fatigue, improvement in role functioning, and a trend towards improvement in depressive symptom severity (Davidson et al., 2001).

When a few CBT strategies are combined and focused specifically on the management of sleep disturbance, they may be termed cognitive behaviour therapy for insomnia (CBT-I) (Smith and Neubauer, 2003). Studies of CBT-I for primary insomnia have demonstrated large effect sizes on a variety of sleep parameters. Benefits of brief CBT-I, including improved sleep parameters and reduced medication use, have continued for follow-up periods up to 2 years after treatment completion (Smith et al., 2005). Studies of CBT-I in medically ill populations indicate similar benefits (Simeit et al., 2004; Espie et al., 2008; Woodward, 2011). Some authors, however, note that patients' access to CBT-I practitioners is limited and cost often is prohibitive (Espie, 2009; Savard et al., 2010).

Future work

Many challenges remain in characterizing and treating sleep disorders in populations with medical illness. Future research must expand our knowledge about the biological dimensions, as well as the behavioural aspects of these disorders. Awareness of accurate diagnosis of sleep disturbances and of effective treatment strategies using both pharmacological and non-pharmacological approaches should be developed.

8.7

The management of bleeding in palliative care

Jose Pereira and Jennifer Brodeur

Introduction to the management of bleeding in palliative care

Bleeding is one of the more distressing symptoms experienced by patients with advanced life-threatening illnesses. It may be the presenting symptom that prompts patients to seek medical attention (Moreno-Otero et al., 1987; Jellema et al., 2010), or the harbinger of disease recurrence and progression. Bleeding is associated with a poorer prognosis in some cancers, such as gastric cancers (Prommer, 2005), and the cause of death in others (Stalfelt et al., 2003; Rimmer et al., 2012). For some patients it is the principal symptom, overshadowing others (Stalfelt et al., 2003).

Frequency of bleeding

The prevalence and incidence of bleeding in patients with progressive, life-limiting illnesses vary depending on the disease and the illness trajectory. In a study of patients with lung cancer, bloody sputum was present at the time of diagnosis in 17% of patients, varying across cancer cell types (Buccheri and Ferrigno, 2004). Throughout the illness, haemoptysis occurs in a quarter to a third of lung cancer patients (Chute et al., 1985; Hopwood and Stephens, 1995) and 3% experience catastrophic terminal haemoptysis (Prommer, 2005). About 10% of patients with renal cancer present with haematuria at the time of diagnosis (Schips et al., 2003). Bleeding occurs in 5–15% of patients with hepatocellular cancer (Zhu et al., 1996; Okuda, 1997).

While most cases of upper gastrointestinal bleeds in patients with cancer are due to gastritis and ulcerative disease, up to 27% are caused by tumour invasion (Shivshanker et al., 1983).

In a study of patients with advanced cancer cared for by a home-based palliative team until death, 2.5% experienced gastrointestinal bleeding (melena or haematemesis) (Mercadante et al., 2000). In patients with acute myeloid leukaemia, bleeding occurred in 44% of cases in the last week of life; cerebral haemorrhage was listed as the cause of death in 9.4% (Stalfelt et al., 2003).

Bleeding also occurs in terminally ill patients with non-cancer diagnoses. Variceal haemorrhage, for example, occurs in 25–35% of patients with cirrhosis (Burroughs, 1993; Sharara and Rockey, 2001). Recent studies have noted a reduced rate of rebleeding in these patients, from 47% in 1980 to 13% in 2000 (Carbonell et al., 2004). There have also been improvements in survival after variceal bleeding (Carbonell et al., 2004).

Causes of bleeding

The causes of bleeding in patients with advanced disease are varied and may sometimes have several aetiologies or aggravating factors in any given patient (DeLoughery, 2009). Gagnon and colleagues proposed three major categories of causes: (1) anatomical (or local), (2) generalized (e.g. coagulation dyscrasias), or (3) a mixed (local and generalized) (Gagnon et al., 1998). Prommer proposes a more detailed classification of six causal categories (Prommer, 2005): (1) cancer invasion and destruction, (2) treatment-related causes, (3) thrombocytopenia/marrow failure, (4) nutritional deficits, (5) drugs, and (6) coagulation disturbances.

The primary tumour may invade tissues, including small and large vessels. Metastatic lesions and the granulation tissue within a malignant wound are often friable and hypervascular, increasing the risk for bleeding. Reduced fibroblast activity and ongoing thrombosis of larger vessels in infected and malignant wounds may render the granulation less resilient to trauma. Minor trauma, such as removal of dressings, may trigger bleeding. Some cancers such as renal cell carcinoma, choriocarcinoma, and melanoma are particularly vascular. In head and neck cancer, the walls of blood vessels may be weakened by exposure to saliva and prior radiation or surgery.

Chemotherapy and/or radiotherapy treatments may affect haemostatic mechanisms and damage mucosae, resulting in bleeding (Peterson and Cariello, 2004; Takemoto et al., 2012). Mucositis of the upper gastrointestinal tract is a frequent complication in patients receiving fractionated radiotherapy with or without concomitant chemotherapy for head and neck cancer and lung cancer (Trotti et al., 2003). Incidence of severe mucositis of the entire gastrointestinal tract can be as high as 75% in patients undergoing hematopoietic stem-cell transplantation (Peterson et al., 2009). Bone marrow transplantation and severe graft-versus-host disease are associated with the risk of haemorrhagic complications (Pihusch, 2004).

Treatment-related causes of bleeding include thrombocytopenia secondary to myelosuppressive chemotherapy such as imatinib mesylate (Croom and Perry, 2003), microangiopathic haemolytic anaemia syndrome associated with agents such as mitomycin (Rosen, 1992), haemorrhagic cystitis secondary to drugs such as cyclophosphamide and ifosfamide, and angiogenesis inhibition with agents such as bevacizumab (Kilickap et al., 2003; Hapani et al., 2010). Post-radiotherapy telangiectasia can cause bleeding following treatments of bladder, cervix, and prostate cancer.

Solid tumours with extensive bone metastases, leukaemias, and lymphomas may cause marrow failure by invading the marrow, resulting in thrombocytopenia (Prommer, 2005). Some cancers, such as prostate cancer, can also cause thrombocytopenia due to disseminated intravascular coagulopathy (DIC). Mucin-producing carcinomas of the prostate, pancreas, lung, breast, ovary, and gastrointestinal tract are associated with increased risk for DIC, as are acute leukaemias (Bick et al., 1996). The increased risk for bleeding in prostate cancer has also been attributed to increased fibrinolysis, preventing healing of the vascular endothelium (Kohli et al., 2003). Thrombocytopenia could occur due to immune-related mechanisms as well as sequestration, from advanced liver disease and associated splenomegaly.

Patients with very advanced disease suffer from a variety of nutritional deficits that could cause or aggravate bleeding. These include deficits of vitamin B_{12}, folate (Stefanini, 1999), zinc (Dunn et al., 2003), and vitamin K (Harrington et al., 2008).

Non-steroidal anti-inflammatory medications may interfere with platelet function or cause gastrointestinal ulceration. The use of anticoagulant medication, particularly warfarin, has been associated with excess bleeding in patients at the end of life Johnson, 1997). A number of commonly used drugs occasionally cause thrombocytopenia. These include trimethoprim-sulfamethoxazole, cimetidine and ranitidine, acetaminophen (paracetamol), carbamazepine, and heparin-related drugs.

Not all episodes of bleeding in patients with advanced cancer are related to the cancer or its treatments. Although rarer, bleeding may be caused by conditions such as idiopathic thrombocytopenic purpura and Goodpasture's syndrome.

Clinical presentation

The clinical presentation of bleeding in the palliative care setting is variable. It may be visible, as in haemoptysis or hematemesis, or invisible, as in cerebral haemorrhaging (Mandybur, 1977) or rupture of a liver mass (Zhu et al., 1996; Akriviadis, 1997). Volumes may vary, from low-grade oozing from a malignant wound to massive and catastrophic in the case of a ruptured carotid artery (Recka et al., 2012). Bleeding may be continuous or intermittent. Bleeding may be localized or from multiple sites as in the case of systemic coagulopathies.

Some patients present with small prodromal bleeding occurring several hours or days before the rupture of a larger artery (Harris and Noble, 2009) referred to as 'sentinel' or 'herald' bleeds. It is prudent to consider most initial presentations of bleeding as sentinel bleeds. This is particularly true of haemoptysis or bleeding from a malignant neck wound (Fernando et al., 1998).

Catastrophic, terminal haemorrhaging warrants special attention because of its dramatic clinical presentation and the profound distress it causes to patients, families, and caregivers (Harris and Noble, 2009). The rapid sequence of events gives little time to support and comfort the patient. Harris and Noble define it as 'a major haemorrhage, from an artery, which is likely to result in death within a period of time that may be as short as minutes, because of the rapid internal or external loss of circulating blood volume' (Harris and Noble, 2009).

Back defined it as major arterial haemorrhage with loss of more than 1.5 L of blood in 30 seconds which will inevitably cause death in minutes (Back, 2001). Prommer defines massive haemoptysis as expectoration of at least 100–600 mL of blood in 24 hours (Prommer, 2005). Fernando et al. used the presence of one or more of the following criteria to define major haemoptysis: (Fernando et al., 1998) bleeding 200 mL or more per 24 hours; bronchial blood loss that caused haemodynamic or respiratory compromise; or bleeding that resulted in a haematocrit of less than 0.30 (< 30%).The terms 'massive' or 'catastrophic' are sometimes preferred over the term 'terminal' haemorrhage because not all large bleeds result in death. Harris and Noble propose that any major bleed should be managed in the same way as there is no way of knowing which will be terminal events (Harris and Noble 2009). The mortality rates of massive haemoptysis may be as high as 60–100% in patients with bronchogenic carcinoma (Fernando et al., 1998; Kvale et al., 2003).

Carotid blow-out (CBO), a complication that has a high mortality rate, usually occurs proximal to the carotid bifurcation and is commonly associated with soft tissue necrosis in the neck (55%) and mucocutaneous fistulas (40%) (Citardi et al., 1995; Powitzky et al., 2010) (see Chapter 14.5). Citardi and colleagues suggested that CBO is a syndrome with three distinct clinical entities (Citardi et al., 1995): (1) 'threatened' CBO (when the artery is clinically exposed or there is radiological evidence of carotid invasion), (2) 'impending' CBO (a herald bleed has settled spontaneously or with treatment), and (3) 'acute' CBO (rupture with profuse bleeding). All three presentations require urgent attention (Harris and Noble, 2009) as even the smallest of bleeds should be taken seriously (Fortunato and Ridge, 1995).

Patients at risk for bleeding

Factors that place cancer patients at increased risk for bleeding have been proposed (Prommer 2005; Harris and Noble, 2009) (see Table 8.7.1). It is important to initiate pre-emptive treatments when possible and to prepare caregivers.

Table 8.7.1 Risk factors for bleeding in cancer patients

Overall risk factors for bleeding in cancer patients (Prommer, 2005)	Risk factors for terminal haemorrhaging in head and neck cancers (Harris and Noble, 2009)
◆ Thrombocytopenia <20,000/µL	◆ Radical neck dissection
◆ Large head and neck cancers	◆ High-dose radiotherapy
◆ Large centrally located lung cancers	◆ Postoperative healing problems
◆ Refractory acute and chronic leukaemias	◆ Visible arterial pulsation
◆ Myelodysplasia	◆ Pharyngocutaneous fistula
◆ Sever liver disease and metastatic liver disease	◆ Fungating tumours with artery invasion
◆ Hepatocellular carcinoma	◆ Direct observation during surgery or imaging (e.g. magnetic resonance imaging) of artery wall invasion
◆ Oral anticoagulants	◆ Sentinel bleed
◆ High-dose radiation therapy

Impact on patients, families, and care providers

Except for in malignant wounds (Goode, 2004; Lo et al., 2008; Alexander, 2009) there are few studies that explore the meaning that patients associate with bleeding and its psychological impact (Maida et al., 2009). In addition to morbidity and mortality, bleeding may also result in increased used of emergency services. In a large Canadian study of cancer patients who visited an emergency department at the end of life, about 2% did so because of gastrointestinal bleeding or haematuria (Barbera et al., 2010).

Management plan

General

Communication and clarifying goals of care

The management plan should be individualized; several factors need to be considered. These include the patient's life expectancy, performance status, quality of life, previous therapies, acuteness of situation, likelihood of reversing or controlling the underlying cause of the bleeding, access to interventions such as interventional radiology, and patient preferences. A newly diagnosed patient with good performance status will be managed differently from a patient at the end of life with a poor performance status.

Establishing goals of care is important, particularly in patients at risk for a major bleed. The discussion should be consistent with a patient's information needs and preferences and the care plan should, amongst others, be compatible with the patient's wishes (Prommer, 2005).

Whether the patient, family, and caregivers should be informed of the risk of terminal haemorrhage poses an ethical dilemma. Arguments for and against full disclosure to patients exist (Frawley and Begley, 2006b; Harris and Noble, 2009). An individualized approach is recommended; finding a balance between information needs against the potential psychological impact of full disclosure (Frawley and Begley, 2006a). Some suggest that, although patients need not be universally informed about the risk, families and caregivers should be made aware so as to prepare them for what could be a very distressing event (Gagnon et al., 1998; Pereira and Phan, 2004). Unprepared caregivers may panic, calling emergency services that are required to institute resuscitative measures. The implications of asking a caregiver and family member to administer prefilled syringes of sedatives in the event of a massive bleed should be considered (Harris and Noble, 2009).

History and physical examination

A comprehensive history and examination is required. The goals of the clinical assessment are to establish the scope of the problem, identify patients at risk and in the setting of active bleeding, identify underlying causes and aggravating factors, and assess its impact on the patient and family.

Current and recent medications as well as past medical history should be reviewed. The benefits versus burden of continuing prophylactic anticoagulation treatments or medications that may be causing or aggravating bleeding need to be assessed. In addition to assessing the location, pattern, and severity of bleeding, the physical examination may also provide valuable clues as to its origin; the presence of multiple sites of bleeding, for example, points to systemic problems.

Investigations

Investigations are warranted in some situations, especially if a patient is not at the end of life. A full blood count and basic coagulation blood work-up may be useful, including the international normalized ratio (INR), activated partial thromboplastin time, platelet count, and fibrinogen level. Coagulation defects vary across different problems (DeLoughery, 2009). Procedures such as endoscopy and angiography may be required in select cases to identify and treat the source of bleeding. Magnetic resonance imaging may be useful when exploring CBO risk in a patient with a fungating neck wound

Prevention

Strategies to prevent or reduce the risk of bleeding should be implemented where possible. Bleeding from ulcerated wounds can be minimized by using non-adherent dressings, maintaining a moist wound bed, and gently irrigating rather than swabbing. Dry dressings should be avoided. Pre-emptive treatments, such as endovascular stents in the case of large neck tumours, may be considered in very select cases. A randomized placebo controlled trial of preventative topical rectal beclometasone dipropionate found a significantly reduced risk of rectal bleeding in patients receiving radiation for prostate cancer (Fuccio et al., 2011). Beta blockers may play a role in preventing bleeding from high-risk oesophageal varices in end-stage liver disease; endoscopic prophylactic sclerotherapy is not recommended in these cases (The Veterans Affairs Cooperative Variceal Sclerotherapy Group, 1991; Pagliaro et al., 1992).

Treatment options

A number of treatment modalities are available. These can be divided into (a) general measures, (b) local measures (see Box 8.7.1), and (c) systemic measures. The decision to select one or the other is dependent on a number of factors. In addition to goals of care, functional status, co-morbidity, and patient preference, they include aetiology of the bleed, availability of the modality, benefit versus burden, and cost. Unfortunately studies in the palliative care setting comparing various modalities and approaches are generally lacking and guidelines are largely based on case reports and expert opinion (Regnard and Makin, 1992; Harris and Noble, 2009).

General measures

General supportive measures include, in addition to proactive planning, the use of dark towels and staying with and comforting the patient in the case of a massive bleed (Harris and Noble, 2009; Harris et al., 2011). General resuscitative measures, including aggressive fluid replacement or blood products, are generally inappropriate in patients with very advanced disease but may be appropriate alongside interventional measures to stop bleeding in some patients.

Management: local modalities

Compression, compression dressings, and packing

Pressure, using surgical gauze and dressings, is the simplest form of haemostasis, particularly in emergency situations. For minimal bleeding, compressive dressings generally suffice (Recka et al.,

Box 8.7.1 Local and systemic modalities

Local modalities[a]

- ◆ **Compression dressings and packing**
- ◆ Topical haemostatic agents:
  - **Absorbable agents**: **gelatin foams, oxidized cellulose, microfibrillar collagen**
  - Biologic agents (*limited usefulness in palliative care*): topical thrombin, fibrin sealants, platelet sealants
  - Alginates
  - **Astringents, sclerosing and vasoconstrictor agents**: silver nitrate, alum solutions, sucralfate, formalin, acetone, epinephrine (adrenaline), topical cocaine, zinc chloride, oxymetazoline
  - Synthetic agents: cyanoacrylates, glutaraldehyde cross-linked albumin
  - Haemostatic dressings: fibrin dressing, chitin/chitosan dressings, mineral zeolite dressings
  - Other: tranexamic acid, steroids
- ◆ **Radiation therapy**
- ◆ **Embolization and balloon tamponade**
- ◆ **Endoscopy:** ligation, sclerosing agent, cauterization, balloon tamponade, thrombin/fibrinogen application
- ◆ Surgery: vessel ligation, resection

Systemic modalities[a]

- ◆ **Antifibrinolytic agents**
- ◆ Somatostatin analogues (octreotide)
- ◆ Vasopressin analogues (desmopressin/DDAVP)
- ◆ **Vitamin K**
- ◆ Blood/plasma products:
  - Platelets
  - Fresh frozen plasma
  - Cryoprecipitate
- ◆ Recombinant coagulation factors (VIIa, VIII, IX)
- ◆ Hyperbaric oxygen therapy
- ◆ Other modalities: pentosanpolysulphate, melatonin, thalidomide

[a] First-line modalities in bold.

2012). With the exception of alginate dressings, most compressive dressings are not inherently haemostatic (Terrill et al., 2003).

Packing, with saline-soaked dressings, surgical swabs, or special haemostatic dressings, is useful for bleeding from accessible hollow organs such as the nose, rectum, and vagina. Haemostatic or vasoconstrictor agents, such as silver nitrate, cocaine, and/or epinephrine (adrenaline) may be added to the dressings. Vaginal bleeding, for example, has been controlled with packs soaked with formaldehyde or acetone (Patsner, 1993; Fletcher et al., 2002). If possible, the frequency of dressings should be reduced and non-adherent dressings used.

Compression can also be achieved with inflatable balloons. Specially designed catheters with inflatable balloons may be used

to control severe posterior nasal bleeding. In emergent cases, urinary catheters have been used. Such measures are temporary since prolonged pressure may cause tissue necrosis.

Topical haemostatic agents

A large number of topical agents are available (see Box 8.7.1). They differ in constitution, mechanisms of action, indication, packaging, and price. Many, such as the absorbable agents and biologic agents, were designed for intraoperative control of minor bleeding during vascular, cardiac, oral, and reconstructive surgery when other conventional methods are ineffective (Achneck et al., 2010). They are often used for one-time applications. A large number of products are available, from powders, sponges, pads, and ribbons, to dual-syringe systems. Their costs vary; some such as topical thrombin and fibrin sealants are prohibitively expensive for multiple applications.

Absorbable products

Absorbable products are amongst the least expensive of the surgical haemostatic products and are easy to apply (Achneck et al., 2010). Gelatin foams can be applied as a sponge, powder, or film (Achneck et al., 2010). The powder is mixed with a sterile saline solution and applied as a paste. Sponges can be applied either dry or saturated with sterile saline or topical thrombin solutions. Unlike oxidized cellulose, the pH of gelatin foams is neutral; so they can be combined with thrombin to provide a physical matrix for fibrin deposition and clotting to be initiated. These products are usually fully absorbed approximately 4–6 weeks following application, except in the nose and nasal pharynx where it liquefies within 2–5 days. Occasionally, gelatin can swell to twice its size and may lead to compressive complications when used in confined spaces or near nerves.

Oxidized regenerated cellulose products are available as sponges and pads and have been used in the palliative setting (Lagman et al., 2002). They are more pliable than the gelatin foams. They should be applied dry, and tend to expand and dissolve in 2–6 weeks.

Microfibrillar collagen is available in sponge and powder forms. The mesh form may be cut to size and conforms well to irregular surfaces. The preparations can be stored at room temperature and are ready to use out of the box. Platelets adhere to the fibres and are activated, resulting in platelet aggregation and thrombus formation (Wagner et al., 1996). It is therefore less effective in patients with severe thrombocytopenia but effective in heparinized patients. It appears to be useful in large areas of parenchymal bleeding (Chapman et al., 2002).

Biologic agents

Thrombin forms the basis of a fibrin clot by promoting the conversion of fibrinogen to fibrin. It requires the presence of fibrinogen. Bovine plasma-derived products are associated with the development of antibodies to thrombin and other clotting factors, while products derived from pooled human plasma cause fewer immunological complications. A recombinant product is now available (Chapman et al., 2007). The bovine and recombinant products require reconstitution in sterile isotonic saline solution, while the human-derived product is 'ready to use'. The human-derived product is available in small vials with syringe and spray applicators. An epistaxis kit is also available. Thrombin may be applied either directly to the bleeding site or soaked in gelatin sponge.

Thrombin vials are for single use only and require frozen storage and thawing before application. They cannot be refrozen.

Fibrin sealants are made of two components: thrombin and fibrinogen (Kanaoka et al., 2001; Mankad and Codispoti, 2001). They are applied with a dual-syringe delivery system that mixes the two components as it is applied (Achneck et al., 2010). The components interact to form a stable fibrin clot. In contrast to passive haemostatic agents such as collagen, alginate, and cellulose products that promote the patient's own blood clotting mechanism, fibrin sealants coagulate independently from patient blood and are therefore useful even in patients with severe coagulopathy. They are derived from pooled or autologous human plasma or bovine plasma and may cause immunological reactions; less so with human-only derived. They are available in 2 mL and 5 mL single dosing syringes and are very costly and need to be thawed prior to usage. Fibrin sealant, instilled via bronchoscopy, has been used to control massive haemoptysis (Pandya et al., 2011).

Platelet sealant is a thrombin/collagen suspension which works in combination with the patient's own plasma to form a fibrin/collagen clot. It is resorbed in 30 days and is intended to be left *in situ*. It is not very practical in the palliative care setting as it requires centrifugation of the patient's own plasma and significant pre-application processing.

Alginates

Alginate dressings are readily available for minor bleeds, particularly oozing from malignant wounds. They are fibre dressings containing alginic acids (mannuronic and guluronic) which are extracted from seaweed species and are available as pads or ribbons (Timmons, 2009). Alginates are best used on wounds with a large amount of exudate; but are not useful in large-volume bleeds. The fibrous dressings form a gel when in contact with wound exudate; the calcium alginate in the dressing forms sodium alginate and calcium ions which in turn support the normal clotting process. The gel prevents the wound from drying out and assists in autolytic debridement. This function precludes alginates from being used in dry or low exuding wounds, as they may adhere to the wound bed.

Alginates require a secondary cover dressing such as a bio-occlusive thin film, hydrogel sheet, or gauze to keep them in place. They can absorb up to 20 times their weight in fluid. Alginates can be rinsed away with saline irrigation, so removal of the dressing does not interfere with healing granulation tissue. Some alginates contain a silver compound which provides antimicrobial protection. Wounds are generally irrigated with sterile saline when the dressings are removed so as to remove the fibres.

Alginates are also useful for deep, undermined wounds as the risk of infection or tissue inflammation is reduced if they are left *in situ*. Alginates are usually changed every 12–48 hours, but in some cases may be left in place for up to 7 days. Wounds with lots of exudates may require more frequent dressing changes (Grocott, 1998).

Astringents, sclerosing, and vasoconstrictor agents

Astringents induce chemical cauterization and are best used to control minor to moderate bleeds. The two most commonly used astringents are silver nitrate and aluminium-based solutions. Silver nitrate acts as a strong oxidizing agent, causing tissue coagulation (Hanif et al., 2003). Silver nitrate, fused with potassium nitrate on the end of thin wooden applicators, has been extensively used in the management of epistaxis. The ends of the sticks are gently applied with minimal pressure to the vessel. It is relatively inexpensive and requires minimal technical skill to apply.

Silver nitrate, in a concentration of 0.5–1% and instilled for 10–20 minutes, has been used to manage bladder bleeding (Jerkins et al., 1986); ureteral stenosis, however, is a potential complication (Vijan et al., 1988).

Intravesical alum bladder irrigations have been described in the management of bladder-related haematuria, with response rates of 66–100% (Ostroff and Chenault, 1982; Arrizabalaga et al., 1987; Octavio and Buizza, 1989). A recommended regimen consists of using a 1% alum solution, dissolving 50 g of alum in 5 L sterile water and irrigating the bladder at 250–300 mL per hour (Choong et al., 2000). Alum (either aluminium ammonium sulphate or aluminium potassium sulphate) causes the precipitation of protein in the interstitial tissue spaces, resulting in decreased capillary permeability, vasoconstriction, constriction of the interstitial spaces, and hardening of the capillary endothelium. The treatment duration is usually 3–4 days, but can be extended up to 1 week. It is generally safe and well tolerated. It should be avoided in patients with renal impairment or very large bladder tumours as aluminium encephalopathy and death have been described in these patients (Murphy et al., 1992; Shoskes et al., 1992). Ureteral fibrosis has been reported.

Sucralfate has a cytoprotective action derived from the production of prostaglandins and promotion of epithelial cell proliferation (Prommer, 2005). Sucralfate enemas (usually 20 mL of 10% sucralfate suspension), applied twice a day until bleeding stopped, successfully controlled bleeding from radiation proctitis (Cotti et al., 2003; Chun et al., 2004). Sucralfate can be mixed with K-Y® Jelly forming a paste for direct application to bleeding sites, including malignant wounds (Regnard 1991; Thomas et al., 1998). A preparation made up of a 1 g tablet of sucralfate, crushed and mixed into 5 mL of water-soluble gel for twice-daily application, has been suggested for malignant wounds (Woodruff 1993).

Topical formalin, usually in concentrations of 4–5%, has been used to control haemorrhaging from radiation proctitis (Biswal et al., 1995b; Roche et al.,1996; Saclarides et al., 1996; Parikh et al., 2003), rectal cancer (Zbar et al., 2005), bladder lesions (Donahue and Frank, 1989; Vicente et al., 1990; Redman and Kletzel, 1994; Fu et al., 1998; Sarnak et al., 1999), vaginal/cervix tumours (Yegappan et al., 1998), and cutaneous ulcers (Adebamowo, 2000). Formalin controls bleeding by fixing tissue, causing the cross-linkage of tissue proteins. Coagulation of tissue also occurs (Parikh et al., 2003). In rectal bleeding it is applied as an irrigation or soaked in gauze. In a case series, topical formalin controlled bleeding in 89% of patients (Cotti et al., 2003). In another series, haemorrhagic proctitis was controlled with 500 mL of a 4% formalin solution instilled in the rectum in 50 mL aliquots (Saclarides et al., 1996). Treatments were done under local, regional, or general anaesthesia. Endoscopy-aided insertion of cotton pledgets soaked in 5% formalin has been used to control bleeding from multiple foci in the bladder (Choong et al., 2000). Intravesicular formalin instillation is done with solutions of 1%, 4%, or 10% for a period of between 5 and 30 minutes (Ghahestani and Shakhssalim, 2009; Guven et al., 2011). Despite good response rates, formalin is associated with severe adverse effects, including spasms, kidney failure, retroperitoneal fibrosis, incontinence, reduced bladder capacities, and even death (Braam et al., 1986).

Acetone-soaked packs may control vaginal bleeding from recurrent pelvic malignancy, particularly in patients who have previously undergone radiotherapy or when embolic techniques are not available (Patsner, 1993).

Vasoconstrictors such as cocaine and epinephrine have been used to control epistaxis (Katz et al., 1990; Chrisman, 2010). Cocaine can be applied to cotton pledgets and packed into the nasopharynx (Kothari et al., 2001); 4 mL of a 4% solution is used. Prostaglandins E_2 and F_2 have been used to control intractable haemorrhagic cystitis but bladder spasms may limit their utility. Epinephrine can also be used but liberal use can lead to necrosis and neurological and cardiac complications. Oxymetazoline is a local vasoconstrictor that works via stimulation of alpha-adrenergic receptors. It has been used to achieve haemostasis perioperatively in nasal surgery (Krempl and Noorily, 1995). Oxymetazoline spray combined with non-occlusive dressing helped to control bleeding in a malignant neck wound (Recka et al., 2012). Successful use of aerosolized vasopressin to stop mild to moderate haemoptysis has been reported in a small series in palliative care (Anwar et al., 2005).

Synthetic agents

A number of synthetic haemostatic agents are used as glues or mechanical sealants intraoperatively, including vascular, oncological (Carmignani et al., 2006; Chen et al., 2009), and cosmetic surgery. They include polyethylene glycol hydrogels, cyanoacrylates, and glutaraldehyde cross-linked albumin. Cyanoacrylates are synthetic resin glues that provide haemostasis by forming polymers when in contact with a basic medium such as blood or water. Lal and colleagues reported successful use of cyanoacrylate glue in a case of intractable bleeding from locally advanced duodenal cancer (Lal et al., 2009). Cyanoacrylate sclerotherapy by endoscopy has been used to stop bleeding of cholecystojejunostomy varices in a patient with pancreatic cancer (Hsu et al., 2010).

Haemostatic dressings

Haemostatic dressings and granules were developed to control ballistic injuries in battlefield injuries (Holcomb et al., 1998; Achneck et al., 2010). To date, there have been no reports of their use in the palliative care settings. The agents include chitin (a polysaccharide with haemostatic properties that is found in arthropod skeletons), chitosan (a deacetylated form of chitin) (Wedmore et al., 2006; Brown et al., 2009), zeolite agents (Neuffer et al., 2004; Rhee et al., 2008; Achneck et al., 2010), and kaolin-containing products (Kheirabadi et al., 2009).

Other haemostatic agents

Topical application of zinc chloride-containing paste (Mohs' paste) achieved haemostasis in bleeding from malignant wounds in five patients with breast cancer (Kakimoto et al., 2010). Local application of antifibrinolytic agents has been reported as has intravesicular instillation of E-aminocaproic acid (Lakhani et al., 1999). Tranexamic acid can also be applied topically to cancer in the rectum, bladder, and pleura (5 g in 50 mL of water, instilled once or twice a day). Tranexamic acid tablets (500 mg) have been crushed and dissolved in 5 mL of normal saline, soaked in gauze, and applied to skin wounds for 10 minutes (Twycross and Wilcock 2014b). It has also been used to control haemothoraces (De Boer et al., 1991), rectal bleeding (McElligott et al., 1991), and bleeding from oral lesions.

Steroid suppositories or enemas have been used in bleeding caused by radiation-induced proctitis (Takemoto et al., 2012). Carboplast (prostaglandin $F_{2\alpha}$) intravesical instillation (at doses of 0.4 mg/dL to 1 mg/dL four times a day alternating with continuous saline bladder irrigation for 2 hours over 4–5 days) has been reported in several case series; with a success rate of up to 54% (Levine and Kranc, 1990; Levine and Jarrard, 1993; Miller et al., 1994; Ippoliti et al., 1995; Laszlo et al., 1995). Bladder spasm is the most common side effect.

Radiation therapy

Radiation therapy (RT) is a very useful modality. RT appears to cause erosion of the surface of blood vessels, leading to formation of thromboses and capillary necroses (Lee et al., 2009). Benefits have been reported in patients with cancers of the lung (Medical Research Council Lung Cancer Working Party, 1992; Brundage et al., 1996; Fernando et al., 1998; Harris and Noble, 2009), uterus and cervix (Halle et al., 1986; Biswal et al., 1995a), ovary (Tinger et al., 2001), bladder (Srinivasan et al., 1994), rectum (Taylor et al., 1987; Hoskin et al., 2004), stomach (Myint, 2000; Tey et al., 2007), haemoptysis from metastatic thyroid cancer (Ulger et al., 2006), sarcoma metastatic to the vagina (Park et al., 2005), and prostate (Thurairaja et al., 2008; Din et al., 2009). Response rates ranging from 45% to 100% across a variety of cancers have been reported (Cihoric et al., 2012). RT was used to control intractable bleeding from a hypervascular mandibular metastasis in a patient with hepatocellular carcinoma (Huang et al., 2007) (see Chapter 12.3).

The reduction of haemoptysis by palliative RT in non-small cell lung cancer has been demonstrated in randomized trials using varying fractions (Bleehen et al., 1992; Langendijk et al., 2000). Response rates vary but are generally high with up to 75% or more of patients responding. Single or hypofractionated doses appear as effective and safe, with minimal toxicity, as multiple fractions in the management of haemoptysis.

Endoluminal brachytherapy is an option for managing bleeding in patients who are not eligible for more aggressive treatment (Klopp et al., 2006; Ozkok et al., 2008). Allison et al., reported the combined use of high-dose rate brachytherapy and flexible metallic stenting for palliation of haemoptysis and shortness of breath due to bronchial obstruction (Allison et al., 2004); haemoptysis resolved within 1 week of therapy.

Positive results have also been reported for the use of RT in the management of refractory haemorrhaging from carcinoma of the uterine cervix. In a small study, six out of 20 patients had a complete response and 12 had a partial response; improvements were noted within 24–48 hours after completing treatment (Biswal, et al., 1995a). In another study, treatment with single fractions of 10 Gy were successful in almost all patients with uterine and cervical cancer (Onsrud et al., 2001).

External beam RT has been shown to control cases of haematuria in patients with advanced bladder cancer. Initial response rates of 60–81% have been reported using single or hypofractionated regimens (Srinivasan et al., 1994; Duchesne et al., 2000; Din et al., 2009). Following intra-urethral brachytherapy, haematuria resolved in 19 of the 23 patients with intractable bleeding from advanced prostate cancer (Thurairaja et al., 2008). Haemostasis usually occurs within a few days. The role of RT for managing bleeding from inoperable renal carcinoma is unclear.

Palliative RT, either alone in varying fractions or in combination with chemotherapy, has shown benefits in controlling bleeding from gastric cancer, with response rates of 51–73% (Tey et al., 2007; Kim et al., 2008; Lee et al., 2009; Asakura et al., 2011). Rebleeding appears to occur in approximately half of the patients who responded. Lee et al. (2009) have suggested the following criteria for palliative radiotherapy to control bleeding in patients with gastric cancer: (a) Eastern Cooperative Oncology Group performance status score 3 or better, (b) expected survival duration of more than a few months, (c) failure or contraindication of other treatment modalities, and (d) oozing cancer bleeding accompanied by intractable pain. Endoscopic confirmation of cancer-related bleeding is suggested to avoid unnecessary RT for bleeding from benign causes, particularly bleeding in the gastrointestinal and urogenital tracts.

The role of RT to control bleeding malignant wounds has not been adequately explored. RT is often not an option in patients presenting with bleeding malignant neck wounds as most cases would have already received maximum doses.

Endoscopy

Endoscopy provides access to bleeding in the upper and lower gastrointestinal (Loftus et al., 1994; Savides and Jensen, 2000), bronchial, and genito-urinary tracts (Kimmey, 2004). It allows the operator to visualize the source of bleeding, take a tissue biopsy if required, and initiate definitive treatment. Once visualized, several options are available (Savides and Jensen, 2000): (a) cauterization or coagulation with electrocautery, heat probes, laser, argon plasma coagulation, or cryotherapy; (b) balloon tamponade; (c) ligation using endoclips or banding; (d) injection of a vasoconstrictor or sclerosing agents such as epinephrine, ethanol (Loscos et al., 1993), or cyanoacrylate; (e) application of haemostatic agents; or (f) instillation of agents for irrigation (Conlan and Hurvitz, 1980). The choice of method varies amongst endoscopists (Tang et al., 2009).

Cauterization can be done with electrocoagulation heat probes, cryotherapy probes, laser, or argon plasma coagulation. Heat probes require direct contact between the probe and the tissue. Neodymium:yttrium aluminium garnet (Nd:YAG) laser allows cauterization of the vessel and, in select cases, vaporization of cancerous tissue (Birnbaum and Mercer, 1990; von Ditfurth et al., 1990). In argon plasma coagulation (APC) (Akhtar et al., 2000; Reichle et al., 2000), a jet of ionized argon gas (plasma) is directed through a probe that is passed through the endoscope. The argon gas is then ionized by a high-voltage discharge and an electrical current is conducted through the jet onto the lesion, thereby coagulating it. There is no physical contact between the probe and the tissue. High-volume bleeds may make visualization difficult (Mathus-Vliegen and Tytgat, 1990; Lee et al., 2009). APC has been used in palliative surgeries of patients with head and neck cancers (Hauser et al., 2002).

Endoscopy has been used at various levels of the gastrointestinal tract, including the oesophagus and stomach (Suzuki et al., 1989; Gupta and Fleischer, 1993; Loscos et al., 1993; Savides et al., 1996; Akhtar et al., 2000), duodenum (Loftus et al., 1994), and rectosigmoid colon (Schrock, 1989; Birnbaum and Mercer, 1990; von Ditfurth et al., 1990; Schulze and Lyng 1994; Chun et al., 2004; Kimmey, 2004). Bipolar probe cauterization has been used to treat radiation-induced rectal bleeding (Chun et al., 2004).

Endoscopic haemostasis of gastric bleeding has provided temporary relief prior to elective surgical palliation for advanced gastric cancer (Cook et al., 1992; Loftus et al., 1994; Savides et al., 1996). Endoscopic sclerotherapy with cyanoacrylate was used to control cholecystojejunostomy variceal bleeding in a patient with pancreatic head cancer (Hsu et al., 2010). In a case series, APC was successful in reducing or halting rectal bleeding related to radiotherapy for prostate cancer (Takemoto et al., 2012).

Endoscopy has been used to control haemoptysis (Freitag, 1993; Knott-Craig et al., 1993; Patel et al., 1994; Kato et al., 1996; D'Amico et al., 2003; Tuller et al., 2004). Kaaragac et al. successfully used neodymium:yttrium aluminum perovskite (Nd:YAP) laser repetitively over the course of the illness of two patients (Karaagac et al., 2005). Balloon catheters may be used as temporary measures (24–48 hours) before proceeding with more definitive treatments such as radiotherapy (Freitag, 1993). Bronchoscopy has been used to instil a variety of agents around or into the lesion, including cold saline, epinephrine solution, antidiuretic hormone derivatives such as ornipressin (Tuller et al., 2004), or thrombin/fibrinogen (Patel et al., 1994; de Gracia et al., 2003). Successful use of fibrin sealant applied via bronchoscopy was reported in a warfarin anticoagulated patient who had presented with massive haemoptysis that did not respond to irrigation with cold saline and epinephrine (Pandya et al., 2011). Definitive treatment with coil embolization via angiography followed.

Cystoscopy-aided laser or argon beam coagulation (Quinlan et al., 1992) of bleeding lesions in the bladder is now considered standard second-line treatment if bladder irrigation and clot evacuation through a three-way catheter is unsuccessful (Choong et al., 2000; Guven et al., 2011). As previously described, a number of agents have been instilled into the bladder for irrigation (including alum, silver nitrate, formalin, e-aminocaproic acid, phenol, prostaglandin F_2/carboplast) or injected around or into the bleeding tissue, including fibrin sealants (Ouwenga et al., 2004; Tirindelli et al., 2009) and cyanacrylate glue (Carmignani et al., 2006). Access to the bladder is through cystoscopy or cystostomy (Baronciani et al., 1995). Continuous bladder irrigation with saline solution can aid in preventing further clotting.

Embolization

Percutaneous transcatheter arterial embolization (TAE) involves the intravascular deposition of haemostatic material to produce permanent or temporary vessel occlusion (Angle et al., 2010). It has been used in many different vascular territories, including bronchial, coeliac, superior and inferior mesenteric, renal, hypogastric, and carotid territories. The potential role of TAE in palliative care has been described (Broadley et al., 1995).

Access to the vessel is usually under local anaesthesia through a femoral or axillary approach. The interventional radiologist performs an arteriogram to identify the vessel responsible for the bleeding and then threads a smaller catheter as close to the site of bleeding as possible—referred to as 'superselection'. The choice of material employed for embolization depends on the size of the vessel and the desired duration of occlusion.

Materials used in embolization include coils, microspheres, gelatin sponge (Gelfoam®) and haemostatic agents such as ethanol, sodium tetradecyl sulfate, cyanoacrylate, and polyvinyl alcohol (Angle et al., 2010). In the case of coils, occlusion occurs as a result of coil-induced thrombosis rather than mechanical

occlusion of the lumen. The thrombogenic effect primarily results from the addition of silk or synthetic fibres. Microcoils can be particularly useful when superselective coil embolization is required. Microspheres are biocompatible, hydrophilic, non-resorbable particles produced from an acrylic polymer and impregnated with porcine gelatin or starch. Microspheres are available in different sizes and are supplied in apyrogenic sterile sodium chloride solution. Gelfoam® is usually absorbed completely, with little tissue reaction, and the vessel recanalizes within a few weeks. Some patients develop postembolization syndrome which is usually transient and is characterized by nausea, vomiting, pain, and fever due to tissue necrosis (Pisco et al., 1989).

Bronchial artery embolization plays a pivotal role in management of massive haemoptysis (Mal et al., 1999; White, 1999; Pandya et al., 2011). Shigemura et al. reported reduced morbidity and mortality in patients with massive haemoptysis with an embolization technique compared to a surgical approach (Shigemura et al., 2009). In a study by Fernando and colleagues, embolization of the bronchial artery gave an initial success rate of 85% (Fernando et al., 1998). However, there was a significant rate of recurrent bleeding (50%). Poyanli et al. described a large series of 140 patients treated with bronchial artery embolization; most had tuberculosis and only four had cancer (Poyanli et al., 2007). Embolization was successful in all but two of the patients immediately post intervention. Two of the patients, both with cancer, experienced fatal bleeds a month after the procedure.

TAE has been used extensively in managing severe bladder or pelvic haemorrhaging (Pisco et al., 1989; Gine et al., 2003; De et al., 2005; Palandri et al., 2005; El-Assmy and Mohsen, 2007; Ghahestani and Shakhssalim, 2009; Delgal et al., 2010; Liguori et al., 2010; Guven et al., 2011). Success rates of 70–100% have been reported. Selective internal iliac embolization is being replaced by superselective embolization of bladder arteries, which is associated with fewer side effects (gluteal pain, claudication, or tissue necrosis and pain) and has a lower recurrence rate.

Endovascular management of head and neck bleeding was initially done with endovascular balloon occlusion of the bleeding vessel (Citardi et al., 1995). This has been replaced with embolization; newer techniques are showing reductions in vascular complications and improvements in survival and quality of life (Morrissey et al., 1997; Chaloupka et al., 1999; Levy et al., 2002; Broomfield et al., 2006; Rimmer et al., 2012). More recently, endovascular stent repair of carotid rupture has been described (Cohen and Rad, 2004; Hoppe et al., 2008). Successful stent grafting in combination with coil embolization has been reported in a patient with impending carotid rupture secondary to head and neck cancer (Bates and Shamsham, 2003). Chang et al. reported the use of endovascular therapy in patients with CBO syndrome; self-expandable stent grafts or insertions of balloons, coils, or acrylic adhesives were used (Chang et al., 2008). Rebleeding occurred in a small number of these patients. Chen and colleagues used a variety of methods (Gelfoam® sponge, coils, microcoils, or combinations of these) to manage carotid bleeding following RT or chemotherapy for head and neck tumours (Chen et al., 2010).

Some authors advocate stents only as an interim measure while more definitive management is planned. Potential complications include infections or extrusion or occlusion of the stent, with subsequent cerebrovascular accident (Simental et al., 2003). Carotid artery rupture is also a risk (Kwok et al., 2001). All things considered, the benefits appear to outweigh the risks (Rimmer et al., 2012).

TAE of the adrenal artery has been reported for controlling gastroduodenal bleeding (Eckstein et al., 1984; Loffroy and Guiu, 2009), and massive retroperitoneal adrenal haemorrhage secondary to lung cancer metastasis (Ambika et al., 2009). Selective intra-arterial terlipressin infusion stopped acute lower gastrointestinal haemorrhage in a patient with abdominal lung cancer mestastases (Favalli et al., 2004). In a retrospective case series of 85 patients undergoing preoperative embolization of tumours or vascular lesions of the head and neck or embolization for refractory tumour bleeding and epistaxis, embolization was achieved in 83.5% of patients (Zahringer et al., 2005). Transhepatic arterioembolization was used to control bleeding in five patients with bleeding from oesophageal varices or direct invasion of the duodenum, transverse colon, or stomach from inoperable hepatocellular cancer (Srivastava et al., 2000) and four patients with spontaneous rupture of hepatocellular carcinoma (Recordare et al., 2002).

Surgery

Palliative surgery to stop severe haemorrhaging may be appropriate in select cases. Surgery may range from ligation of a vessel, to fulguration and excision of tissue (Baum et al., 1993). Cystectomies have been successfully performed to control massive intractable bladder haemorrhaging (Choong et al., 2000; Ghahestani and Shakhssalim, 2009; Guven et al., 2011). Laparoscopic cystoprostatectomy and mini-laparotomy ileal conduit diversion were successfully performed in one patient with radiation-induced haemorrhagic cystitis following treatment for prostate cancer (Alkan et al., 2006). Schneider and colleagues performed a segmental duodenal resection with side-to-side duodenojejunostomy in a patient with occult gastrointestinal bleeding due to metastatic endometrial cancer (Schneider et al., 2005). Witz et al. reported three patients with head and neck cancers whose carotid arteries were successfully ligated following acute or imminent carotid artery rupture (Witz et al., 2002). Ligation of a vessel was successful in some patients who presented with bleeding from radiation proctitis (Yegappan et al., 1998). Pulmonary resections to manage massive haemoptysis may be considered in very exceptional situations (Gourin and Garzon, 1974; Jewkes et al., 1983).

Management: systemic modalities

Antifibrinolytic agents

Antifibrinolytic drugs can be useful to control bleeding in patients who are unable to get definitive haemostatic treatment such as irradiation in a previously irradiated field, or patients who are too frail for invasive procedures such as embolization (Prommer, 2005). They are synthetic drugs that stabilize clots by blocking the binding sites of plasminogen, thereby inhibiting the conversion of plasminogen into plasmin. This results in decreased lysis of fibrin clots.

Tranexamic acid (TA) and epsilon aminocaproic acid (EACA) are the two most commonly used antifibrinolytic agents and can be administered orally or intravenously; TA is more potent than EACA *in vitro* and is also a weak direct inhibitor of plasmin.

Antifibrinolytic drugs have been used successfully in a variety of oncological and non-oncological settings (Biggs et al., 1976; Chandra, 1978) to assist in controlling bleeding in

thrombocytopenic patients (Garewal and Durie, 1985; Kalmadi et al., 2006), DIC (Cooper et al., 1992), lung cancer (Kaufman and Wise, 1993), mesothelioma (De Boer et al., 1991), gastric cancer (Roberts et al., 2010), and leukaemia (Avvisati et al., 1989; Shpilberg et al., 1995).

In the palliative care setting, Dean and Tuffin found that cessation of bleeding occurred in 14 out of 16 cancer patients treated with TA for a variety of bleeding problems, including haematuria, haemoptysis, and bleeding from fungating tumours and the rectum (Dean and Tuffin, 1997). The average time until significant improvement in bleeding was 2 days and for complete cessation was 4 days.

Doses of tranexamic acid were 1.5 g followed by 1 g three times a day. Aminocaproic acid was dosed at a 5 g load followed by 1 g four times a day. Treatment was continued for another 7 days after the bleeding stopped. Others have recommended similar doses (Twycross and Wilcock, 2014a). If ineffective after 3 days, the dose of TA can be increased to 1.5–2 g three times a day, with a maximum dose of 2 g four times a day. The suggested intravenous dose of TA is 10 mg/kg over 5–10 minutes. The intravenous route is generally reserved for patients who are unable to swallow oral medications. Treatment can be restarted if bleeding resumes. For EACA, a stat dose of 5 g orally (or 4–5 g intravenously in 250 mL of 0.9% saline for 8 hours or until the bleeding stops) is recommended, followed by daily doses of 5–30 g orally or intravenously in divided doses at 4–6-hour intervals, with a maximum daily dose of 30 g per day orally or intravenously (Twycross and Wilcock, 2014a).

The most common adverse effects are gastrointestinal (nausea, vomiting, and diarrhoea), occurring in about 25% of cases. Adverse effects appear to be dose dependent and thromboembolism is uncommon (Hashimoto et al., 1994). EACA and TA are excreted mainly unchanged in the urine. Doses therefore need to be reduced in renal impairment. It is generally recommended that these drugs not be used in DIC. Caution is advised in the case of haematuria as there is a risk of clot formation causing ureteric obstruction or urinary retention (Twycross and Wilcock, 2014a).

In patients with thrombocytopenic haemorrhage, 66% achieved a complete response and 17% a partial response with EACA treatment (Kalmadi et al., 2006). The median initial dose was 4 g per day and the median dose during the whole course of treatment was 6 g per day (range, 2–24 g per day). Aminocaproic acid was successfully used to manage upper gastrointestinal bleeding in a patient with metastatic gastric cancer who wished to avoid invasive procedures (Roberts et al., 2010) Benefits have also been reported with TA in managing bleeding during treatment of acute myeloid leukaemia (Shpilberg et al., 1995).

Somatostatin analogues (octreotide)

Octreotide, an analogue of somatostatin, has been used to manage upper gastrointestinal bleeds, including peptic ulcers, and oesophageal varices (Lin et al., 1995; D'Amico et al., 2003). It has also been used perioperatively to reduce bleeding in pancreatic cancer resections (Halloran et al., 2002). Somatostatin reduces splanchnic flow and pressure by causing venous dilatation, thereby reducing portal pressure and portal venous flow. A starting dose of 50–100 micrograms subcutaneously or intravenously twice daily is recommended (Lamberts et al., 1996). The dose may be titrated, up to 600 micrograms per day if needed. An alternative regimen of

a bolus of 50 micrograms given intravenously or subcutaneously, followed by a continuous subcutaneous or intravenous infusion of 50 micrograms/hour for 48 hours, has been suggested (Burroughs et al., 1990). Few side effects are reported at low doses but nausea, abdominal discomfort, and diarrhoea may occur with doses greater than 100 micrograms/hour.

Vasopressin analogues

Vasopressin is a posterior pituitary hormone that causes splanchnic arteriolar constriction and reduction in portal pressure (Octavio and Buizza, 1989). The vasopressin analogue 1-desamino-8-D-arginine vasopressin (desmopressin, DDAVP) is the treatment of choice for patients with von Willebrand disease and mild haemophilia A. The compound has also proved useful for the treatment of patients with other inherited or acquired haemostasis disorders. It has been used in the management of variceal bleeding related to portal hypertension (Gross et al., 2001; D'Amico et al., 2003).

In cancer care, a small pilot study evaluated the use of vasopressin for the management of bleeding in patients with various haematological malignancies and thrombocytopenia (Castaman et al., 1997). All the patients responded to a single infusion of desmopressin (0.4 micrograms/kg) diluted in 100 mL of isotonic saline and infused over 30 minutes; no toxicities were reported. Vasopressin therapy, given in doses of 0.1–0.4 mg by continuous infusion, stopped bleeding in about half of patients with stomach cancer (Prommer 2005). Terlipressin (triglycyl lysine-vasopressin), a long-acting vasopressin analogue, was used to control acute, severe lower gastrointestinal bleeding in a patient with gastric metastases from a lung primary (Favalli et al., 2004). Selective angiography was used to administer the drug into the middle colic artery.

Aerosolized vasopressin has been reported in the management of mild to moderate recurrent haemoptysis in palliative patients (Anwar et al., 2005). Five units (1 mL) of ornithine-8-vasopressin, diluted in 1 or 2 mL of physiological saline solution and administered in aerosol, as needed, was used.

Vitamin K

Vitamin K (phytonadione) is fat soluble and is necessary for the hepatic production of a number of clotting factors, including factors II (prothrombin), VII, IX, and X. Liver disease, decreased intake, small bowel disease or resection, and biliary obstruction can lead to deficiencies in these factors. Vitamin K is indicated in the management of bleeding from oral anticoagulants, liver disease, and DIC.

Oral administration of vitamin K is the preferred route (Whitling et al., 1998). Although its onset of action is slower than the intravenous route, it is more reliable than the intravenous and subcutaneous routes. Serious allergic reactions are more frequent with intravenous administration (Riegert-Johnson and Volcheck, 2002); 1.9% of patients (Shields et al., 2001). The onset of action of the intravenous route is as soon as 4 hours. Intravenous administration should be slow, not exceeding 1 mg per minute. Oral vitamin K lowers INR levels more rapidly than subcutaneous vitamin K in patients with excessive oral anticoagulation (Crowther et al., 2002). For most situations, the oral route will result in reliable results with an onset of action within 12 hours (Whitling et al., 1998).

A number of regimens have been recommended for managing INR levels. For non-bleeding patients with elevated INRs less than 5, warfarin can simply be omitted or the dose lowered. A study comparing 2.5 mg oral vitamin K versus omission alone in 30 asymptomatic patients with INR levels of 6–10 found that treatment with oral vitamin K (accompanied by holding further warfarin dosing) reduced the time to achieve a normal INR by a day (Patel et al., 2000). Other studies found similar results (Fondevila et al., 2001).

For INRs in the 5–10 range, the next doses of warfarin should be held and 1–2.5 mg of vitamin K given orally (DeLoughery, 2009). For INRs greater than 10, 2.5–5 mg of vitamin K should be given with the expectation that the INR will be lowered in 24–48 hours (DeLoughery, 2009).

If the patient requires rapid full reversal because of bleeding or the need for surgery when the INR is high, intravenous vitamin K and fresh frozen plasma (FFP) should be considered (DeLoughery, 2009). Note that one unit of plasma raises, on average, coagulation factors by only 5% therefore large doses (15 mg/kg or 4–5 units) must be given. In the case of intracranial haemorrhage occurring in patients taking warfarin, 10 mg of vitamin K may be given slowly intravenously alongside FFP (Aguilar et al., 2007). Recombinant factor VIIa may be effective in reversing warfarin-induced bleeding in these cases (Aguilar et al., 2007).

Blood and plasma products

Platelets

There appears to be lack of consensus on when to transfuse platelets in patients with advanced disease. Some guidelines suggest prophylactic transfusions triggered by predefined platelet counts (usually $10–20 \times 10^9$/L). Others recommend platelets transfusions only when bleeding occurs or when there are additional risk factors (Schiffer et al., 2001; British Society for Haematology, 2003). Not all thrombocytopenic patients require or benefit from platelet transfusion and the decision to administer transfusion is not based solely on the platelet count but should be individualized for specific clinical settings and patient circumstances (Wandt et al., 2005).

Salacz and colleagues reviewed the management of thrombocytopenia in bone marrow failure (Salacz et al., 2007). They recommend considering prophylaxis with aminocaproic acid (500–1000 mg four times a day) in high-risk patients. If a prophylactic transfusion strategy is appropriate, a platelet count should be taken. If the count is 10×10^9/L or lower, continue with regularly scheduled platelet counts; initially weekly and then up to 3 weeks apart if the patient remains asymptomatic. Consider a platelet transfusion if platelet levels are 5×10^9/L or lower. A higher threshold can be considered if there are coexistent conditions such as coagulopathy or a recent episode of bleeding. If bleeding occurs with counts less than or equal to 10×10^9/L, consider therapeutic transfusions of platelets. If platelet counts are consistently greater than 10×10^9/L, then the patient should be followed clinically without scheduled platelet counts.

Platelet transfusion is rarely needed in patients with increased platelet destruction such as autoimmune or drug-associated immune thrombocytopenia, and is relatively contraindicated in patients with thrombotic thrombocytopenic purpura because of concerns about the risk of precipitating thromboses (Schiffer et al., 2001). Many patients with chronic, stable, severe thrombocytopenia can be observed without prophylactic transfusion, reserving transfusions for episodes of haemorrhage or during time of active chemotherapy.

A recent Cochrane review concluded that there is no evidence that a prophylactic platelet transfusion policy prevents bleeding; but the review was unable to make a final recommendation regarding prophylactic transfusion versus therapeutic treatment (Estcourt et al, 2012). Risk factors that would sway towards considering prophylactic transfusions when the count was below 10×10^9/L may include sepsis, concurrent antibiotic use, or other haematological disorders.

Although guidelines may vary, it is generally accepted that a count of greater than 50×10^9/L (or 50,000/μL) is sufficient for most invasive procedures and surgeries. Platelet counts of greater than 100×10^9/L (> 100,000/μL) are recommended for ophthalmic and neurosurgery. Higher transfusion thresholds may be appropriate for patients with platelet dysfunction.

Transfused platelets have a short life span and will need to be re-dosed within 3–4 days if given for prophylaxis. Suboptimal increases can be seen due to non-immune destruction or immune refractoriness. Clinicians should suspect immune-mediated refractoriness to platelet transfusions if post-transfusion increases are minimal. This can be confirmed by screening for the presence of lymphocytotoxic (anti-HLA) antibodies. Patients with autoimmune destruction of platelets, such as ITP, may not receive therapeutic benefit from prophylactic transfusion, but may however benefit from therapeutic transfusions.

Severe thrombocytopenia presents many difficult management choices at the end of life and may pose an ethical dilemma in some situations. The use of platelet transfusions in this patient population presents complex issues; platelets are logistically more difficult to transfuse than red cells and carry risks including acute febrile episodes, alloimmunization, and infection. Platelet transfusion in the setting of advanced cancer should be on a case-by-case basis with the aim of controlling symptoms. The short half-life of platelets limits the usefulness of platelet transfusions in patients with end-stage disease. Moreover, the half-life decreases as the platelet count drops. Indications for the transfusion of platelets in patients with advanced haematological malignancies have been recommended (Lassauniere et al., 1996) and include (a) continuous bleeding of the mouth and gums, (b) overt haemorrhage (gastrointestinal tract, gynaecological, urinary), (c) extensive and painful hematoma, (d) recent disturbed vision (in the setting of thrombocytopenia), (e) severe and recent headache (in the setting of thrombocytopenia), (f) severe anaemia (and thrombocytopenia). Detailed reviews of the management of blood dyscrasias in patients with cancer (DeLoughery, 2009) and terminally ill patients with haematological malignancies (Salacz et al., 2007; Gertz 2009) are reported elsewhere.

Fresh frozen plasma

Generally, haemostasis can be achieved when the activity of coagulation factors is at least 25–30% of normal, assuming the absence of inhibitors (including heparin) and the presence of adequate fibrinogen levels (> 100 mg/dL) (Prommer, 2005). FFP contains all the plasma clotting factors and is the most commonly used plasma product to correct severe clotting factor deficiencies in urgent situations, particularly coagulopathies that are attributable

to multiple clotting factor deficiency states as in liver disease, DIC, or warfarin anticoagulation. It is used to prevent bleeding prior to an urgent invasive procedure (e.g. thoracentesis) in patients requiring replacement of multiple coagulation factors, including patients over-coagulated with warfarin. Usually, there is an increase of at least 1.5 times the normal prothrombin time or partial thromboplastin time, or an INR of 1.6 or above before clinically important factor deficiency exists. This corresponds to factor levels lower than 30% of normal.

The volume of each unit is usually 200–250 mL. A dose of about 15 mL/kg (10–20 mL/kg) of FFP is usually recommended and translates to about 4 units (about 800 mL). (American Society of Anesthesiologists Task Force, 1996). This is expected to increase factor levels by 20–30% and fibrinogen levels by about 1 g/L. Volume overload may be a risk in some patients. The frequency of the transfusion depends on the half-life of the deficient factor(s). However, coagulation screening tests may be poor predictors of coagulation factor levels.

Reversal of warfarin anticoagulation with plasma is indicated only if significant bleeding or risk is present. Often it will require recurrent transfusion to maintain normal factor levels. Otherwise, reversal can be achieved by giving vitamin K or holding warfarin 2–3 days prior to a planned procedure. Recombinant or factor VIII concentrates should be used to replace factor VIII. FFP should not be used for haemophilia B (factor IX) deficiency unless factor IX concentrate is not available.

Cryoprecipitate

Cryoprecipitate is a concentrated blood component made by thawing FFP between 1°C and 6°C. Each unit (usually 10–15 mL) contains a minimum of 80 IU of factor VIII (stabilizes fibrin) and at least 150 mg of fibrinogen, in addition to significant amounts of von Willebrand factor (promotes platelet adhesion), factor XIII, and fibronectin. It is primarily used to treat patients bleeding as a result of reduced levels of fibrinogen activity (functional defects or deficiency in amount). Better treatments are now available for von Willebrand disease, haemophilia A and B, and factor XIII deficiency.

Cryoprecipitate is indicated in association with bleeding or prior to an invasive procedure when the following are present: (a) hypofibrinogenaemia due to reduced synthesis (severe liver disease), consumption (e.g. DIC), dilution following massive transfusions, or inherited deficiency; (b) von Willebrand disease when desmopressin (DDAVP) is ineffective or contraindicated and von Willebrand factor-containing concentrates are not immediately available; (c) haemophilia A when factor VIII concentrate is not immediately available; (d) factor XIII deficiency; and (e) uraemia with bleeding if the patient is unresponsive to other treatments such as dialysis, and DDAVP. For fibrinogen replacement, 2 units of cryoprecipitate per 10 kg of body weight generally raise fibrinogen concentration by 100 mg/dL, except in cases of DIC or continued bleeding with massive transfusion. Treatment should therefore be based on clinical status with a goal of achieving and maintaining a fibrinogen concentration of 100 mg/dL.

Recombinant coagulation factors (VIIa, VIII, IX)

Several recombinant factors are now available, including recombinant factors VIII, IX and VIIa.

Recombinant factor VIIa (rFVIIa) is currently approved for use in haemophilia patients with inhibitors. It has apparent value in a variety of other situations, including massive bleeding resulting from massive trauma and bleeding from liver disease (Kenet et al., 1999; Roberts et al., 2004; Dutton et al., 2011), but its role in these settings is controversial. Recombinant factor VIIa has been reported to have value in a variety of disorders involving thrombocytopenia (Goodnough, 2004) and/or platelet dysfunction, including benefit for patients who are refractory to platelet transfusions (Vidarsson and Onundarson, 2000). A recent meta-analysis concluded that treatment with high doses of rFVIIa in off-label indications may significantly increase the risk of arterial but not venous thromboembolic events, especially among the elderly (Levi et al., 2010). A multicenter, placebo controlled trial of rFVIIa in cirrhotic patients with gastrointestinal haemorrhage failed to show a beneficial effect of rFVIIa over standard therapy (Bosch et al., 2004). However, post hoc analysis showed a subpopulation in which it could be useful, namely Child–Pugh B and C cirrhotic patients.

Hyperbaric oxygen therapy

Hyperbaric oxygen is thought to promote granulation tissue and neovascularization and to cause vasoconstriction, which decreases haemorrhaging. Case series have reported response rates of up to 85% from hyperbaric oxygen therapy for patients with bleeding from radiation- or chemotherapy-induced cystitis (Schoenrock and Cianci, 1986; Weiss et al., 1994; Bevers et al., 1995; Del Pizzo et al., 1998; Corman et al., 2003; Bratsas et al., 2004). The downside of this treatment is that it requires multiple treatments (up to 20 sessions), each lasting 90 minutes. Contraindications include active cancer, active viral infection, pneumothorax, treatment with doxorubicin or cisplatin, and ear reconstruction.

Other modalities (pentosanpolysulphate, melatonin, thalidomide)

Oral sodium pentosanpolysulphate has been reported in a small case series to control chronic haematuria secondary to pelvic irradiation (Parsons, 1986; Toren and Norman, 2005). The therapy consisted of 100 mg of oral sodium pentosanpolysulphate three times per day; the average time to control bleeding was 4–7 weeks of therapy. Precisely how sodium pentosanpolysulphate controls haematuria is unknown, but it is postulated to increase the natural defence of the bladder–urine interface by coating the lining of the bladder. Oral sodium pentosanpolysulphate has no detectable anticoagulant activity, is safe, and not toxic

Recent pilot studies suggest that melatonin (MLT) may ameliorate thrombocytopenia in patients being treated for cancer (Lissoni et al., 1995; Lissoni et al., 1999). Similar benefits have been reported in cases with refractory idiopathic thrombocytopenic purpura (Todisco and Rossi, 2002; Todisco et al., 2003). Recommended dosage is 20 mg/day (orally) during the dark period of the day. One study suggested a greater decrease in the frequency of thrombocytopenia and lymphocytopenia in patients treated with MLT than in those who received supportive care alone (Lissoni, 2002).

Thalidomide, given its antiangiogenic properties, has been reported in a palliative patient who experienced severe upper gastrointestinal bleeding secondary to gastric cancer (Lambert and Ward, 2009). Bleeding settled within 1 week of starting 300 mg of thalidomide nocte.

Specific clinical scenarios in palliative care

Management of terminal haemorrhaging

The options for managing terminal haemorrhage can be divided into three categories (Harris and Noble, 2009): (1) general supportive measures such as the use of dark towels and staying with and comforting the patient; (2) general resuscitative measures such as fluid replacement; and (3) specific measures to stop the bleeding such as wound packing, haemostatic agents, haemostatic radiotherapy, and interventional radiology.

Sedative medications to alleviate patient distress and provide comfort are often recommended (MacMillan and Struthers, 1987; Regnard and Makin, 1992; Fortunato and Ridge, 1995; Gagnon et al., 1998; Oneschuk, 1998; Prommer, 2005; Frawley and Begley, 2006a). It is important to note that the intent is to relieve distress and not to hasten death. Midazolam is the most frequently recommended drug because of its rapid onset and short duration of action (Oneschuk, 1998). The commonly recommended routes are intravenous or subcutaneously, at doses of between 2.5 and 10 mg. Some guidelines suggest a repeat dose within 5–10 minutes if necessary. The intramuscular route has been suggested but bioavailability of this route may be compromised by peripheral circulation shutdown during hypovolemic shock

Harris and colleagues recently explored the utility of crisis medication in the management of terminal haemorrhage by interviewing 11 nurses who had managed such events (Harris et al., 2011). Participants reported crisis medication (such as midazolam) to have little role in many cases. Terminal haemorrhage often occurred rapidly, with the majority of patients dying before medications could be administered. Many events had not been predicted and so anticipatory prescribing of crisis medications did not always occur. A focus on accessing crisis medicines was done to the detriment of staying with and supporting the patient and using dark-coloured towels, which were reported to be the most useful measures. The researchers stressed that crisis medications, although generally not useful, may be of benefit in some situations, specifically those in which bleeding occurs over several hours.

Harris and Noble (2009) and Regnard and Makin (1992) have published guidelines in this area.

Bleeding oesophageal varices

Current therapies and recommendations for the management of oesophageal and gastric variceal haemorrhage from advanced liver disease are published elsewhere (Garcia-Tsao et al., 2007). A meta-analysis recommends pharmacological management (vasopressin, nitroglycerin, terlipressin, somatostatin, or octreotide) over endoscopic sclerotherapy as first-line treatment of variceal bleeding (D'Amico et al., 2003). The use of beta blockers is not recommended during acute episodes of bleeding.

When endoscopy is used, variceal ligation appears to be generally preferred over sclerotherapy (Garcia-Pagan and Bosch, 2005; Garcia-Tsao et al., 2007). A meta-analysis showed superiority of endoscopic (sclerotherapy or variceal ligation) plus pharmacological (octreotide, somatostatin, vapreotide) therapy over endoscopic therapy alone (Banares et al., 2002). Despite urgent endoscopic and/or pharmacological therapy, variceal bleeding cannot be controlled or recurs early in about 10–20% of patients (Banares et al., 2002). Shunt therapy, either shunt surgery or transjugular intrahepatic portosystemic shunt (TIPS), has proven clinical efficacy as salvage therapy for patients who fail to respond to endoscopic or pharmacological therapy (Sanyal et al., 1996).

Balloon tamponade is effective in controlling bleeding temporarily with immediate control of haemorrhage in over 80% of patients (Avgerinos and Armonis, 1994). However, its use is associated with potentially lethal complications such as aspiration and necrosis and perforation of the oesophagus. Therefore, it should be restricted to patients with uncontrollable bleeding for whom a more definitive therapy such as TIPS is planned within 24 hours.

Haemorrhagic bladder

Three reviews of the topic provide a comprehensive review of the management of intractable bladder haemorrhaging in cancer care (Choong et al., 2000; Ghahestani and Shakhssalim, 2009; Guven et al., 2011) (see also Chapter 8.4). They highlight considerable variation in practices and recommendations.

Ghahestani and Shakhssalim propose alum instillations or radiotherapy, after irrigation and evacuation of blood clots, as first-line options. In the case of a sloughing tumour as aetiology, internal iliac artery embolization is a second-line option, while hyperbaric oxygenation and embolization or transurethral fulguration are second-line options in the case of radiation cystitis. Formalin, because of significant adverse effects, is relegated to a last-resort option. Guven et al. also suggest intravesical irrigation with alum, EACA or silver nitrate as first-line options, followed by hyperbaric oxygen in the case of haemorrhagic cystitis or radiation cystitis and arterial embolization, with formalin irrigations and surgery as last-resort options (Guven et al., 2011).

Guven et al. suggest that the first step in the treatment of haemorrhagic cystitis should be directed towards making sure that the bladder does not become overly distended. Bladder outlet obstruction from clots can lead to urosepsis, bladder rupture, and renal failure. Clot evacuation can be performed at the bedside by carefully placing a large, stiff-walled haematuria catheter. After clot evacuation, if haematuria persists, a three-way catheter can be inserted and continuous bladder irrigation with saline can be started. All clots must be removed before continuous irrigation is started to avoid over distention and bladder rupture. The patient should be vigorously hydrated using oral and/or intravenous fluids to keep clots from reforming. If clot evacuation is unsuccessful with this approach, the patient should undergo cystoscopy with clot evacuation and consideration of treatments previously described, including fulguration and instillation/injection of agents.

A variety of approaches have been reported. These include instillation of astringents and other agents (including alum, silver nitrate, formalin, prostaglandin F_2, EACA, phenol), intravesical hydrostatic pressure treatment with fluid instillation or compression balloons (but there is a risk for bladder rupture) (Antonsen et al., 1986; Choong et al., 2000), hyperbaric oxygen therapy, transarterial embolization, and surgery as last-resort options (ranging from percutaneous nephrostomy diversion (Pomer et al., 1983; Sneiders and Pryor, 1993) to cystectomy (Zebic et al., 2005; Fergany et al., 2009).

Last-resort options include urinary diversion (prevents urine urokinase from coming into contact with the fragile haemorrhagic mucosa) and radical cystectomy (Zebic et al., 2005; Alkan et al., 2006).

Malignant wounds

Slow capillary oozing is common in malignant wounds. The use of sucralfate paste or an alginate often suffices (Thomas et al., 1998; Emflorgo, 2014). For heavier bleeding, haemostatic surgical dressings will provide rapid haemostasis and can be left on the wound and covered with an appropriate dressing. A number of other options are available and these are described above and elsewhere (Grocott, 2000; McDonald and Lesage, 2006).

Conclusion

Bleeding in the palliative care setting may have a variety of causes and clinical presentations. It is often complicated by a number of co-morbidities and underlying pathologies. It is often very distressing to patients, families, and caregivers. A large number of treatment modalities, local and systemic, are available to address bleeding and massive haemorrhages. The large majority of evidence in support of these modalities, however, is based on case reports, case series, and expert opinion, with only a small number of large randomized studies. Selecting between the different modalities is therefore seldom guided by comparative studies between the modalities. A number of factors need to be considered when selecting between modalities and the overall care approach. These include patient prognosis and expected survival, access to modalities, quality of life, functional status, and ultimately goals of care and patient wishes.

Sexual dysfunction: discussing patient sexuality and intimacy in palliative care

Amanda Hordern

Introduction to sexual dysfunction

Experiencing a life-limiting illness has the potential to radically transform every aspect of a person's life, including how they feel about themselves, their body, and their sense of self within intimate and sexual relationships. For many terminally ill people, intimate and sexual moments are a vital aspect of their life, providing a sense of connectedness and assisting the person to explore and find meaning to living, dying, and death (Rothenberg and Dupras, 2010). Entering the palliative phase of any disease frequently results in a reappraisal of life priorities and relationships in the remainder of life. This has the potential to directly impact the manner in which a person connects at the deepest level with a significant other, at a time when chronic and debilitating illness may precipitate a longing for intimate touch and communication. Sexual expression through all of life, but particularly during end-of-life phases, provides a vital form of communication, reassurance, tenderness, and validation of self when grappling with the vulnerability of changing health and wellness (Lemieux et al., 2004; Shell, 2008; Redelman, 2010; Gianotten and Hordern, 2011; Vitrano et al., 2011). Gianotten challenges health professionals to consider that sexual and intimate moments provide a welcome respite and distraction from all that is going as death approaches (Gianotten, 2007). Yet few health professionals view patients in their care as sexual beings and if they do, they struggle to know what and how to raise the topic of sexuality and intimacy within their clinical roles (Hordern and Street, 2007a, 2007b; Gianotten and Hordern, 2011). The following chapter will:

◆ define patient sexuality and intimacy in the context of palliative care

◆ explore the impact of natural ageing and treatment for cancer and chronic illnesses

◆ provide an introduction to opening communication and providing practical strategies to support the patient through intimate and sexual changes.

What is sexuality and intimacy?

Sexuality and intimacy are lived experiences that mean different things to different people, at different stages of their lives. There has been a reassuring shift in recent cancer and palliative care literature from a traditional, medicalized, and functional focus on patient sexuality, where the emphasis has remained on rates of penetration and orgasmic responses, strength of erections, libido, and menopausal status (Schover, 2005; Miles et al., 2007; Potter, 2007; Ochsenkuhn et al., 2011) to a more person-centred definition of sexuality, where psychological aspects of sexual identity have been described more extensively (Manne et al., 2007; Manne and Badr, 2009; Manne et al., 2010; Cleary and Hegarty, 2011). A particularly poignant definition is 'sexuality is the process of giving and receiving sexual pleasure and is closely connected to a sense of being. Sexuality is a feeling of belonging, of being accepted by another, and the conviction that we are worthy to live and enjoy life' (Shell, 2008).

Intimacy has been defined as the 'sharing of identity, closeness, and reciprocal rapport' (Mercadante et al., 2010), where the emphasis is usually on emotional closeness and intimate communication rather than sexual function. When viewed in this context, a patient's sexuality and intimacy have the potential to be altered and redefined, at every stage of life-limiting illness.

Health benefits of sexual and intimate expression

Sexuality and intimacy can reduce emotional distress, anxiety, stress, and depression (Redeleman, 2010) and improve psychosocial responses to living with a cancer diagnosis (Sadovsky et al., 2010). Gianotten and Hordern (2011) outline a comprehensive list of the benefits including the following:

◆ Pain-relieving effects of sexual expression that is enjoyable.

◆ A distraction from the day-to-day challenges.

◆ Evidence to support a heightened pain threshold. Muscle relaxation following sexual stimulation and orgasm can reduce muscular tension for many hours, having a positive effect on inducing sleep. The same authors discuss the release of oxytocin after skin contact, body massage and sexual intercourse which has been associated with increased levels of trust and intimacy between couples as well as lower anxiety and fewer depressive symptoms.

The impact of a life-limiting illness on a person's sexual and intimate world

Despite increasing emphasis on patient sexuality in the general cancer and cancer survivorship literature, patient and carer sexuality in the context of palliative care has only recently been receiving attention (Lemieux et al., 2004; Hordern, 2008; Anderson, 2009; Gianotten and Hordern, 2011).

Lemieux et al. (2004) conducted seminal work exploring the patient's perspective of sexuality in palliative care and highlighted that sexuality remained an important aspect of patients' lives even until the last weeks and days of the person's life. Nine out of the ten participants interviewed for this study reiterated the importance of being given an opportunity to discuss intimate and sexual changes with a health professional, yet only one had been given the opportunity. Lemieux suggested that the focus of sexuality changed from an emphasis on intercourse before the disease, to an emphasis on longing to be touched through hand, body, kissing, hugging, and 'meaningful' eye contact as the disease advanced. These findings support the earlier work of Anath and colleagues (2003) who used a cross-sectional, survey to find that sexual function was more affected in palliative care patients than in the other control group of patients from a general practice clinic.

Rothenberg and Dupras (2010) used the Kübler-Ross five-stage of death theory to explore the impact of impending death on the sexual and intimate world of palliative care patients. Drawing upon qualitative data obtained through a small number of clinical interviews, this discussion paper illuminates the range of sexual issues emerging for people during the final phases of their lives. Case studies were used to highlight how the phases of denial, anger, bargaining, depression, and acceptance all impacted sexual and intimate expression. This work revealed the relationship between health professionals validating the topic by opening a discussion and dying patients being able to actively shape their final intimate and sexual connections, enabling patients to find meaning in their last weeks and days.

As difficult and rare as it is to quantify sexuality and intimacy in the face of advanced disease, Vitrano et al. (2011) explored the attitudes and feelings of people with advanced cancer to sexual and intimate practices before and after their diagnosis. Of the 65 male and female respondents, most respondents (86%) felt it was important to be offered the opportunity to discuss changes to sexuality with trained professionals and half (47%) of the respondents felt sexuality was very important for psychological well-being.

While the study did not explore the rate of discussions patients had with their health-care professionals, it was interesting to note that 60% of the patients in this study did not feel less attractive than prior to their diagnosis; however, only 30% respondents felt satisfied with their sexual activity compared to 67% feeling satisfied with their sexual activity prior to the diagnosis. Whilst the reasons for these findings were not explicated in the study, one could assume that if people facing these issues were provided with an opportunity to explore the challenges, and receive practical and evidence-based solutions, then satisfaction rates may have increased.

Assessing the need

Drawing upon findings from research into cancer and sexuality, it becomes apparent that even when a cancer diagnosis directly impacts body parts traditionally associated with sexual expression, such as breasts, prostate, and genital organs, patients are rarely given an opportunity to engage in meaningful discussions with health professionals about how to cope with these changes. A study highlighted this when a sexual well-being for people with breast cancer survey was conducted by Ussher et al. (2011). Out of 2210 respondents, 1956 women (88.5%) reported changes to their sexual well-being, including emotional consequences, physical changes, changes to self and femininity, and reconciliation of self to changes. By contrast, only 25% of respondents had discussed sexual well-being with a health professional, despite high levels of distress associated with sexual changes. Furthermore, over half of the sample of 1907 participants who responded to the question 'Have you obtained information about breast cancer and sexual well-being?' said no (n = 1117). These results reveal a gulf between patient expectation and experience, with unmet needs emerging from an area of cancer care that is well resourced (breast cancer) and could raise the profile of sexuality. The likelihood of these findings being far more exaggerated in cancer and palliative care areas which have not received the same research focus as breast cancer would be highly likely. This has been confirmed by Low et al. (2009), who stated that sexuality is ill-defined and under-reported in people experiencing head and neck cancer. In a qualitative study exploring the effects of lung cancer on physical and emotional intimacy for 13 married couples, most patients and spouses perceived sexuality and intimacy were still important to them since the lung cancer diagnosis yet very few respondents had discussed this with a health professional (Tessler Lindau et al., 2011).

The partner's perspective

The partners' perspectives of experiencing end-of-life issues have rarely been described in the palliative care literature. An Australian study has shed light on the intimate and sexual disruptions experienced by carers who are partners of people with cancer (Gilbert et al., 2010). When Gilbert and colleagues interviewed 20 participants who were partners across a range of cancer types, stages, and age groups, they found that all partners reported a decrease in levels of sexual expression and frequency of intercourse. The authors highlighted the experience of some partners who were unable to negotiate other forms of intimacy when penetration was no longer an option. They also described a group of participants who managed to successfully 'renegotiate' their sexual experiences of sex, drawing on mutual masturbation, self-masturbation, manual stimulation, oral sex, use of massage and vibrators as alternate forms of sexual expression, bringing couples closer together (Gilbert et al., 2010). This study also highlighted the importance of couple communication, where poorer communication decreased both relationship and sexual satisfaction. When couples found it difficult to communicate about their own sexual needs and concerns, a cycle increasing distance occurred between the partners causing isolation, fear, and distress. Due to the lack of research into the impact of sexuality and intimacy on the partner in non-cancer-related areas of palliative care, one can assume that these findings are transferable to other life-limiting diseases.

Health professionals can play an important role in assisting both the patient and their partner to communicate about the impact of advanced disease on intimacy and sexuality (Cort et al., 2004; Manne and Badr, 2009; Street et al., 2009; Manne et al., 2010).

Barriers and challenges of discussing patient sexuality in the clinical setting

Despite the integral role human sexuality and intimacy plays across a person's entire life, patient sexuality and intimate needs are rarely addressed in clinical care, let alone in the cancer and palliative care setting (Manne et al., 2010; Ussher et al., 2011).The challenges faced by health-care professionals who 'don't know where to begin' in raising the topic of patient sexuality have been discussed throughout the literature. Hordern and Street (2007b, 2007d) explored issues of intimacy and sexuality in cancer and palliative care, through a lens of reflexivity, enabling them to critically examine the structures, rules, and ideas that traditionally shape and influence patients' and health professionals' interactions. This was done through in-depth interviews with 32 health professionals representing a multidisciplinary team, a critical review of the literature, and a contextual analysis of 33 national and international cancer and palliative care clinical practice guidelines. The majority of health professionals did not see their patients as sexual beings, avoiding the topic, feeling vulnerable to the reactions of patients and colleagues, and rarely taking the risk of venturing into such a taboo topic with patients in their care. If sexuality were ever raised, it was done from the safety of a medicalized perspective, where sexuality could be reduced to measuring erectile function, menopausal status, or levels of libido and the emphasis on the communication remained at the level of 'fighting the cancer' (Hordern and Street, 2007b). Unchecked assumptions about the patient's sexuality were frequently made on the patient's behalf, based on the person's age, gender, stage of disease, culture, and partnership status (Hordern and Street, 2007c).

The same researchers also interviewed 50 patients across a range of ages, cancer types, and stages (who were increasingly armed with information downloaded from the Internet). People wanted to play an active role in decision-making. The patients wanted information and support about how to live with and manage the side effects of treatment that was impacting their sexual and intimate worlds, how others cope, and the choices they could make to regain sexual confidence until the end of life. Hordern and Street suggested that these mismatched expectations between patient and health professionals could be overcome by health professionals reflecting upon and recognizing the personal and professional influences that shape their beliefs about patient sexuality and checking their assumptions with the patients in their care (Hordern and Street, 2007b, 2007d).With the dearth of research into the area of communicating about patient sexuality in the non-cancer palliative care context, one can assume that the key barriers and challenges in the communication process are transferable to other advanced and terminal disease states.

Whose role is it to raise the topic?

Although patients' sexuality has been recognized as an important aspect impacting quality of life in clinical practice guidelines for psychosocial care of people with cancer (National Cancer Institute / National Breast and Ovarian Cancer Centre) and in National Consensus Project for Quality Palliative Care (2004), little guidance has been offered on best practice approaches to discussing patient sexuality and intimacy in clinical care. Cagle and Bolte (2009) propose that multidisciplinary teams are required to delegate a team member who will address issues of intimacy and sexuality, taking an advocacy role in ensuring patient-centred sexuality discussions occur. These authors suggest social workers are well equipped to conduct discussions and take on patient-centred roles within teams. Similarly, de Vocht et al. (2011) proposes that a team approach with clearly defined roles and referral pathways for different team members is required to ensure patient sexuality is on the agenda. These authors propose that all team members have a responsibility to be 'spotters' for identifying sexuality and intimacy issues in the palliative care context, and that designated 'skilled companions' within the team take on the more in-depth advocacy and coordinated method of patient-centred communication about these issues as they emerge. De Vocht et al. (2011) propose that the skilled companions are primarily well-educated nurses who show an interest in this area of health care. Other authors suggest that that as long as the communication is patient-centred, well documented, and that the patient feels well supported with information and practical strategies, then the type of health professional providing this level of communication is irrelevant (Hordern and Street, 2007a; Woodhouse and Baldwin, 2008; Hawkins et al., 2009). Cort et al. emphasize that it is the openness of the health professional committed to incorporating patient sexuality and intimacy into routine health care that results in growing confidence in the required communication skills to achieve this. Health professionals do not require specialist training in sexuality to achieve patient-centred outcomes and patients want links to their regular team rather than to a separate sexual counsellor (Cort et al., 2004). Hordern et al. (2009) propose that a brief communication skills training model for clinicians has the potential to reduce perceived barriers and increase confidence and frequency of discussing the topic of sexuality in the clinical setting.

Normal ageing processes for women

Irrespective of health and disease status, men and women experience changes to sexual function as a result of natural ageing processes. For example, in natural menopause the vaginal tissue becomes drier, thinner, and more fragile. There is a reduced amount of natural lubrication and a shortening in the length and width of the vagina (Hickey et al., 2008). There are also physical changes to the labia, which shrink in size, exposing the clitoris, so that some of the sensitivity and involuntary contractions after orgasm are altered (Gianotten, 2007). Experiencing pain related to a dry vagina and a decrease in the intensity and speed of a sexual response may result in a loss of libido. The frequency of these symptoms varies among women and is less marked with regular intercourse (Quinn, 2007). Women also may experience mood changes, night sweats, fatigue, and changes to their body shape as they age (Hickey et al., 2008). These issues do not equate to women becoming asexual but do raise challenges for older women who may choose to embark on new relationships or to explore their sexual identity from a non-reproductive focus.

Normal ageing processes for men

As a man experiences physiological changes related to ageing, he is more likely to increase the time required to achieve an erection. Changes may include the erection being less rigid for extended periods without ejaculation and the amount of seminal fluid decreases

(Corona et al., 2010). A man's orgasmic strength and pleasure may also lessen throughout the ageing process (Gianotten, 2007; Corona et al., 2010), and older men may experience a decrease in the size and firmness of the testes and a change in testicular elevation (Shell and Smith, 1994). Erectile dysfunction has also been attributed to many common drugs including some medications for hypertension or depression, interferon-based therapies, excessive alcohol consumption, and cigarette smoking (Corona et al., 2010).

With so many predisposing factors relating to erectile dysfunction, it is important for health professionals to assess accurately and differentiate between physical and psychological causes of erectile dysfunction and loss of libido. With adequate support and information, many men who are unable to experience an erection are able to explore more flexible forms of intimacy with a partner such as massage, hugging, oral sex, and sexual responses to fantasies produced without physical touch (Gilbert et al., 2010). Therefore it is important to emphasize to men that they do not need an erection to experience orgasm, ejaculate, or feel intimately and sexually connected to their partner.

Impact of cancer treatment and chronic illness on sexuality

Facing advanced cancer, living extended periods with chronic and debilitating disease and entering the palliative phase of illness inevitably brings a range of physical and emotional responses to the person, and their carers, and families. People frequently say they are 'on an emotional and physical roller coaster ride' as they face changes that have the potential to transform how they view themselves as a man or a woman. Many medical conditions such as cancer, hyper- and hypo-tension, diabetes, renal failure, depression, stroke, multiple sclerosis, and Parkinson's disease have all been associated with changes to sexual function in men and women (Wylie and Kenney, 2010). Irrespective of age or partnership status, chronic illness, fatigue, depression, anxiety, surgery, living with uncertainty, or just feeling unwell, can cause a person to look at their body differently and make them more sensitive to the reactions of partners, other family members, and friends. When these issues are combined with fatigue, dyspnoea, incontinence, disfigurement, pain, nausea and vomiting, weight changes, fluid retention, xerostomia, and other forms of alteration to body image, it is difficult to overstate the enormity of the impact on a person's overall body image and confidence (Hordern, 2012).

Understanding the impact of previous cancer treatment on a person's sexuality can provide a deeper understanding and insight into the complex loss, change, and grief associated with a person's altered sexuality and intimacy in the palliative care setting. Even when non-genital or non-sexual areas of a person's body have been affected by surgery or disease, a person's intimate and sexual world has the potential to be altered. Catheters, colostomy bags, subcutaneous medicines, syringe drivers, intravenous poles, and enteral feeding tubes can become intrusive to intimate moments such as holding hands, cuddling, and kissing. For highly detailed information about the sexual ramifications of a broad range of cancer types and treatment see Sadovsky et al. (2010).

Impact of chemotherapy

Treatment-induced infertility may result from chemotherapy, radiotherapy, and hormone treatment (Su et al., 2008; Stovall and

McGee, 2010). The effects of chemotherapy on reproductive capacity depend on the age, sex, and chemotherapy regimen (treatment dose, cycles, and time between treatments). The impact of radiotherapy on fertility is determined by the location and size of the radiation field, the total dose, and dose intensity. Thus the residual effect of therapy on the reproductive capacity of both men and women is complex and individually determined, ranging from little or no effects to prolonged and permanent sterility (Otkay and Meirow, 2007). It is important that options for preserving fertility are routinely discussed with patients prior to commencement of fertility compromising treatment and due to the complexity and individual variation it is advised that these discussions take place with reproductive specialists (Su et al., 2008; Stovall and McGee, 2010).

Women are often anxious and seek practical advice on managing the symptoms of treatment induced menopause such as vaginal dryness, atrophy, reduced libido, and hot flushes (Leyden Wiggens and Dizon, 2008). In premature menopause, the vaginal mucosa will remain thin and fragile and therefore easily irritated by intercourse, resulting in dyspareunia. Dyspareunia combined with treatment-induced vaginal dryness can inevitably lead women to avoid sexual intimacy of any type, for fear it will lead to painful intercourse and moderate to severe vaginal discomfort for women (Su et al., 2008; Stovall and McGee, 2010). This also has the potential to impact the quality of life for women in day-to-day activities like wearing jeans, sitting in trousers for long periods of time, and experiencing routine medical examinations. Experiencing these vaginal symptoms for extended periods can become debilitating to women, irrespective of age, disease, or relationship status. For practical advice on managing these side effects, refer to the 'Vaginal moisturizers, lubricants, and topical oestrogen' section later in this chapter.

Chemotherapy can also reduce circulating androgens. In both men and menstruating women, androgens act in the body to promote sexual desire and arousability (Hickey et al., 2008) so that men and women may experience changes in mood, energy, and libido as a result of their treatment. Hormonal manipulation, particularly in treatment for metastatic prostate and breast cancer, can also reduce circulating androgens (Couper, 2007; Hickey et al., 2008). Patients claim that these physical and psychological symptoms may persist for months or years after completion of treatment yet there is a paucity of literature around the length of time that people may experience reduced libido and arousal and evidence-based approaches to managing these side effects of treatment (Ochsenkuhn et al., 2011).

Safe sex while undergoing chemotherapy

Cytotoxic waste can be excreted through any blood and body fluid during chemotherapy, hence the need for partner protection in the first 48 hours after completion of the chemotherapy (Cancer Council Victoria, 2012a). Surprisingly little research has been done in this area of partner protection after cytotoxic therapy; however, general advice can be offered to people undergoing chemotherapy (including oral regimens) to wear a condom for sexual intercourse or use a dental dam for oral sex (Schover, 2008). Dental dams are approximately A4-sized latex that can be purchased from sex shops (not dentists!), in a variety of colours and flavours and protect the partner's mouth from sexually transmitted infections and cytotoxic irritation. Similarly a condom or

a dental dam should be used to cover sex toys like vibrators and dildos which require washing after each use.

Side effects of radiotherapy

Radiotherapy and women

Sexuality can also be affected by radiotherapy—side effects of treatment include fatigue, nausea, diarrhoea, and skin reactions. All have the potential to affect the way people feel about themselves. Pelvic and intracavity radiation can result in vaginal tissue becoming thinner, ulcerated, and scarred, making sexual intercourse very painful. Vascular damage to the pelvic or vaginal areas results in a reduced blood flow to the area, often leading to the vagina being less lubricated and less dilated (Quinn, 2007). In severe cases, the scarring and vaginal atrophy can be so marked that the vagina shortens and shrinks in width, making it difficult or impossible for the woman to have sexual intercourse. During treatment a woman can be encouraged to have sexual intercourse, or use a vaginal vibrator or dilator three or four times a week to reduce the chances of her vagina shrinking (Quinn, 2007).

Radiotherapy and men

Radiotherapy to the testes and total body irradiation in men as part of stem cell transplant can also result in men becoming permanently infertile (Stovall and McGee, 2010). Vascular insufficiency caused by pelvic or testicular irradiation may result in erectile dysfunction (Shell and Smith, 1994). A spinal cord lesion may affect the nerve centres that control erectile function and neurologic erectile dysfunction can be induced by damage to the prostatic nerve plexus during radical pelvic surgery. Erectile dysfunction rates for both radiotherapy and surgery (including robotic) after prostate cancer are similar, despite the belief that some prostate treatment is more successful than others (Barry et al., 2012; Cooperberg et al., 2012). More research is required to determine whether the long-term benefits of high-frequency ultrasound will reduce incidence or severity of erectile dysfunction experienced by men as a result of their cancer treatment (Barry et al., 2012; Cooperberg et al., 2012).

Myths and misconceptions

Many myths and misconceptions exist about being 'radioactive' following radiotherapy. Couples fear having sexual intercourse during radiotherapy for fear of transmitting radiation from one person to the other. Other people ask if it is safe to cuddle and kiss, hold beloved grandchildren, or even sit in the same car or lie in the same bed while having radiotherapy. It is important for health professionals to explain to patients and carers that external beam radiation does not leave the body radioactive; nor do radiation implants once they are removed from the body (Cancer Council Victoria, 2012b). While temporary internal radiation implants are in place, guidelines recommend that patients avoid all close contact with people, especially children under 18 years of age and pregnant women. Visitors are advised to sit approximately 2 metres from the bed and remain in the hospital room only 30 minutes each day (American Cancer Society, 2011). Once the temporary implant is removed, sexual and intimate contact is considered safe for the partner. People with permanent implants (using lower radiation) are advised to avoid close contact with people for the first few days while the radiation is most active and then to use condoms for several days post procedure (American Cancer Society, 2011; Cancer Council Victoria, 2012b).

Addressing the sexual and intimate needs of hidden communities in palliative care

Heterosexual norms

People who deviate from heterosexual norms of society (Rondahl et al., 2006), young adolescents, and the elderly all share some form of discrimination when it comes to health professionals avoiding or failing to discuss patient sexuality in a palliative care context (Redelman, 2010). Same-sex, bisexual, transsexual, and transgender populations enter a health-care system that not only fails to view patients as sexual beings, but does little to encourage open and honest discussions about the impact a life-limiting diagnosis may have on minority groups who are often hidden from view and feel too vulnerable to have a voice, in a system where homophobia and heterosexism is prevalent (Rondahl et al., 2006; Hyde, 2007). Added to that, any attempt to explore the impact a cancer diagnosis or chronic illness has on intimate and sexual relationships is almost always considered and discussed through the lens of a heterosexual health system (Hordern and Street, 2007b, 2997c), where dominant heterosexual assumptions hinder free expressions of sexuality for all minority groups (De Santis and Vasquez, 2010; Redelman, 2010). Non-heterosexual relationships can vary from heterosexual relationships in terms of communication, conflict negotiation, and connectedness (Gilbert et al., 2009) so that discrimination against non-heterosexual minority groups can result in profound loss of identity and isolation (Hordern and Currow, 2003). The resultant grief, pain, and suffering become deep sadness, particularly in the face of a life-limiting illness (Redelman, 2010). Health professionals play a vital role in recognizing not only the assumptions they bring to practice but also the structures and influences which can positively or negatively impact and shape a person's ability to embrace intimacy and sexuality. Irrespective of the sexual orientation of the clinician, this must be part of practice so that sexuality is viewed as 'life affirming way of achieving intimacy and human contact' (Gilbert et al., 2009, p. 537).

Young adolescents

Similarly, the unique sexual and intimate needs of adolescents and young adults who face end-of-life issues have been largely ignored (Zebrack, 2011). For example, what has been identified is that when a person experiences a cancer diagnosis as an adolescent or young adult it has direct ramifications on their ability to develop a positive self-esteem, body image, sexual identity, reproductive capacity, communication with peers, and confidence associated with entering the dating world. Parental and health-care dependency, confronting mortality at such a young age, and experiencing late effects and ongoing palliative care issues make this another priority area for health professionals to increase their understanding of, and willingness to, communicate about patient sexuality and intimacy (Schover, 1997; Thaler DeMers, 2001).

Single people facing chronic illness

Similarly, the impact of experiencing life-limiting illness as a single person and for those entering new relationships, irrespective of how poor the prognosis, is another area that requires attention in the palliative care arena. Issues such as a desire to seek or engage

in a new sexual relationship are challenging for patients who are in a palliative phase of their disease. Lack of confidence can be compounded by changes to body image, scars, leaking orifices and odours (Lawton, 1998, 2000), fears of being rejected, and lack of uninterrupted time and energy (Shell, 2008). Yet remarkably, the majority of palliative care clinicians can vividly recall patients who have formalized relationships with wedding ceremonies around a hospice bed, or participated in symbolic ceremonies that recognized and validated significant relationships involving a patient with very advanced disease and their (relatively new) partner.

Ageist assumptions

Similar discrimination is felt by the elderly whose sexual identity is written off and discounted as soon as they age (Hordern and Street, 2007b, 2007d; Shell, 2008). It has been refreshing to note that researchers, particularly from the fields of palliative care have been embracing opportunities to explore how people engage in many forms of sexuality as a form of intimate expression and communication, particularly when grappling with cognitive, physical, and life-limiting changes associated with ageing (Cort et al., 2004; Mercadante et al., 2010). Discussing sexuality late in the course of a life-limiting disease could be perceived as distasteful, an enduring taboo, or breaching social norms. Yet sexual expression can also be life affirming, an antidote for pain and misery, and provide a deep connection to another—which is important to most of humankind irrespective of the age, sexual orientation or disability (Gianotten, 2007; Cagle and Bolte, 2009; Gianotten and Hordern, 2011). When illness is incurable, there are social rules and norms about what is acceptable pre- and post-death and each individual has a unique opportunity to seek comfort in a relationship or shying away from such new adventures, depending on the individual need (Cort et al., 2004; Rothenberg and Dupra, 2010; Ussher et al., 2011).

Similarly, opening communication about life and new relationships after the death of a partner warrants discussion as part of regular palliative care follow-up (Cort et al., 2004). Complex and varying emotions are enmeshed in the phases of loss and grief post death of a partner and while some shy away from new relationships, others seek comfort from the sexual release and physical contact of a new lover (Gianotten, 2007). Social etiquette and cultural 'rules' vary about the length of time required after the death of a partner before pursuing new intimate and sexual experiences (Cort et al., 2004). Importantly however, a study has found that couples who communicated more frequently about how the man would cope physically and emotionally after a wife's death to cancer resulted in less guilt and potentially better psychological health 6 months after the death than men who did not have such discussions with their wives (Miao Jonasson et al., 2011). Although the authors do not make the link, one could suggest that reduced feelings of guilt and better psychological health would be more conclusive to better sexual and intimate health after death and bereavement of the partner.

Not surprisingly, patients frequently report that even though they feel it is a health professional's responsibility to raise the topic, health professionals rarely do (Hawkins et al., 2009). Discussions about the impact of an advanced life-limiting illness on intimate and sexual aspects of a person's life and the provision of information relating to physical, psychological, and relationship changes after a diagnosis, remain an unmet need (Stead et al., 2001, 2007; Canada et al., 2005; Ussher et al., 2011).

Opening the communication

If sexuality and intimacy are raised as an important and valid part of patient assessment in the palliative care setting, practical solutions to many issues can be offered to the patient and their partners, so that treasured moments of meaningful and intimate connections can occur until the moment of death. Unless the topic is raised by a health professional, people are likely to suffer in silence, as sexual and intimate relationships decline. Offering opportunities to discuss intimate and sexual ramifications of a life-limiting illness demonstrates that a health professional regards this as a legitimate and important topic that is open for discussion along the whole illness trajectory (Katz, 2009; Sadovsky et al., 2010).

Recognizing the barriers and assumptions in health professional communication

Few health professionals feel comfortable or confident raising the topic of patient sexuality in palliative care settings (Hordern and Street, 2007b, 2007d), yet people affected by progressive life-limiting illnesses often search for ways to deal with altered self-perception and body image, negotiating relationships with partners or the desire for practical ways to adjust to living with sexual and intimate changes after alterations to health. In general terms, the majority of patients search for how other people cope in similar situations, what is 'normal', and ways to adapt to many of the side effects of treatment that impact upon their sexual and intimate world (Hordern and Street, 2007b, 2007c).

Health professionals' attitudes and barriers that prevent conversations about patient intimacy and sexuality include:

- lack of time
- the belief that the patient is too ill or not interested in sex
- belief that disfigured bodies are not sexually attractive
- fear of opening a 'Pandora's box'
- transgressing medico-legal boundaries
- the presence of third parties at the consult (Sunquist and Yee 2003).

Barriers to discussions about patient sexuality in the context of cancer may also arise because health professionals believe their conversations may be construed as disrespectful and inappropriate by the patient, where gender, age, disease, partnership status, culture, socioeconomic factors, and religion all contribute to health professionals' avoidance of the topic (Sunquist and Yee, 2003; Hordern and Street, 2007d).

Health professionals often worry about what their patients or colleagues would think of them if they raised the topic of sexuality and intimacy in the clinical setting, particularly when they have little sexual experience themselves or struggle to communicate about such difficult topics in their personal lives (Hordern and Street, 2007a, 2007b, 2007c, 2007d). Reflecting on personal definitions of sexuality and intimacy and how this may impact on feelings of discomfort, embarrassment, or awkwardness when raising the topic of patient sexuality is a good starting place.

Recognizing one's own comfort zone is vital for effective, open, and patient-centred communication, and this will improve with practice and experience. Validating the importance of the topic,

ensuring confidentiality, and moving from a less sensitive to more sensitive topics are all vital elements in open communication about sexuality. Few patients will actually bring up the subject of sexuality unless the health professional caring for them provides permission by raising the topic as part of routine health assessment.

Conversation starters may be as follows:

◆ Many people who have undergone this kind of treatment tell me they experience sexual or intimate changes. How has this been for you?

◆ How has your sexual confidence changed since . . . ?

◆ How has all of this made you feel about yourself as a man/a woman?

◆ How do you think this treatment has affected the way you feel about yourself or your relationship with your partner?

◆ Now let's focus on the more intimate changes you may have experienced since this all began.

◆ It is also important for me to support you through the personal side of this management plan. Let's spend some time exploring some of the sexual and intimate issues you may have been facing . . .

◆ Sometimes a person's body image changes with this illness . . .

Health professionals who continue to feel uncomfortable about discussing sexuality with patients should, with the patient's permission, arrange referral to another health professional and document this in the patient's history. With adequate information, support, and training, health professionals can become aware of their assumptions and barriers, and increase their confidence and frequency in discussing sexuality and intimacy with patients in their care (Hordern et al., 2009).

Dispelling myths and clarifying beliefs

Health professionals often make assumptions about a person's knowledge and understanding of human anatomy and how their body works, without checking baseline knowledge and beliefs. This may result in the patient or their partner failing to really understand the whole conversation (Katz, 2005). Furthermore, many people subscribe to the myths that sexual activity can spread the cancer to the partner, or that any sexual activity can cause cancer (Katz, 2005), make the cancer or life-limiting disease worse, or negate the benefits of treatment. It is not uncommon for patients to express beliefs that past actions such as extramarital affairs, abortions, illegitimate children, and other 'sins of the past' have contributed to their ill health (Kishore et al., 2007).

Strategies for helping people help themselves

Patients want practical strategies and approaches to engaging in sensual body touch, communicating more openly about sex with their partners that will result in increasing expressions of affection, and more sensual aspects of intimacy (Canada et al., 2005). Validating sexuality and intimacy in the context of palliative care legitimizes the notion that sexuality can be impacted but not destroyed by life-limiting illness and people need permission to divert attention and energy to their body image, rather than solely

focusing on the illness (Shell, 2008). Discussing the extensive range of vaginal moisturizers and lubricants that are available is a helpful way to support men and women through managing the side effects of natural ageing processes and reducing side effects of medical treatments.

Vaginal moisturizers, lubricants, and topical oestrogen

Differentiating lubricants from vaginal moisturizers and topical oestrogen is a good place to begin the conversation as there are important differences in their formulas and instructions for use (Leyden Wiggens and Dizon, 2008; Carter et al., 2011). Vaginal moisturizers are a helpful way to optimize hydration of the vaginal mucosa and relieve some of the symptoms associated with atrophy, yet little clinical research has been published in this area. Replens® (<http://www.replens.com.au/>) is an example of a vaginal moisturizer containing purified water, glycerine, mineral oil, hydrogenated palm oil, and sorbic acid, and in two small studies has been shown to offer a non-hormonal alternative for the management of vaginal dryness and irritation, as well as providing vaginal comfort when used three times a week to daily use (Leyden Wiggens and Dizon, 2008; Carter et al., 2011).

Regular use of lubrication to the genital areas can promote awareness of new erotic zones, changes in foreplay patterns, and validation that exploring intimacy, sensuality, and sexuality (no matter what stage of illness) is good for the mind and body. Lubricants can also prevent genital irritation, abrasions, and vaginal tears (Carter et al., 2011). Water- or silicon-based lubricants that are oestrogen free (for oestrogen-dependent cancers) and do not contain perfumes or colourings can be purchased at a pharmacy and suit many people. Both silicon- and water-based lubricants can be broken down with warm soapy water, and generally, silicon-based lubricants last longer but may be more expensive. However, some water-based lubricants do contain glycerine, increasing the risk of yeast infections (such as *Candida albicans*) as do oil-based lubricants. There are many options available and it is advisable to encourage patients to try different options until they find one that suits them. It is best to instruct patients to apply the lubrication to their genital areas and to their partner's (if applicable) prior to any manual caressing, intercourse, or use of vibrators.

Vaginal oestrogen

Lowered oestrogen levels as a result of natural ageing or treatment-induced menopause, is associated with vaginal pain and dryness, which has the potential to negatively impact sexual function and enjoyment (Carter et al., 2011).Topical or systemic oestrogen therapy is an effective treatment for managing vaginal symptoms; however, the whole issue of hormone replacement therapy is complex and controversial. Carter et al. (2011) provide a comprehensive review of benefits, risks, and knowledge to date, as do Hickey et al. (2008).

Managing a range of common side effects

Many of the palliative care population experience dyspnoea, pain, degenerative muscle weakness, fatigue, nausea and vomiting, incontinence, and xerostomia, all of which have the potential to negatively impact sexual function and confidence. Table 8.8.1 provides some practical approaches to managing these symptoms, to enhance sexual and intimate expression (Shell, 2008).

Table 8.8.1 Approaches to managing physical issues impacting sexual function

Pain	◆ Pain management—as pain negatively impacts libido and sexual performance ◆ Dyspareunia due to vaginal dryness from radiation therapy, chemotherapy, or hormone therapy. Vaginal moisturizer Replens® (<http://www.replens.com.au/>), lubricating products such Pjur® water-based/silicon-based products (<http://www.pjur.com/>), and SYLK® (<http://www.sylk.co.uk/>) may be helpful
Dyspnoea	◆ Medical assessment and management of the dyspnoea ◆ Practical measures include a well-ventilated room with fan and comfortable bed (consider water bed) ◆ Encourage patient to explore gentle intimacy with partner (gentle hugging, hand holding, soft caressing, or light massage with oils or creams). Use water bed to conserve energy ◆ During sex, control shortness of breath with pursed-lip breathing. Take extra pillows and covers off the bed to create open sensation. Avoid long kisses on the mouth to take away fear of 'not getting enough air'. Avoid positions that restrict breathing or put pressure on the chest (Shell, 2008)
Fatigue and weakness	◆ Set aside a time of the day when patient feels most energy and encourage them to set the scene; phone on answer machine, nap first, ensure privacy and light candles, play music, burn oils to create intimate atmosphere with self or partner ◆ Explore different positions to conserve energy. A warm bath together, lying on side, explore oral and mutual masturbation options for self and/or partner ◆ Avoid extreme temperature, heavy meals, and alcohol
Nausea and vomiting	◆ Medical assessment and antiemetic regimen ◆ Avoid use of oils, perfumes, and deodorants ◆ Explore gentle sensuality as above
Xerostomia	◆ Education on regular oral hygiene ◆ Artificial saliva (consider Moi-Stir® <http://www.kingswood-labs.com/>, Optimoist® spray, Saliva Substitute® liquid and Xero–Lube® Artificial Saliva sodium-free spray ◆ Saliva stimulants: over-the-counter (OTC) saliva stimulants include Natrol Dry Mouth Relief® lozenges may be dissolved in the mouth three times daily ◆ Pilocarpine tablets: Salagen® stimulates the salivary glands to produce saliva
Incontinence	◆ Encourage use of bath and shower as places for foreplay and post-coital relaxation ◆ Utilize shower chair, disabled baths, fluffy towels over an incontinent sheet for intimate foreplay and sexual contact

Providing privacy in the clinical setting

Many situations arise in the clinical setting through lack of privacy, which is created at an architectural level in most institutions. How can we offer people the privacy they have had throughout their lives when there are no locks on doors, only a flimsy curtain shields semi-private rooms, and only single beds are provided? There is also a general acceptance that health professionals have the right to 'barge' into any room at any time of day or night to 'attend' to a patient, irrespective of whether the door is closed or a visitor is present.

Placing 'do not disturb' signs on patients' doors when people request some privacy, knocking before entry, and announcing arrival prior to sweeping back curtains all create a respectful environment. Some palliative care organizations have ensured there is at least one double bed in the setting, which patients and their partners can use, to create intimate and private shared moments. Incorporating the topic of patient sexuality and intimacy into the routine assessment of patients entering the clinical setting invites an open discussion about what needs to be put into place to ensure privacy and respect for intimate and sexual expression up until the moment of death. Partners may wish to bathe the patient or to have the opportunity to shower or bathe together. Couples may find comfort knowing they can intimately hold one another in bed, nap, or sleep together with the certainty that they will not be disturbed by health professionals for negotiated periods of time through the day. If designated sensuality areas (private rooms with double beds, massage oils, access to music, satin sheets, boas, etc.) are actively promoted by health professionals, inpatients will feel they legitimately have an opportunity to be intimate with themselves or their partner for as long as they are able or desire. Similarly, community-based palliative care can encourage the hiring of double hospital beds and embrace intimate sensual moments to legitimize the need for people to remain connected with others until they die.

Having realistic expectations

When people have faced considerable changes to their physical and emotional health it is common for them to fear any form of intimacy that will be painful or 'may make things worse'. Patients frequently wonder: 'Is my partner still attracted to me?' 'Will everything be able to work as it did?' 'How can I bear to look at my body?' 'How do other people cope with these changes?' 'Will I ever feel interested in sex again?' 'Will I ever find a new partner after all I have been through and all that lies ahead?' Relearning to love a changed body, have sexual confidence, and explore new techniques and expressions of intimacy that suit the stage of the disease require changes to ways of expressing intimacy, past foreplay patterns, or sexual positions, and takes time. Advise patients and their partners that first attempts may be disappointing but that with time and patience, people can relearn the feeling of sexual pleasure and intimate connection until they die.

Coping with physical disfigurement

Some people are happy to be naked with their partner despite physical disfigurement. Others are not. Some women wear soft lacy camisoles or night wear to conceal the scars of surgery. Others use the power of fantasy to imagine themselves as 'whole' people with two breasts or without a syringe driver or colostomy bag. Many men have spoken about the confidence they feel in taking the time to dress up for sex, with vests and cummerbunds to conceal scars and altered body parts. Granting patients permission to explore these options is usually the most crucial step in the

communication process and having access to a private room as an inpatient offers a remarkable step forward in acknowledging the intimate and sexual needs of the palliative care community.

Setting the scene

Encouraging patients to set a 'date' with themselves and or their partner validates the importance of promoting intimacy and sexuality throughout all phases of care. Creating a relaxed and comfortable environment to explore sensual and intimate moments can be achieved by encouraging patients to block out times of the day when they experience energy, allowing the phone to divert to an answering machine, setting the scene with candles, soft lighting, and favourite music. Encouraging patients to dress up into clothing that makes them feel more sensually confident, showering or bathing alone or with a partner, using soft fluffy towels on the bedding to absorb any incontinence, and exploring their body to find out what feels satisfying, are the type of practical strategies patients often search for. Taking the pressure off intercourse and encouraging people to rebuild intimate and sensual enjoyment takes time, practise, and a willingness to try new things.

Pelvic floor muscle control and self-stimulation

There is increasing evidence that teaching muscle awareness and control can enhance sexual function, increase blood flow to the clitoris and penile area, and enhance sexual arousal in men and women (Carter et al. 2011). Self-stimulation using masturbation is not only viewed by sex therapists as a normal activity, it is used as a form of therapy for the majority of sexual changes that arise from chronic illness and significant life changes. Making this an 'okay' topic by suggesting to people that they may like to 'have a try yourself', can set the scene for undisturbed sexual and intimate exploration after physical and emotional changes arising from illness. If individuals no longer know what and how they like to be touched, it would be difficult for them to convey this to a partner and this type of sensual self-exploration may give them the confidence to review and potentially alter previous sexual patterns and habits. Along with pelvic floor awareness, self-stimulation using lubrication with digital or oral exploration, with or without a vibrator, can enhance sexual response rates, increase arousal, confidence, and have broader health benefits (Cass, 2004; Gianotten and Hordern, 2011).

Conclusion

In conclusion, the more comfortable you feel about your own sexuality the more likely you will be to respond to and address issues relating to the sexual and intimate worlds of patients in your care. If you have given patients permission to discuss their sexuality with you there is a good chance that they will bring up issues when they feel ready to address them. Every person has a different comfort zone, and recognizing the barriers and assumptions brought to clinical practice is a good place to begin. Raising the topic, validating sexual and intimate changes in the context of palliative care, and offering practical strategies have the potential to legitimize intimate and sexual expression until the moment of death.

SECTION 9

Common symptoms and disorders: pain

Principles of drug therapy: focus on opioids

Ruth Branford, Emily Wighton, and Joy Ross

Introduction to principles of drug therapy: focus on opioids

An understanding of the principles of clinical pharmacology is essential to enable clinicians to prescribe drugs safely and effectively. When prescribing any drug the intention is to gain a therapeutic effect (e.g. the use of opioids to reduce pain), while avoiding harm (e.g. opioid-induced drowsiness). All drugs have the potential to cause side effects, many of which are predictable from knowledge of clinical pharmacology.

Patients with serious or life-threatening illness present challenges to the safe and effective use of medications. Patient-related factors, such as age, gender, and co-morbidities, may influence the choice of drug, starting dose, and route of administration. Most patients receive multiple drugs and clinicians must always be mindful of the risk of drug–drug interactions. Given the risks of polypharmacy in those with advanced illness, options for concurrent non-drug therapy always should be considered. This is certainly important in the case of pain, for which a holistic approach, one that acknowledges that pharmacotherapy is only one strategy among many that may yield favourable outcomes, is often best.

Opioids and other drugs that have the potential for misuse or abuse, addiction, or drug diversion (see Chapter 9.5) are commonly used in palliative care, and these drugs are regulated to a greater or lesser extent in every country. Prescribers may need to make adjustments based on the wider social context implicated in these regulations, and impact of taking medications that may be inconsistently available or arduous to prescribe. In some countries, excessive regulation impedes patient access, particularly in community settings. Clinicians may need to consider whether therapy can be more effectively provided in different care settings (e.g. hospital versus community) or when using specific drugs or formulations, or rates of titration and monitoring. Inclusion of a drug, such as codeine or morphine, on the World Health Organization (WHO) Model List of Essential Medicines (WHO, 2013) increases the likelihood of availability, but does not mean unrestricted access in every country (Junger et al., 2013). Indeed, opioid drugs exemplify the international variation in access that characterizes many types of drugs; some provide their populations with a large number of different opioids and opioid formulations, whereas others fail to ensure access to any. The WHO continues to seek to improve international access to controlled drugs, in particular opioids.

With increasing health-care costs, groups of clinical, pharmacy, and finance professionals are working to promote cost-effective and safer prescribing. In the United Kingdom, efficacy and cost-effectiveness of drugs are assessed at a national level by the National Centre for Health and Care Excellence (NICE). Consideration of cost-effectiveness is now an integral part of the rationale for appropriate prescribing.

Guidelines and formularies

Clinical guidelines are recommendations, based on appraisal of the best available evidence. When evidence is limited or absent, expert opinion is necessary to guide and support best practice. For example, most of the evidence-based guidelines for opioid use in palliative care that have been developed by the European Association of Palliative Care are based on weak evidence (Caraceni et al., 2012). In addition to the development of guidelines by professional societies, national guidances (e.g. NICE (2012) or Scottish Intercollegiate Guidelines Network (2008)) have been developed to help inform local, regional, or hospital-specific practices in a manner that considers local variation in resources and practice. A working knowledge of both international guidelines and national guidances is essential.

Formularies are also a useful resource to guide the prescribing and dispensing of medicines. Many provide detailed information about formulations and doses of drugs. If a formulary is promoted or required in practice, it is important to consider the target audience and the context for any recommendations provided. In palliative care, the most widely recognized formulary is the *Palliative Care Formulary* (Palliativedrugs.com, 2012). This is regularly updated and includes advice about the many drugs that are used off-licence in the palliative care setting. Other generic formularies, such as the *British National Formulary* (BNF), include a much wider selection of medications (Joint Formulary Committee, 2014). The choice of drugs in local or regional formularies is often restricted due to budget constraints.

Efficacy, effectiveness, and cost-effectiveness

Evidence-based medicine (EBM) is centred on the judicious use of current best evidence about the risks and benefits of interventions to inform clinical decision-making. The principles of EBM are discussed in detail in Chapter 19.2. It is important to recognize that the evidence provided by clinical trials evaluates the efficacy

of an intervention, such as an opioid, in an ideal/controlled setting. Strict inclusion and exclusion criteria are applied and an enriched or selected sample may be studied, with structured and often short-term follow-up. Conducting high-quality clinical trials in the palliative care setting is especially challenging (Kaasa et al., 2006) and the evidence used to inform prescribing in patients with advanced illness typically originates from studies of relatively healthier populations.

Effectiveness should be distinguished from efficacy. Effectiveness refers to the benefits and burdens of a drug in the wider context, at a population level and as part of everyday practice. Information about efficacy is needed to identify substances that have the potential for clinical benefit; information about effectiveness provides more relevant and actionable information about the likelihood and extent of the therapeutic effect in a given patient.

Cost-effectiveness refers to a comparison of effectiveness for a target indication against cost, that is, the ratio of effectiveness to cost. Clearly, it is more efficient to use the cheaper of two drugs that are equally effective and safe, and this information often informs local guidance.

Therapeutic benefit and risk

From the clinical perspective, the expectation of benefit must be compared to the expectation of risk to determine whether treatment or a change in treatment is justified. Although it can be difficult to estimate the balance between the potential risks and benefits of a particular treatment in an individual case, it is necessary to do so before action is taken.

The likelihood of benefit or risk in the individual is informed by an understanding of likely outcomes in the population overall. Two broad measures that can be useful as part of this assessment are number needed to treat (NNT) and number needed to harm (NNH). The NNT estimates the number of patients that would need to be given a treatment for one of them to achieve a desired outcome (e.g. 50% pain relief). The NNH is calculated for adverse effects in a similar way. Although these measures have been criticized because they are derived from controlled clinical trials data, they nevertheless provide a useful point of comparison among drugs (Christensen and Kristiansen, 2006).

The cut-offs in pain relief or severity of an adverse effect used to calculate the NNT and NNH, respectively, are accepted by convention. In fact, perceived benefit or risk may be strongly influenced by individual variation or therapeutic context. For example, patients with severe pain may feel that a 30% or smaller reduction in pain relief is clinically meaningful. In addition, some patients may be willing to tolerate mild/moderate side effects to achieve a small improvement in pain control if this translates into improved function or quality of life. Knowledge of the patient's drug history in terms of previous success or failures of treatment will also guide choice of drug in prescribing. Prescribers also must always check individual patient factors, such as renal function and known allergies, to further inform assessment of risk/harm and potential for drug interactions.

Information about side effects of a drug must continue to be gathered after the drug is licensed. This is particularly important when a drug is used in the palliative care context, which is usually characterized by patients with advanced illness and the use of multiple drugs adapted for off-licence indications. In these situations, the use of a drug may be associated with a side effect liability quite different than that expected based on clinical trials information.

Principles of clinical pharmacology

Clinical pharmacology is broadly divided into pharmacokinetics ('what the body does to the drug') and pharmacodynamics ('what the drug does to the body'). In palliative medicine, drugs are not often used to cure or modify underlying disease but are predominantly focused on improving symptoms. They often are administered with the intent to continue treatment until death. Knowledge of pharmacokinetic variation, between patients and across time as disease worsens, combined with an understanding of the basic modes of drug action, underpins the logical selection and use of the most appropriate treatment.

Pharmacokinetics

Pharmacokinetics encompasses the *a*bsorption, *d*istribution, *m*etabolism, and *e*xcretion of drugs (ADME). Detailed descriptions of each of these processes are available in pharmacology textbooks. To some extent, inter-individual variation in kinetics is genetically determined. Each process also is influenced by many other factors, however, and in the the palliative care setting, these also contribute to large inter-individual variation and the potential for significant changes across time (Box 9.1.1).

Box 9.1.1 Factors affecting pharmacokinetics

◆ Age. Both pharmacokinetic and pharmacodynamic factors change at the extremes of age. Metabolism and volume of distribution are often reduced in the elderly leading to increased free drug concentrations in the plasma. Hepatic blood flow may have declined by 40–50% by age 75, with reduced clearance of opioids. Increased central nervous system sensitivity to opioid effects is also found in the elderly.

◆ Hepatic disease has unpredictable effects. Although there may be little clinical consequence, severe hepatic failure with coexisting encephalopathy can lead to a marked increase in sensitivity to drug effects. Reduction in plasma protein concentration, which occurs with liver failure, will also have an effect on plasma concentrations of free unbound drug.

◆ Renal failure has a significant impact on drug response. Some of this effect is due to changes in the concentrations of parent drug and metabolites. Some is related to pharmacodynamic changes apparent when drug effects compound the uraemic state. Drugs with active, renally-cleared metabolites, for example, morphine, tend to be more problematic because of metabolite accumulation.

◆ Obesity results in a larger volume of distribution and prolonged elimination $t_{1/2}$.

◆ Hypothermia, hyperthermia, hypotension, and hypovolaemia may also result in variable absorption, distribution and metabolism of opioids.

Absorption

At the cellular level, absorption occurs across lipid cell membranes and is a passive process along a concentration gradient. For most drugs, this process takes place in the small intestine. As long as the drug is in solution, has a degree of lipid solubility, and there is sufficient surface area and time for diffusion in the small bowel, then problems should not arise.

A reduced rate of absorption may occur if there is delayed emptying of the stomach. This might arise as part of a pathological process or pharmacological agents that slow gastric motility, such as anticholinergic drugs or opioid analgesics.

Many drugs are now formulated as modified-release preparations, which need to remain in the small bowel for a specified period to achieve the expected absorption profile. In patients with either increased or decreased gastrointestinal transit time, there is a risk that the expected time–action relationship may not materialize. In either case, the prolonged duration or extent of therapeutic effects may be lost.

Bioavailability

Absorption and bioavailability are not the same. The bioavailability of a drug is the percentage of administered drug that gains access unchanged to the systemic circulation. Bioavailability is of most clinical relevance after oral administration. Extensive first-pass hepatic metabolism results in relatively low bioavailability and/or large inter-individual variability for some drugs. For example, the bioavailability of oral morphine is just 35% on average and the range is 15–64%, whereas oxycodone has a bioavailability of 75% and range of 60–87%. The difference in bioavailability complicates the challenge of safe dose selection when changing between oral and parenteral routes and is one of the main reasons that dose titration is essential to identify an effective opioid dose.

Bioavailability can be altered by disease processes that affect hepatic function, or by exposure to drugs that either induce or inhibit enzymes of the cytochrome P450 (CYP450) system. In patients with chronic liver disease, for example, blood may be 'shunted' from portal to systemic vessels; this bypasses hepatic enzymes, reduces the first-pass effect, and increases bioavailability. These changes in hepatic function may have a profound effect on drug levels after oral administration but relatively little effect when the drug is given parenterally.

Distribution

The volume of distribution (V_d) is a theoretical volume in which the total amount of drug would need to be uniformly distributed to achieve the blood concentration. For very lipophilic drugs which are taken up into fat stores or muscle, such as fentanyl, the volume may be many times body size.

The V_d is important as a determinant of half-life ($t_{1/2}$) and is also of theoretical importance in the calculation of the loading dose of a drug where one is needed. Changes caused by disease, such as cachexia or renal failure, may shift a drug's concentration–time relationships. Other related processes with potentially profound effects on drug kinetics or dynamics also may occur as a result of alteration in body composition or physicochemical environment. For example, all opioids are weak bases and dissociate into free-base and ionized fractions when dissolved in solution. The ionized form is active at the receptor site, whereas the free-base form is more lipid soluble. The relative proportions of ionized and unionized drug are dependent on pH and pK_a, and may change with the effects of disease.

All opioids also bind to plasma proteins, such as albumin and glycoproteins, in varying degrees. Opioid molecules which are unbound and unionized are capable of diffusing to the site of action, the proportion of which is known as the diffusible fraction. The concentration of the diffusible fraction and other factors such as lipid solubility determine the speed of onset of the drug. The diffusible fraction of a drug may change with hypoalbuminaemia associated with advanced illness.

A high lipid solubility facilitates diffusion across the blood–brain barrier into the brain and therefore is associated with a rapid onset of action. However this view is simplistic in that it is the ionized form that is active at opioid receptor. Speed of onset is therefore better represented as a complex function of both lipid solubility and percentage of the drug that ionized at physiological pH. Morphine has a high diffusible fraction but low lipid solubility which results in a slow onset of action. Alfentanil, however, has both a high diffusible fraction and a higher lipid solubility, which together explain the more rapid onset of action. Baseline values for both drugs may shift with varied disease-related factors that alter V_d, protein binding or the proportion of the ionized form of the drug.

Metabolism

Drug biotransformation takes place mainly in the liver and contributes both to the rate of elimination of a drug and its bioavailability. The rate at which metabolism proceeds usually determines the clearance; however, where removal is particularly rapid (high extraction ratio) the rate of delivery of drug to the liver rather than the rate of metabolism, may determine clearance (flow-dependent kinetics). For such drugs, if liver blood flow is markedly reduced, drug accumulation will result.

The biochemical processes of drug metabolism are complex. Two phases of metabolism are usually described. Phase I reactions involve oxidation, reduction, hydrolysis, hydration, dethioacetylation, and isomerization. Of these reactions, oxidation catalysed by members the CYP450 superfamily of enzymes are the most important and best characterized. Phase II reactions usually involves conjugation; this may take the form of glucuronidation, glycosylation, sulphation, methylation, acetylation, or conjugation with glutathione or certain amino acids. All of the reactions involve the production of products which are more water-soluble and amenable to excretion by the kidney. In some circumstances, phase II reactions may take place without a prior phase I reaction. When phase I reactions do occur, they may prepare the drug molecule for a phase II reaction by producing or uncovering a chemically reactive group, which then forms the substrate for a phase II reaction.

Most opioid metabolism, both phase I and II reactions, occurs in the liver. Hydrophilic metabolites are predominantly excreted renally, although a small amount may be excreted in the bile or unchanged in the urine. Opioid metabolites may be active and contribute to both the overall analgesic and side effect profile (Smith, 2011). Metabolism of individual opioids is shown in Table 9.1.1.

Elimination

The two major organs of elimination are the liver and kidneys, both of which are susceptible to pharmacological and pathophysiological sources of variability. Clearance is defined as the volume

Table 9.1.1 Properties of commonly used opioids in palliative medicine

Drug	pK_a	Oral bioavailability (%)	Lipophilicity	Protein binding (%)	Volume of distribution	Metabolic enzymes	Active metabolites	Excreted unchanged in urine (%)	Half-life
Morphine	7.9	15–64	+	30	3–5 L/kg	UGT2B7	M6G (A) M3G (CNS+)	10	1.7–3 hours
Codeine	8.2	60–90	+	20	3–4 L/kg	UGT2B7 CYP2D6	Morphine (A)	0	2–4 hours
Diamorphine	7.6	–	++	–	70 L	Esterases	Morphine (A)	Minimal	2–3 minutes

of blood which is completely cleared of the drug in a unit of time and reflects the efficiency of the elimination process. It is usually measured in mL/minute or L/hour. It is a major determinant of $t_{\frac{1}{2}}$ and of the steady-state drug concentration.

Half-life

This is perhaps the most well-known and commonly used pharmacokinetic parameter. The elimination half-life ($t_{\frac{1}{2}}$) is a measure of the time taken for half the drug in the body to be removed and generally correlates closely with duration of action. After repeated dosing is initiated, or the dose of an existing regimen is changed, five to six half-lives are required to approach steady-state concentration, irrespective of the route of administration or dosing interval. Drugs with a long $t_{\frac{1}{2}}$ accumulate for a relatively prolonged period of time, and as a result, the concentration may surpass the effective therapeutic range and build up to toxic levels. In the clinical setting, this accumulation has largely been a problem during methadone therapy. Methadone is exceptionally complex because its slow elimination phase is highly variable (beta $t_{\frac{1}{2}}$, 15–60 hours) and preceded by a rapid distribution phase ($t_{\frac{1}{2}}$, 2–3 hours); the overall half-life is relatively long (> 20 hours).

Steady-state plasma concentration

The aim of any dosing regimen in an individual patient is to achieve a concentration of drug in the blood that is high enough to give the intended effect without producing side effects. This concentration can never be completely steady as peaks will occur at the point of maximum drug absorption after administration, and troughs will occur immediately before each dose (Fig. 9.1.1). The degree of swing between peak and trough concentrations is determined by the drug's elimination $t_{\frac{1}{2}}$ and the frequency of drug administration.

Time to reach steady-state plasma concentration

The time taken for a drug to reach steady-state plasma concentration is dependent on the half-life. As noted, five to six half-lives are required to approach steady-state drug concentration if the same dose of drug is given at a constant time interval; four $t_{\frac{1}{2}}$ yields approximately 95% of this concentration. This applies only to drug where elimination is governed by 'first-order' kinetics. Fortunately, this comprises the vast majority of drugs, including opioids. Phenytoin is a notable exception, which involves both 'first-' and 'zero-order' processes.

The $t_{\frac{1}{2}}$ of morphine is 2–4 hours. Therefore, when morphine is administered every 4 hours, steady state will be 95% achieved
Fig. 9.1.1 Steady-state plasma concentration of a short-acting drug showing peaks and troughs after each dose.

after approximately 16 hours. Titration of the dose on a daily basis ensures that dose changes are occurring at steady state. In contrast, the methadone requires approximately 4–7 days, and occasionally much longer, to achieve steady state. Taking this into consideration a loading dose of methadone is often used followed by a period of cautious titration (after a number of days) to minimize the risk of toxicity.

Pharmacodynamics

Drugs produce their effects on the body by binding with receptors, modifying enzyme processes, or by direct chemical or physical actions. Opioids exert their influence by interacting with opioid receptors (primarily the mu opioid receptor).

Receptors

Receptors are specialized proteins within the cell membrane which are integral for communication between the cell and the outside world. They are highly specific for certain ligands, such as specific hormones, cytokines and/or drugs.

Opioid receptors

Opioid receptors were originally classified by pharmacological activity and later by molecular sequencing (Pasternak, 2004). There are three types of classical opioid receptor: μ (mu) or MOR, κ (kappa) or KOR, and δ (delta) or DOR. Another opioid-like receptor has been identified named the nociceptin or orphanin FQ peptide receptor or NOR (Mollereau et al., 1994).

The three classical receptors are activated differentially by the endogenous opioids (encephalins, endorphins, and dynorphins) (Table 9.1.2). Exogenous opioids, such as morphine, act primarily at the MOR. Different opioids may show differential binding to sites on the MOR and may also bind to other opioid or non-opioid receptors (Pasternak and Pan, 2011).

The opioid receptors belong to the superfamily of G protein-coupled receptors. Each consists of an extracellular N-terminus, seven transmembrane helices, three extra and intracellular loops, and an intracellular C-terminus. Each receptor type is coded for by a different gene (Meng et al., 1993; Knapp et al., 1994; Wang et al., 1994). The three receptors share a high degree of homology with most variation found in the extracellular loops and N-terminal domains (Minami and Satoh, 1995). The extracellular loops are particularly important as they determine ligand binding. Opioid receptors are widely, yet differentially, distributed in both central and peripheral nervous systems (Table 9.1.2) (Minami and Satoh, 1995).

The μ-opioid receptor. The μ-opioid receptor is clinically the most important of the family is, as it is responsible for the inhibition of nociceptive pathways and is exploited by all exogenous opioids. Knockout studies in mice show that the MOR is essential for morphine-induced analgesia (Matthes et al., 1996). Many of the unwanted effects of opioids are also related to activity at this receptor (Table 9.1.2). The MOR is expressed on central and peripheral neurons, and the latter are up-regulated in response to inflammatory stimuli. Peripherally, MOR are found pre- and post-synaptically. For example, approximately 70% of MOR receptors in the dorsal horn are expressed on the primary afferent terminations (presynaptic), where they modulate afferent transmission (Stein et al., 2003). At a cellular level, μ-opioid receptor activation results in an overall inhibitory effect (Box 9.1.2).

Table 9.1.2 Classical opioid receptor genes, distribution, endogenous ligands, and function

Receptor	Gene	Expression*	Endogenous ligand	Function
Mu (μ) MOR	OPRM1	Central nervous system: ◆ Brain including cerebral cortex, thalamus, hypothalamus, striatum, amygdala, periaqueductal grey. ◆ Spinal cord, pre- and postsynaptic neurons Peripheral nervous system Immune cells	◆ Beta-endorphin ◆ Encephalins ◆ Endomorphins	◆ Analgesia ◆ Respiratory depression ◆ Reduced GI motility ◆ Miosis ◆ Euphoria ◆ Sedation ◆ Physical dependence
Kappa (κ) KOR	OPRK1	Central nervous system: ◆ Brain including cerebral cortex, thalamus, hypothalamus, striatum, periaqueductal grey ◆ Spinal cord Peripheral nervous system	◆ Dynorphins	◆ Analgesia ◆ Miosis ◆ Dysphoria ◆ Hallucinations ◆ Sedation
Delta (δ) DOR	OPRD1	Central nervous system: ◆ Brain including cerebral cortex, striatum, olfactory bulb Peripheral nervous system	◆ Encephalins ◆ Beta-endorphin	◆ Analgesia ◆ Respiratory depression ◆ Reduced gastrointestinal motility ◆ Tolerance ◆ Mood regulation

Box 9.1.2 Downstream consequences of μ-opioid receptor activation

◆ Inhibition of adenylyl cyclase

◆ Increased opening of potassium channels (hyperpolarization of post-synaptic neurons, reduced synaptic transmission)

◆ Inhibition of calcium channels (decreases pre-synaptic neurotransmitter release).

δ- and κ-opioid receptors. δ- and κ-opioid receptors also are involved in the modulation of pain. Knock-out studies in mice show that KOR may influence chemical visceral pain and thermal nociception (Simonin et al., 1998). Studies with selective opioid antagonists suggest that oxycodone analgesia depends on binding to the KOR receptor (Smith et al., 2001); other studies indicate that oxycodone is more like morphine and exerts its analgesic effects through MOR activation (Kalso et al., 1990; Chen et al., 1991; Yoburn et al., 1995). Pharmacological studies also suggest a role for KOR in mediating the dysphoric and sedative effects of opioids (Mark, 1990).

Combination opioid receptor knockout studies suggest that DOR plays a role in modulating mechanical and inflammatory pain (Martin et al., 2003). δ-opioid receptor knock-out mice also do not exhibit analgesic tolerance to morphine (Nitsche et al., 2002).

G-protein-coupled receptors, including MOR, KOR and DOR, have been shown to form different configurations, including homo- and hetero-dimers and oligomers, with unique internalization and activation pathways. Dimerization modulates receptor pharmacology and this process could present targets for novel interventions (Milligan, 2005). The development of MOR-DOR heteromers exemplifies this potential. There is evidence that there is an increased abundance of MOR–DOR heteromers in chronic pain and/or chronic exposure to morphine, and that ligand binding to DOR in the context of MOR-DOR is not associated with the development of opioid tolerance, in contrast to ligand binding to DOR alone. MOR-DOR may represent a new pharmacological target with the potential induce analgesia without tolerance (Costantino et al., 2012).

Modulation of opioid responses

Genetic polymorphism caused by alternative splicing of mRNA has been shown to give rise to various human MOR receptor subtypes. Much of the variation is found in the intracellular C-terminal domain and includes the creation of potential phosphorylation sites (Pasternak and Pan, 2011). These receptor subtypes have differential expression patterns and demonstrate activation profiles that vary among the various MOR agonists; they are likely to explain some of the clinical variation in opioid response (Pasternak, 2004). Genetic polymorphism also may be involved individual variation in pain responses. For example, the minor T allele of *OPRM1* rs563649 is associated with higher expression levels of the MOR-1K isoform and also with high pain sensitivity (Shabalina et al., 2009).

Other cellular adaptations are likely to be involved in the varied responses to chronic opioid exposure, such as variation in the development of tolerance (Ferguson, 2001; Bailey and Connor, 2005). Chronic morphine exposure leads to little change in MOR expression but does seem to produce changes in the non-neuronal population of glial cells, with increased activation provoking central sensitization (Watkins et al., 2005).

Although it is widely accepted that clinically relevant pharmacological tolerance to opioid analgesic effects is not an issue for the majority of patients with cancer-related pain, it is difficult to assess analgesic tolerance clinically (Chang et al., 2007). There does not appear to be a simple correlation between exposure to opioids and induction of analgesic tolerance. A process of adaptation occurs, which is likely to depend on diverse factors, but this process cannot be fully explained on the basis of current knowledge of cellular mechanisms.

Agonists, agonist–antagonists, and antagonists

Based on their interactions with receptors, opioid compounds can be divided into agonist, agonist–antagonist, and antagonist classes (Table 9.1.3). Most opioids used in the clinical setting are full agonist drugs. Opioid antagonists, such as naloxone and naltrexone, bind to MOR and produce no agonist activity. Agonist–antagonist drugs include a group of mixed agonist–antagonists, which are agonists at one or more opioid receptor subtypes and antagonists at others, and partial agonists. The mixed agonist–antagonists, such as pentazocine, are seldom used in the management of patients with advanced illness. Buprenorphine is a partial agonist that is being used more as an analgesic with the advent of a transdermal delivery system. Buprenorphine is believed to have a ceiling effect at doses of 8–16 mg/day (Walsh and Eissenberg, 2003). However as the recommended analgesic doses are much lower than the ceiling dose (equivalent to up to 3–4 mg/day, or 2 × 70-microgram/hour patches), buprenorphine typically is used with doses in the linear part of the dose-response curve and clinically performs as a full agonist during the management of pain. At the higher doses used to treat heroin addiction, the partial agonist effect may be encountered (Greenwald et al., 2003).

Efficacy, potency, and relative potency

Efficacy is defined by the maximal response induced by administration of the active agent. In practice, this is determined by the degree of analgesia produced following dose escalation through a range limited by the development of adverse effects. Potency, in contrast, reflects the dose–response relationship and is typically defined by the intensity of a specified effect, such as analgesia, associated with a specific dose. Potency is influenced by pharmacokinetic factors (i.e. how much of the drug enters the body's systemic circulation and then reaches the receptors) and by affinity to drug receptors.

Clinically, the utility of potency measurements is created by comparing drugs using relative potency ratios, or the ratio of doses required to produce the same analgesic effect. The relative potency of each of the commonly used opioids is based upon a comparison with 10 mg of oral morphine. Data from single-and repeated-dose studies in patients with acute or chronic pain have been used to develop 'equianalgesic' or dose conversion tables. The term 'equianalgesic' is however misleading as there is wide inter-individual differences in response to different opioids and such tables should be used only as a guide when switching between opioids (Riley et al., 2006). In particular, care should be exercised when switching from one opioid to another as part of the management of opioid toxicity. In this situation, conservative conversions should be used followed by individual titration. Opioid switching is discussed in detail in Chapter 9.4.

The clinical utility of an opioid therapy is determined by a favourable balance between analgesic efficacy and side effects. Many variables may influence whether a dose exists that yields this balance. These include intensity of pain; prior opioid exposure in terms of drug, duration, and dose (and the degree of cross-tolerance that this confers); age; route of administration; level of consciousness and metabolic abnormalities; and genetic polymorphism in the expression of relevant enzymes or receptors (Droney et al., 2012).

Opioid combination therapy. The clinical use of combinations of different opioids is increasing with the aims to (a) improve analgesia, (b) reduce side effects, and (c) limit the development of opioid tolerance. The rationale behind this practice is to utilize

Table 9.1.3 Table of opioid receptor agonists and antagonists

Receptor effect	Description	Examples
Agonists	An agonist is a drug that has affinity for and binds to cell receptors to induce changes in the cell that stimulate physiological activity The agonist opioid drugs have no clinically relevant ceiling effect to analgesia	Morphine Diamorphine Oxycodone Pethidine Hydromorphone Methadone Fentanyl Tramadol
Partial agonist	A partial agonist has low intrinsic activity (efficacy) so that its dose–response curve exhibits a ceiling effect at less than the maximum effect produced by a full agonist	Buprenorphine
Antagonist	Antagonist drugs have no intrinsic pharmacological action but can interfere with the action of an agonist Competitive antagonists bind to the same receptor and compete for receptor sites, whereas non-competitive antagonists block the effects of the agonist in some other way	Naloxone Naltrexone
Mixed agonist–antagonist	The mixed agonist–antagonist drugs produce agonist effects at one receptor and antagonist effects at another	Pentazocine Butorphanol Nalbuphine

the inherent differences in the pharmacodynamic and pharmacokinetic properties of this group of drugs to maximize potential benefit and minimize adverse effects (Fallon and Laird, 2011). Hypotheses of the pharmacodynamic mechanisms include splice variation in opioid receptors, the receptor activation versus endocytosis (RAVE) theory, and the formation of opioid receptor homo- and heterodimers which results in changes to G-protein signalling cascades (Davis et al., 2005).

In animal studies, there is some evidence of analgesic synergism between methadone and other µ-agonist opioids (Bolan et al., 2002). In addition two small retrospective case series of patients with uncontrolled cancer-related pain have reported that low dose methadone in combination with existing opioid improved analgesia (McKenna and Nicholson, 2011; Haughey et al., 2012).

A combination product of oxycodone with morphine in a fixed-dose ratio 3:2 is currently being evaluated in clinical trials (MoxDuo®). It has been trialled in phase II and phase III studies for the management of acute postoperative pain and results suggest that there may be a difference in side effect profile when compared with the individual opioids (Webster et al., 2010; Richards et al., 2011; Webster, 2012). There are currently no trials published in the chronic pain or cancer pain setting.

Further research into the use of opioid combinations in warranted. The potential benefits from this strategy must be weighed against other factors, such as poor patient compliance, confusion over dosing, and prescriber dosing errors, along with potentially unanticipated increased side effects.

Drugs which alter enzyme activity or have a direct chemical or physical action

Some drugs exert effects by affecting enzyme processes, rather than by binding to receptors. Many act by inhibition of enzyme actions. For example, non-steroidal anti-inflammatory drugs block the effect of the enzyme cyclooxygenase and thereby interfere with the synthesis of prostaglandins and exert anti-inflammatory activity.

Other drugs produce intended effects through a direct chemical or physical action. Antacids are an example of drugs with a direct chemical action; they are bases which neutralize gastric acid. Drugs with a physical mode of action include the bulk laxatives, such as ispaghula husk.

Drug interaction

Patients with palliative care needs may already be receiving drugs for a variety of conditions. Some may still be beneficial but others may no longer contribute to improving prognosis or symptoms. Rationalization of the therapeutic regimen always should be considered. If further drugs to relieve symptoms are added, this adds to the potential for drug interaction. Interaction is adverse if it causes therapeutic failure or toxicity from any one drug. Remembering all the possible drug interactions is virtually impossible, but knowledge of the underlying mechanisms of drug interaction can put the prescriber on guard together with frequent consultation with prescribing information is important.

Adverse drug reactions

An adverse drug reaction can be defined as an unwanted or harmful reaction experienced following administration of a drug, or combination of drugs, under normal conditions of use that is suspected of being related to the drug. For example opioids act via the µ-opioid receptor to slow gut transit and cause constipation.

Box 9.1.3 Opioid side effects listed by system
Gastrointestinal system
◆ Nausea
◆ Constipation
◆ Dry mouth
◆ Vomiting
◆ Ileus
Nervous system
◆ Somnolence
◆ Confusion
◆ Myoclonus
◆ Abnormal dreams
◆ Hallucinations
◆ Hyperalgesia
Genitourinary system
◆ Urinary retention
Respiratory system
◆ Cough decreased
◆ Respiratory depression
Skin
◆ Hyperhidrosis
◆ Pruritus
Endocrine
◆ Hypogonadism
◆ Immunosuppression

Opioid-related side effects are summarized in Box 9.1.3 and can be transient or persistent. Chapter 9.4 describes in more detail the principles of opioid switching which can reduce individual adverse drug reactions.

Opioid analgesics are one of the drugs most frequently associated with adverse drug events. A study of 3695 inpatient adverse drug reactions found that 16% were attributable to opioids (Davies et al., 2009). Risk of opioid drug reactions increases in older patients, in those with underlying cardiac or respiratory disease, and when co-prescribed with other sedative medications such as benzodiazepines (Bernard and Bruera, 2000).

Pharmacokinetic drug interaction

Pharmacokinetic interaction arises through alterations in the rate and extent of absorption and changes in metabolism (both pre-systemic and elimination), distribution, and renal excretion. The clinical impact of theoretical interactions can be difficult to predict.

Drugs such as metoclopramide and anticholinergics, which alter the rate of gastric emptying, may affect the speed of absorption of other agents. Some drugs bind others in the gastrointestinal tract and affect their bioavailability. For example, care is necessary if

antacid preparations, iron salts, or cholestyramine are used concurrently with certain drugs.

Drug interactions resulting from changes in the rate of metabolism by the liver will result both in changes of bioavailability for those drugs with a significant first-pass effect, and decreased clearance. Steady-state concentrations of drug may be profoundly affected.

A number of drugs (particularly phenobarbital, carbamazepine, phenytoin and rifampicin) are capable of inducing the cytochrome P450 and glucuronidase enzymes in the liver. There are a myriad of substrates for this interaction, including methadone, warfarin, corticosteroids, and anticonvulsant drugs. Increased pre-systemic metabolism may result in the need to increased doses to achieve therapeutic levels. Conversely some drugs may inhibit CYP enzymes, individually or as an entire superfamily (Table 9.1.4). Certain foodstuffs may also induce or inhibit hepatic enzyme systems; for example, grapefruit contains furanocoumarins which inhibit CYP3A (Hanley et al., 2011).

The most important drug interactions in the kidney involve competition between agents for active tubular secretion. Active tubular secretion is used by organic acids, and the most frequent interactions are caused by the loop diuretics and some non-steroidal anti-inflammatory drugs. Although renal excretion of some drugs is pH dependent, in general this has minor implications in normal therapeutics. There are a few exceptions, however; for example, methadone's renal clearance is considerably enhanced by concurrent use of urinary acidifiers such as acetazolamide (Bellward et al., 1977).

Pharmacodynamic drug interaction

Some drug–drug interactions occur at a receptor level. For example, buprenorphine is a partial agonist and morphine is a full agonist, and morphine-induced analgesia may be reversed or limited by competition at the receptor level if buprenorphine is added.

Drug formulations and route of administration

The preferred route of administration for many drugs including opioids is oral. Oral formulations of opioids include immediate-release (IR) syrups, tablets or capsules, and modified-release (MR) tablets or capsules. MR formulations slowly release the drug into the gut, allowing treatment once or twice daily depending on the formulation (e.g. morphine, oxycodone). Care must be taken in prescribing, such that the correct formulation is dispensed, and when more than one formulation is given (e.g. IR and MR) the patient understands how and when to use each preparation.

Opioid drugs can also be given by other routes, including, transdermal, transmucosal (sublingual, buccal, nasal, rectal), and parenteral by injection either intravenously or more commonly subcutaneously. Fentanyl and buprenorphine products have been formulated for the transmucosal and transdermal routes. In addition specialist pain services may use epidural or intrathecal opioids in the palliative setting where appropriate. Prescriptions of these drugs should specify the exact formulation, as formulations differ in systemic availability and may not be interchangeable.

Immediate and modified-release formulations

IR preparations are absorbed in the stomach or proximal small bowel, so that absorption is complete within a few hours on ingestion. For example, IR morphine and oxycodone reach peak effects within 1 hour. Modified- or sustained-release formulations allow a drug to be released over 12–24 hours, resulting in a smoother concentration profile of the drug in the blood, extended duration of action, and reduction in tablet burden for the patient.

Transmucosal preparations

Drugs that are absorbed through the buccal, nasal, or rectal mucosa avoid first-pass metabolism in the liver by uptake into veins that drain directly into the systemic circulation. This results in higher bioavailability and often a faster onset of action when compared to the oral route. IR transmucosal fentanyl products may be useful in treatment of breakthrough/incident pain. The rapid speed of onset of action (approximately 10 minutes) and short duration of action (≥ 1 hour) may sometimes be more suited to the temporal characteristics of breakthrough/incident pain than conventional IR opioid (Twycross et al., 2012; Davies et al., 2013). There does not, however, appear to be a meaningful relationship between background opioid dose and the effective dose of transmucosal fentanyl, and therefore, titration is essential (Zeppetella, 2011).

Transdermal preparations

Some lipid-soluble drugs are well absorbed through the skin, and their transdermal delivery via 'patches' allows controlled release over many hours or days. Opioid examples include fentanyl and buprenorphine. Different formulations have been developed and are not interchangeable and preparations may last for 3–7 days depending on drug/formulation. Clinical trials suggest good patient satisfaction with this mode of delivery. Care must be taken, given the wide variability in drug absorption, especially in cachexic or pyrexial patients (Heiskanen et al., 2009).

Parenteral preparations for subcutaneous, intravenous, and intrathecal delivery

The preferred parenteral route of administration in palliative patients is subcutaneous and opioids may be given as stat injections or as a continuous subcutaneous infusion. When continuous subcutaneous infusions are used and multiple drugs combined, care must be taken to ensure drug interactions are avoided, as precipitation of one drug in solution will clearly limit therapeutic effect (e.g. cyclizine and oxycodone are not compatible) (Dickman et al., 2002).

Combination formulations in oral therapy

Combination products are attractive and may aid compliance by reducing tablet burden. To be effective, the frequency of administration of the two drugs should be the same. Combination products to not allow for titration of one drug without the other, and this may be a concern with some combinations. For example, concerns have been raised regarding combinations of opioid analgesics with paracetamol because of the need to limit titration of the paracetamol and risk of liver damage in overdose.

The patient's use of a drug: compliance and adherence

Compliance or adherence is the extent to which a patient follows a prescribed drug regimen. It is important that decisions regarding treatment are jointly made by the prescriber and patient. Allowing adequate time to explain principles and goals of therapy, expected benefit and possible side effects, and plans for review and follow-up is essential. In addition, exploration of patient

(and family) concerns regarding addiction, tolerance, side effects, or fear that treatment implies the final stages of life are essential when using opioids for patients with advanced illness (NICE, 2012). The proactive management or prevention of side effects, for example, provision of laxatives for opioid-induced constipation, can improve compliance. In general, more complex regimens with high frequency of administration and/or multiple drugs reduce compliance.

Pharmacogenomics

Pharmacogenomics is the study of how genetic variation influences response to drugs. It is the cornerstone of personalized medicine, which aims to tailor treatment to the individual to maximize efficacy and minimize adverse reactions. Two techniques have been used to study pharmacogenomics: the candidate gene approach and genome-wide association. The candidate gene approach targets single nucleotide polymorphisms (SNPs) in genes already known to be important in pharmacokinetic (e.g. drug metabolizing enzymes, drug transporters) and pharmacodynamic (e.g. receptors, ion channels, enzymes) pathways. Genome-wide association studies cast a much wider net examining millions of SNPs across the entire genome at a time and may therefore provide new biological insights into mechanisms (Wilke et al., 2008).

In recent years, the field of pharmacogenomics has exploded to provide a wealth of information to inform personalized prescribing across the medical specialties. In oncology, response to certain chemotherapy agents can now be predicted, for example, variation in *UGT1A1* is associated with severe neutropenia from irinotecan (Innocenti et al., 2004). In cardiology, response to warfarin, statins, and clopidogrel have all been associated with genetic factors (Johnson and Cavallari, 2013). In HIV medicine, screening programmes have been used to reduce the risk of hypersensitivity reactions to abacavir by testing for *HLA B*5701*, which is associated with the condition (Mallal et al., 2008). Work continues on how this knowledge may best be translated into clinical practice (Johnson et al., 2012).

Opioid pharmacogenomics

Study of the CYP enzyme 2D6 (*CYP2D6*) gene has provided perhaps the best examples of how pharmacokinetics and ultimately opioid response is linked to genetic variation. CYP2D6 is involved in the metabolism of several opioids including codeine, tramadol, and oxycodone. Over 70 *CYP2D6* alleles have been described which directly affect the final protein; these include SNPs, deletions, insertions, and copy number variation (Leandro-Garcia et al., 2009). The sum functional effect of this variation has been classified into four main phenotypes: poor, intermediate, extensive, and ultrarapid metabolizers.

Codeine is partially (10%) metabolized to morphine by CYP2D6 (Lotsch, 2005). Approximately 10% of Caucasians are poor metabolizers and experience little analgesia from codeine (Sindrup et al., 1990; Persson et al., 1995). Conversely 3% of Caucasians are ultrarapid metabolizers and have a higher incidence of codeine-related adverse reactions (Kirchheiner et al., 2007). There have been case reports of fatal neonatal opioid toxicity in children breastfed by mothers who are ultrarapid metabolizers following ingestion of codeine (Madadi et al., 2007). The CYP2D6 phenotype has also been suggested to affect response to tramadol and oxycodone by altering ratios of the parent opioid to the more active metabolites (Samer et al., 2003, 2010b), although the clinical relevance of this is debated (Gronlund et al., 2010; Samer et al., 2010a, 2010b; Andreassen et al., 2012).

Pharmacodynamic candidate gene studies in palliative care patients suggest that opioid receptor SNPs, for example, *OPRM1* A118G, influence patients' requirements for opioids (Klepstad et al., 2004; Campa et al., 2008; Walter and Lotsch, 2009). Individual pain susceptibility also influences analgesic response, and therefore, many more candidate genes from pain signalling and modulatory pathways, for example, *COMT* (Rakvag et al., 2005; Rakvag et al., 2008), also may be important in opioid responsiveness.

Pain experience and opioid response are complex traits and therefore influenced by a myriad of gene–gene and gene–environment interactions. Recently, genetic association studies have begun to explore interactions between variants from more than one gene. This has thus far been limited to two candidate SNPs at a time (Reyes-Gibby et al., 2007; Campa et al., 2008). The concept of gene–gene/environment interactions or epistasis provides a huge challenge for the future of opioid pharmacogenetics, both practical and analytical. Further work needs to be done to unpick the complexities behind opioid response to be able to develop a useful predictive tool to inform clinical practice.

Pathophysiology of pain in cancer and other terminal illnesses

Richard M. Gordon-Williams and Anthony H. Dickenson

Introduction to pathophysiology of pain in terminal illness

Acute pain involves a series of excitatory events at peripheral and central levels that faithfully transmit signals about noxious events, leading to clinical reports of pain that usually have an overt relationship to identifiable peripheral damage, lesion, or abnormality. In contrast, clinically important chronic pains have altered neurophysiological and pharmacological substrates at many levels, from the periphery to the central nervous system (CNS), and the relationship between noxious phenomena and the level of pain experienced can become altered. Clinically, pain may be present, or unexpectedly severe, in the absence of an explanatory peripheral process. Plasticity, the ability of the nervous system to alter in response to injury-evoked dysfunction, leads to changes that can be observed throughout the pathways involved in the perception of pain.

Exploitation of continually developing pharmacological, anatomical, molecular, and genomic techniques is providing a basis for understanding the molecular and cellular mechanisms that contribute to the pain associated with varied pathophysiologies. Some chronic pains arise from persistent damage to tissue, such as that from arthritis, whereas others arise in the absence of these changes. Plasticity may alter pain responses in all these cases, but may be particularly notable with chronic neuropathic pains, which can arise from injury, a lesion, or a disease to either the peripheral or central nervous somatosensory systems.

Patients with cancer may develop injury to somatic or visceral tissues, or damage to neural structures. The aetiology may be related to the tumour itself, to various antineoplastic therapies, or to comorbid disorders. Cancer pain, therefore, often has a mix of mechanisms. Some mechanisms are broadly characterized as nociceptive, and some of these are inflammatory. Others are neuropathic. This complexity, which is shared by other types of advanced illnesses, such as HIV/AIDS, can complicate treatment but also offer more treatment options—a double-edged sword.

Recent animal studies are shedding light on some of the specific mechanisms underlying cancer pain. Importantly, whereas nociceptive pain results from activation of sensory afferents, neuropathic pain originates from damage to nerves and may prominently feature disturbances in ion channels. Thus, treatments aimed at the peripheral mechanisms are different for these two types of pain.

Plasticity in the nervous system in response to injury may lead to characteristic symptoms that contribute to the pain experience. These include expanded receptive fields, increased amplitude of response to a given stimulus (hyperalgesia), pain elicited by normally innocuous stimuli (allodynia), and spontaneous pain in the absence of external stimuli. Sensory deficits can also exist in neuropathic pain. In addition, as pain persists, affective and emotional responses must be considered along with the sensory aspects of the stimulus. It is clear that, although the sensory and psychological aspects of pain are separable, the neural pathways that contribute to these aspects of pain are interlinked. Furthermore, at both peripheral and central sites, there are mechanisms that can amplify and prolong the painful stimulus so that the pain becomes greater—this can result in severe pain in the presence of relatively minor peripheral pathology. This chapter considers these signalling systems and changes therein in the context of pain in cancer.

Anatomy of pain

Primary afferents and inputs to the dorsal horn

The dorsal horn receives sensory information from somatosensory receptors in the periphery via primary afferents. The area of the dorsal horn in which these primary afferents terminate is determined by the type of primary afferent and, therefore, the nature of the information that they carry. Different sensory inputs are carried by fibres of different thickness, from thick myelinated to thin and unmyelinated. Due to the differing degrees of myelination, these different groups exhibit differing conduction velocities at which they transmit a stimulus. The largest of the afferent sensory fibres, with thick myelin sheaths, are the Aβ fibres that carry information from muscle and tendons; these are the fastest conducting. A subset of thickly myelinated fibres carries mostly information from cutaneous mechanoreceptors; these usually do not transmit nociceptive signals. Neurons that carry nociceptive information include the thinly myelinated Aδ nociceptors and the thin unmyelinated C fibres. The latter two types of fibres are therefore pivotal in detection of potentially harmful stimuli in the external environment.

Aδ and C fibres terminate primarily in the superficial laminae of the dorsal horn, namely lamina I, which is an area intrinsically important in pain processing due to its large output to supraspinal areas. The large majority of neurons found within lamina I are nociceptive-specific; these neurons have small receptive fields

and respond to only noxious pinch and/or heat stimulation. This region also contains a smaller population of polymodal neurons that are also cold responsive (Andrew and Craig, 2002; Craig and Andrew, 2002) and also a small population of so-called wide dynamic range (WDR) neurons that code throughout innocuous and noxious stimulus intensities (Seagrove et al., 2004). Finally, other neurons that respond purely to itch-inducing stimuli or to non-noxious heat have been noted (Light et al., 1993; Andrew and Craig, 2001).

Lamina I neurons have been shown to project to areas in the brain, such as the periaqueductal grey (PAG), lateral parabrachial nucleus, thalamus, nucleus tractus solitarius, and the medullary reticular formation (Todd, 2002). A large number of projection neurons from lamina I express the receptor for substance P, which is also known as neurokinin 1 (Todd et al., 2000). This group of neurons is the origin of a spinobulbospinal loop that ascends from the cord to the brain and then drives descending controls back to the cord; in this way the circuit can control dorsal horn excitability from higher centres (Bannister et al., 2009).

Deep dorsal horn neurons are mostly WDR neurons and consequently have larger receptive fields than the neuronal populations of the superficial dorsal horn (SDH). Projections from the deep dorsal horn neurons have been shown to be mainly to the reticular nuclei (Raboisson et al., 1996) and to the thalamus in the spinothalamic pathways. These nuclei of the brain have good connections with areas concerned with primary somatosensory cortex and therefore discriminatory perception of pain.

Acute pain

Peripheral sensitization

Peripheral receptors and channels involved in transduction of nociceptive stimuli in the periphery (see Fig. 9.2.1). The diagram depicts a C fibre and a polymodal nociceptor comprising numerous receptors and channels activated by voltage changes (voltage-gated ion channels) or chemical mediators of pain. The latter mediators include adenosine (acting at P2Y), bradykinin (B2), prostaglandin (endoprostinoid receptor (EP)), noradrenaline (β2), protons (acid sensing ion channel (ASIC)/TRPV1), heat/capsaicin (TRPV1), adenosine triphosphate (ATP) (P2X), and nerve growth factor (NGF) (trkA/p75). The precise molecular identity of a mechanoreceptor is still unclear.

In order to sense the external environment, it is necessary to convert peripheral stimuli into signals that can be carried by nerves to the CNS, a process known as transduction. There are a number of transduction molecules on the peripheral neuron that allow detection of a wide range of both exogenous and endogenous stimuli. While the full pharmacology and physiology of each of these peripheral sensory transducers falls outside the scope of this chapter, Table 9.2.1 illustrates a number of mechanisms through which a peripheral neuron can sense the peripheral environment. Needless to say, the actions of these transducers have a large part to play in pathological states where tissue and nerves are damaged, including cancer pain.

Transduction molecules seem to be highly preserved throughout evolution, with homology found throughout non-mammalian and mammalian species. This suggests the huge importance of an animal's ability to sense its surroundings (Caterina and Julius, 2001). Peripheral tissue damage and subsequent local inflammation can cause the release of a wide variety of chemical factors that are able to sensitize primary afferent fibres. Pro-inflammatory compounds also can be released by nerve endings themselves in a process known as neurogenic inflammation.

Neurogenic inflammation is one of the mechanisms of peripheral sensitization and can further amplify the peripheral response of nociceptors. Peripheral terminations of nociceptors may arborize over a large area. Activation of peripheral afferents may cause neuromodulator release from nearby peripheral branches into peripheral tissues. These include factors such as substance P, neuropeptide Y, calcitonin gene-related peptide (CGRP), ATP, and glutamate. These compounds may act on peripheral blood vessels, mast cells, and sympathetic nerve fibres, leading to an increase
Fig. 9.2.1 Peripheral receptors and channels involved in transduction of nociceptive stimuli in the periphery. The diagram depicts a C fibre where the polymodal nociceptor is comprised of numerous receptors, channels activated by voltage changes (voltage-gated ion channels) or chemical mediators of pain. Adenosine (acting at P2Y), bradykinin (B2), prostaglandin (endoprostinoid receptor, EP), noradrenaline (β2), protons (acid sensing ion channel, ASIC/TRPV1), heat/capsaicin (TRPV1), ATP (P2X), NGF (trkA/p75). The precise molecular identity of a mechanoreceptor is still unclear.

Table 9.2.1 Algogenic ligands: their origins and their cognate receptors

Ligand	Origin	Receptor
H+	Tissue damage, macrophages	ASIC, TRPV1
Bradykinin	Macrophages, mast cells	B2/B1 (TRPV1)
Histamine	Mast cells	H1
Prostaglandins	Mast cells, fibroblasts	EP
Nerve growth factor	Macrophage, fibroblasts	TrkA
ATP	Platelets, sympathetic terminals	P2X3
Adenosine	Tissue damage	A1/A2
5-HT	Platelets, mast cells	5-HTr
IL-1	Macrophage	IL-1r
Heat	Exogenous, inflammation	TRPV
Cold		TRPM8

in vasodilation, vascular permeability, and therefore plasma extravasation, causing erythema and oedema. Serotonin, bradykinin, glutamate, NGF, and other cytokines in the inflammatory infiltrate can cause further activation of primary afferent fibres and help propagate nociception when tissue is damaged and the production of these molecules is promoted.

Peripheral sensitization also involves change in ion channels. TRPV1 is a ligand-gated ion channel that is responsive to noxious heat and capsaicin, the pungent component of chilli peppers (Caterina and Julius, 2001). This channel is able to drive a neural response when exposed to noxious heat in the normal physiological setting. When inflammation occurs, however, a decrease in local tissue acidity can potentiate the channel's response so that it is active at temperatures nearer body temperature (Caterina and Julius, 2001). This is a good example of how inflammation may cause a lowering of the nociceptive threshold in peripheral fibres and how hyperalgesia can result. A hugely intriguing point of note is that a receptor for noxious mechanical transduction, a much more obvious clinical issue, has yet to be fully elucidated. As mechanical allodynia presents such a large problem in the clinic, a cognate receptor for mechanical noxious stimuli may be of great therapeutic benefit.

Ion channels

There is very strong evidence pointing to the key role of ion channels in the production of electrical activity within sensory nerves and altered function of these channels after nerve damage (Suzuki et al., 2002). This evidence ranges from preclinical studies, the actions of drugs used in patients, and the discovery of familial pain disorders. Ion channels are important in the occurrence of altered transduction and disordered neural activity in damaged and intact fibres when neuropathy occurs.

The opening of sodium channels depolarizes neurons and generates the action potential. Injury to peripheral nerve can alter the normal arrangement of these channels along the length of a nerve. This is particularly notable in the development of neuromas after axons have been injured. Neuromas are associated with 'ectopic' electrical activity, which results from the accumulation of sodium channels at this site of injury. There also are many reports of altered distribution and levels of these channels in adjacent nerves, not

just the damaged ones. Some inherited pain disorders arise from genetic mutations that either increase or decrease the functioning of a specific sodium channel subtype known as Nav 1.7 (Yang et al., 2004; Cox et al., 2006). Less dramatic polymorphisms in this channel impact on the level of pain experienced in several groups of pain patients. The latter observation suggests that inherited variations in channel function might be behind some of the variability in pain within patient groups (Reimann et al., 2010). Blockers of the channels Nav1.7 and Nav1.8, the major pain-related channels, have been described but have yet to reach the clinic. Thus, treatments presently use non-selective blockers, such as lidocaine and some anticonvulsants (e.g. carbamazepine, which is approved for the treatment of trigeminal neuralgia (Suzuki et al., 2002).

Central sensitization

While peripheral mechanisms play a large role in development of pain states, a large amount of interest has been generated in the CNS's abilities to amplify the inputs it receives from the peripheral nervous system and therefore cause an increased perception of pain. The mechanisms are multiple and complex, and again, involve changes in ion channel functioning. At spinal levels, upregulation and enhancement of transmitter release occurs via calcium channels. The drugs gabapentin and pregabalin modulate the function of these channels and, in this way, reduce transmitter release and excessive hyperexcitability.

One mechanism at the spinal level that has relevance to pain perception is called 'wind up'. 'Winding up' of neuronal responses is made possible by the physiological properties of the N-methyl-D-aspartate (NMDA) receptor (Seagrove et al., 2004). The NMDA receptor is a ligand-gated ion channel whose central pore is, under normal neuronal activity, blocked by a magnesium ion. Due to this, the NMDA receptor plays little part in normal neuronal activity. However, after prolonged peripheral C-fibre nociceptive drive, increased presynaptic release of neurotransmitters, such as glutamate and substance P, causes depolarization of the postsynaptic neurons via their actions on the α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) and neurokinin 1(NK1) receptors, respectively (Bannister et al., 2009). This membrane depolarization allows the release of the magnesium ion blocking the pore of the NMDA receptor, and calcium to flow through the pore, further increasing postsynaptic excitability. The influx of calcium through the NMDA receptor allows short-term changes, such as phosphorylation of AMPA and NMDA receptors in the postsynaptic membrane. All these events lead to the potentiation of postsynaptic response. NMDA receptor blockers, such as ketamine and MK-801, have been shown to be effective in the reduction of neuronal actions and pain behaviours in animal models of acute and chronic pain, as well as in human acute and chronic pain states. However, due to the widespread nature and important role that the NMDA receptor plays in many other physiological systems, NMDA blockers may cause unacceptable neurological side effects, resulting in a limited utility in the clinic.

Pathophysiology of chronic cancer pain
Aetiology

Pain is prevalent in populations with active cancer or other serious or life-threatening illnesses. As noted, cancer pain may be due

directly to the tumour (tissue or nerve destruction) or may occur as a result of cancer therapy (e.g. chemotherapy-induced neuropathic pain). Bone is a common site of metastatic disease, exceeded only by lung and liver (Tubiana-Hulin, 1991), and bone pain is the most common cause of pain among patients with active cancer. Metastatic disease in bone occurs in 64–80% of those with solid tumours (Mercadante et al., 1997), and cancer-induced bone pain affects 28% of hospice inpatients, 34% of those patients in cancer pain clinics (Banning et al., 1991), and 45% of advanced cancer patients followed at home (Mercadante et al., 1997). This epidemiology highlights the need to find better drug therapies to combat pain in the clinical setting and recent progress in understanding bone pain illustrates the potential of translational research that links discoveries in the laboratory with potentially useful clinical treatments.

Animal models of cancer-induced bone pain

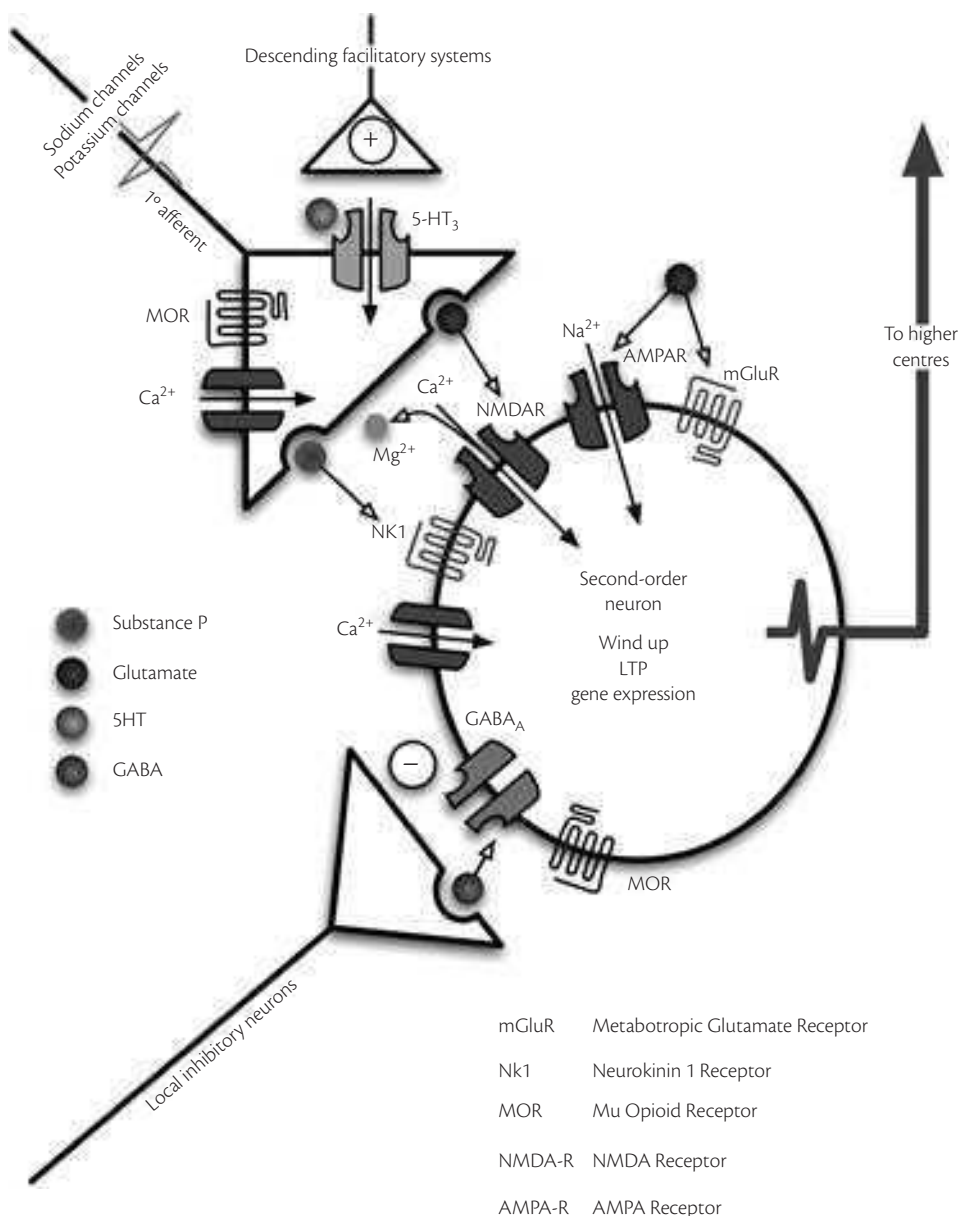
Until recent years, advances in the treatment of malignant bone pain were hindered by the lack of knowledge of the basic mechanisms of disease (Fig. 9.2.2). Original attempts at modelling this pathology involved administering a systemic bolus injection of metastatic tumour cells. This, however, led to systemically unwell animals, from which it was hard to draw conclusions about underlying mechanisms specific to pain rather than those related to systemic cancer (Kostenuik et al., 1993; Sasaki et al., 1998). As a consequence of these recognized deficiencies in earlier models, a number of novel approaches were developed to elucidate the mechanisms of cancer-induced bone pain. These new models rely on injecting a bolus of a variety of different tumour cells into either the long bones or the calcaneum of rodents. In general,


Fig. 9.2.2 Pharmacology of a central synapse of the nociceptive pathway. For details see text.

this leads to the progressive and reliable development of pain-like behaviours to either mechanical or thermal stimuli in the post-operative period. This model has been used to explore a number of pharmacological, genetic and anatomical manipulations. As a result, some basic mechanisms have now been uncovered.

Pain arising from tumour within the bone

Originally, evidence supporting innervation of tumours was limited, and therefore the precise peripheral mechanisms underlying bone pain were of great debate (see also Chapter 13.2). While there were suspect players implicated in the generation of this particular pain state, such as primary afferents, interactions in the bone/cancer microenvironment, tumour-associated macrophages and others, none had substantial support. The information was insufficient to determine whether bone pain was related to neural mechanisms, to inflammation, or to other processes. Indeed, to this day the question remains: 'Is bone cancer pain one of neuropathic or inflammatory origin?' Answering this question will involve dissecting apart the various mechanisms implicated thus far.

Structure and innervation of bone

Bone is not simply a framework to support and protect the body's internal organs. It is an active tissue and plays key roles as a reservoir for calcium and phosphate and as a source of blood cells from the bone marrow. Its mechanical characteristics permit movements via actions of the muscles. The multitude of functions carried out by bone is reflected in its complex physiology and innervation.

Structure of bone

There are two main types of bone which differ in structure and density: cortical bone and trabecular bone. Cortical bone is the dense outer layer of all bones, representing nearly 80% of all skeletal mass; it has a high resistance to torsion and bending forces. The periosteum forms the fibrous sheath surrounding the outer surface of cortical bone. Trabecular bone is found in the epiphyseal regions of long bones and constitutes a large proportion of the bone tissue of the ribs, spine, and skull. Paradoxically, this tissue type represents 20% of the skeletal mass, yet 80% of its surface area. Trabecular bone has a much less dense, woven appearance, created by interspersed trabeculae (plates) and bars of bone adjacent to red marrow cavities. For these reasons, it has more of an elastic characteristic compared with cortical bone. The cavities are connected through canaliculi, through which they receive their blood supply. Trabecular bone undergoes a greater amount of constitutive remodelling compared with the dense cortical bone and therefore bone pathology is often largely evident in bone of this type.

The remodelling of bone is reliant on an equilibrium of two main cell groups (Blair, 1998; Mackie, 2003): osteoclasts and osteoblasts. Osteoblasts are derived from primitive mesenchymal cells and are responsible for bone formation through the secretion of an array of extracellular matrix proteins (type I collagen, proteoglycans). Once osteoblasts have finished their function, they either apoptose or terminally differentiate into osteocytes, which remain viable surrounded by the bone matrix. Osteoblasts also have the interesting role of interacting with osteoclast progenitors and therefore regulate osteoclast activity.

Osteoclasts are derived from the monocyte-macrophage lineage and are the primary bone resorption cells. They are of great interest in bone pathologies such as osteoporosis and cancer-related bone pain. While a specialized cell for bone degradation may seem counterintuitive, it permits regulation of extracellular calcium and periodic bone repair, as well as remodelling in response to mechanical loads (Blair, 1998). An acidic extracellular micro-environment is highly important for an osteoclast to function properly as it is involved in the predominant mechanism through which osteoclasts degrade the base mineral hydroxyapatite. High expression of the vacuolar-(v) type electrogenic ATP-H+ channel is found along the ruffled border of the resorptive surface of an osteoclast, permitting the required development of an acidic environment of around pH 4.0–4.5 (Blair, 1998).

Mechanisms of cancer-induced bone pain

Innervation of bone

Even though it has been shown since the 1500s that nerve fibres are present in mineralized bone and the marrow cavity, tracing along the paths of blood vessels, the consensus of thought had been that pain arising from bone was principally the result of dense periosteal innervations (Mundy, 2002; Foley, 2004). While the periosteum is the most densely innervated structure, the bone marrow space receives the highest number of sensory and sympathetic fibres (Mantyh et al., 2002). Mineralized bone also receives a high volume of sympathetic and sensory fibres, more so than that of the densely innervated periosteum. All of the bone marrow, mineralized bone, and the periosteum receive both myelinated and unmyelinated sensory afferent fibres, as well as sympathetic fibres. Interestingly, of these small diameter unmyelinated fibres (presumably C-fibre population), only the CGRP trkA expressing peptidergic neurons are found to innervate bone and not the non-peptidergic IB4 labelled populations.

The theory that pain arising from bone metastases is only the result of structural weakness leading to mechanical distortion of the periosteum by innocuous stressors did not explain pain arising from bone with little or no radiographic evidence of periosteum involvement. Models of cancer-induced bone pain have now highlighted a number of other mechanisms that may be important both in peripheral and central sites.

Peripheral mechanisms of cancer-induced bone pain

Factors released in the periphery

Changes in the periphery have been shown to cause peripheral sensitization of the primary nociceptive afferents, and this peripheral sensitization can, in turn, drive central changes and hyperexcitability. When considering a tumour seeded within a bone, it is important to recognize that this includes not only cancer cells but also an inflammatory infiltrate, including macrophages, neutrophils, and T-lymphocytes (Mantyh et al., 2002). The immune-mediated response to the tumour leads to the release of a plethora of factors, such as cytokines, interleukins (ILs), chemokines, prostanoids, growth factors, and endothelins (Suzuki and Yamada, 1994; Safieh-Garabedian et al., 1995).

Peripheral nociceptors have an array of receptors that respond to these algogenic agents in the periphery. These factors are therefore

able to sensitize and/or directly excite nociceptive fibres by acting on these peripheral receptors and lowering their threshold for activation. Pharmacological manipulation of these factors in a murine model of cancer-induced bone pain has shown promise in reducing measures of pain behaviour. Antagonism of endothelins, tumour necrosis factor alpha (TNFα), and bradykinin, all reduced pain behaviours (Baamonde et al., 2004; Wacnik et al., 2005), and endothelin antagonism also reduced central neurochemical markers that have been associated with the development of cancer-induced bone pain (Sorkin et al., 1997). As previously stated, the peptidergic CGRP-expressing neurons are the exclusive group of unmyelinated neurons that innervate the bone (Davar, 2001). This group of neurons express the receptor for NGF, namely trkA/p75. Macrophages, tumour cells, and other immune cells associated with the tumour mass have been previously shown to express NGF (Vega et al., 2003). The use of a NGF sequestering antibody attenuated both early and late phases of pain in the murine model of cancer-induced bone pain (Halvorson et al., 2005; Sevcik et al., 2005b) and reduced central markers of this pain state. Due to the exclusivity of trkA expressing peptidergic neurons in the bone, antagonism of this fibre type means that there can be no compensatory mechanisms in a differing fibre type.

Most importantly, as a tumour grows, there is a progressive increase in the innervation of the tissue, driven by NGF that is secreted by tumour-associated stromal cells. This pathological sprouting leads to a hyper-innervation of bone. Since almost all of the fibres express the receptor for NGF, sequestration of NGF has been shown to block both the reorganization of the sensory fibres and the associated nociceptive responses seen in models of cancer pain (Jimenez-Andrade et al., 2010).

Recently, emphasis has turned to ATP, which is present within all cells and is a purine that is algogenic and will be released into local tissues by damage. ATP has long been recognized as a local pain mediator and it is now clear that the P2X2/3 receptors are activated at peripheral and central levels in a model of cancer-induced bone pain. The data suggest that ATP may increase the activation of the central terminals of sensory afferents and so enhance spinal hyperexcitability (Kaan et al., 2010). Another receptor for ATP is the P2X7 receptor and this has been implicated in a number of animal pain models and also as a contributor to pain levels in postoperative and osteoarthritis patients. However, in a bone cancer model, deletion of the receptor had no effects on the pain behaviour, again reiterating the point that cancer pain is different from other pain conditions (Hansen et al., 2011).

The osteoclast and acidosis

With an uncertain relationship between bone destruction and pain, a number of other mechanisms for the generation of this pain state have been studied, one of which involves the activation of osteoclasts. Osteolytic tumours have been widely studied in the animal literature and have been shown to involve the recruitment of osteoclasts within the bone, leading to bone resorption. Primary tumours in bone (i.e. osteosarcoma) and secondary tumours in bone (i.e. metastatic spread from primary lung, breast, or prostate tumours) each have a profile of effects on the remodelling of bone. While some have a mainly osteolytic profile (i.e. osteosarcoma) others have a predominately osteoblastic profile (i.e. prostate carcinoma). However, in both osteolytic and osteoblastic tumours abnormal osteoclast regulation has been proposed as

both a mechanism through which tumours destroy bone and a process that generates pain in cancer patients.

Cancer-induced bone destruction has been shown to be osteoclast-mediated, and, in a proportion of cases, dependent on the receptor activator of nuclear factor kappa B (RANK)/RANK ligand (RANKL) regulatory axis. In the non-pathological situation, osteoblast and osteoclast activity are in equilibrium so that normal bone remodelling can occur (Wacnik et al., 2005). In the presence of the growth factor colony stimulating factor-1 (CSF-1), osteoblasts expressing RANKL bind to RANK on local osteoclasts and osteoclast progenitor cells to stimulate bone resorption. This in turn stimulates nearby osteoblast activity and local bone formation (Boyle et al., 2003). It has been shown that metastatic cancer cells release a number of factors that may disrupt this axis, among the most important of which is parathyroid-hormone-related peptide (PTHrP). Metastatic breast cancer in bone has a higher expression of PTHrP than metastases in soft tissue (Powell et al., 1991). In light of this, it is apparent that PTHrP causes up-regulation of RANKL on osteoblast cells, which causes terminal differentiation of osteoclast progenitor cells (Guise, 2000). Activated T lymphocytes in the immune infiltrate of the tumour mass may also express RANKL and cause further osteoclast activation (Kong et al., 1999).

Given the importance of the RANK/RANKL regulatory axis, it is unsurprising that osteoprotegerin, the soluble ligand of RANKL, has shown efficacy in preventing cancer-induced bone destruction in animal models of osteolytic skeletal destruction (Clohisy et al., 1995). Additionally, osteoprotegerin attenuates development of pain behaviours in a murine model of osteolytic sarcoma bone pain (Honore et al., 2000). As mentioned previously, osteoclasts rely on an acidic extracellular microenvironment at the osteoclast/bone interface to facilitate resorption (Delaisse and Vaes, 1992). Moreover, increased osteoclast activation leads to a decreased extracellular pH. CGRP fibres that innervate the marrow or mineralized bone express ASIC (Safieh-Garabedian et al., 1995), as well as TRPV1 (Tominaga et al., 1998). Both of these channels are either sensitized or excited by protons and therefore likely to cause nociceptive transmission due to a decrease in extracellular pH. The increase in osteoclast actions may not be solely responsible for the decrease in extracellular pH, as tumours themselves lower the extracellular pH in order to assist invasion into surrounding tissues (Stubbs et al., 2000).

Both TRPV1 antagonism and TRPV1 knock-out in murine models of bone-cancer pain show attenuation of pain behaviours (Ghilardi et al., 2005). However, in these models, both osteoclast inhibition and TRPV1 antagonism does not completely attenuate all facets of the pain behaviours seen, even in light of the fact that osteoprotegerin almost completely prevented bone destruction and osteoclast activation (Guise, 2000; Kaan et al., 2010). This suggests that while osteoclast-induced acidosis and structural weakening may play an important role in the development of malignant bone pain, it is not the sole mechanism through which this pain is generated.

Structural damage to the bone and damage to nerves

Increased osteoclast activity in this setting may also cause structural weakness. Mechanical stress upon the periosteum and its distension due to tumour burden may well result in peripheral fibre activation and the sensation of pain (Mach et al., 2002). It

would be expected that the tumour growing within bone would damage the distal processes of nerves within the bone marrow, mineralized bone, and the periosteum. Studies in animal models suggest that this is indeed the case. A marker for neuronal cell injury ATF-3, which is up-regulated in the dorsal root ganglion in peripheral neuropathic pain models, is also found to be up-regulated in models of malignant bone pain. Of interest is that gabapentin, a drug that has been shown to be efficacious in models of neuropathic pain, has also been shown to be of benefit in models of cancer-induced bone pain (Sevcik, 2004; Donovan-Rodriguez et al., 2005). This suggests that nerve injury may play a role in the development of bone cancer pain. Mechanisms underlying neuropathic pain will be discussed in greater depth later in this chapter.

Central mechanisms of cancer-induced bone pain

It is also clear that the CNS undergoes changes that aid the maintenance of this pain state. The early murine models of cancer-induced bone pain involving confinement of tumour (NCTC 2472 sarcoma cells) within the femur established the neurochemical 'fingerprint' of cancer-induced bone pain. Confinement of tumour to within the bone not only leads to development of postoperative behavioural signs of pain, but increased osteoclastic bone destruction in the periphery (Schwei et al., 1999). However, of greater interest in this murine model of malignant pain were the immunohistochemical studies showing a number of central cellular and neurochemical changes in the segments of the spinal cord relating to the peripheral input. The spinal cord segments that receive afferent input from tumour-laden femur showed a massive astrocyte hypertrophy and elevation of the pro-hyperalgesic peptide dynorphin (Schwei et al., 1999). These changes were seen exclusively in the side of the spinal cord ipsilateral to the affected limb and not on the contralateral side. Glia, a family of which astrocytes are a member, are in the normal situation quiescent. Upon becoming activated, glia release a myriad of pro-inflammatory cytokines, including IL-1, TNF, IL-6, reactive oxygen species, nitric oxide, prostaglandins, excitatory amino acids, and ATP (Watkins and Maier, 2003). This in turn can cause enhanced second-order neuron excitability within the dorsal horn and further exaggerate primary afferent neurotransmitter release. It has also been demonstrated in murine models that normally non-noxious palpation of the affected femur not only produced nocifensive behaviour but an increase in substance P receptor internalization and an increase in c-Fos expression in lamina I neurons of the dorsal horn (Schwei et al., 1999).

These findings provide a weight of evidence showing that primary afferent fibres are sensitized following tumour growth in the periphery. This astrocytosis, increased dynorphin expression, increased substance P internalization, and increased c-Fos expression has been shown in models of inflammatory and/or neuropathic pain. While substance P levels in primary afferent neurons have been shown to increase in inflammatory models and decrease in neuropathic models, levels remain unchanged in cancer-induced bone pain states. However, the coexistence of all these features in cancer-induced bone pain provides evidence that this is a unique pain state that may have mechanisms similar to inflammation and neuropathy (Schwei et al., 1999). Furthermore, this may well be the basis of reasoning behind why conventional treatments have failed thus far in the battle with malignant bone pain and further highlights the need for unique pharmacotherapy (Fig. 9.2.3).

By recording second-order neurons in the dorsal horn of the spinal cord using in vivo electrophysiology, we can gain an idea of the supra-threshold response to peripheral stimuli that cannot be ascertained using behavioural techniques (Urch et al., 2003; Donovan-Rodriguez et al., 2005). Neurons can be characterized, based on their responses to mechanical, thermal, and electrically evoked stimuli. The SDH is predominantly populated with nociceptive specific (NS) neurons, which respond to nociceptive stimuli. These cells are distinguished from WDR neurons, which respond to a wide range of both noxious and innocuous stimuli (Seagrove, 2004). Establishment of cancer-induced bone pain changes the ratio of WDR:NS neurons in the SDH from the 26% WDR:74% NS in a sham animal to 47% WDR to 53% in the pathological setting (Stubbs et al., 2000). The phenotype shift seen in the superficial dorsal horn was also paralleled by the development of superficial and deep dorsal horn neuronal hyperexcitability to mechanical, thermal, and electrical stimuli, further suggesting ongoing central sensitization. Furthermore, these lamina I neurons that become hyperexcitable after cancer-induced bone pain now show a *de novo* or increased responsivity in the innocuous range (Stubbs et al., 2000). Thus pain selective neurons can now be activated by innocuous stimuli. This may allow the limbic areas of the brain, concerned with affective/emotional aspects of pain, to have an influence via the parabrachial pathways, and also increase the effects of low-threshold stimuli. Plausibly, this may result in affective areas of the brain now being dominated by painful messages and so relate to the distress and co-morbidities such as fear, anxiety, mood changes and sleep disorders caused by pain.

This hyperexcitability in lamina I also plays a role in further maintaining neuronal dorsal horn hyperexcitability through descending facilitations. Spinal events are not only controlled by afferent input but also by descending controls from higher centres (Bannister et al., 2009). Higher-order cognitive and emotional processes such as anxiety, mood, and attention can influence perceived pain. Such phenomena are enabled by the convergence of somatic and limbic systems into such descending modulatory systems. Areas in the midbrain and brainstem, such as the PAG and the rostroventral medial medulla (RVM), are key structures in the descending modulatory repertoire (Bannister et al., 2009). Such a system is important as it provides neural networks by which cognitive and emotional states can influence pain processing at the level of the spinal cord (Suzuki et al., 2004; Bannister et al., 2009). In short, these circuits allow the brain to exert some control over spinal pain events. Recent animal studies suggest that in addition to inhibitory systems, there are important descending facilitations that can be engaged by external and internal processes, and act to enhance intrinsic spinal mechanisms of pain. Lamina I neurons expressing the substance P receptor NK1 form the origin of a spinobulbospinal loop, which relays through the RVM (Todd, 2002; Bannister et al., 2009). The RVM has been highlighted as a key area involved with descending facilitations which are thought to be mediated through the 5-hydroxytryptamine type 3 (5-HT$_3$) receptor. Blockade of spinal 5-HT$_3$ receptors with intrathecal ondansetron reduces the mechanical and thermal evoked responses of superficial and deep dorsal horn neurons (Bannister et al., 2009). This suggests that descending facilitations are indeed
Fig. 9.2.3 A summary of the peripheral mechanisms of cancer-induced bone pain. Increased expression of RANKL (ligand for RANK, receptor activator of nuclear κ B—activator of osteoclast progenitor cells, OCP), on osteoblasts (due to interaction with tumour cells via PTHrP) and activated T cells in the tumour mass causes increased activation of osteoclasts. An increasingly acidic extracellular environment may activate/sensitize peripheral neurons, by activating TRPV1/ASIC on the peripheral neuron (see Fig. 9.2.1). This in conjunction factors release from tumour cells, bone matrix, and tumour-associated immune cells that are known to sensitize primary afferents acting at their cognate receptors (see text) on primary afferent neurons innervating the bone. Disease progression may lead to further bone destruction and a swelling of the periosteum leading to activation of periosteal nerve fibres and the transmission of noxious stimuli.

important in amplifying nociceptive transmission from the dorsal horn to higher centres (Suzuki et al., 2004; Bannister et al., 2009).

Mechanisms of cancer-induced bone pain related to treatment

Current therapies give researchers a great insight into the possible mechanisms underlying cancer pain. Opioids are the mainstay of treatment of severe malignant pain in the clinic (Mercadante et al 1997). However, while the benefits to be gained from opioid therapy are obvious, opioid treatment is associated with a large number of side effects, such as nausea, vomiting, constipation, sedation, and delirium. At the high doses sometimes required to relieve persistent cancer pain, these side effects become even more problematic to control and, in some cases, may be the reason for inadequate analgesia. In line with clinical evidence, opioids are effective in reducing pain-like behaviours in a number of animal models of cancer-induced bone pain.

Early data from murine models suggest that higher doses of morphine were required to attenuate cancer-induced bone pain

than those needed in inflammatory pain, and this point was used to further highlight the mechanistic differences between these two pain states (Luger et al., 2002). The relatively low efficacy of acute morphine has since been further validated (Mercadante et al., 1997; Vermeirsch et al., 2004); however, a situation that more closely mimicked the clinical paradigm was sought. A bi-daily injection schedule over 5 days after the establishment of the pain state has been shown to be highly effective in reducing behavioural signs of cancer-induced bone pain (Urch et al., 2005). This regimen also was found to be more efficacious than a single acute dose (Sevcik et al., 2004). However, even in light of this, behavioural measurements taken pre and post the final morphine administration, at peak disease progression, indicated a significantly reduced analgesia between consecutive morphine administrations. This is not to say that the analgesia provided by morphine completely wore off between doses. Behavioural signs of pain were still, 12 hours after the last dose, significantly reduced from that of the vehicle-treated animals and no different from that of the acutely treated group. However this may help to explain the requirement for escalated doses of opioids to treat severe cancer-induced bone pain.

Chronic, but not acute, gabapentin administration also has been shown to be effective in these models (Donovan-Rodriguez et al., 2005; Peters et al., 2005). Gabapentin acts by binding to the calcium channel accessory subunit α2δ. This implies a role of α2δ in the pathology underlying this pain state. Yet looking at the response of neurons in chronic morphine and chronic gabapentin regimens highlights two differing mechanisms involved in cancer-related bone pain. While chronic morphine and gabapentin administration both lead to behavioural attenuation of pain, chronic morphine treatment was unable to completely reset dorsal horn excitability and the associated phenotype shift towards the WDR neuronal population in superficial dorsal horn (Urch et al., 2005). The bias of superficial neurons toward the WDR phenotype, even in the presence of morphine analgesia, suggests that low-threshold inputs to the spinal cord may still access areas of the brain concerned with both pain affect and perception. This is a possible physiological mechanism through which breakthrough pain may remain refractory to morphine analgesia in the clinic. In contrast, gabapentin completely attenuated dorsal horn excitability and reversed the phenotype shift of WDR:NS ratio back towards that seen in a normal animal (Donovan-Rodriguez et al., 2005). This suggests that while morphine may cause behavioural attenuation of pain, it is not acting on the mechanisms that are intricately involved in producing those behavioural signs. On the other hand, gabapentin is able to inhibit the mechanisms that lead to cancer-induced bone pain rather than merely blocking sensory inputs as seen with morphine. Upon the termination of gabapentin treatment, pain behaviours and dorsal horn excitability returned to their hyperexcitable 'pathological' state, implicating neuronal physiological mechanisms rather than anatomical changes to be key in development of cancer-induced bone pain.

Peripheral opioids may also have a role to play in the management of malignant cancer pain. In support of this potential is evidence showing that loperamide, the peripheral mu opioid receptor agonist, is able to attenuate thermal hyperalgesia in a murine model of cancer-induced bone pain (Menendez et al., 2003).

Non-steroidal anti-inflammatory drugs (NSAIDs) are the first step on the World Health Organization's (WHO) ladder for the use of analgesics for the relief of cancer pain. Although NSAIDs are still used as an analgesic additive even after increased pain severity (Mercadante et al., 1997), the clinical data supporting their efficacy is limited (Urch, 2004). NSAIDs inhibit the cyclooxygenase (COX) enzyme and therefore attenuate the synthesis of prostaglandins from arachidonic acid. This ultimately prevents sensitization or activation of primary afferents by prostaglandins produced locally by tumour cells and/or the immune response. Inhibition of the COX-2 enzyme, the local inducible form of COX, using three different COX-2 selective inhibitors in a rat and murine models of cancer-induced bone pain has been shown to be effective in ameliorating behavioural pain signs. In both these studies, chronic COX-2 inhibition has been shown to be better at attenuating pain-like signs than a single acute dose. Chronic administration reduced tumour burden and bone destruction (Sabino et al., 2002; Fox et al., 2004), suggesting that COX-2 inhibition may be acting at multiple sites rather than at a single point in a pathway.

Bisphosphonates are used widely in the clinical setting and prevent bone resorption by osteoclast inhibition. Bisphosphonates were able to reduce pain scores, as well as bone and sensory nerve destruction, in both rat and mouse models of cancer-induced bone pain (Sevcik et al., 2004; Walker et al., 2002). However, tumour burden was found to not be affected, with both tumour burden and tumour necrosis increasing (Sevcik et al., 2004). Bisphosphonates, therefore, may have a role to play in reducing bone pain in malignancy, especially if combined with other analgesics (Mercadante et al., 1997).

Radiotherapy of tumours within bone causes analgesia but the mechanism is still unclear. Radiotherapy in the murine model of bone cancer pain reduced tumour burden by more than 75% (Goblirsch et al., 2005). However, it did not affect the osteoclast density, suggesting that radiotherapy causes analgesia via direct mechanisms on tumour cells themselves.

Pain arising from tumour within soft tissues

While pain arising from bone is a common clinical problem, pain arising from soft tissue can also be painful. The pathophysiology in this pain state, however, is still not clear. A novel model of pancreatic cancer pain has been developed to elucidate the relationship between disease progression and pain development (Lindsay et al., 2005). This model uses a transgenic mouse that develops pancreatic cancer and shows changes similar to that seen in the human condition. These include tumour growth, increased innervation, macrophage infiltration, weight loss, and pain. More significantly, pain was only evident at a point at which cancer progression was highly advanced. Sensory innervation has now been quantified and models such as these will hopefully provide mechanistic insights in to the development of pancreatic cancer pain in the future.

Neuropathic pain

The International Association for the Study of Pain (IASP) defines neuropathic pain as 'pain initiated or caused by a primary lesion or dysfunction in the nervous system'. This may not be a complete definition of neuropathic pain, and the definition is changing to be 'a lesion or disease' affecting the 'sensory nervous system' (Treede et al., 2008). These definitions hint at broad mechanisms. After nerve injury occurs, there are large-scale changes that occur within the peripheral and central nervous systems. This nerve plasticity has been heavily scrutinized and some of these plastic changes have been proposed as possible important mechanisms for the generation of pain in neuropathic states.

Mechanisms of cytotoxic neuropathy

Neuropathic pain may arise in the palliative care setting for a multitude of reasons. Nerve damage is known to occur as a result of tumour compressing a nerve, surgical resection, radiotherapy, and chemotherapy. Numerous pre-clinical animal models have been developed in an effort to elucidate the basic mechanisms involved in the generation and maintenance of neuropathic pain. These include models of peripheral nerve injury (common in traumatic neuropathic pain) and chemotherapy-induced neuropathic pain. Peripheral lesions to nerves are obvious, and therefore many models of traumatic peripheral nerve injury exist. Consequently, a multitude of mechanisms have been implicated in painful peripheral nerve lesions. It would be wrong to believe that mechanisms of peripheral nerve injury are the same whether caused by chemical injury, constriction, or by the surgeon's

scalpel. It is for these reasons that the pharmacotherapy of different types of neuropathic pain should differ. One only has to look at the different responsiveness of trigeminal neuralgia and other neuropathic pain syndromes to drugs such as carbamazepine to see that mechanisms underlying these neuropathies must differ. Iatrogenic neuropathic pain caused by various drug treatments is well recognized. Theoretically, it should be of no surprise that chemotherapeutic agents and antiretrovirals, compounds which broadly act through inhibiting cellular processes, may have neuropathic side effects.

The chemotherapy agents vincristine and paclitaxel and the nucleoside reverse transcriptase inhibitors (NRTIs) such as dideoxycytidine have a well-established history of causing painful neuropathy (Berger et al., 1993; Forsyth et al., 1997), with the incidence of painful neuropathies in paclitaxel-treated patients suggested to be around 22% (Forsyth et al., 1997). Paclitaxel binds to microtubules and promotes hyperpolymerization. This interferes with the mitotic spindle formation and promotes cellular arrest in the metaphase-anaphase transition, and consequently apoptosis (Jordan et al., 1996; Yvon et al., 1999). As the precise mechanism of paclitaxel-induced neuropathy is still not clear, it has been assumed that the binding of paclitaxel to microtubules of neurons, which consequently prevents anterograde and reterograde axonal transport, could lead to a neuropathic state. However, these proposed mechanisms of both tumour apoptosis and neuropathy have been questioned, and the precise mechanisms are still not clear (Komiya and Tashiro, 1988; Fan, 1999). Another chemotherapeutic agent, vincristine, is said to act via a similar mechanism, inhibiting normal polymerization of β-tubulin, leading to abnormal spindle function. Early studies showed that epineural injection of paclitaxel caused oedema and axonal degeneration (Roytta and Raine, 1986) along with interference of axonal transport and microtubule anomalies. However, a number of sources have doubted the theory that axonal degeneration and microtubule anomalies occur, citing the unusually high concentrations of paclitaxel in the epineural injections responsible for the local axonal reactions (Polomano and Bennett, 2001). These local epineural injections allowed paclitaxel to bypass the liver, so that any metabolites usually involved in the development of pathology would not be present.

Mitochondria have now been shown to play an important role in the establishment of some pain states, especially chemotherapy and NRTI-induced neuropathic pain. Change in mitochondrial function has been shown to be involved in the pathogenesis of neurodegenerative diseases; however, this has not previously been widely studied in pain. In patients, neuropathies solely due to disarray in mitochondrial function have been shown to have an increased incidence of developing pain (Finsterer, 2004).

These mitochondrial effects may be relevant to the mechanisms described recently in models of chemotherapy-induced neuropathic pain that are more akin to the clinical scenario. Low-dose systemic injections of paclitaxel produced mechanical hypersensitivity, yet even at the stage of peak pain-like behaviours, there were no signs of axonal degeneration, markedly altered microtubules, or impairment of axonal transport (Flatters and Bennett, 2006). However, abnormal mitochondria in C fibres and myelinated axons were noted and this was suggested to be the cause of paclitaxel's actions. In this model, it was proposed that paclitaxel's binding to mitochondria caused opening of the mitochondria

permeability transition pore, causing calcium ion influx into the cytosol. This mitochondrial calcium efflux has been suggested to be both the cause of mitochondrial swelling as well as of primary afferent excitability and pain behaviour (Flatters and Bennett, 2006). The T-type calcium channel blocker ethosuximide, α2δ calcium channel subunit ligand, gabapentin, and calcium chelators, all block neuropathic pain behaviours caused by chemotherapeutic agents (Flatters and Bennett, 2004; Xiao et al., 2006).

Mitochondrial damage is also the proposed mechanism for the neuropathy seen after treatment with NRTIs for HIV/AIDs (Joseph et al., 2004; Joseph and Levine, 2006). The mitochondrial electron transport chain and its end product, ATP, have also been a suggested pathological player in the development of neuropathic pain due to both chemotherapy and antiretroviral treatment; however, the downstream targets in the pathological setting are still to be elucidated (Joseph and Levine, 2006). It has also been noted that both paclitaxel- and vincristine-evoked painful peripheral neuropathies show a loss of innervation of the epidermal sensory fibres as well as the Langerhans cells, the skin's resident immune cells. Whether this is a causal or merely consequential finding is yet to be shown (Siau et al., 2006).

Pain associated with HIV infection

Iatrogenic neuropathic pain due to treatment with NRTIs is not the only cause of neuropathic pain in HIV/AIDS patients. Around 10–15% of all HIV-1 infected patients have a symptomatic distal polyneuropathy (Verma, 2001), a proportion of which experience pain as a result. It has been shown that direct infection of neurons by HIV has a negligible incidence rate and it is for this reason that the attention of researchers turned to the neuroimmune system. An envelope protein of HIV-1, gp120 has been widely shown to produce hindpaw hypersensitivity to thermal and mechanical stimuli when injected into the intrathecal space (Milligan et al., 2001), as well as directly to the sciatic nerve of the rat (Herzberg, and Sagen, 2001). Astrocytes and microglia have been shown to bind to the virus epitope gp120, which in turn causes their activation. Milligan et al. showed that attenuating glial activation ameliorates the development of behavioural hypersensitivity of animals once exposed to gp120 (Milligan et al., 2001). In this study, the response of microglia and astrocytes to gp120 was blocked. As mentioned previously, activation of glia in the spinal cord by exogenous factors, such as gp120, causes the transcription and release of factors such as prostaglandins, excitatory amino acids, IL-1, and IL-6 as well as inducing nitric oxide synthetase expression in glial cells (Kreutzberg, 1996; Kong et al., 1996). The release of these factors from glia in the dorsal horn may well be able to directly excite local sensory neurons and propagate the sensation of pain, even without the presence of a peripheral pathology. The development of spinal sensitization has been put forward as an explanation for why pains in HIV-1 infected patients commonly present without obvious peripheral pathologies and are vague and diffuse in nature (Breitbart et al., 1996; Hewitt et al., 1997).

Mechanisms underlying the generation of pain in neuropathy

Many changes in the periphery have been implicated in the development of neuropathic pain, but none have been more heavily

studied than the role of ion channel dysregulation on peripheral nerves. Normally, tactile stimulation of sensory nerve terminals in the skin, viscera, or bone leads to the propagation of an action potential and sensory signalling. However, after nerve injury, many peripheral nerves display ectopic discharge, which may lead to an increased barrage of nociceptive signalling onto dorsal horn transmission neurons without a peripheral stimulus. Electrophysiologically, neuronal responses of second-order deep dorsal horn neurons are heightened after nerve injury in rodent models, with an increase in receptive field size and an increased response to natural stimuli applied to the hindpaw. This goes hand in hand with increased spontaneous activity and hyperexcitability of these neurons.

Changes in the sodium channel populations on peripheral nerves and their subsequent aberrant activity have been of great interest due to their key role in setting neuronal excitability and therefore the development of pain states (Suzuki et al., 2002; Cox et al., 2006; Cummins et al., 2007). Expression of sets of sodium channels on the peripheral neurons shows plasticity after nerve injury. The mRNA of NaV1.3, a usually embryonic TTX-sensitive current, has been found to increase after axotomy and this may play a role in the generation of ectopic activity in peripheral nerve fibres. The sensory neuron specific sodium channel, NaV1.8 is also thought to play a key role in the generation of abnormal sensory signalling following nerve injury. NaV1.8 protein is markedly decreased in the dorsal root ganglion of predominantly small fibres after nerve injury. This is paralleled by an increase in immunoreactivity of the channel in the distal axons and nerve terminals, representing a redistribution of the channel to the distal sites of the neuron, where it may take part in the development of hyperexcitability and increased nociceptive transmission. Both in humans and animals, sodium channel accumulation has been shown to occur around the neuroma formed at the site of the nerve lesion. This has long been the pharmacological basis for the use of drugs such as carbamazepine, lamotrigine, and local anaesthetics in patients with neuropathic pain. After nerve injury, demyelination and abnormal trafficking of sodium channels occurs along the membrane of injured nerves and maybe in the uninjured neighbours. This may lower the threshold for activation and induce ectopic activity in the peripheral nerve. This contributes to the development of central sensitization and amplification of peripheral events, possibly leading to the allodynia and hyperalgesia seen in patients (see Suzuki et al., 2002; Cox et al., 2006).

Voltage-gated calcium channels (VGCCs) may also play a large hand in the increased peripheral nociceptive drive in neuropathic pain. VGCCs play a key role in permitting neurotransmitter release from the presynaptic terminal and, therefore, the postsynaptic propagation of the sensory signal. As with sodium channels, there are a large number of calcium channels that play a role in neuronal excitability. Activation of calcium channels by peripheral electrical events causes the inward flow of calcium and allows neurotransmitter vesicle exocytosis and thus postsynaptic depolarization. However, VGCCs not only have presynaptic actions but also act at the postsynaptic site, allowing activation of postsynaptic second messenger cascades. This may lead to altered gene expression, protein synthesis, and therefore long-term plastic changes. Long-term potentiation of dorsal horn neurons, caused by repetitive afferent stimulation, may be of importance

in maintaining exaggerated neuronal responses for long periods after increased peripheral drive has subsided (Rygh et al., 2006).

Specific targeting of these VGCCs and their accessory subunits seems to be beneficial in the treatment of neuropathic pain, with novel drugs acting at these sites now available. Gabapentin and its newer analogue pregabalin have shown benefit to patients with neuropathic pain. Their target is thought to be the α2δ accessory subunit of calcium channels. Gabapentin has been shown to be effective in reducing neuronal responses in a model of neuropathic pain (Suzuki et al., 2005). However, gabapentin's inability to reduce neuronal responses in normal animals highlights a clear state dependency of gabapentin's action and implicates a role for the α2δ subunit in neuropathic pain pathology. The α2δ subunit has been shown to up-regulate after nerve injury and this correlates not only with the development of behavioural allodynia in these animals but also with gabapentin's behavioural antiallodynic efficacy (Luo et al., 2001). Gabapentin's actions have now been characterized in many differing animal models of neuropathic pain including a model of chemotheraputic paclitaxel-induced neuropathic pain (Xiao et al., 2006).

Another target for the treatment of neuropathic pain is the N-type calcium channel. It was shown that blockade of the N-type calcium channel with ω-conotoxin-GIVA reduced dorsal horn neuronal responses in animals with neuropathic pain and that the release of substance P and CGRP from primary afferents was N-type dependent (Matthews and Dickenson, 2001). An analogue of ω-conotoxin-GIVA, ziconotide, has now been developed and is now licensed for the treatment of neuropathic pain.

In addition to spinal changes, higher brain centres are able to facilitate dorsal horn neuronal activity. An ascending descending facilitatory pathway seems to play a critical role in chronic pain states, such as neuropathic pain. Superficial dorsal horn NK1 neurons project to higher brainstem nuclei, such as the parabrachial nucleus, which receives connections from amygdala and hypothalamus and may explain the ability of emotion to affect pain processing (Bannister et al., 2009). Along with the affective implications, these brainstem nuclei form a part of a spinal-bulbo-spinal loop, which through the RVM, can facilitate dorsal horn neuronal responses. Ablation of these NK1-expressing projection neurons, using a saporin toxin conjugated to substance P, is able to attenuate dorsal horn neuronal responses to stimuli evoked in the periphery (Suzuki et al., 2005). Using an antagonist of the excitatory 5-HT$_3$ receptor, it is clear that these descending facilitations are in the large part serotonergic acting at the 5-HT$_3$ receptor in the spinal cord. These descending facilitations contribute to maintaining central sensitization in pathological pain states and may well aid the development of tactile allodynia seen in patients with chronic pain. The analgesia produced by tricyclic antidepressants and serotonin-norepinephrine reuptake inhibitors are no doubt due to interactions with these descending controls, which are altered in many pain states, including cancer pain (Dickenson and Ghandehari, 2007; Bannister et al., 2009).

Astonishingly, gabapentin's actions in reducing neuronal responses in nerve-ligated animals were blocked by both the ablation of these superficial projection neurons and by the application of ondansetron (Suzuki et al., 2005). However, the activation of the 5-HT$_3$ receptor allowed gabapentin to reduce neuronal responses in normal animals, suggesting that this supraspinal loop needs to be in place for gabapentin's action to be unmasked.

Conclusion

Any advances in the understanding and treatment of pain in cancer and other terminal illnesses will need to be based on a better understanding of pain mechanisms, so that existing therapies can be used with greater efficacy. Further knowledge of these mechanisms is a basis for the development of future therapeutic approaches based on controlling the pathophysiology, as well as the pain itself.

This chapter illustrates how important advances in understanding the pathophysiology of pain have been made in recent years and provide a basis for improvements in the treatment of the pain, distress, and co-morbidities. Tumour growing in the periphery elicits a series of changes that run from peripheral tissue and nerve, causes profound changes in spinal cord function, and in the final experience of pain, involves complex circuits in the brain that link pain with affective function.

9.3

Definition and assessment of chronic pain in advanced disease

Clare Rayment and Michael I. Bennett

Background to chronic pain in advanced disease

Definition of chronic pain in advanced disease

The International Association for the Study of Pain (IASP, 2011) defines pain as an 'unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage'. Chronic pain is defined as 'pain which persists beyond the usual course of healing or is associated with chronic pathological illness which causes continuous pain or pain which recurs at intervals for months of years' (Bonica, 1990). Pain is always subjective, corresponding to what the patient describes. This point, which is emphasized by the IASP, underscores the observation that correlation between observed behaviour and patient reports of pain may be poor as individual response to pain varies considerably. All pain-related behaviour, including verbal report, is influenced by its perceived meaning, and an individual's culture, ethnicity, and mood (Cleeland et al., 1996; Twycross, 1997). Verbal report is the simplest to interpret clinically, but other behaviours are relevant to a broader understanding of the pain. In those patients unable to communicate effectively, such as infants or those who are cognitively impaired, changes in behaviour may be the key clinical finding.

The concept of 'total pain' acknowledges the physical, psychological, social, and spiritual influence on a patient's perception of pain, and the multidimensional effects it has on a person's life (Saunders, 1967; Portenoy and Lesage, 1999; Zaza and Baine, 2002; Foley, 2004; Ferreira et al., 2008; Portenoy, 2011). Without attention to all these areas, pain relief is unlikely to be optimal (Saunders, 1967).

Defining the likely pathophysiology of the pain is an essential part of the broader understanding which may help enable appropriate treatment. Nociceptive pain is defined as 'pain that arises from actual or threatened damage to non-neural tissue and is due to the activation of nociceptors' (IASP, 2011). In contrast, neuropathic pain is defined by the Neuropathic Pain Special Interest Group (NeuPSIG) of the IASP as 'pain caused by a lesion or disease of the somatosensory nervous system'. It is often then further classified as peripheral or central and by anatomical site and disease. Both these terms are descriptions of pain, not diagnoses.

Breakthrough pain is the term most widely used to describe variations in quality, intensity, and timing of pain on a background of stable pain control (Haugen et al., 2010). It can be predictable, unpredictable, spontaneous, or evoked with the same quality or a different quality to the baseline pain (Portenoy et al., 2006; Hagen et al., 2008). Patients with uncontrolled breakthrough pain are more likely to have a poorer quality of life and be depressed (Portenoy et al., 1999).

Pathophysiology and aetiology of pain in advanced disease

Pain occurs in more than 50% of patients with advanced disease, and although the 'analgesic ladder' approach to treatment promulgated by the World Health Organization is both accepted as the mainstay therapy and widely disseminated, pain is undertreated (Solano et al., 2006; van den Beuken-van Everdingen et al., 2007a; DeAndrea et al., 2008; Breivik et al., 2009). Unrelieved pain interferes with daily functioning and quality of life. It may have multiple negative effects, interfering with sleep, activity, and interaction with others, and causing psychological and existential distress (Sheinfeld et al., 2012).

Most of the empirical evidence about pain in advanced disease has been related to patients with cancer, but a review by Solano et al. (2006) shows that pain is a common feature of advanced disease in all patients regardless of the underlying pathology. Prevalence of pain in cancer patients was 35–96%, in those with heart disease, 41–77%, AIDS, 63–80%, chronic obstructive pulmonary disease (COPD), 34–77%, and renal disease, 47–50% (Solano et al., 2006). However, what is not clear is whether this pain is a result of the underlying advanced disease or associated co-morbidities. For example, a patient with COPD may have severe back pain but this may be due to osteoporotic fractures as a result of long-term steroid use.

In cancer patients, pain is more common as the disease progresses. A systematic review of 52 articles focusing on patients with cancer found that the prevalence was 64–74% in those with advanced disease, 59% of those on anti-cancer treatment, and 33% in those that had been cured of their cancer (Hearn and Higginson, 2003; van den Beuken-van Everdingen et al., 2007b). These findings are similar to those in a recent European Pain in Cancer survey of over 5000 patients in 11 European countries, which showed an overall pain prevalence of 72% of patients with cancer in the community (Breivik et al., 2009). Prevalence rates of pain associated with different types of cancer vary in the literature, but

overall rates all remain over 50%. Breivik et al. (2009) found that the highest prevalence rates, of over 85%, were associated with cancers of the pancreas, bone, brain, lymphoma, lung, and head and neck.

Although confirming that pain is an extremely common symptom among diverse populations with serious illness, the specific prevalence rates must be interpreted with caution. Pain is heterogeneous and prevalence rates are affected by the setting of the patient, such as a specialist pain or a general respiratory clinic.

Pain prevalence may be related to aetiology. Pain may be due to a direct effect of underlying advanced disease or its treatment; an indirect effect of the disease, such as pressure sores from immobility; or a disorder unrelated to the primary disease, such as osteoarthritis. One survey observed that 76% of patients with cancer have pain directly related to the cancer, 11% have pain related to cancer treatment, 5% have pain due to an indirect effect, and 8% have pain due to unrelated conditions (Grond et al., 1996).

A study of patients with chronic cancer pain observed that somatic pains were more common (71%) than either neuropathic (39%) or visceral (34%) pains (Caraceni and Portenoy, 1999). Many patients experience both nociceptive and neuropathic pain, and the origin of pain must be considered when interpreting prevalence rates. In neuropathic cancer pain, for example, although the majority of pains are caused by cancer (64%), a significantly higher proportion is caused by cancer treatment (20%) in comparison with all cancer patients (Bennett et al., 2012).

The pathophysiology of pain affects its impact on patients and treatment. Patients with neuropathic pain have been shown to have greater pain intensity, a worse quality of life, and a greater negative impact on their daily living than patients with nociceptive pain (Torrance et al., 2006; Smith et al., 2007; Bouhassira et al., 2008). Similarly, those with neuropathic cancer pain have been shown to have a worse quality of life, poorer performance status, and a need for both higher opioid doses and a longer time to achieve pain control than those with nociceptive pain (Fainsinger et al., 2010; Rayment et al., 2013).

Further clouding interpretation of prevalence figures is the observation that patients often report more than one pain (Twycross and Fairfield, 1982). For example, a systematic review found that, on average, patients with cancer have two pains, 20% of which are neuropathic in origin; these patients with multiple types of pain contribute to a 40% prevalence rate for neuropathic pain overall (Bennett et al., 2012).

Finally, pain prevalence must be interpreted in light of severity and other factors. Pain severity varies, but as a minimum, more than one-third of patients with cancer pain grade their pain as either moderate or severe (van den Beuken-van Everdingen et al., 2007b; deAndrea et al., 2008). In hospitalized patients with cancer, patients reported a pain score of 3.7 on a 0–10 numerical rating scale for average pain; two-thirds of patients reported that their worst pain was higher than 5 (Klepstad et al., 2002; Yates et al., 2002). In the community, 93% of those patients who experienced cancer pain at least several times a month rated the severity as moderate to severe, 44% described it as severe, and 3% regarded it as the worst pain imaginable (Breivik et al., 2009).

Like pain itself, under-treatment has many influencing factors. Discrepancies between patient and physician rating of pain severity are one such predictor (deAndrea et al., 2008). Under-treatment also is more likely when patients have a better performance status

or are in the early stages of their diseases, findings that may suggest a reluctance to believe that those with early disease can have severe pain or an increased likelihood that those with advanced disease are managed by specialists (deAndrea et al., 2008).

It is not clear if older age has an effect on pain management. Evidence from the cancer population suggests that there are no differences in pain intensity but older people may require less or more analgesia than the younger population, perhaps due to altered physiology (Vigano et al., 1998; Mercadante and Arcuri, 2007; Hall et al., 2003; Mercadante et al., 2006; van den Beuken-van Everdingen et al., 2007b; Bennett et al., 2009). Older patients also do not have more adverse effects or more need for opioid switching (Mercadante et al., 2006). However, they may have different attitudes towards opioids and therefore may be more reluctant to use these drugs (Yeager et al., 1997; Closs et al., 2009). Gender does not alter pain prevalence rates, but education level and ethnicity may (van den Beuken-van Everdingen et al., 2007b; deAndrea et al., 2008).

Characterizing the pain complaint

Assessing a patient's pain should be a continual process supported by communication between patient, carer, and clinician. The aims are to characterize the complaint, correctly identify the underlying pathophysiology, and determine the effect of pain on the patient's life. All of this information informs the management plan. Without this focus on a comprehensive assessment, pain treatment becomes less targeted and less effective.

A history and clinical examination are vital for pain assessment and radiological and laboratory tests may be indicated. Inadequate pain control is most often due to a poor history and examination (Grossman et al., 1992; Von Roenn et al., 1993). Establishing the effect of pain on the person's quality of life and activities of daily living, recording previous effects of analgesic treatments, and exploring the patient's goals and expectations are crucial in being able to effectively treat all aspects of pain's impact on the person. Creating a trusting, open relationship encourages communication and allows patients to be involved in the management of their pain. Concerns generated by the experience of fear, such as worry about cancer progression or about the risks of addiction or tolerance to opioids, may affect the information given to the clinician.

The clinical history of pain

The acronym SOCRATES is useful in prompting systematic assessment of pain characteristics: *S*ite, *O*nset, *C*haracter, *R*adiation, *A*ssociated factors, *T*iming, *E*xacerbating/relieving factors, and *S*everity (Box 9.3.1). As previously mentioned, patients often report more than one pain and it is important to ascertain a pain history for each pain a patient reports, as its cause and therefore treatment may vary. Answers to these questions provide clues as to the likely underlying cause. For example, a patient who describes unpredictable severe shooting and stabbing pains in both toes and feet, with no radiation, may well be describing a peripheral neuropathic pain perhaps related to previous chemotherapy. In contrast, a patient describing severe shooting and stabbing pains radiating down both legs to their feet, which is worse on movement, may be describing impending cauda equina/spinal cord compression. Management of these two syndromes is substantially different

Box 9.3.2 Patient's description of neuropathic pain

As far as I can remember, my pain started during the second week of the radiotherapy and chemotherapy. In total I had six chemotherapy and 30 radiotherapy sessions over a 6-week period. I found the radiotherapy was the most painful. Not during treatment—it was the aftereffects. The headache seemed to get worse on a daily basis.

Trying to explain the pain is difficult. It is like hundreds of needles inside my head. I ended up trying to relate it to other pain I have suffered over my lifetime. For instance, ear infection at its worst, very bad migraine, tonsillitis. If you could imagine all this pain in one blast it is about right, maybe even worse. At this time of my life I was lucky if I managed to have an hour or two of undisturbed sleep. Now 10 months down the line, I am finding it much easier to cope as my nerve ends are healing. The medication as a pain patch has definitely been a great help with the nerve pain.

---

and requires physicians' knowledge of the underlying disease and likely prognosis.

The pain assessment also must clarify the history of the underlying disease process, including previous treatments and current status. This information informs both treatment selection and prognostication. Similarly, a history of other symptoms is needed to both predict the impact of pain therapy and assist in the development of a broader plan of care for symptom control.

For those patients who are cognitively impaired it can be harder to ascertain symptoms and there must be increased reliance on non-verbal cues, as well as proxy reports from families and other carers who can highlight abnormal behaviours. A recent Norwegian cluster randomized controlled trial of patients in nursing homes with moderate to severe Alzheimer's dementia and significant behavioural disturbances showed significant benefit in agitation in patients who received analgesia, the vast majority receiving just regular paracetamol (Husebo et al., 2011).

Character

> English, which can express the thoughts of Hamlet and the tragedy of Lear, has no words for the shiver and the headache. . . . The merest schoolgirl, when she falls in love, has Shakespeare or Keats to speak her mind for her; but let a sufferer try to describe a pain in his head to a doctor and language at once runs dry. (Virginia Woolf, *On Being Ill*)

Although patients often find it difficult to articulate the character of their pains, it is important to elicit descriptors as a step in diagnosing the underlying pathophysiology. Nociceptive pain is divided into somatic pain, which arises from injury to the soft tissues and bone, and visceral pain, which arises from injury to internal organs. Somatic pain is usually well localized and described as aching, sharp, or throbbing. In contrast, visceral pain due to obstruction of a hollow viscus is poorly localized and can be described as gnawing or cramping; injury to other tissues, such deep fascia, or organs such as the heart, may be described as pressure or a deep pain. Visceral pain is commonly referred, such as shoulder tip pain from diaphragmatic irritation. Patients often find visceral pain harder to describe than somatic pain (Bennett et al., 2005; Osta and Bruera, 2008).

Neuropathic pain is often described as numb or burning with sharp, shooting pains on movement. Patients may describe spontaneous pains in the absence of any stimuli or evoked pains such as allodynia (painful response to a non-painful stimulus), hyperalgesia (increased painful response to a painful stimulus), and hyperpathia (delayed and prolonged response to painful stimulus). Due to cancer's natural history, neuropathic pain can

evolve as masses increase in size; over time, many patients with tumour-related neuropathic pain experience the emergence of deep aching related to the underlying lesion. See Box 9.3.2 for an example of a patient's description of neuropathic pain from head and neck cancer.

Neurological signs may precede pain and reflect the distribution and severity of nerve injury (Twycross, 1995). Sensory changes, weakness, and altered tendon reflexes can localize the site of injury and help clarify the aetiology of the pain.

However, distinguishing between neuropathic and nociceptive pain on the basis of pain descriptors alone is not easy. A study in non-cancer patients found that while patients with peripheral neuropathic pain reported more descriptors such as hot, cold, sensitive, itchy, and significantly less dull and deep than those with nociceptive pain, they still used nociceptive descriptors, although to a lesser extent (Dworkin et al., 2007). A study in lung cancer patients found that several words traditionally thought to describe neuropathic pain such as burning, shooting, tingling, and cold did not distinguish between the two pains (Wilkie et al., 2001).

As noted, individual pains also can have more than one mechanism. A patient describing pain from a vertebral metastasis that is compressing a nerve root is likely to describe features of both nociceptive and neuropathic pain. This would be classified as mixed pain or a more useful term to aid management may be whether the pain is more or less neuropathic in nature (Bennett et al., 2006).

Associated features

Pain is associated with many features that may be clinically important or predict treatment response. For example, interference is the extent to which pain has affected aspects of a patient's life. It is important to analyse because the extent to which pain interferes in various functional domains may enable better classification of its cause or predict those patients who are likely to have a poor response to management and a longer time to pain control. Although pain interference is strongly related to pain intensity at a group level (Serlin et al., 1995), there are significant inter-individual differences. In addition there are differences in reported levels of pain-related interference between patients with

and without advanced medical illness: at any level of pain intensity, those without advanced illness report greater interference (Fayers et al., 2011).

Other associated features also are important. A recent longitudinal study by Knudsen et al. (2012) confirmed that pain intensity, incident pain, and younger patients predicted more complex pain and longer time to achieve pain control. In an international multicentre study, Fainsinger et al. (2010) showed that these three domains and psychological distress and neuropathic pain were associated with a longer time to pain control. Those with addictive behaviours, a history of drug or alcohol abuse, did not take longer to reach stable pain control but required higher opioid doses. Alcoholism is a major predictor of rapid escalation of opioids and opioid-related neurotoxicity (Bruera et al., 1995).

In addition, sleep disturbance, lack of social support, and concerns over finances and family all affect the impact pain has on the patient. Given this complexity, the treatment of pain with analgesics alone is unlikely to optimize outcomes. Working within a multiprofessional team to target and help each domain while expertly providing analgesics is more likely to result in better pain management for the patient.

Severity

It is important to assess the severity of pain, as the greater its severity the more impact it has on daily functioning and quality of life (Serlin et al., 1995). Various pain measurement tools can be applied to this task, ranging from simple unidimensional scales such as the visual analogue scale (VAS), to more complex pain questionnaires (see following sections). For some patients, facial scales may be more useful in establishing the severity of pain.

In the clinical setting, pain severity usually is measured by asking patients to rate their pains on a 0–10 scale or as mild, moderate, or severe. The response to this question may provide enough information to help initiate appropriate treatment, as well as its urgency. It may also help to establish the underlying cause of the pain; for example, severe pain on movement may support a diagnosis of a fracture, whereas mild pain may suggest osteoarthritis. Ongoing assessment of pain severity enables evaluation of interventions, and monitoring of variation over hours or days can help establish factors which worsen or ease the pain. All this information may be useful when there is a large team caring for the patient (Twycross, 1995).

Pain measurement scales

Intensity 0–10

Visual, categorical numerical, and categorical verbal rating scales are validated and used as tools to measure intensity of pain (Caraceni et al., 2002; Hjermstad et al., 2011) (see also Chapter 7.2). The VAS is a 10 cm line labelled at each end with the minimum or maximum extremes of what is being measured. In measuring pain, these anchors often are 'no pain' and 'pain as bad as you can imagine'. Patients indicate their pain severity on the line. Categorical numerical scales ask the patient to rate their pain on an 11-point numeric scale (e.g. '0 to 10, where 0 is no pain and 10 is pain as bad as you can imagine') or on a 5-point numeric scale (e.g., a 0–4 scale with the same anchors), and categorical verbal scales provide verbal descriptors, such as none, mild, moderate,

or severe. They are reliable and can be used clinically and in research. Expert consensus recommended an 11-point numerical rating scale with 'no pain' and 'pain as bad as you can imagine' as anchors for the assessment of chronic pain including cancer pain (Dworkin et al., 2005; Kaasa et al., 2011).

Brief Pain Inventory

The Brief Pain Inventory (BPI) (Daut et al., 1983; Cleeland and Rayn, 1994) has long (15 minutes) and short versions; either a health-care professional or patient can complete it. The short version assesses pain severity from four frames of reference—'pain right now', 'pain at its best', 'pain at its worst', and 'pain on average'—and also measures pain relief using a VAS. A pain schematic shows the localization of pain, and pain interference during the last 24 hours is determined in terms of various domains, for example, general activity, mood, walking ability, normal work, relations with other people, sleep, mood, and enjoyment of life. The longer version of the BPI also records information about medical history, has pain descriptors, and asks about interference with daily activities in the last month and last week. The BPI has been translated and validated in many languages. The short form has been recommended for cancer pain assessment (Caraceni et al., 2002).

McGill Pain Questionnaire

The McGill Pain Questionnaire (MPQ) is another self-report tool validated in cancer patients. It assesses intensity, quality, temporal pattern, relieving and exacerbating factors, and site of pain. Intensity is assessed on a categorical verbal rating scale, which uses the descriptors mild, discomforting, distressing, horrible, and excruciating (Melzack, 1987). It has been validated in the cancer pain population (Graham et al., 1980; Dudgeon et al., 1993).

Neuropathic pain screening tools

Various neuropathic screening tools exist (Bennett et al., 2007). The Leeds Assessment of Neuropathic Signs and Symptoms has five self-report pain items and two clinical examination items (Bennett 2001). PainDETECT is another self-report questionnaire consisting of seven questions related to the quality of the pain, a body map, and two further questions on radiation and timing (Freynhagen et al., 2006). The Douleur Neuropathique en 4 questions or DN4 has seven symptom and three clinical examination questions (Bouhassira et al., 2005), while the Neuropathic Pain Questionnaire has ten questions on sensation and two on affect (Krause and Backonja, 2003). All have been validated in populations without cancer and emerging evidence suggests that for screening tools in cancer populations these tools may be less reliable or require adapting (Rayment et al., 2013).

Alberta Breakthrough Pain Assessment Tool

The Alberta Breakthrough Pain Assessment Tool was developed for use in clinical studies. There are 15 patient answered questions and questions on aetiology, pathophysiology, medications, and descriptions of the pain for the health-care professional.

Clinical examination

Clinical examination is essential to ensure accurate diagnosis of the pathophysiology of pain. It not only aids accurate diagnosis but also allows for assessment of comorbidities and the patient's

overall physical state. This information is essential when considering management strategies.

A neurological examination often provides valuable information and is essential if neuropathic pain is suspected. The recent IASP guidelines for neuropathic pain underline the importance of clinical examination for an accurate diagnosis (Haanpää et al., 2011), and the recent NeuPSIG guidance (Haanpää et al., 2011) proposed a four-criterion grading system for non-cancer neuropathic pain highlighting the importance of examination in this subgroup. This guidance indicates that the examination of the patient with presumed neuropathic pain should demonstrate that the pain is neuroanatomically plausible and the patient has a history suggestive of a relevant lesion or disease of the central somatosensory or peripheral nervous system. With these criteria, neuropathic pain may be considered possible if there is at least one confirmatory bedside measurement, and probable if there is at least one confirmatory test. If all four of these criteria are met, then neuropathic pain may be considered definite.

Confirmatory imaging will help in the assessment of pain if there is doubt as to its cause or if it may lead to further directed treatment, such as radiotherapy (Twycross, 1995). Analgesia should not be withheld while a diagnosis is being obtained. Plain radiography and bone scintigraphy may help in determining the appropriateness of radiotherapy or orthopaedic intervention. Computed tomography and magnetic resonance imaging help determine the causes of intrathoracic or intra-abdominal and pelvic pain, and nerve conduction studies may help localize the lesion.

Assessing pain in context of a palliative plan of care

Patients with advanced disease face many challenges. Pain is often only one symptom of an illness that may have been associated with many losses—normality, independence, health, and the future. The significance of pain varies among individuals; a patient with peripheral neuropathic pain due to diabetes may be very distressed but a patient with ischaemic heart disease may believe chest pain means they are dying. It is still common for people to believe that severe pain is unavoidable in advancing illness, especially cancer, and this may place extra suffering on patients. It therefore is a clinical imperative to understand a patient's understanding of the cause of their pain, and their concerns about management and what may happen in the future. This inevitably needs to be done with consideration for other symptoms. Other factors are important to help predict response to treatment. For example, organ failure, cachexia, and age affect pharmacokinetics and response to treatment, and should be considered within any management plan.

It is essential when considering a management plan to consider both the potential benefits and burdens. Performance status and likely prognosis may alter what treatment is offered. For example, a patient with pain from a femoral fracture due to metastatic disease who has been gradually deteriorating for many months, was bed bound before the fracture and is anorectic, cachetic, and fatigued with a prognosis of days will not benefit from radiotherapy, while a patient with a similar pain due to a femoral fracture who was walking and independent prior to the fracture, and has a prognosis of many months, should be considered for both orthopaedic and oncological intervention.

Explanation of the cause of pain and its management needs to be made not only to the patients but to any carers/family that the patient identifies as helping in their day-to-day life. Their understanding may be crucial in designing and implementing management. Consideration also needs to be made as to whether initial assessment and management is better done in an inpatient unit or on an outpatient basis.

Continuing assessment of pain and its response to management is vital in ensuring that patients get the treatment they deserve. Clinicians working within a multidisciplinary team with expertise in nursing, social work, physiotherapy, occupational therapy, spiritual care, and complementary therapies ensure a holistic assessment is made of a patient's pain and a holistic management plan is implemented.

Opioid therapy: optimizing analgesic outcomes

Marie T. Fallon and Nathan I. Cherny

Introduction to opioid therapy

Treatment with analgesic drugs is the mainstay of cancer pain management (World Health Organization (WHO), 1996; Portenoy and Lesage, 1999). Although concurrent use of other approaches and interventions may be appropriate in many patients, and necessary in some, analgesic drugs are needed in almost every case. Drugs whose primary clinical action is the relief of pain are conventionally classified on the basis of their activity at opioid receptors as either opioid or non-opioid analgesics. A third class, adjuvant analgesics, are drugs with other primary indications that can be effective analgesics in specific circumstances. The major group of drugs used in cancer pain management is the opioid analgesics.

During the last 30 years, there has been a dramatic increase in our knowledge of the sites and mechanism of action of the opioids. The development of analytical methods has also been of great importance in facilitating pharmacokinetic studies of the disposition and fate of opioids in patients. More recently, advances in genomic research have indicated the potential importance of pharmacogenetic factors in the response to opioid analgesics (Lötsch et al., 2002a, 2009). These studies have begun to offer us a better understanding of some of the sources of variation between individuals in their response to opioids and to suggest ways of minimizing some of their adverse effects. Although there are gaps in our knowledge of opioid pharmacology, the rational and appropriate use of these drugs is based on their clinical pharmacological properties demonstrated in well-controlled clinical trials. However, in order to reflect the dramatic increase in pre-clinical opioid research in recent years, this chapter has been divided into two; a pre-clinical and a clinical section.

Terminology

In this chapter and throughout this textbook, we have adopted the following conventions in terminology:

Opiate is a specific term that is used to describe drugs derived from the juice of the opium poppy. For example, morphine is an opiate but methadone (a completely synthetic drug) is not (Hughes and Kosterlitz 1983).

Opioid is a general term that includes naturally occurring, semi-synthetic, and synthetic drugs which produce their effects by combining with opioid receptors and are stereospecifically antagonized by naloxone. In this context we refer to opioid agonists, opioid antagonists, opioid peptides, and opioid receptors.

Narcotic is commonly used to describe morphine-like drugs and other drugs of abuse. The term is derived from the Greek *narke*, meaning numbness or torpor. Since this is an imprecise and pejorative term that is not useful in a pharmacological context, its use with reference to opioids is discouraged. The term narcotic is not used in this book.

Section 1: pre-clinical pharmacology

Opioid receptors

Opioid receptors were originally classified by pharmacological activity in animal preparations and later, by molecular sequence. The three main receptors were classified as μ (mu) or OP3, κ (kappa) or OP1, and δ (delta) or OP2. Another opioid-like receptor has been identified; it is termed the nociceptin orphanin FQ peptide receptor. Receptor nomenclature has changed several times in the last few years; the current International Union of Pharmacology (IUPHAR) classification is MOP (mu), KOP (kappa), DOP (delta), and NOP for the nociceptin orphanin FQ peptide receptor (Table 9.4.1).

The formerly identified sigma receptor is not a true opioid receptor and is not included in the opioid receptor group. Opioid receptors are widely distributed in both central and peripheral nervous systems. One of the characteristics of DNA and RNA is known as sequencing and this can be an indicator of normal biological processes, pathogenic processes, and/or response to a therapeutic or other interventions (see Box 9.4.1 for definitions of key terms in the discipline of pharmacogenomics and pharmacogenetics).

The mu, delta, and kappa receptors are very similar, sharing over 70% sequence homology, whilst the orphan receptor shares only 50% sequence homology (Pasternak 2001). Extensive pre-mRNA splicing gives rise to numerous splice-variants also known as receptor subtypes. The mu receptor gene has been shown to have 25 different splice variants in mice, eight in rats, and 11 in humans. These splice variants are controlled by diverse promoters. It has been demonstrated that different splice variants exhibit differences in agonist-induced G-protein activation, adenylyl cyclase activity, and receptor internalization or endocytosis. In addition, some differences can lead to modification of phosphorylation, membrane translation, scaffolding protein binding, and G-protein binding (Reisine and Pasternak, 1996). The potential activation and destination of the receptor is changed by such modifications. The different effects of currently available opioids are dependent on complex interactions at various receptors

Table 9.4.1 Classification of opioid receptors

Receptor	Molecular classification	Endogenous ligand	Site
Mu	OP3	Beta-endorphin, leu-and met-encephalin; endomorphins	Peripheral inflammation; pre- and postsynaptic neurons in spinal cord, periaqueductal grey, nucleus raphe magnus, thalamus, cortex
Kappa	OP1	Dynorphins	Spinal cord, supraspinal, hypothalamus
Delta	OP2	Encephalins, beta-endorphin	Olfactory centres, motor integration areas in cortex, limited distribution in nociception areas
Orphan	ORL-1 (opioid-like receptor)	Nociceptin	Spinal cord

Source: Data from UpToDate.

and they function as neurotransmitters, neuromodulators, and neurohormones.

The three families of endogenous opioid peptides are well characterized. They are the endorphins, encephalins, and dynorphines, which have binding affinities to all the receptors. Each family originates from a different gene, their precursors being pro-opiomelanocortin, proencephalin and prodynorphin. The endogenous tetrapeptide endomorphins 1 and 2 do not have an identified precursor; however, they are potent agonists acting very specifically at the mu receptor and they play a role in modulating inflammatory pain. Peripherally they interact extensively with immune cells, primarily in inflammatory states, when beta-endorphin-containing cells as well as signalling molecules (vascular P-selectin and intercellular adhesion molecule-I) which stimulate these cells, are up-regulated (Martin et al., 1976).

The receptor family

The mu opioid receptor

This is clinically the most important of all the receptor families. It is the main opioid receptor responsible for inhibition of nociceptive pathways, and is exploited by all exogenous opioids (Pasternak 1993). Many of the unwanted effects of opioids are also related to activity at this receptor.

Expression

The mu receptor is expressed on central and peripheral neurons, although in the latter it is only activated in response to inflammatory stimuli. Peripherally, mu receptors are found pre- and postsynaptically, for example, in the dorsal horn; approximately 70% are expressed on the primary afferent terminations (presynaptic) modulating afferent transmission (Sindrup et al., 1991). Mu receptors are present on C and A delta fibres, the sympathetic nervous system, and immune cells. Centrally, they are expressed widely including the cerebral cortex, the amygdala, and the periaqueductal grey. In the periaqueductal grey, the presence of mu receptors on inhibitory neurons seems to lead to disinhibition of descending pathways resulting in excitation, as opposed to the more usual result of inhibition of neural transmission.

The relative contribution of each binding site to the overall analgesic effects of systemic opioids has not been investigated. We do understand from both the pre-clinical and clinical paradigm of inflammatory pain, that the pain state itself is highly likely to have a major role in the pattern of binding. The receptor undergoes pre- and post-transcriptional splicing and alteration, leading to a huge variation in the activation state of the receptor (Pasternak 2001).

The delta receptor

Evidence suggests that other opioid endogenous ligands and receptors are linked to analgesic response and to mu receptor activation. It is interesting that deletion of the delta receptor gene and pre-proencephalins inhibits the development of morphine tolerance, but not withdrawal, in mice (Inturrisi et al., 1983). On the other hand, the potency of mu agonists can be increased by the co-administration of a delta agonist, and such co-administration can induce a translocation of delta receptors to the cell surface. This pre-clinical information is of interest in relation to methadone, which has strong delta, as well as mu, activity.

The kappa receptor

Kappa receptors are also involved in pain, in particular, in response to inflammation (peripherally); however, activation is associated clinically with a number of unpleasant side effects, such as nausea and vomiting and dysphoria. The latter have limited their clinical development for pain of gastrointestinal aetiology, which is often associated with inflammation.

The ORL-1 receptor

The ORL-1 receptor was identified because of its homology with classical opioid receptor types. Its natural ligand is 'nociceptin' or 'orphanin'. There is a suggestion that centrally ORL-1 agonists appear to antagonize mu opioids but this is not yet clearly elucidated. The ORL-1 receptor is involved in modulation of a range of biological functions including the stress response, movement, memory, cardiovascular, and renal mechanisms (Pasternak 2001).

Opioid receptors: structure and function

The opioid receptors belong to the superfamily of seven transmembrane-spanning G protein-coupled receptors (GPCRs). The three major opioid receptors (mu, delta, and kappa) originate from different genes. Each of the transcribed receptor proteins consists of an extracellular N-terminus, seven transmembrane helices, three extra- and intracellular loops, and an intracellular C-terminus characteristic of GPCRs.

The opioid receptor belongs to the rhodopsin family of GPCR (Christensen, 1993; Raynor et al., 1995; Heiskanen et al., 1998). The extracellular regions are involved in opioid binding and intracellular domains interact with G proteins. GPCRs were originally thought to function as monomers in a 1:1 stochiometric ratio with downstream heterotrimeric G proteins (Traynor, 1996). Their primary function is to transmit extracellular stimuli to intracellular signals. Opioid receptors are transduced by the Gi/Go proteins which are relatively resistant to tolerance or desensitization. Transport proteins, metabolizing enzymes, opioid receptors, and

Box 9.4.1 Terminology in pharmacogenomics

Genomic biomarker

Definition

A genomic biomarker is defined as:

A measurable DNA or RNA characteristic that is an indicator of normal biologic processes, pathogenic processes, and/or response to therapeutic or other intervention.

Additional information

1. The definition for a genomic biomarker is not limited to human samples.

2. A genomic biomarker could, for example, reflect:

   - the expression of a gene
   - the function of a gene
   - the regulation of a gene.

3. A genomic biomarker can consist of one or more deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) characteristics.

4. The definition for a genomic biomarker does not include the measurement and characterization of proteins or low-molecular-weight metabolites.

5. DNA characteristics include, but are not limited to

   - single nucleotide polymorphisms (SNPs)
   - variability of short sequence repeats
   - DNA modification, for example,methylation
   - insertions
   - deletions
   - copy number variation
   - cytogenic rearrangements, for example, translocations, duplications, deletions, or inversions

7. RNA characteristics include, but are not limited to:

   - RNA sequence
   - RNA expression levels
   - RNA processing, for example, splicing and editing
   - microRNA levels.

Pharmacogenomics and pharmacogenetics

Definitions

Pharmacogenomics

Pharmacogenomics (PGx) is defined as:

The investigation of variations of DNA and RNA characteristics as related to drug response.

Pharmacogenetics

Pharmacogenetics (PGt) is a subset of pharmacogenomics and is defined as:

The influence of variations in DNA sequence on drug response.

Additional information

1. PGx and PGt are applied to activities such as drug discovery, drug development, and clinical practice.

2. Drug response includes drug disposition (pharmacokinetics (PK)) and drug effect (pharmacodynamics (PD)).

3. The term drug should be considered synonymous with investigational (medicinal) product, medicinal product, and pharmaceutical product (including vaccines and other biological products)

4. The definition of PGx and PGt does not include other disciplines such as proteomics and metabonomics.

Box 9.4.2 Factors influencing opioid effectiveness

◆ Absorption

◆ Distribution

◆ Metabolism

◆ Excretion

◆ Intrinsic efficacy at receptors:

  • transport proteins

  • metabolizing enzymes

  • opioid receptors

  • second messenger molecules.

---

second messenger molecules are central to the effect of opioids (Box 9.4.2). At a cellular level, mu receptor activation has an overall inhibitory effect via:

◆ inhibition of adenylyl cyclase

◆ increased opening of potassium channels (hyperpolarization of postsynaptic neurons, reduced synaptic transmission) and

◆ inhibition of calcium channels (decreases presynaptic neurotransmitter release).

Opioid receptors and the accompanying G proteins interact with a vast array of other intracellular proteins that are responsible for trafficking receptors to the cell membrane, anchoring, and scaffolding proteins. This combination of events alters the response of the receptor to a ligand. GPCRs, including mu, kappa, and delta receptors, have been shown to form different configurations including dimers, homo-, and hetero-oligomers, which have relevance in internalization and activation pathways (Hennessy and Spiers, 2007). This is discussed further in the section on receptor activation versus endocytosis (RAVE). Dimerization modulates receptor pharmacology and this process could present targets for novel interventions (Pasternak, 2001).

Modulation of opioid responses

There are multiple cellular adaptations in response to chronic opioid exposure, which may lead to tolerance (Inturrisi et al., 1983). Tolerance to exogenous opioids is relatively easy to produce in animal studies, where repeated doses of a given opioid rapidly lead to loss of efficacy in response to noxious stimuli. Cellular processes which occur in response to chronic ligand binding to mu receptors include diminution of spare opioid receptors, decreased receptor density, altered coupling, activation and phosphorylation of G proteins, and alteration of downstream pathways (Heiskanen et al., 1998).

It has been reported that chronic exposure to mu or delta agonists induces and up-regulates the pro-excitatory peptides, calcitonin-gene-related peptide (CGRP), substance P, and protein kinase C (responsible for phosphorylation). There is some evidence that the N-methyl-D-aspartate receptor (NMDA) or neurokinin 1 (NK1) receptors may play a role in acute tolerance. Interactions with the orphanin (NOP) receptor may also be important. The effect of these adaptations is to lead to a pro-excitatory state and an attenuation of the inhibitory effects of opioid activation (WHO, 1986; Johnson 1997).

Endogenous peptides such as neuropeptide FF, cholecystokinin, nociception, and dynorphin exhibit anti-opioid actions, which in turn modulate the physiological action and outcome of opioid agonists. Chronic morphine exposure leads to little change in mu receptor expression. There are interesting changes in the non-neuronal population of glial cells, with increased activation in response to chronic morphine exposure (Christensen 1993). Glia have come under increased scrutiny in many pain states. Although previously glia were considered an inert, supporting structure, there is increasing evidence of a key role, particularly in central sensitization where glia may modulate chronic opioid analgesia.

It is widely accepted that clinically relevant pharmacological tolerance to opioid analgesic effects is not relevant for the majority of patients with cancer-related pain. It is however difficult to assess analgesic tolerance clinically (Johnson 1997). There does not appear to be a simple correlation between exposure to opioids and induction of analgesic tolerance. A process of adaptation occurs which is highly likely to depend on many factors which do not necessarily relate easily to current knowledge of cellular processes.

Receptor activation versus endocytosis

The use of more than one opioid or partial opioid substitutions (or rotations) has been reported to reduce agitated terminal delirium, opioid tolerance, and dose escalation (WHO 1986; Ventafridda et al., 1987; Takeda, 1990). The potential benefits have been explained on the basis of RAVE. This is discussed here only to give the reader a complete picture of the evolving theories around opioid function. Potent opioids that activate but do not internalize or recycle the receptor are said to have a high RAVE value. Opioids which cause receptor endocytosis curtail opioid signalling. Paradoxically, sustained opioid signalling causes adenylyl cyclase superactivation and counter-opioid responses (Inturrisi et al., 1983; Walker et al., 1988; Goisis et al., 1989; Schug et al., 1990; Zech et al., 1995; Mercadante 1999).

The opioid receptor binding site is different for each opioid. The number of receptors needed to be activated in order to suppress adenylyl cyclase (a hallmark for analgesia) differs significantly between major opioid receptors. This difference is not related to receptor density or to the amount of intracellular G protein (Raynor et al., 1995). Opioid alkaloids (morphine, methadone, fentanyl) bind within the core of the transmembrane portion of the receptor, whereas large peptidyl ligands bind to the extracellular loops (Inturrisi et al., 1983; McQuay and Moore, 1997; Kalso et al., 1998).

A single receptor has the ability to activate multiple G protein heterotrimers independent of receptor density. Receptor conformation changes as a result of opioid binding and subsequently determines the efficacy of receptor activation and G-protein interactions. Opioid receptors naturally oscillate between active and inactive states. Full agonists stabilize the receptor in an active conformation; partial agonists favour receptor conformation between fully active and inactive states. Opioid antagonists stabilize the receptor in an inactive conformation and prevent G protein activation. Antagonists can become opioid agonists when mutations occur within the fourth membrane helix (TM4) which influences receptor conformation and G protein interactions. The efficiency by which an opioid activates the receptor is dependent on the conformation that allows G proteins to interact with certain transmembrane helices (TM1 and TM7) and the C-terminus (Raynor et al., 1995).

Opioid receptor conformational changes trigger conformational changes in the alpha subunit of G proteins (G alpha) that dissociate GDP from the alpha subunit of the G protein complex and promotes GTP binding to the G alpha subunit. The other component of the G protein (G beta-gamma) is released for downstream signalling. Receptor signalling is curtailed by regulators of G-protein signalling (RGS) and certain kinases (Jadad and Browman, 1995; Heiskanen et al., 1998). G-protein activation inhibits cyclic AMP production by adenylyl cyclase, and also initiates counter-opioid responses and receptor desensitization through the activation of G protein-coupled receptor kinase (GRK) as well as other protein kinases such as protein kinases A and C and mitogen-activated protein kinase (MAPK) (Benedetti et al., 2000; Cleary, 2000; Walsh, 2000).

GPCR activity is balanced by molecular signals that govern receptor desensitization and resensitization. Mechanisms by which receptors are desensitized involve GRK, RGS, kinases, and receptor endocytosis. Receptor desensitization, which is the diminution of receptor responsiveness to agonist activation over time, also represents an important mechanism which limits opioid tolerance. Desensitization prevents acute and chronic overstimulation (or, in the case of opioids, over inhibition) by agonists (Ventafridda et al., 1987). Receptor mechanisms that paradoxically reduce signalling (GRK) are responsible for resensitization by directing receptor trafficking into endocytosis and resensitization (Ventafridda et al., 1987). These acute desensitization processes may be a protective mechanism whereby cells adapt to avoid physiological tolerance by attenuating receptor response to a new sustainable level.

Endocytosis or internalization

G-protein activation (partially G beta-gamma subunits) activates GRK-2 which phosphorylates the C-terminus of the opioid receptor, as well as the second (TM2) and third transmembrane helices (TM3) (Ventafridda et al., 1987). Beta arrestin binds to the phosphorylated receptor, which then binds to clathrin pits within the membrane. Dynamin, a type of GTPase, causes fission of the membrane which results in the formation of small phosphorylase-rich endosomes (Walker et al., 1988; Agency for Health Care Policy and Research: Cancer Pain Management Panel, 1994; Heiskanen et al., 1998; Cleary, 2000; Hanks et al., 2001). The receptor is dephosphorylated within the endosome and returned resensitized to the membrane surface (or catabolized in the process of down-regulation) (Ventafridda et al., 1987). The degree of endocytosis is highly variable and depends on the opioid. Peptides and lipophilic alkaloid opioids (methadone and fentanyl) readily induce receptor endocytosis and recycling (Kristiansen, 2004). Clinically, both methadone and fentanyl have higher opioid intrinsic efficacy, and in some animal models reduced adenylyl cyclase superactivation associated with opioid tolerance (Schug et al., 1990; Agency for Health Care Policy and Research: Cancer Pain Management Panel, 1994; Sindrup and Brosen, 1995; Poulsen et al., 1996; McQuay and Moore, 1997; Mercadante, 1999). Morphine, on the other hand, is believed to activate MAPK resulting in opioid receptor phosphorylation and prevents internalization.

Genetic modulation of the response to opioid analgesics

Pharmacogenomics is currently an intensely studied area of medicine to which great hope and expectations are attached (Takeda, 1990). Research investigating the relationship between the genetic variability among individuals and susceptibility to disease, clinical symptoms or treatment responses has been growing exponentially.

There is considerable variability in response to opioid analgesics in clinical practice and in the balance of wanted and unwanted in individual patients. Pharmacogenetic factors are believed to play important roles in this variability. Possible candidates are polymorphisms in drug metabolizing enzymes, drug transporters, opioid receptors, or in the structures involved in the perception and processing of nociceptive information (Walker et al., 1988), all of which may result in the modulation of the pharmacokinetic or pharmacodynamic effects of opioid analgesics.

Candidate genetic polymorphisms are, of course, only identified on the basis of our current understanding of opioid analgesic mechanisms. Despite sufficient possible candidates with potential importance for pain therapy, evidence for a modulation of the effects of analgesics is only available for a few genes (Table 9.4.2). A variety of polymorphisms have been shown to be important for pain perception and processing and early work suggested that the mu-1 opioid receptor (*OPRM-1*) gene polymorphisms may relate to opioid dose requirements and side effects (de Crean et al., 1996). The numerous subtypes related to spice variants and alleles of the *OPRM-1* gene which result in genetic variations, helps explain the large intra-individual and inter-individual variation in response to the different mu agonist opioids (Pasternak, 2014). More than 100 polymorphisms have been identified in the human mu-opioid receptor gene alone, and some of these variants, such as the A118G nucleotide substitution, have been shown to alter the binding affinities of different opioids (Lötsch et al., 2002b; Beyer et al., 2004) and to effect analgesic outcomes (Chou et al., 2006; Hayashida et al., 2008; Zhang et al., 2010).

Identification of such polymorphisms in an individual patient would currently not provide an immediate individual therapeutic benefit. Benefit will only be obtained when pharmacogenetic testing provides a basis for individual drug selection or dosing. There are also polymorphisms which affect the plasma concentrations of analgesics but while this does not necessarily have any direct clinical implications as yet, the knowledge on the highly variable degree of codeine metabolism has influenced clinical prescribing in many countries (Lötsch, 2009).

Potential clinical applications

The substantial developments in the understanding of genetic polymorphisms, study of mutations affecting opioid receptors, activation, ligand response, and pain processing are of great interest, but as yet do not have direct clinical applications. The implications for clinical practice are that all known active pharmacogenetic variants would need to be tested.

One of the great challenges in translating pre-clinical and early clinical evidence to the clinic, especially concerning genetic modulation, is the undisputed complexity involved in pain perception in individual patients on the background of a heterogenous spectrum of pain syndromes along with environmental and behavioural factors. Improved, more robust clinical phenotyping is necessary in all genetic studies to allow better understanding and meaningful interpretation of any findings. Researchers and clinicians need to agree on well-defined, measurable end points and, of course, agree on how we will measure such end points (see also Chapter 19.1).

Table 9.4.2 Evidence for statistically significant pharmacogenetic modulation of the therapeutic effects of analgesic drugs and their consequences. The clinical significance of these effects has not been established

Gene	Frequency of affected subjects (%)	Affected analgesics (positive available evidence)
OPRM1 (mu opioid receptor)	17.2	Morphine (Goisis et al., 1989)
		M6G (Barnes and Goodwin, 1983; Rowell et al., 1983; Moore et al., 1997; Lötsch et al., 2002)
COMT (catechol-O-methyl transferase)	46.2	Morphine (Crome et al., 1984; Barnes et al., 1985)
	Protective to opioid central side effects	
MC1R (melanocortin-1 receptor)	2 (Inturrisi et al., 1982)	Morphine (Inturrisi et al., 1982)
	4.5	M6G (Inturrisi et al., 1982)
	4.3	Pentazocine (Beaver, 1984)
	3 (Inturrisi et al., 1982)	
CYP2D6 (cytochrome P450 2D6)	2 (Schug et al., 1990)	Codeine (Perrier and Gibaldi, 1972; Rosenberg et al., 1993; Lötsch et al., 2009)
	20.7 (Schug et al., 1990)	
	2 (Schug et al., 1990)	Tramadol (Zech et al., 1995)
	0.9 (Schug et al., 1990)	Codeine (McQuay and Moore, 1997; Mercadante 1999)
	0.1 (Schug et al., 1990)	
	0 (Schug et al., 1990)	
	2 (Schug et al., 1990)	
P-glycoprotein	47.6	Morphine (Kalso et al., 1998)
ABCB1 (adenosine triphosphate-binding cassette subfamily B member 1)	Protective to opioid central side effects	Morphine (Crome et al., 1984)
ABCB1 is also known as MDR-1 (multidrug resistance-1 gene)		

Opioid structure

The structures of opioid analgesics are diverse, although for most opioids it is usually the laevorotatory (*levo*)- stereoisomer that is the active compound. The structures of some of the common agents are shown. Those in current use include phenanthrenes (e.g. morphine), phenylpiperidines (e.g. fentanyl), and diphenylpropylamines (e.g. methadone). Structural modification affects agonist activity and alters physicochemical properties such as lipid solubility. Tertiary nitrogen is necessary for activity, separated from a quaternary carbon by an ethylene chain. Chemical modifications that produce quaternary nitrogen significantly reduce potency, due to decreased central nervous system (CNS) penetration. If the methyl group on the nitrogen is changed, antagonism of analgesia can be produced.

Other important positions for activity and metabolism, as seen on the morphine molecule, include the C-3 phenol group (the distance of this from the nitrogen affects activity) and the C-6 alcohol group. Potency may be increased by hydroxylation of the C-3 phenol; oxidation of C-6 (e.g. hydromorphone); double acetylation at C-3 and C-6 (e.g. diamorphine); hydroxylation of C-14 and reducing the double bond at C-7/8. Further additions at the C-3 OH group reduce activity. A short chain alkyl substitution is found in mixed agonist–antagonists, hydroxylation, or bromination of C-14 produces full antagonists, and removal or substitution of the methyl group reduces agonist activity (Hanks et al., 2001).

Pharmacokinetics and physicochemical properties

Knowledge of the specific physicochemical properties and pharmacokinetics of individual agents is important in determining the optimal route of drug delivery in order to achieve an effective receptor site concentration for an appropriate duration of action.

All opioids are weak bases. The relative proportion of free and ionized fractions is dependent on plasma pH and the pK_a of the particular opioid. The amount of opioid diffusing to the site of action (diffusible fraction) is dependent on lipid solubility, concentration gradient, and degree of binding. Plasma protein concentrations of albumin and acid glycoprotein as well as tissue binding determine the availability of the unbound, unionized fraction. This diffusible fraction moves into tissue sites in the brain and elsewhere; the amount reaching receptors is dependant not only on lipophilicity, but also the amount of non-specific tissue binding (e.g. CNS lipids).

The ionized, protonated form is active at the receptor site. This has important implications for speed and duration of activity. For example, morphine is relatively hydrophilic and penetrates the blood-brain barrier slowly. However, a large mass of any given dose eventually reaches the receptor site due to low levels of non-specific tissue-binding. This effect-site equilibration time ($t_{1/2}$keo) is measured by assessing the effect of opioids on the electroencephalogram. The offset time may also be prolonged with resultant longer duration of action than would be expected from the plasma $t_{1/2}$. Most opioids have a very steep dose–response curve. Therefore, if the dose is near the minimum effective analgesic concentration, very small fluctuations in plasma or effect-site concentrations can lead to large changes in the level of analgesia (Agency for Health Care Policy and Research: Cancer Pain Management Panel,1994).

Opioids tend to have a large volume of distribution (V_d) because of their high lipid solubility. A consequence of this can be that redistribution, particularly after a bolus dose or short infusion,

Table 9.4.3 Metabolism and excretion of some opioids

Drug	Metabolism	Faeces	Urine
Morphine	Glucuonidation Sulphation N-dealkylation	Trace	90% in 24 h (10% morphine; 70% glucuronides; 10% 3-sulphate; 1% normorphine; 3% normorphine glucuronide)
Codeine	O-demethylation Glucuronidation	Trace	86% in 24 h (5–10% codeine; 60% codeine glucuronide; 5–15% morphine (mainly conjugated); trace normorphine)
Diamorphine	O-deacetylation Glucuronidation	Trace	80% in 24 h (5–7% morphine; 90% morphine glucuronides; 1% 6-acetylmorphine; 0.1% diamorphine)
Buprenorphine	Glucuronidation N-dealkylation	70%. Mainly unchanged	2–13% in 7 days. Mainly N-dealkylbuprenorphine (and glucuronide), buprenorphine-3-glucuronide
Meperidine (pethidine)	N-demethylation Hydrolysis	No evidence of excretion	70% in 24 h (10% meperidine; 10% normeperidine; 20% mepridinic acid; 16% meperidinic acid glucuronide; 8% normeperidinic acid; 10% normeperidinic acid glucuronide; plus small amounts of other metabolites)
Methadone	N-dealkylation	30%	60% in 24 h (33% methadone; 43% EDDP; 10% EMDP plus small amounts of other metabolites)
Fentanyl	N-dealkylation Hydroxylation	9%	70% in 4 days (5–25% fentanyl; 50% 4-N-(N-proprionylanilino-piperidine) plus other metabolites)

can have significant effects on plasma concentrations. In addition, first-pass effects in the lung can remove significant amounts of drug from the circulation, reducing the initial peak plasma concentration. However, the drug re-enters the plasma several minutes later. Plasma concentrations of opioids such as fentanyl can be affected by this. Other lipophilic amines such as lidocaine and propranolol can be affected similarly and may reduce pulmonary uptake of co-administered opioids.

After prolonged infusion, significant sequestration in fat stores and other body tissues can occur for highly lipid soluble opioids. This is reflected in the 'context-sensitive $t_{1/2}$', that is, the time taken for the plasma concentration to fall by 50% after the infusion has stopped. The context-sensitive $t_{1/2}$ is increased after prolonged infusion for most opioids. For example, the elimination $t_{1/2}$ for fentanyl after bolus administration is 3–5 hours, but increases to 7–12 hours after prolonged infusion.

Most opioid metabolism occurs in the liver (phase I and II reactions) with the hydrophilic metabolites predominantly excreted renally, although a small amount may be excreted in the bile or unchanged in the urine. As a result, hepatic blood flow is one of the major determinants of plasma clearance. Metabolism of individual drugs is shown in Table 9.4.3. Enterohepatic re-circulation may occur when water-soluble metabolites excreted in the gut may be metabolized by gut flora to the parent opioid and then re-absorbed. Lipid soluble opioids may diffuse into the stomach, become ionized due to the low pH and then re-absorbed in the small intestine; this results in a secondary peak in plasma concentrations.

A summary of physicochemical and pharmacokinetic properties of some opioids is shown in Table 9.4.4. Metabolism (including production of active metabolites), distribution between different tissues, and elimination, all interact within individual subjects to produce clinically important actions at receptor sites. The physicochemical and pharmacokinetic properties of opioids can change when used for chronic pain relief.

Factors affecting pharmacokinetics include:

◆ *Age.* Age is important due to both pharmacokinetic and pharmacodynamic factors. Metabolism and volume of distribution are often reduced in the elderly, leading to increased free drug concentrations in the plasma. Hepatic blood flow may have declined by 40–50% by age 75, with reduced clearance of opioids. Increased CNS sensitivity to opioid effects is also found in the elderly.

◆ *Hepatic disease* has unpredictable effects, although there may be little clinical difference unless there is coexisting encephalopathy. Reductions in plasma protein concentrations will also have effects on plasma concentrations of free unbound drug.

◆ *Renal failure* may have significant effects for opioids with renally excreted active metabolites such as morphine and diamorphine.

◆ *Obesity* will result in a larger volume of distribution and prolonged elimination $t_{1/2}$.

◆ *Hypothermia, hypotension and hypovolaemia* may also result in variable absorption and altered distribution and metabolism of opioids.

Agonists, antagonists, potency, and efficacy

Based on their interactions with the various receptor subtypes, opioid compounds can be divided into agonist, agonist–antagonist, and antagonist classes (Table 9.4.5).

Agonists

An agonist is a drug that has affinity for and binds to cell receptors to induce changes in the cell that stimulate physiological activity. The agonist opioid drugs have no clinically relevant ceiling effect to analgesia. As the dose is raised, analgesic effects increase in a log linear function, until either analgesia is achieved or dose-limiting adverse effects supervene. Efficacy is defined by the maximal response induced by administration of the active agent. In practice, this is determined by the degree of analgesia produced following dose escalation through a range limited by the development of adverse effects. Potency, in contrast, reflects the dose–response relationship. Potency is influenced by pharmacokinetic factors (i.e. how much of the drug enters the body's systemic circulation and then reaches the receptors) and by affinity to drug receptors.

Table 9.4.4 Pharmacokinetic and physiochemical properties of some opioids

Opioid	pK_a	Protein binding (%)	Octanol: water partition coefficient	Terminal $t_{1/2}$ (h)	Clearance (mL/kg/min)	Volume of distribution L/kg	Duration of action (h)
Morphine	7.9	30	6	1.7–3.0	15–20	3–5	3–5
Oxycodone	8.5	45	0.7	3–4	13	2–3	2–4
Codeine	8.2	20	0.6	2–4	9–13	2.5–3.5	4–6
Meperidine	8.5	70	39	3–5	8–18	3–5	2–4
Fentanyl	8.4	90	813	2–4	10–20	3–5	1–1.5
Alfentanil	6.5	91	128	1–2	4–9	0.4–1	0.25–0.4
Remifentanil	7.3	70	18	0.1–0.2	40–60	0.3–0.4	2–5 min
Methadone	8.3	90	26–57	15–20	2	5	4–8

Table 9.4.5 Classification of opioids for pain management

Opioid type	Medications	Notes about therapy
Pure agonists	Codeine[a] Hydrocodone Dihydrocodeine Morphine Hydromorphone Fentanyl Oxycodone Oxymorphone Levorphanol Methadone Meperidine	Mainstay of therapy in many countries for moderate to severe cancer pain No clinically relevant ceiling effect to analgesia; as dose is raised, analgesic effects increase until analgesia is achieved or dose-limiting side effects supervene Meperidine and propoxyphene are not preferred due to potential effects of toxic metabolites Methadone must be used with caution; only clinicians who are knowledgeable about the risks posed by long and variable $t_{1/2}$, unpredictable potency, and potential for QTc prolongation should use this drug without guidance

Agonists–antagonists	Partial agonists:
	  buprenorphine
	Mixed agonist–antagonists:
	  butorphanol
	  dezocine
	  nalbuphine
	  pentazocine
		Agonists–antagonists include mu-receptor agonists with lower intrinsic efficacy (partial agonists) and drugs that have agonist effects at one opioid receptor and antagonist effects at another (mixed agonist–antagonists)
		Most were developed to be less attractive to individuals with the disease of addiction; this characteristic does not rationalize widespread use for cancer pain
		All have a ceiling effect for analgesia
		All have the potential to induce acute abstinence in patients with physical dependency to agonist opioids
		Some (pentazocine and butorphanol) have a high risk of psychotomimetic side effects.
		Buprenorphine is available in a transdermal patch and may be of use in relatively opioid-naïve cancer patients

Pure antagonists	Alvimopan Methylnaltrexone Naloxone Naltrexone Nalmefene	Compete with endogenous and exogenous opioids at mu-receptor sites. Administered for prevention or reversal of opioid effects Alvimopan and methylnaltrexone have been developed specifically to treat opioid-induced bowel dysfunction
Mixed mechanism drugs	Tramadol Tapentadol	Centrally acting analgesics that have agonist actions at the mu-receptor and block reuptake of monoamines

[a] With a greater understanding of the variable handling of codeine and larger number of step 3 opioid options, codeine use is declining in many countries.
Fig. 9.4.1 Dose-response curves for two full opioid agonists (A and B) similar in efficacy but different in potency (A is more potent than B).

Fig. 9.4.2 Dose–response curves for two full opioid agonists (A and B) and a partial opioid agonist C.

The concepts of efficacy and potency are illustrated in Fig. 9.4.1, which shows the dose–response curves for two drugs A and B. If the logarithm of dose is plotted against response an agonist will produce an S-shaped or sigmoid curve. The efficacy of the two drugs, defined by maximum response is the same. Drug A produces the same response as B but at a lower dose, and therefore is described as more potent.

Antagonist

Antagonist drugs have no intrinsic pharmacological action but can interfere with the action of an agonist. Competitive antagonists bind to the same receptor and compete for receptor sites, whereas non-competitive antagonists block the effects of the agonist in some other way.

Opioid antagonists

Naloxone (short acting) and naltrexone (long acting) are opioid antagonists and block mu, delta, and kappa receptors equally. They are generally only used to reverse respiratory depression associated with opioid overdose as they will also reverse analgesia. Recently, however, combined opioid and peripherally acting antagonist preparations such as oxycodone/naltrexone have been made available for the prevention/management of opioid-induced constipation.

Agonist–antagonist

The agonist–antagonist analgesics can, in turn, be subdivided into the mixed agonist–antagonists and the partial agonists, a distinction also based on specific patterns of drug–receptor interaction. Both the partial agonist and agonist–antagonist drugs have a ceiling effect for analgesia, and although they produce analgesia in the opioid-naive patient, in theory they can precipitate withdrawal in patients who are physically dependent on morphine-like drugs. For these reasons, they have been considered generally to have a limited role in the management of patients with cancer pain.

Mixed agonist–antagonists

The mixed agonist–antagonist drugs produce agonist effects at one receptor and antagonist effects at another. Pentazocine is the prototype agonist–antagonist: it has agonist effects at kappa receptors and weak mu antagonist actions. Thus, in addition to analgesia, pentazocine may produce kappa-mediated psychotomimetic effects not seen with full or partial mu agonists. When a mixed agonist–antagonist is administered together with an agonist, the antagonist effect at the mu receptor can generate an acute withdrawal syndrome.

Partial agonists
A partial agonist has low intrinsic activity (efficacy) so that its dose–response curve exhibits a ceiling effect at less than the maximum effect produced by a full agonist. Buprenorphine is the main example of a partial agonist opioid. Increasing the dose of such a drug above its ceiling does not result in any further increase in response. This phenomenon is illustrated in Fig. 9.4.2 in which C is a partial agonist. C is more potent than B (in the lower part of the curve it will produce the same response at a lower dose), but is less effective than both A and B because of its ceiling effect.

When a partial agonist is administered together with an agonist, displacement of the agonist can cause a net reduction in pharmacological action which may be sufficient to generate an acute withdrawal syndrome. Whilst this is a theoretical possibility with morphine and buprenorphine, no such interaction has been reported. Similarly, it has been suggested that the effects of morphine may be blocked in a patient switched from buprenorphine, because of the prolonged action of buprenorphine and the assumption that it will 'antagonize' the effect of morphine. This has been one of the reasons why buprenorphine has not been used in cancer pain management. However, the recent development of a transdermal formulation of buprenorphine may encourage its use in chronic cancer pain (and chronic non-cancer pain). An analgesic ceiling with buprenorphine is only reached at doses of 8–16 mg or more in 24 hours (Sindrup and Brosen, 1995). When used in usual recommended doses (for example, two patches of 70 micrograms/h of transdermal buprenorphine, equivalent to 3–4 mg per 24 hours) buprenorphine can be considered a full mu agonist since at these doses its effect will lie on the linear part of the dose–response curve.

Mixed mechanism drugs

Tramadol and tapentadol are both centrally acting analgesics whose mechanism of action depends on both mu agonism and monoamine (serotonin and norephinephrine (noradrenaline)) reuptake inhibition. There is no evidence that tramadol is superior to pure mu agonists for cancer pain (Wilder-Smith et al., 1994; Leppert, 2009). It is used widely in some countries as an alternative step 2 approach. Tapentadol is a relatively new drug with little evidence for use in cancer pain (Mercadante et al., 2013). The monoaminergic mechanism results in a ceiling dose with both of these drugs

Relative potency and equianalgesic doses

Relative potency is the ratio of the doses of two analgesics required to produce the same analgesic effect. By convention, the relative potency of each of the commonly used opioids is based upon a comparison with 10 mg of parenteral morphine. Data

from single- and repeated-dose studies in patients with acute or chronic pain have been used to develop an equianalgesic dose table (Table 9.4.6) that provides guidelines for dose selection when the drug or route of administration is changed. The information contained in the equianalgesic dose table does not represent standard doses, nor is it intended as an absolute guideline for dose selection. Many variables may influence the appropriate dose for an individual patient, including intensity of pain, prior opioid exposure in terms of drug, duration, and dose (and the degree of cross-tolerance that this confers), age, route of administration, level of consciousness, metabolic abnormalities (see following paragraphs), and genetic polymorphism in the expression of relevant enzymes or receptors. In particular, care should be exercised when switching from opioid to another as part of the management of opioid toxicity. In this situation highly conservative conversions should be used.

Dose–response relationship

As noted earlier, there is no ceiling to the analgesic effects of full agonist opioids. As the dose is raised, analgesic effects increase as a log linear function. In practice, the appearance of adverse effects, including confusion, sedation, nausea, vomiting, or respiratory depression, imposes a limit on the useful dose of an opioid agonist. Thus the efficacy of any particular drug in an individual patient will be determined by the degree of analgesia produced following dose escalation to intolerable and unmanageable side effects.

Section II: clinical aspects of opioid analgesia

The role of opioids in the management of cancer pain

Analgesic therapy with opioids, non-opioids, and adjuvant analgesics is developed for the individual patient through a process of continuous evaluation so that a favourable balance between pain relief and adverse pharmacological effects is maintained.

The analgesic ladder

An expert committee convened by the Cancer and Palliative Care Unit of the WHO proposed a structured approach to drug selection for cancer pain, which has become known as the 'WHO analgesic ladder' (Poulsen et al., 1996; WHO, 1996). When combined with appropriate dosing guidelines, this approach is capable of providing adequate relief to 70–90% of patients (Sawe et al., 1981a; Hoskin et al., 1989; De Conno et al., 1991; Kopp, 2000; Benyhe, 1994; St Charles et al., 1997; Innes et al., 1998). Emphasizing that the intensity of pain, rather than its specific aetiology, should be the prime consideration in analgesic selection, the approach advocates three basic steps (Fig. 9.4.3). This strategy should be integrated with non-pharmacological methods of cancer pain control including, radiotherapy, chemotherapy, hormone therapy, surgery, anaesthetic interventions, physiotherapy, and psychological/cognitive approaches:

◆ Patients with mild cancer-related pain should be treated with a non-opioid analgesic, which should be combined with adjuvant drugs if a specific indication for these exists. For example, a patient with mild to moderate arm pain caused by radiation-induced brachial plexopathy may benefit when a tricyclic antidepressant is added to paracetamol (acetaminophen) (Sawe et al., 1983; Gourlay et al., 1991).

◆ Patients who are relatively non-tolerant and present with moderate pain, or who fail to achieve adequate relief after a trial of a non-opioid analgesic, may be treated with an opioid conventionally used for mild to moderate pain (formerly known as a 'weak' opioid). This treatment is typically accomplished using a combination product containing a non-opioid (e.g. aspirin or paracetamol) and an opioid (such as codeine or oxycodone). This combination can also be coadministered with an adjuvant analgesic. The doses of these combination products can be increased until the maximum dose of the non-opioid analgesic is attained (e.g. 4000–6000 mg paracetamol); beyond this dose, the opioid contained in the combination product could be increased as a single agent, or the patient could be switched to an opioid conventionally used in step 3.

◆ Patients who present with severe pain, or who fail to achieve adequate relief following appropriate administration of drugs on the second step of the analgesic ladder, should receive an opioid conventionally used for moderate to severe pain (formerly known as a 'strong' opioid). This group includes morphine, diamorphine, fentanyl, oxycodone, phenazocine, hydromorphone, methadone, levorphanol, and oxymorphone. There is no inherent superiority of one opioid over another and treatment is individualized (Caraceni et al., 2012). These drugs may also be combined with a non-opioid analgesic or an adjuvant drug. Clearly, the boundary between opioids used in the second and third steps of the analgesic ladder is somewhat artificial since low doses of morphine or other opioids for severe pain can be less effective than high doses of codeine or propoxyphene.

According to these guidelines, a trial of opioid therapy should be given to all patients with pain of moderate or greater severity.

The evidence of the long-term efficacy of this approach and the evidence base underlying its recommendations has been the subject of criticism (Persson et al., 1992). However, this approach has been fundamental to improving cancer pain control on a worldwide basis. In recent years, application of the WHO ladder has been evolving in some countries towards omitting the second step. This is for several reasons:

1. Improved understanding of problems associated with the metabolism of codeine (Lötsch 2009)

2. A wider range of step 3 opioids and use of these drugs at a low dose instead of traditional step 2 opioids (Shimomura et al., 1971; Osborne et al., 1986; Pasternak et al., 1987; Paul et al., 1989; Caraceni, 2012).

3. An evolving suspicion that using a low dose of a step 3 opioid will be a more efficient way of controlling pain than starting at step 2 and moving upwards to a different drug. An international randomized controlled trial of the traditional three-step approach versus a two-step approach is underway (UK Clinical Research Network : Portfolio Database, n.d.).

Despite these reservations, the guiding principle that analgesic selection should be primarily determined by the severity of the pain remains sound, and continues to be widely endorsed (Paul et al., 1989; Osborne et al., 1992; Radbruch et al., 1996).

Opioid analgesics

The division of opioid agonists into 'weak' or 'strong' opioids, which was incorporated into the original analgesic ladder

Table 9.4.6 Opioid analgesics (pure mu agonists) used for the treatment of chronic pain

Morphine-like agonists	Equi-analgesic doses[a]	$t_{1/2}$ (h)	Peak effect (h)	Duration (h)	Toxicity	Comments	Oral bioavailability (%)	Active metabolites
Morphine	10 SC	2–3	0.5–1	3–6	Constipation, nausea, sedation most common; respiratory depression rare in cancer patients	Standard comparison for opioids; multiple routes available	20–30	M6G
	20–60 PO[b]	2–3	1.5–2	4–7				
Sustained-release morphine	20–60 PO[b]	2–3	3–4	8–12		Twice daily administration	20–30	M6G
Sustained-release morphine	20–60 PO[b]	2–3	4–6	24		Once-a-day morphine approved in some countries	20–30	M6G
Hydromorphone	1.5 SC	2–3	0.5–1	3–4	Same as morphine	Used for multiple routes	35–80	No
	7.5 PO	2–3	1–2	3–4				
Oxycodone	20–30	2–3	1	3–6	Same as morphine	Combined with aspirin or paracetamol (acetaminophen), for moderate pain in USA; available orally without non-opioid for severe pain	60–90	Oxymorphone
Sustained-release oxycodone	20–30	2–3	3–4	8–12				Oxymorphone
Oxymorphone	1 SC	—	0.5–1	3–6	Same as morphine	No oral formulation		Glucuronides
	10 PR	—	1.5–3	4–6				
Pethidine (meperidine)	75 SC	2–3	0.5–1	3–4	Same as morphine + CNS excitation; contraindicated in those on MAOIss	Not used for cancer pain due to toxicity in higher doses and short $t_{1/2}$	30–60	Norpethidine
Diamorphine	5 SC	0.5	0.5–1	4–5	Same as morphine	Analgesic action due to metabolites, predominantly morphine; only available in some countries		Morphine
Levorphanol	2 SC	12–16	0.5–1	4–6	Same as morphine	With long $t_{1/2}$, accumulation occurs after beginning or increasing dose		No
	4 PO							
Methadone[c]	10 SC	12–>150	0.5–1.5	4–8	Same as morphine	Risk of delayed toxicity due to accumulation; useful to start dosing on PRN schedule	60–90	No
	20 PO (see text)							
Codeine		2–3	1.5–2	3–6	Same as morphine	Usually combined with non-opioid	60–90	Morphine
	200 PO							

Table 9.4.6 Continued

Morphine-like agonists	Equi-analgesic doses[a]	$t_{\frac{1}{2}}$ (h)	Peak effect (h)	Duration (h)	Toxicity	Comments	Oral bioavailability (%)	Active metabolites
Propoxyphene HCl (dextropropoxyphene)	—	12	1.5–2	3–6	Same as morphine plus seizures with overdose	Toxic metabolite accumulates but not significant at doses used clinically; usually combined with non-opioid	40	Norpropoxyphene
Propoxyphene napsylate (dextropropoxyphene)	—	12	1.5–2	3–6	Same as hydrochloride	Same as hydrochloride	40	Norpropoxyphene
Hydrocodone	—	2–4	0.5–1	3–4	Same as morphine	Only available combined with paracetamol; only available in some countries		Hydromorphone
Dihydrocodeine	—	2–4	0.5–1	3–4	Same as morphine	Only available combined with aspirin or paracetamol in some countries	20	Morphine
Fentanyl	—	3–12	—	—	Same as morphine	Can be administered as a continuous IV or SC infusion; based on clinical experience, 100 micrograms/h is roughly equianalgesic to morphine 4 mg/h IV	25/buccal <2/oral	No
Fentanyl transdermal system	—	13–22	—	48–72	Same as morphine	Based on clinical experience 100 micrograms/h is roughly equianalgesic to morphine 4 mg/h; recent study indicates a ratio of oral morphine: transdermal fentanyl of 100: 1	90/transdermal	No

[a] Dose that provides analgesia equivalent to 10 mg IM morphine. These ratios are only guidelines when switching drugs or routes of administration.

[b] Extensive survey data suggest that the relative potency of IM: PO or SC: PO morphine of 1: 6 changes to 1: 2–3 with chronic dosing.

[c] When switching from another opioid to methadone, the potency of methadone is much greater than indicated in this table.

Fig. 9.4.4 The chemical structures of morphine and codeine.

proposed by the WHO, was not based on fundamental differences in their pharmacology, but rather reflected the customary manner in which these drugs were used. In this chapter, we will refer to opioids for mild to moderate pain and opioids for moderate to severe pain rather than 'weak' or 'strong' opioids. This terminology is now incorporated into the current version of the WHO analgesic ladder.

Opioids for mild to moderate pain

Codeine

Codeine (methylmorphine) is a naturally occurring opium alkaloid used as an analgesic, antitussive, and antidiarrhoeal agent (Fig. 9.4.4). Codeine is much less potent than morphine and produces its analgesic effects in part by binding to mu opioid receptors but with low affinity and, in part through biotransformation to morphine by cytochrome P450 (CYP) 2D6 (sparteine oxygenase) which exhibits genetic polymorphism. Approximately 7% of Caucasians lack CYP2D6 activity (poor metabolizers) due to inheritance of two non-functional alleles and in these individuals codeine has a diminished analgesic effect (Portenoy et al., 1991, 1992).

Codeine phosphate is absorbed well from the gastrointestinal tract, but oral bioavailability varies considerably between individuals (from 12% to 84% in one study (Vree and Verwey-van Wissen, 1992). The main metabolite is codeine-6-glucuronide, with much smaller amounts of norcodeine, morphine, and morphine 3- and 6-glucuronides also being produced (de Crean et al., 1996). The usual oral dose of codeine is 30–60 mg and its duration of action is 4–6 hours.

Codeine is not generally given as a single agent when used orally as an analgesic, but is usually combined with a non-opioid and recent systematic reviews confirm that the combination of codeine
and paracetamol is more effective than paracetamol alone (Peat et al., 1991; Penson et al., 2000a). A sustained-release formulation of codeine is available in some countries. When changing from regular administration of a codeine/non-opioid combination to morphine, patients receiving a total daily dose of 240–360 mg codeine are usually started on 60 mg morphine daily.

Dihydrocodeine

Dihydrocodeine is a semisynthetic analogue of codeine that is used as an analgesic, antitussive, and antidiarrhoeal agent. When administered by mouth, dihydrocodeine is equianalgesic to codeine. However, when administered parenterally, it is approximately twice as potent as codeine. This may be explained by the consistently poorer bioavailability of dihydrocodeine (20%), which probably results from hepatic pre-systemic metabolism (Moore et al., 1997).

The usual starting dose is 30 mg every 4–6 hours (by mouth), and this may be increased to 60 mg. However, dihydrocodeine appears to have a narrower therapeutic index than codeine, with a high incidence of adverse effects at the 60 mg dose. A controlled-release formulation of dihydrocodeine is available in several countries.

There have been a number of reports of severe toxicity associated with dihydrocodeine in patients with impaired renal function (Smith et al., 1990; Hanks 1991). The mechanism is not clear because of the limited data available on the pharmacokinetics of this drug, although it seems most likely that the cause is accumulation of active glucuronide metabolites, as occurs with morphine.

There is confusion about the relative analgesic potency of dihydrocodeine. It seems reasonable to assume that oral dihydrocodeine is roughly equipotent to oral codeine, and to use a similar conversion ratio when changing to morphine.

Dextropropoxyphene

Propoxyphene is a synthetic derivative of methadone, and its dextrorotatory stereoisomer dextropropoxyphene is responsible for its analgesic activity. Dextropropoxyphene is a mu agonist with low receptor affinity similar to that of codeine. It is readily absorbed from the gastrointestinal tract with peak serum levels about 2 hours after administration. The mean elimination $t_{1/2}$ is about 12 hours, with steady state levels being reached after 3–4 days of regular administration every 6–8 hours. The $t_{1/2}$ may be very long (over 50 hours) in elderly patients (Rowell et al., 1983).

Dextropropoxyphene undergoes extensive first-pass metabolism. Its principal metabolite is norpropoxyphene, which is active but penetrates the brain to a much lesser extent and has much weaker opioid effects. Norpropoxyphene has a longer $t_{1/2}$ (about 23 hours) than dextropropoxyphene itself and accumulates in

plasma (Barnes and Goodwin 1983). Norpropoxyphene accumulation is associated with excitatory effects, including tremulousness and seizures.

The analgesic efficacy and relative potency of dextropropoxyphene have been questioned. This is in part because single-dose studies comparing aspirin, paracetamol, and non-steroidal anti-inflammatory drugs (NSAIDs), including ibuprofen 400 mg, mefenamic acid 250 mg, and fenoprofen 50 mg, have shown dextropropoxyphene to be a less effective analgesic (Barnes et al., 1985). A more recent systematic review found that paracetamol alone is as effective as the combination of paracetamol with dextropropoxyphene though the studies included were again all single-dose studies (Crome et al., 1984). Single-dose studies may be misleading, as is the case with single-dose studies of oral morphine.

The extensive first-pass metabolism of dextropropoxyphene is dose-dependent such that the systemic availability of the drug increases with increasing oral doses (Perrier and Gibaldi, 1972). Thus, with regular administration, there is enhanced bioavailability and some degree of accumulation because of the long elimination half-lives of the parent drug and its main metabolite. Both dextropropoxyphene and norpropoxyphene reach plasma concentrations in the steady state which are five to seven times greater than those found after the first dose. There is, therefore, a pharmacokinetic basis for believing that repeated doses of dextropropoxyphene are likely to be more effective than single doses. The usual starting dose of morphine for patients receiving dextropropoxyphene–paracetamol combinations every 4–6 hours (representing 260–390 mg of dextropropoxyphene daily) is 60 mg per day.

For a long time, a combination of dextropropoxyphene and paracetamol was the most commonly prescribed analgesic in the United Kingdom and some Scandinavian countries, but it received much adverse publicity because of its lethal effects in overdose and fears about its addiction potential. Part of this concern was stimulated by its very widespread use. In addition to usual opioid adverse effects, propoxyphene may rarely induce a hepatotoxic reaction (Beaver 1984), cardiac conduction disorder (Li Wan Po and Zhang, 1997), and potentially dangerous drug interactions have been reported when propoxyphene has been administered along with carbamazepine (Perrier and Gibaldi, 1972), warfarin (Perrier and Gibaldi, 1972), or alcohol (Hantson et al., 1995). Currently, however, there is insufficient evidence to conclude that dextropropoxyphene is inherently more toxic than codeine or other opioids of similar efficacy, nor is there evidence that one is more effective than another. In the United Kingdom, dextropropoxyphene in combination with paracetamol has been removed from the general prescribing list because of an association with fatal drug overdose; however, dextropropoxyphene remains available in several countries.

Oxycodone

Oxycodone is a semi-synthetic congener of morphine, which has been on the market for 80 years but until relatively recently was only available in formulations which effectively circumscribed its use. In the United States, it has been prescribed in low-dose combination products with a non-opioid for oral administration (usually 5 mg of oxycodone with either aspirin or paracetamol) and has traditionally been used as a step 2 analgesic. Historically, it had only been used as a rectal suppository in the United Kingdom,

and had been widely used by mouth as a first line step 2 and 3 opioid in Scandinavia (Pippenger 1987).

Over the past 20 years, oxycodone has been produced as a single agent in new oral formulations, both normal release and sustained release, which has substantially improved the convenience of administration. In many countries sustained-release oxycodone is available in 5, 10, 20, 40, and 80 mg formulations with a corresponding range of normal-release formulations. Oxycodone is increasingly used as a step 3 opioid, though the low-dose formulations allow its use at step 2 also (Savarese et al., 1986; Poulain et al., 1988; Gourlay et al., 1997). Oxycodone probably provides the best example of the overlap in efficacy between opioids at steps 2 and 3; however, other opioids now also fulfil this role (see following paragraphs).

In some countries, it is available in a combination slow-release formulation with naloxone in a 2:1 ratio. There is evidence that at moderate doses this formulation is associated with a reduced prevalence and severity of constipation (Ahmedzai et al., 2012).

Tramadol

Tramadol is a centrally acting analgesic which possesses opioid agonist properties and may also activate monoaminergic spinal inhibition of pain (Justice and Kline 1988). It has modest affinity with mu opioid receptors, with weak affinity to delta and kappa receptors, and its analgesic effect is reversed by naloxone. Unlike other opioids, it also inhibits the uptake of noradrenaline and serotonin, and in an animal model systemically administered yohimbine or ritanserin blocks tramadol-induced analgesia, suggesting that this effect contributes significantly to the drug's analgesic action (Justice and Kline, 1988; Leppert 2009).

Tramadol can be administered orally, rectally, intravenously, subcutaneously, or intramuscularly. In many countries, it is available in both normal- and sustained-release formulations. Parenterally, 50–150 mg of tramadol is equianalgesic to 5–15 mg morphine (Whittington 1984). There are insufficient data for a reliable assessment of its oral-to-parenteral relative analgesic potency and estimates range from 1:4 to 1:10 (Kaiko et al., 1981; Ripamonti et al., 1997).

Oral tramadol has demonstrated efficacy in the management of chronic cancer pain of moderate severity (Kaiko et al., 1981; Davis and Walsh 2001). Few patients with severe pain are adequately managed by tramadol (Grochow et al., 1989; Ripamonti et al., 1997; Davis and Walsh 2001). Tramadol has a similar side effect profile to morphine, but may cause less constipation and respiratory depression at equianalgesic doses.

A systematic review demonstrates a lack of evidence to support the routine use of tramadol as a step 2 analgesic in cancer pain (Tassinari et al., 2011).

Tapentadol

Several mechanisms can be proposed to explain an apparent synergistic analgesic action between mu-opioid and α2-adrenergic receptor agonists. Combining both effects in a single molecule eliminates the potential for drug–drug interactions inherent in multiple drug therapy. Tapentadol is the first approved centrally acting analgesic having both mu-opioid receptor agonist and noradrenaline (norepinephrine) reuptake inhibition activity with minimal serotonin reuptake inhibition. This dual mode of action is of interest, however cancer pain studies with tapentadol are

awaited. Having limited protein binding, no active metabolites and no significant microsomal enzyme induction or inhibition, tapentadol has a limited potential for drug–drug interactions. Clinical trial evidence in acute and chronic non-cancer pain and neuropathic pain seems to support an opioid-sparing effect that reduces some of the typical opioid-related adverse effects (Hatrick and Rozek 2011; Riemsma et al., 2011).

While rapidly absorbed, the oral bioavailability of tapentadol under fasting conditions is only 32% due to an extensive first-pass effect (Tzschentke et al., 2006; LabelDataPlus, 2011). Only 20% of the drug is bound to plasma protein. Its $t_{1/2}$ of 4.9 hours permits achievement of steady-state concentrations at 25–30 hours when tapentadol is administered orally every 6 hours (Tzschentke et al., 2006, 2007). Extensive metabolism, primarily by the uridine diphosphate-glucuronosyltransferase (UGT) enzymes UGT1A9 and UGT2B7, results in renal elimination of inactive glucuronide or sulphate conjugates, with tapentadol-0-glucuronide being the major metabolite (Tzschentke et al., 2007; Kneip et al., 2008). Tapentadol follows first-order elimination kinetics over a wide range of conditions. Moderate hepatic dysfunction, however, warrants dose reduction (Xu et al., 2010; LabelDataPlus, 2011). Tapentadol is not recommended and should not be given to patients with severe hepatic dysfunction.

Since tapentadol is a noradrenaline reuptake inhibitor, it is contraindicated in patients receiving monoamine oxidase inhibitors (MAOIs) within the previous 14 days. Despite minimal serotonergic effect, theoretically a serotonin syndrome might be precipitated by concomitant use with serotonin noradrenaline reuptake inhibitor (SNRI), selective serotonin reuptake inhibitor (SSRI), TCA, MAOI, or serotonin 5-HT$_{IB/ID}$ receptor agonist (triptan) medications (LabelDataPlus, 2011).

The second step of the analgesic ladder

As previously described, by convention, formulations combining aspirin or paracetamol with a low dose of codeine, oxycodone, or propoxyphene have been recommended for pain of moderate intensity (step 2 of the analgesic ladder). This recommendation was pragmatic rather than evidence based. It reflected the concern that in many parts of the world it would be unacceptable to use morphine or other potent opioids for moderate pain.

The most frequently employed step 2 analgesics in cancer pain are combination preparations containing 300–500 mg paracetamol with 30 mg codeine, 32.5 mg dextropropoxyphene, or 5 mg oxycodone. The combination of dextropropoxyphene with paracetamol has been withdrawn in the United Kingdom and other parts of the world because of its lethal effects in overdose, and is much less used generally. Codeine plus paracetamol is still used in combination at step 2. As already discussed, the use of codeine is however evolving and is now used less frequently.

Studies comparing single doses of opioid/non-opioid combinations with various NSAIDs in postoperative pain have shown advantages for the latter in terms of greater efficacy and fewer adverse effects (Sawe et al., 1981b; Mercadante et al., 1996; Mathew and Storey, 1999). Chronic use of NSAIDs may negate any advantage in terms of unwanted effects, although at present there are no comparative data for chronic cancer pain. NSAIDs are increasingly employed as step 2 analgesics.

Given the limitations of the conventional approach many clinicians now use a variety of single agent opioid agonists, some

previously designated as 'step 3' opioids, in an appropriate dose, for moderate pain. Over recent years, sustained-release formulations of oxycodone, tramadol, and morphine in dose formulations appropriate for pain of moderate severity have become widely available and are now often used in this setting. This practice is supported by evidence of efficacy (Poulain et al., 1988; Bruera et al., 1991; Davis and Walsh, 2001).

The partial agonist opioid buprenorphine also may be used in this setting since it has recently become available in a transdermal formulation. A low-dose formulation of transdermal fentanyl (12 micrograms/hour) is designed for use in patients who may be opioid naive. More clinical trial data are required to clarify some of the issues surrounding these trends in opioid prescribing.

Opioids for moderate to severe pain

Morphine

Morphine is a potent mu-agonist drug that was first introduced into clinical use almost 200 years ago. It is the main naturally occurring alkaloid of opium derived from the poppy *Papaver somniferum* and is available for therapeutic use as the sulphate, hydrochloride, and tartrate. Recent evidence suggests that biosynthetic pathways for morphine exist in animal and human tissues such as liver, blood, and brain (Kalso et al., 1991). Its chemical structure is shown in Fig. 9.4.5. The WHO has placed oral morphine on the Essential Drug List, and preparations are available for oral, rectal, parenteral, and intraspinal administration.

Bioavailability

Morphine is available in four oral formulations: an elixir, a normal-release tablet, a modified-release tablet or capsule (of which there are now several preparations using different sustained-release mechanisms), and sustained-release suspensions. Absorption of morphine after oral administration occurs predominantly in the alkaline medium of the upper small bowel (morphine is a weak base) and is more or less complete. After oral administration, extensive pre-systemic elimination of the drug occurs predominantly in the liver. In healthy volunteers and cancer patients, the average bioavailability for oral morphine is 20–30% (Szeto et al., 1977; Umans and Inturrisi, 1982; Eisendrath et al., 1987). Like all other pharmacokinetic parameters, bioavailability demonstrates marked inter-individual variability. In patients with normal renal function the plasma $t_{1/2}$ (2–3 hours) is somewhat shorter than the duration of analgesia (4–6 hours). The pharmacokinetics remain linear with repetitive administration, and there does not appear to be autoinduction of biotransformation even following large chronic doses (Glare and Walsh, 1993). Rectal morphine bioavailability is similar to the oral route.

Morphine is relatively hydrophilic and, when administered epidurally or intrathecally, it is not rapidly absorbed into the systemic circulation. This results in a long $t_{1/2}$ in cerebrospinal fluid (90–120 minutes) and extensive rostral redistribution (Heiskanen and Kalso, 1997).

Morphine metabolism

About 90% of morphine is converted into metabolites (Fig. 9.4.5), principally the glucuronide conjugates morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G); minor metabolites include codeine, normorphine, and morphine ethereal sulphate. The liver appears to be the predominant site of metabolism in humans, although in animal models extrahepatic metabolism
Fig. 9.4.5 The metabolites of morphine.

has been demonstrated in the small bowel and the proximal renal tubule of rodents. These sites may become important where liver function is impaired. M3G is the major metabolite and in recent years there has been some controversy about its possible role as an opioid antagonist or in mediating some of the adverse effects of morphine.

Morphine-6-glucuronide

M6G binds to opioid receptors (Hanks and Hawkins, 2000) and produces potent opioid effects in animals (Houde 1986; Agency for Health Care Policy and Research: Acute Pain Management Panel, 1992; Sarhill et al., 2001) and humans (Brose et al., 1991; Moulin et al., 1991; Agency for Health Care Policy and Research: Acute Pain Management Panel, 1992; Hays et al., 1994). M6G excretion by the kidney is directly related to creatinine clearance (Raffa et al., 1992); its elimination $t_{1/2}$ is 2–3 hours in patients with normal renal function (similar to that of morphine) but becomes progressively longer with deteriorating function, resulting in significant accumulation (Raffa et al., 1992). In patients with impaired renal function, M6G may accumulate in blood and cerebrospinal fluid (Lee et al., 1993), and high concentrations of this metabolite have been associated with toxicity (Moulin et al., 1991, Dixon et al., 1983). These data warrant caution when administering morphine to patients with renal impairment. Patients who are receiving regular morphine and develop acute renal failure in a previously stable situation (e.g. a rapidly developing obstructive uropathy in a patient with pelvic malignancy) may develop a sudden onset of signs and symptoms of opioid toxicity, necessitating temporary withdrawal of the morphine and subsequent dose reduction, and/or less frequent administration.

M6G is thought to be a potent analgesic and studies in acute postoperative pain are currently ongoing. There are some, albeit limited, data to suggest that M6G has fewer side effects than morphine (van Dorp et al., 2008).

Morphine-3-glucuronide

For many years, it has been assumed that M3G is inert as is the case with most glucuronide metabolites (Wilder Smith et al., 1994). Behavioural studies in rodents, however, suggested that M3G produces a functional antagonism of the analgesic effects of morphine and its active metabolite M6G (Kaiko et al., 1996; Salzman et al., 1999). There is also some evidence in animal models that M3G may be responsible for the CNS excitatory adverse effects seen with morphine, such as myoclonus (Eddy and Lee, 1959; Wilder Smith et al., 1994).

It is now clear that M3G does not bind to opioid receptors. Data from electrophysiological animal models indicate no evidence of an antagonistic effect of M3G (Grond et al., 1999) and recent studies in human volunteers indicate that M3G appears to be devoid of significant activity (Moulin et al., 1988; Rogers, 1991a). In particular, there is no evidence of functional antagonism of morphine or M6G in humans and overall it seems that M3G plays no significant role in the pharmacodynamics of morphine.

Oral to parenteral relative potency

Single-dose studies of morphine in postoperative cancer patients demonstrated an oral-to-intramuscular potency ratio of 1:6 (Petzke et al., 2001). However, empirical clinical practice using chronically administered oral morphine in cancer patients has generated a different ratio of 1:3 or 1:2 (Hess et al., 1972; Mather, 1983). The reason for the discrepancy between relative potency estimates derived from single-dose versus chronic dosing studies is probably associated with both methodology (Radbruch et al., 1996) and the pharmacokinetics and pharmacodynamics of M6G (McEvoy et al., 1996). It is possible that M6G accumulation relative to morphine may be greater with oral than with parenteral administration; this would lead to an increase in the relative potency of the orally administered drug when given on a chronic basis.

The important principle for clinical practice is that there is a difference in relative analgesic potency when the route of administration is changed, and that adjustment of dose is necessary in order to achieve an equivalent effect and to avoid either underdosing or toxicity. The usual practice when converting from oral morphine to subcutaneous morphine (or diamorphine) is to divide the oral dose by two or three (Osborne et al., 1986).

Parenteral morphine

The inorganic salts of morphine (morphine sulphate and morphine hydrochloride) have limited solubility. Standard formulations are available up to 20 mg/mL, and morphine can be constituted from lyophilized power up to 50 mg/mL. Morphine tartrate is substantially more soluble and, in some countries, is formulated in a concentration of 80 mg/mL.

Sustained-release morphine preparations

The development of modified-release morphine preparations has had a major impact on clinical practice. These preparations, which are usually administered on a 12-hour schedule, provide a much more convenient means of administering oral morphine (St Charles et al., 1997). Several preparations are available worldwide with a range of dose formulations (10, 15, 30, 60, 100, and 200 mg depending on the country), allowing considerable flexibility in their use. Some preparations allow once-daily administration

and sustained-release suspensions are also available (Innes et al., 1998).

In contrast with morphine solution or normal-release tablets, where peak plasma concentrations are achieved within the first hour followed by a rapid decline and an elimination $t_{1/2}$ of 2–4 hours, sustained-release morphine typically achieves peak plasma concentrations 3–6 hours after administration, the peak is attenuated, and plasma concentrations are sustained over a 12- or 24-hour period (Portenoy et al., 1993; Jeal and Benfield, 1997; Megens et al., 1998). The type and incidence of adverse effects with sustained-release morphine and normal-release oral morphine appear to be similar with the currently available formulations.

Although some clinicians advocate the use of sustained-release morphine when initiating morphine therapy in cancer patients, a normal-release preparation is generally recommended in the dose titration period (Caraceni et al., 2012).

Initial dose titration using sustained-release morphine is difficult because of the delay in achieving peak plasma concentrations, the attenuation of peak concentrations, and the long duration of action. In this situation, dose finding is performed more efficiently with a short-acting morphine preparation. Once the effective dose is identified using a normal-release formulation, this may be changed to a sustained-release preparation using a milligram-to-milligram conversion. For the same reasons, sustained-release morphine is not appropriate for the treatment of acute pain or 'breakthrough' pain (BTP). A normal-release morphine preparation should be provided to patients stabilized on sustained-release morphine to be used 'as required' for BTP.

Diamorphine (heroin)

Diamorphine (diacetylmorphine) is a semi-synthetic analogue of morphine and has a long tradition of use for cancer pain in the United Kingdom. It is only available for legal medicinal use in the United Kingdom and Canada.

Following oral administration of diamorphine, only morphine can be measured in the patient's blood. The use of oral diamorphine is an inefficient way of delivering morphine to the systemic circulation. There is no good basis to believe that there is any difference between these two drugs when given by mouth. Sublingual administration of diamorphine has been advocated by some but, as discussed below, this route is not appropriate for either morphine or diamorphine because of poor absorption. It has been thought that diamorphine does not itself bind to the mu opioid receptor but must be biotransformed to 6-acetylmorphine and morphine to produce its analgesic effect (Kopp, 2000). However, recent studies with mor-knockout mice seem to indicate that it does not produce its effects through mu receptor binding and may have effects at other receptors (Benyhe, 1994). This may explain some of the pharmacodynamic differences between morphine and diamorphine when given parenterally.

Since diamorphine is more soluble and lipophilic than morphine, it does have some advantages for parenteral administration. When administered by subcutaneous or intramuscular injection, diamorphine is approximately twice as potent as morphine. There are also differences between diamorphine and morphine administered by intravenous injection: diamorphine has a marginally quicker onset of action, produces greater sedation, and possibly less vomiting (Sawe et al., 1981a). This may be explained by different receptor binding. The greater solubility of diamorphine (shared also with hydromorphone and morphine tartrate)

is of particular advantage for patients who require large doses of subcutaneous opioids.

Methadone

Methadone is a synthetic opioid with an oral-to-parenteral potency ratio of 1:2 and an oral bioavailability greater than 85%. In single-dose studies, methadone is only marginally more potent than morphine; however, with repeated administration it is several times more potent. Methadone has a very long plasma $t_{1/2}$, averaging approximately 24 hours (with a range from 12 to over 150 hours) (Hoskin et al., 1989; Gourlay et al., 1991). Whereas most patients can be well controlled on 8–12-hour dosing, some patients require dosing at a 4–8-hour interval to maintain analgesic effects (Sawe et al., 1983). Methadone may be a useful alternative to morphine, but its safe administration requires knowledge of its pharmacology and experience of its use.

After treatment is initiated or the dose is increased, plasma concentration rises over a prolonged period, and this may be associated with a delayed onset of side effects. Consequently, patients must be followed closely until there is reasonable certainty that a steady state plasma concentration has been approached (approximately 1 week). Serious adverse effects can be avoided if the initial period of dosing is accomplished with 'as needed' administration (Max et al., 1985). When steady state has been achieved, scheduled dose frequency should be determined by the duration of analgesia following each dose (Paul et al., 1989).

Oral and parenteral preparations of methadone are available. Subcutaneous infusion is possible (Shimomura et al., 1971) but caution is required since local skin toxicity may be a problem (Pasternak et al., 1987).

The equianalgesic dose ratio of morphine to methadone has been a matter of confusion and controversy. Data from cross-over studies with morphine and methadone and hydromorphone and methadone indicate that methadone is much more potent than previously described in literature, and that the ratio correlates with the total opioid dose administered before switching to methadone (Osborne et al., 1986). Among patients receiving oral equivalent doses of morphine (< 90mg/daily), the ratio is 4:1, a ratio of 8:1 for patients receiving 90–300 mg/day and for patients receiving greater than 300 mg morphine/day, a ratio of 12:1 should be used (Benitez-Rosario et al., 2009; Chatham et al., 2013).

Pethidine (meperidine)

Pethidine is a synthetic opioid with agonist effects similar to those of morphine but a profile of potential adverse effects that limits its utility as an analgesic for chronic cancer pain. Intramuscular pethidine 75 mg is equivalent to 10 mg of intramuscular morphine. Pethidine has an oral bioavailability of 40–60%, and its oral-to-parenteral potency ratio is 1:4. It is more lipophilic than morphine, and produces a faster onset and shorter duration of analgesia of 2–3 hours.

Pethidine is *N*-demethylated to norpethidine, which is an active metabolite that is twice as potent as a convulsant and half as potent as an analgesic compared with its parent compound. Accumulation of norpethidine after repetitive dosing of pethidine can result in central nervous system excitability characterized by subtle mood effects, tremors, multifocal myoclonus, and occasionally, seizures (Osborne et al., 1992; Portenoy et al., 1992). Naloxone does not reverse pethidine-induced seizures, and it is possible that its administration to patients receiving pethidine

chronically could precipitate seizures by blocking the depressant action of pethidine and allowing the convulsant activity of norpethidine to become manifest (Portenoy et al., 1991). If naloxone is necessary in this situation, it should be diluted and slowly titrated while appropriate seizure precautions are taken.

Selective toxicity of pethidine can also occur following administration to patients receiving monoamine oxidase inhibitors. This combination may produce a syndrome characterized by hyperpyrexia, muscle rigidity, and seizures which may occasionally be fatal (D'Honneur et al., 1994). The pathophysiology of this syndrome is related to excess availability of serotonin at the 5-HT_{1A}-receptor in the central nervous system.

Although accumulation of norpethidine is most likely to affect patients with overt renal disease, toxicity is sometimes observed in patients with normal renal function. These potential adverse effects contraindicate pethidine for the management of chronic cancer pain. Given the availability of alternative drugs that lack these toxicities, its use in acute pain management is also not recommended (Lehmann and Zech, 1992).

Hydromorphone

Hydromorphone is another morphine congener. It is about five times more potent than morphine and can be administered by the oral, rectal, parenteral, and intraspinal routes. Its oral bioavailability varies from 35% to 80% (Peat et al., 1991). Its $t_{\frac{1}{2}}$ is 1.5–3 hours and it has a short duration of action. Although it is largely excreted unchanged by the kidney, it is partially metabolized in the liver to a 3-glucuronide, which is excreted by the kidneys (Peat et al., 1991; Penson et al., 2000a).

Its solubility, the availability of a high-concentration preparation (10 mg/mL), and high bioavailability by the subcutaneous route (78%) make it particularly suitable for subcutaneous infusion (Penson et al., 2000b). In the United States, it is routinely available in oral, rectal, and injectable formulations, and a sustained-release oral formulation (Hanks 1991).

For patients who require very high opioid doses via the subcutaneous route, hydromorphone can be constituted in concentrations of up to 50 mg/mL from lyophilized powder. It has also been administered via the epidural and intrathecal routes to manage acute and chronic pain. In fact for newer intrathecal pump devices, hydromorphone rather than diamorphine should be used because of device interactions with the latter. Hydromorphone is hydrophilic and, when administered via the epidural route, its pharmacokinetic profile, including its long $t_{\frac{1}{2}}$ and extensive rostral distribution in cerebrospinal fluid, is similar to that of morphine (Smith et al., 1990).

The equianalgesic ratio of parenteral morphine to hydromorphone has been a matter of controversy. There is evidence that potency ratios for hydromorphone are not bidirectional. An equianalgesic ratio of 7:1 is quoted when switching from morphine to hydromorphone but ratios of 4:1–8:1 are reported when switching in the other direction. The reported oral equianalgesic ratio for morphine to hydromorphone is 7.5:1, so when converting from oral to subcutaneous hydromorphone, the dose should be divided by two, presuming an oral to parenteral potency ratio for morphine of 1:2 (Gong et al., 1992).

Although some studies suggest a more favourable side effect profile than morphine, there is conflicting evidence. It is highly likely, as with all opioids, that it will depend on the individual patient. Systematic reviews of hydromorphone in cancer pain did not find any significant differences between hydromorphone and oxycodone for acute and chronic pain (Yaksh and Harty, 1987) and place it clearly as an alternative to morphine with no inferiority nor superiority (Pigni et al., 2011).

Levorphanol

Levorphanol is a morphine congener with a long $t_{\frac{1}{2}}$ (12–16 hours) (Labella et al., 1979). It shares a number of pharmacological properties with methadone. It is five times more potent than morphine and has an oral-to-parenteral potency ratio of 1:2 (Hewett et al., 1993). Like methadone, the discrepancy between plasma $t_{\frac{1}{2}}$ (12–16 hours) and duration of analgesia (4–6 hours) may predispose to drug accumulation following the initiation of therapy or dose escalation. Although dose titration needs to be done carefully in the opioid-naive patient, problems with drug accumulation appear to be less than those produced by methadone.

In the United States, levorphanol is generally used as a second-line agent in patients with chronic pain who cannot tolerate morphine. The possibility that this drug may be particularly useful in morphine-tolerant patients has been proposed on the basis of its affinity for kappa and delta receptors that are presumably not involved in morphine analgesia (Penson et al., 2001). It seems also to have NMDA antagonist activity. It is no longer available in the United Kingdom or Canada.

It has been suggested that because of the unique properties of levorphanol, it may prove useful to re-evaluate this drug in clinical studies (McNulty, 2007; Prommer, 2007).

Oxycodone

As previously described, oxycodone is a synthetic morphine congener that has a high oral bioavailability (60–90%) and an analgesic potency 30–50% greater than morphine (Houde et al., 1965; Hanks et al., 1987). Since the development of sustained-release formulations in doses suitable for severe pain, it is now widely used for this indication. The sustained-release formulation is available in a wide range of dose formulations (5, 10, 20, 40, and 80 mg) (Hanks and Hawkins, 2000) and has a duration of action of 8–12 hours. The sustained-release formulation achieves effective therapeutic levels within an hour (Kaiko, 1996) and appears to be suitable for dose titration (Salzman et al., 1999).

Oxycodone pectinate is available in the United Kingdom as a 30 mg rectal suppository which has a delayed absorption and prolonged duration of effect (Kaiko, 1986).

There has been confusion about the relative efficacy of oxycodone. It had been viewed primarily as a 'step 2' opioid because it had for long been available in low dose in combination products with non-opioid analgesics. It seems clear that the relative potency of oxycodone has been underestimated in early clinical studies in which it appeared to be less potent than morphine. Subsequent studies indicate that it is more potent, in a ratio of about 1.5:1 (Bruera et al., 1998).

There remains uncertainty also about the role of its active metabolite oxymorphone which accounts for 10% of its metabolites, in mediating the effects of oxycodone. However, current evidence suggests that the metabolites of oxycodone including oxymorphone do not contribute significantly to its pharmacological effects (Hanks, 1989).

A recent systematic review of oxycodone in cancer pain concluded that there is no evidence of a significant difference in

analgesia or adverse effects between oxycodone and morphine or hydromorphone (King et al., 2011).

Oxymorphone

Oxymorphone is a lipophilic congener of morphine formerly available as a rectal formulation. It is now available in the United States in oral normal- and sustained-release preparations. It has a predictable dose response and linear pharmacokinetics. The injectable formulation is ten times more potent than morphine (Forman et al., 1993). The plasma $t_{1/2}$ of oxymorphone is 1.2–2 hours, and its duration of action is 3–5 hours. It is less likely to produce histamine release than morphine (Savarese et al., 1986), and may be particularly useful for patients who develop itch in response to other opioids (Poulain et al., 1988). It is not metabolized through CYP3A4 or CXP2D6 which is useful for avoiding drug–drug interactions.

A pilot of the effectiveness and safety of oral extended-release oxymorphone for the treatment of cancer pain, reported favourably. Patients stabilized on CR morphine or CR oxycodone were safely and rapidly converted to a lower milligram dose of oxymorphone ER that provided adequate pain relief with similar tolerability (Sloan et al., 2005; Slatkin et al., 2010).

Oxymorphone is currently not available in the United Kingdom.

Fentanyl

Fentanyl is a semi-synthetic opioid and is a highly selective mu agonist (Gourlay et al., 1997) that is about 80 times as potent as parenteral morphine in the non-tolerant acute pain patient. It is also extremely lipophilic and is extensively taken up into fatty tissue (Inturrisi et al., 1984). Its elimination $t_{1/2}$ ranges from 3 to 12 hours and is influenced by the duration of prior administration and the extent of fat sequestration. Fentanyl has been used mainly as an intravenous anaesthetic agent and continues to be used parenterally as a pre-medication for painful procedures and in continuous infusions. When used intravenously, fentanyl has a very short duration of action of 0.5–1 hours. This is related to the rapid re-distribution of the drug into body tissues rather than to hepatic and renal elimination (Pasternak and Standifer, 1995). The development of a transdermal system and an oral transmucosal formulation has broadened the clinical utility of fentanyl for the management of cancer pain.

Transdermal fentanyl

The low molecular weight and high lipid solubility of fentanyl facilitate absorption through the skin and a transdermal formulation that delivers 12.5, 25, 50, 75, or 100 micrograms/hour is widely available (Kaiko et al., 1981; Ripamonti et al., 1997; Davis and Walsh, 2001). Modern formulations incorporate the fentanyl in the adhesive matrix. The drug is released at a nearly constant amount per unit time along a concentration gradient from the patch to the skin. After application of the transdermal system, serum fentanyl concentration increases gradually, usually levelling off after 12–24 hours, and then remaining stable for a time before declining slowly. When the patch is removed, serum concentration falls 50% in approximately 17 hours (range 13–22 hours) (Grouchow et al., 1989). The slow onset of effect after application and an equally slow decline in effect after removal are consistent with the development of a subcutaneous depot of drug that maintains the plasma concentration. There is significant interindividual variability in fentanyl bioavailability by this route

and dose titration is necessary (Grouchow et al., 1989). The dosing interval for each system is usually 72 hours, but interindividual pharmacokinetic variability is large and some patients require a dosing interval of 48 hours (Sawe et al., 1981b; Gibbs, 2009; Yang et al., 2010).

Familiarity with the kinetics of the transdermal system is essential for optimal use. Since there is a delay of 8–12 hours in achieving effective analgesia after initial application of the patch, it is necessary to provide alternative analgesia for this initial period. It is prudent to apply the patch in the early hours of the day so that the patient can be observed as blood levels rise over the ensuing 12 hours to minimize the risk of overdosing during sleep. Significant concentrations of fentanyl can remain in the plasma for up to 24 hours after removal of the patch because of delayed release from tissue and subcutaneous depots. Neither age nor patch location appears to affect fentanyl absorption from the transdermal system (Davis and Walsh, 2001). There is a potential for temperature-dependent increases in fentanyl release from the system associated with increased skin permeability in patients with fever, who should be monitored for opioid side effects. Patients should also avoid exposing the patch to direct external heat.

Empirically, the indications for the transdermal route include intolerance of oral medication, poor compliance with oral medication, and occasionally the desire to provide a trial of fentanyl to patients who have reacted unfavourably to other opioids. However, there are a number of limitations. The delay in onset of analgesia and in the establishment of steady state blood levels require the liberal use of an alternative short-acting opioid (usually morphine) for breakthrough pain during the early treatment period. Because of its 3-day duration of action, transdermal fentanyl is generally unsuitable for patients with unstable pain, and if a patient's pain goes out of control management may be complicated because of the delay in re-establishing steady state. If dose reductions are required or discontinuation is indicated, the continuing absorption following patch removal must be taken into account. Poor patch adhesion may be a problem in some patients. Set against these considerations are the advantages in terms of convenience and compliance and there is high patient acceptability of this mode of administration. Additionally there are experimental and clinical data to suggest that transdermal fentanyl is associated with less constipation than morphine (Mercadante et al., 1996).

Empirical observations suggest that a 100-microgram/hour fentanyl patch is approximately equianalgesic to 2–4 mg/hour of intravenous morphine (or equivalent). The relative potency ratio that is applicable when converting patients from oral morphine to transdermal fentanyl has been the subject of some controversy, but the dosing recommendations of the manufacturer seem provide a reasonable guideline. The patch should be placed in an area where skin movement is limited, such as the upper anterior chest wall or either side of the midline on the back, preferably the lower back. Studies have shown that all areas of skin absorb the drug at roughly the same rate (Davis and Walsh, 2001). Since the adhesive strips on these patches are less than optimal, securing the patch with non-irritant tape is often necessary.

Transdermal fentanyl currently recommended for patients whose opioid requirements are stable (Caraceni et al., 2012) and in general it is likely to be a second-line choice. However, for suitable patients it works well and they like it (Mathew and Storey, 1999).
Fig. 9.4.6 Pain relief gap.

Oral transmucosal fentanyl citrate (OTFC)

An oral transmucosal formulation of fentanyl (which incorporates the drug in a hardened lozenge on a stick) that is absorbed across the buccal mucosa, has been available in many countries since the 1990s for the management of BTP. The lozenge is rubbed gently against the inside of the cheek until it has dissolved. The formulation is rapidly absorbed and achieves blood levels and time to peak effect that are comparable to parenterally administered fentanyl. Indeed, the time to onset of analgesia is 5–10 minutes (Eisendrath et al., 1987; Bruera et al., 1991; Szeto et al., 1997; Ripamonti et al., 1998), and studies in cancer patients suggest that it can provide rapid and very effective relief of BTP in well-chosen patients Formulations incorporating 200, 400, 600, 800, and 1600 micrograms are available. The most common adverse effects associated with this formulation are somnolence, nausea, and dizziness. One interesting observation which has emerged from the clinical trials and clinical use is that the successful dose of OTFC cannot be predicted and is not directly related to the daily dose of regular opioids being received for background pain.

OTFC was followed by a variety of other fentanyl preparations for BTP which are discussed below.

The oral immediate-release opioids have an extensive first-pass effect and are hydrophilic in nature, which slows the onset of analgesia to approximately 30 minutes and more. By the time these agents reach their peak of effect the pain has usually already resolved, unless of course the BTP is of longer duration (Fig. 9.4.6).

Rapid-onset oral fentanyl preparations

These are given either by the buccal or the sublingual route with the primary rationale being that the oral mucosa is very permeable. Although the oral mucosa is constantly washed by saliva which may disturb placement of devices like adhesive discs, its higher permeability could produce rapid onset of action and makes this an appropriate route for drugs administered for the management of BTP. Various formulations exist including fentanyl buccal tablets (FBT), OTFC as described above, and sublingual fentanyl citrate oral disintegrating tablet (ODT).

A Cochrane review examined opioids for the management of breakthrough (episodic) pain in cancer patients (Zeppetella and Ribeiro, 2006). As is the case with the methodology employed in Cochrane reviews, results were limited to randomized studies resulting in only four trials meeting the inclusion criteria (Christie et al., 1998; Farrar et al., 1998; Portenoy et al., 1999b; Coluzzi et al., 2001). All four studies involved OTFC and this was shown to be superior to placebo, normal-release morphine, and previously used rescue medications. A mixed treatment analysis

has also been conducted which demonstrated that FBT, ODT, and OTFC are more efficacious than oral morphine for breakthrough cancer pain (Jandhyala et al., 2013).

Rapid-onset nasal fentanyl preparations

The other main route of administering fentanyl is nasally. The nasal preparations are either unmodified fentanyl which results in a high, early peak or fentanyl in a pectin which also results in an early peak but the peak is attenuated due to the pectin delivery system. The unmodified fentanyl spray, intranasal fentanyl spray (INFS), has been shown to provide clinically relevant reductions in pain intensity and superior efficacy to OTFC (Kress et al., 2009; Mercadante et al., 2009). The pectin-based preparation fentanyl pectin nasal spray (FPNS) has also been shown to be superior to placebo and morphine in breakthrough pain (Taylor et al., 2010; Fallon et al., 2011).

Other drugs

Drugs such as phenazocine, dextromoramide, and dipipanone are now largely obsolete in chronic pain management.

Agonist–antagonist opioid analgesics

The agonist–antagonist opioid analgesics are a heterogeneous group of drugs with moderate-to-strong analgesic activity, comparable with that of the agonist opioids such as codeine and morphine. The group includes drugs which act as an agonist or partial agonist at one receptor and as an antagonist at another (pentazocine, dezocine, butorphanol, nalbuphine)—'the mixed agonist–antagonists'—and drugs acting as a partial agonist at a single receptor (buprenorphine). These two groups of drugs can be also classified as nalorphine- or morphine-like. Meptazinol fits neither classification and occupies a separate category. The place of this group of drugs in chronic cancer pain has been limited (Brose et al., 1991). However, the recent development of a transdermal formulation of buprenorphine may allow its more widespread use in both chronic cancer and non-cancer pain.

Mixed agonist–antagonist analgesics

The agonist–antagonists produce analgesia in the opioid-naive patient but may precipitate withdrawal in patients who are physically dependent on morphine-like drugs. Therefore, when used for chronic pain, they should be tried before repeated administration of a morphine-like agonist drug.

Pentazocine, butorphanol, and nalbuphine are mu antagonists and kappa agonists or partial agonists. All three drugs are strong analgesics when given by injection: pentazocine is one-sixth to one-third as potent as morphine, nalbuphine is roughly equipotent with morphine, and butorphanol is 3.5–7 times as potent. The duration of analgesia is similar to that of morphine (3–4 hours). Oral pentazocine is closer in analgesic efficacy to aspirin and paracetamol than the weaker opioid analgesics, such as codeine. Neither nalbuphine nor butorphanol is available as an oral formulation, and butorphanol is no longer available in any form in the United Kingdom.

At usual therapeutic doses, nalbuphine and butorphanol have respiratory depressant effects equivalent to that of morphine (although the duration of such effects may be longer with butorphanol). Unlike morphine, there appears to be a ceiling to both the respiratory depression and the analgesic action.

All three drugs have a lower abuse potential than the agonist opioid analgesics such as morphine. However, all have been subject to abuse and misuse, and pentazocine (but not the others) is subject to controlled drug restrictions. In North America, the oral preparation of pentazocine is marketed in combination with naloxone (but is available without naloxone elsewhere).

Meptazinol is a synthetic hexahydroazepine derivative with opioid agonist and antagonist properties, but is unlike either the nalorphine-type agonist–antagonists or buprenorphine. Meptazinol has central cholinergic properties which may account at least in part for its analgesic effects. Receptor-binding studies show it to be a specific mu1 agonist. Meptazinol is one-tenth as potent as morphine by intramuscular injection and has a duration of action of about 4 hours. Some studies have shown adverse effects to be more frequent than with morphine, although respiratory depression and constipation appear to be less.

In therapeutic doses, the mixed agonists–antagonists may produce certain self-limiting psychotomimetic effects in some patients; pentazocine is the most common drug associated with these effects. These drugs play a very limited role in the management of chronic cancer pain because the incidence and severity of the psychotomimetic effects increase with dose escalation, and nalbuphine and butorphanol are only available for parenteral use.

A transnasal formulation of butorphanol is now on the market in the United States, but there is no reported experience of its use in the management of chronic cancer pain.

Partial agonist analgesics

Buprenorphine is a semi-synthetic derivative of thebaine and chemically closely related to the strong agonist etorphine. Buprenorphine is a true partial agonist at the mu receptor and exhibits a ceiling effect in dose response curves in various animal models. In some, a bell-shaped curve is seen, indicating that at doses above a certain level the pharmacological effect actually decreases with increasing dose (Collins et al., 1996). Buprenorphine has until recently only been available by injection or for sublingual administration. A dose of 0.4 mg sublingually gives similar analgesia to 0.2–0.3 mg intramuscularly, with an onset of analgesia within 30–60 minutes of administration and a duration of 6–9 hours (Lawlor et al., 1997). In contrast, if taken orally, buprenorphine is a poor analgesic due to extensive pre-systemic elimination (Dixon et al., 1983). The long duration of analgesia with buprenorphine may be related to its affinity for the mu-opioid receptor and an unusually slow dissociation constant for the drug–receptor complex.

Buprenorphine has been in clinical use for more than 30 years and has been evaluated in a variety of acute pain models. Direct single dose comparisons with other analgesics such as morphine is complicated by its long duration of action, but results from a number of studies in postoperative pain suggest that single doses of 0.3 mg buprenorphine parenterally or 0.4 mg sublingually give equivalent analgesia to 10–15 mg intramuscular morphine. A ceiling effect for analgesia in humans has not been clearly demonstrated.

Buprenorphine produces typical opioid adverse effects. Overall the available data (which are limited) suggest that the incidence of common adverse effects compared with morphine is similar. Naloxone appears to be relatively ineffective in reversing opioid effects due to buprenorphine (Wallenstein et al., 1986). Clinical experience does not necessarily agree with this. Buprenorphine was introduced in high-dose sublingual tablet formulations in 1999 for the management of drug dependence. This potential use of the drug has long been recognized (Moulin et al., 1988) and it has been suggested that there is less overdose risk compared with other opioids (Kalso and Vainio, 1990).

Buprenorphine is available in a patch for transdermal administration. The drug is incorporated in a polymer adhesive matrix which controls the release of the drug by diffusion. There are two preparations; one lasting 4 days and the other 7. Three patch sizes of the 4-day preparation are available delivering 35, 52.5, and 70 mg buprenorphine per hour. Therapeutic plasma concentrations are achieved within 11–21 hours and steady state between the second and third applications of the patch. The 7-day patch also comes in three sizes, delivering 5, 10, and 20 mg buprenorphine per hour. At usual clinical doses of 3–4 mg per 24 hours buprenorphine functions as a pure mu agonist.

Transdermal buprenorphine has been licensed for use in both cancer pain and non-cancer pain. The lack of renal excretion (majority excreted unchanged in stool) makes this of potential use in renal dysfunction.

Principles of opioid administration

The effective clinical use of opioid drugs requires familiarity with the different drugs available, routes of administration, dosing guidelines, and potential adverse effects.

Indications

A trial of opioid therapy should be given to all patients with pain of moderate or greater severity, irrespective of the underlying pathophysiological mechanism. As discussed in Chapter 13.3, the suggestion that some forms of pain, such as neuropathic pain, are intrinsically refractory to opioid analgesia has been refuted by several studies that demonstrate that pain mechanisms do not accurately predict analgesic outcome from opioid therapy (Poyhia et al., 1993). Given the variability of response, all opioid trials in the clinical setting should include dose titration until adequate analgesia occurs or intolerable adverse effects supervene. This approach will identify those responders who can gain substantial clinical benefit from opioid therapy.

Patients whose pain is not easily controlled with an opioid analgesic because of troublesome adverse effects may benefit from alternative strategies and these are discussed below.

Drug selection

The factors that influence opioid selection include pain intensity, pharmacokinetic considerations and available formulations, previous adverse effects, and the presence of coexisting disease.

Pain intensity

Patients who present with severe pain are usually treated with a 'step 3' opioid (morphine, hydromorphone, oxycodone, oxymorphone, fentanyl, methadone, or levorphanol). Patients with moderate pain are conventionally treated with a combination product containing paracetamol or aspirin plus a conventional step 2 opioid (codeine, dihydrocodeine, hydrocodone, oxycodone (low dose), and propoxyphene), although increasingly, low dose of a step 3 opioid is used instead of a step 2 opioid.

Pharmacokinetic considerations and type of formulation

Any of the available agonist opioids can be selected for the opioid-naive patient without major organ failure. Short-$t_{1/2}$ opioids (morphine, hydromorphone, oxycodone, or oxymorphone) are generally favoured because they are easier to titrate than the long-$t_{1/2}$ drugs, which require a longer period to approach steady state plasma concentrations. Among the short-$t_{1/2}$ opioids, the range of available formulations often influences specific drug selection. For ambulatory patients who are able to tolerate oral opioids, morphine sulphate is generally preferred since it has a short $t_{1/2}$ and is easy to titrate in its normal-release form; it is also available as sustained-release preparations that allow 12- and 24-hour dosing intervals. The long-$t_{1/2}$ opioids methadone and levorphanol are not usually considered for first-line therapy because they can be difficult to titrate and present challenging management problems if delayed toxicity develops as plasma concentrations gradually rise following dose increments. For the reasons previously described, the use of pethidine, dextromoramide, and dipipanone for the management of cancer pain is discouraged.

When the oral route of opioid administration is contraindicated, the available routes of administration may become an important consideration in opioid selection. Fentanyl and buprenorphine are available for administration by the transdermal route. Although most of the full agonist drugs are well absorbed by subcutaneous infusion, some (like morphine tartrate, hydromorphone, and diamorphine) are more suitable by virtue of their high solubility and low irritability. Methadone and fentanyl may produce significant local irritation when administered by the subcutaneous route. For cultural and aesthetic reasons, the subcutaneous route is often preferred to rectal administration. Subcutaneous infusion may be also preferable in patients at the end of life because it is less disruptive than using intermittent analgesic suppositories when nursing a sick patient.

Response to previous trials of opioid therapy

It is always important to review the response to previous trials of opioid therapy. If the current opioid is well tolerated, it is usually continued unless difficulties in dose titration occur or the required dose cannot be administered conventionally. If dose-limiting side effects develop, a trial of an alternative opioid should be considered as discussed in the section on adverse effects.

Coexisting disease

Pharmacokinetic studies of pethidine, pentazocine, and propoxyphene have revealed that liver disease may decrease the clearance and increase the bioavailability and half-lives of these drugs (Kaiko et al., 1996; Salzman et al., 1999). These changes may result in above-normal plasma concentrations. Mild or moderate hepatic impairment has only a minor impact on morphine clearance (Eddy and Lee, 1959); however, advanced disease may be associated with reduced elimination (Hermens et al., 1985).

Patients with renal impairment may accumulate the active metabolites of propoxyphene (norpropoxyphene), pethidine (norpethidine), and morphine (M6G). Particular caution is required in the administration of these drugs to such patients (Hess et al., 1972; Mather, 1983; Yeadon and Kitchen, 1988; Rogers, 1991a; Raffa et al., 1992). Until more data are available, it may be wise to assume that other opioids with active metabolites may produce similar problems of toxicity in patients with impaired renal function. On this basis buprenorphine, fentanyl and alfentanil show potential advantages in renal impairment.

Morphine has been the standard step 3 opioid analgesic against which others are measured and is the most widely available in a variety of oral formulations (De Conno et al., 1991). It has limitations; the systemic availability of morphine by the oral route is poor (20–30%) and this contributes to the sometimes unpredictable onset of action and great interindividual variability in dose requirements and response. Active metabolites may contribute to toxicity particularly in patients with renal impairment (Mather, 1983). Sometimes the pain does not respond well or completely to morphine, notably neuropathic pain. However, none of the alternatives to morphine has so far demonstrated advantages which would make it preferable in routine use as the first-line oral opioid for cancer pain. Morphine remains the standard but for reasons of familiarity, availability and cost. A recent systematic review identified that there is no superiority of any of the commonly used opioids for moderate to severe pain over another (Caraceni, 2012). Early pilot work by Reid and Hanks comparing standard three-step approach with morphine versus a two-step approach with oxycodone indicates that such a two-step approach may be superior in terms of time to effective pain relief with all the associated secondary gains (Reid, 2007).

Routes of administration

Opioids should be administered by the least invasive and safest route capable of providing adequate analgesia. In a survey of patients with advanced cancer, more than half required two or more routes of administration prior to death, and almost a quarter required three or more (Lehmann and Zech, 1992).

Oral administration

The oral route of opioid administration remains the most important and appropriate in routine practice. Orally administered drugs have a slower onset of action, a delayed peak time, and a longer duration of effect compared with parenterally administered drugs. The time to peak effect depends on the drug and the nature of the formulation. For most normal-release oral formulations, peak effect is typically achieved within 60 minutes. The oral route of drug administration is inappropriate for patients who have impaired swallowing or gastrointestinal obstruction, and for some patients who require a rapid onset of analgesia. For patients who require very high doses, the inability to prescribe a manageable oral opioid regimen may be an indication for the use of a non-oral route.

When given orally, the opioids differ substantially with respect to their relative analgesic potency compared with parenteral administration. To some extent, this reflects differences in pre-systemic metabolism, that is, the degree to which they are inactivated as they are absorbed from the gastrointestinal tract and pass through the liver into the systemic circulation. As indicated in Box 9.4.2, morphine, diamorphine, pethidine, hydromorphone, and oxymorphone have ratios of oral to parenteral potency ranging from 1:3 to 1:12. Methadone, levorphanol, and oxycodone are subject to less pre-systemic elimination and also demonstrate a lower oral-to-parenteral potency ratio of at least 1:2. Failure to recognize these differences may result in a substantial reduction in analgesia when a change from parenteral to oral administration is attempted without upward titration of the dose, or toxic effects when changing in the opposite direction.

Rectal administration

The rectal route is a non-invasive alternative to parenteral routes for patients unable to use oral opioids. Rectal suppositories containing morphine, hydromorphone, oxymorphone, and oxycodone are available. The pharmacokinetics and bioavailability of drugs given rectally may differ from that of oral administration because of delayed or limited absorption and partial bypassing of pre-systemic hepatic metabolism. In practice, however, the potency of opioids administered rectally is approximately equal to that achieved by oral dosing (Varvel et al., 1989). In contrast with morphine, rectal oxycodone appears to have a delayed absorption and prolonged duration of action.

For many patients, the rectal route is not used because it is more convenient to convert directly to a subcutaneous infusion of opioid using a portable syringe driver or similar device.

Parenteral administration

Bolus injections via parenteral routes of administration are considered for patients who have impaired swallowing or gastrointestinal obstruction, those who require a rapid onset of analgesia, and those who require very high doses that cannot be conveniently administered by other methods. Repeated parenteral bolus injections, which can be delivered by the intravenous, intramuscular, or subcutaneous routes, may be complicated by the occurrence of untoward 'bolus' effects (toxicity at peak concentration and/or pain breakthrough at the trough). Intravenous bolus provides the most rapid onset; the time to peak effect correlates with the lipid solubility of the opioid, ranging from 2 to 5 minutes for methadone and from 10 to 15 minutes for morphine.

Although repeated intramuscular injections are commonplace in some countries, they are painful and offer no pharmacokinetic advantage, and their use is not recommended (Lehmann and Zech, 1992; Caraceni et al., 2012). Repeated bolus doses, if required, can be accomplished without frequent skin punctures by using an indwelling intravenous or subcutaneous infusion device. To deliver repeated subcutaneous injections, a 25–27 gauge 'butterfly' can be left under the skin for up to a week (Southam, 1995). The discomfort associated with this technique is partially related to the volume to be injected; it can be minimized by the use of concentrated formulations.

Continuous infusions

Continuous infusions avoid the problems associated with the 'bolus effect' and can be administered intravenously or subcutaneously (Portenoy et al., 1993; Jeal and Benfield, 1997). Continuous subcutaneous infusion using a portable battery-operated syringe driver or other similar device was originally devised to administer infusions of desferrioxamine to patients with thalassemia, but was subsequently used to deliver diamorphine to patients with advanced cancer who were unable to take oral drugs (Megens et al., 1998). This technique is now well established in palliative care and is used to administer analgesics, antiemetics, anxiolytic sedatives, and dexamethasone.

Ambulatory infusion devices vary in complexity, cost, and ability to provide patient-controlled 'rescue doses' as an adjunct to a continuous basal infusion. A variety of devices have been employed, all designed to be lightweight and portable, and in one case, disposable. Opioids suitable for continuous subcutaneous infusion must be soluble, well absorbed and non-irritant. Extensive experience has been reported with morphine, diamorphine, hydromorphone, fentanyl, and oxymorphone (Portenoy

et al., 1993; Haazen et al., 1999; Penson et al., 2000b). Methadone (Pasternak et al., 1987) and fentanyl appear to be relative irritants and are best avoided by this route.

Studies suggest that dosing with subcutaneous administration can proceed in a manner identical to continuous intravenous infusion: a postoperative study comparing patients who received an identical dose of morphine by either intravenous or subcutaneous infusion found no difference in blood levels (Payne et al., 1998), and a controlled study of hydromorphone calculated a bioavailability of 78% for the subcutaneous route and observed that analgesic outcome was identical during intravenous or subcutaneous infusion. To maintain the comfort of an infusion site, the subcutaneous infusion rate should not exceed 5 mL/hour. Subcutaneous infusion has become the first choice when parenteral analgesia is required in palliative care patients.

Continuous intravenous infusion may be the most appropriate way of delivering an opioid for patients with a pre-existing implanted central line, when there is a need for infusion of a large volume of solution, or when using methadone. If continuous intravenous infusion must be continued on a long-term basis, a permanent central venous port is recommended.

Continuous infusions of drug combinations may be indicated when pain is accompanied by nausea, anxiety, or agitation. In such cases an antiemetic, neuroleptic, or anxiolytic may be combined with an opioid provided that it is non-irritant, miscible, and stable in combined solution. As noted later in the text, a variety of different combinations of drugs are commonly given by continuous infusion (Fine et al., 1991). However, the stability/compatibility of many of these combinations is not known. The compatibility of drug combinations is dependent on a number of factors, including the types of drugs, the concentrations of drugs, the diluent and temperature, and ultraviolet light. A database of compatible drug combinations is now available on the Internet (http://www.palliativedrugs.com). Generally infusions should contain as few drugs as possible, preferably no more than three. The absence of precipitation within a drug mixture is not synonymous with compatibility between the drugs in that mixture (Farrar et al., 1998).

Epidural, intrathecal, and intraventricular administration

The discovery of opioid receptors in the dorsal horn of the spinal cord led to the development of intraspinal opioid delivery techniques. In general, they provide a longer duration of analgesia at doses lower than required by systemic administration. The delivery of low opioid doses near the sites of action in the spinal cord may decrease supraspinally mediated adverse effects (see Chapter 13.2).

Opioid selection for intraspinal delivery is influenced by several factors. Hydrophilic drugs, such as morphine and hydromorphone, have a prolonged $t_{1/2}$ in cerebrospinal fluid and significant rostral redistribution (Christie et al., 1998). Lipophilic opioids, such as fentanyl and sufentanil, have less rostral redistribution and therefore fewer prolonged adverse effects if these become a problem.

The addition of local anaesthetic such as bupivacaine to an epidural or intrathecal opioid has been demonstrated to improve analgesia without increasing toxicity (Faull et al., 1994; Egan et al., 2000). Unlike in acute postoperative pain, where a large volume of low concentration local anaesthetic is used, in chronic cancer pain, a small volume of high concentration of local anaesthetic is

preferred and can be mixed with an appropriate dose of a small volume of opioid.

The initial conversion of opioid dose from systemic subcutaneous diamorphine or morphine is:

- epidural—1/10 of systemic dose
- intrathecal—1/10 of epidural dose.

Thus, if a patient were on 100 mg of subcutaneous morphine or diamorphine/day, the equivalent epidural dose would be 10 mg, and the equivalent intrathecal dose would be 1 mg/day.

The initial solution used for epidural infusion is usually:

- 9 mL 0.5% bupivacaine
- 150 micrograms clonidine
- morphine or diamorphine dose according to individual patient requirements (as calculated above). This gives a total volume of 10 mL infused over 24 hours.

The initial solution used for intrathecal infusion is normally around 1/10 of the above, that is:

- 1 mL 0.5% bupivacaine
- 15 micrograms clonidine
- morphine or diamorphine according to individual patient requirements.

Hydromorphone is sometimes preferred to morphine for use in programmable intrathecal pumps because of incompatibility between some of the commonly-used devices and morphine.

There are no clinical studies comparing the intrathecal and epidural routes in cancer pain. The epidural route is sometimes preferred because the techniques to accomplish long-term administration are simpler. A combined analysis of adverse effects observed in numerous trials of epidural or intrathecal administration suggests that the risks associated with these techniques are similar. The potential morbidity associated with these procedures emphasizes the need for a well-trained clinician and long-term monitoring for individual patients.

Limited experience suggests that the administration of an opioid into the cerebral ventricles can provide long-term analgesia in selected patients. This technique has been used for patients with upper-body or head pain or with severe diffuse pain. Schedules have included both intermittent injection via an Ommaya reservoir and continual infusion using an implanted pump.

The indication for the spinal routes of administration of opioid analgesics in palliative care patients is discussed in more detail in Chapter 13.2.

Other routes and modes of administration

Transdermal
As previously described, fentanyl and buprenorphine are available in a transdermal formulation and their use is discussed above.

Sublingual
Sublingual absorption could potentially occur with any opioid, but bioavailability is very poor with drugs that are not highly lipophilic (Rance, 1979; Hoskin and Hanks, 1991). A sublingual preparation of buprenorphine is available in some countries, although not in the United States. Anecdotally, sublingual morphine has also been reported to be effective; given the poor sublingual absorption of this drug, this efficacy may be related in part to swallowing of the dose. Methadone is well absorbed sublingually. Sublingual administration has been discussed earlier.

Topical
There are several case series and one very small randomized controlled trial that examine the role of topical morphine for local analgesia. The small amount of existing evidence seems to point to a role in some situations, for example, cutaneous ulcers or tumour with cutaneous inflammation. Doses of 10–40 mg of morphine are used in simple gel, saline soaks, or local anaesthetic gel (Bullingham et al., 1981, 1983; Gal, 1989). Randomized controlled trials in non-malignant cutaneous pain, for example, burns or photodynamic therapy, have been negative.

Changing the route of administration

As described earlier, when changing from the oral to parenteral routes, or vice versa, an adjustment in dose is required to avoid either toxic effects or a reduction in analgesia. The ratios of oral to parenteral relative potency given in Table 9.4.5 are estimates and should not be taken as precise figures but used as guidelines to achieve a roughly equianalgesic effect. There is considerable variation between patients, and upward or downward adjustment may then be required for individual patients.

The slower onset of analgesia after oral administration often requires some adaptation on the part of a patient who is accustomed to the more rapid onset seen after parenteral opioid. In some patients, the problems associated with switching from the parenteral to the oral route of opioid administration may need to be minimized by slowly reducing the parenteral dose and increasing the oral dose over a 2–3-day period.

Usually, no dose adjustment is required when patients are switched from the subcutaneous to the intravenous route or vice versa.

Scheduling opioid administration

'Around-the-clock' dosing
To provide the patient with continuous relief by preventing the pain from recurring, patients with continuous or frequent pain are usually scheduled for 'around-the-clock' dosing. However, clinical vigilance is required in patients with no previous opioid exposure and those administered drugs with long half-lives. With methadone, for example, delayed toxicity may develop as plasma concentration rises slowly towards steady-state levels.

Rescue doses
All patients who receive an around-the-clock opioid regimen should also be offered a 'rescue dose', that is, a supplemental dose given on an as-needed basis to treat pain that breaks through the regular schedule (De Conno et al., 1991). The integration of scheduled dosing with rescue doses provides a method for safe and rational stepwise dose escalation and is applicable to all routes of opioid administration. The rescue drug is typically identical to that administered on a continuous basis, with the exception of transdermal fentanyl and methadone; the use of an alternative short-$t_{1/2}$ opioid is recommended for the rescue dose when these drugs are used. The frequency with which the rescue dose can be administered depends on the time to peak effect for the drug and the route of administration. Oral rescue doses can be offered up to

every 60–90 minutes, and parenteral rescue doses can be offered up to every 15–30 minutes.

Clinical experience suggests that the size of the rescue dose should usually be equivalent to one-sixth of the 24-hour baseline dose, that is, the same as the 4-hourly dose of opioid. The magnitude of the rescue dose should be individualized and some patients with low baseline pain but severe exacerbations may require rescue doses that are substantially larger. As discussed in this chapter, in the setting of clinical trials where rescue doses are individualized, the effective doses rarely turn out to be one-sixth of the 24-hour dose.

Scheduling with sustained-release formulations

Sustained-release formulations can reduce the inconvenience associated with around-the-clock administration. These formulations should not be used for rapid titration of the dose in patients with severe pain. Sustained-release oral morphine sulphate and oxycodone, and transdermal fentanyl are now widely used, and sustained-release formulations of codeine, tramadol, and hydromorphone have been introduced in various countries.

A normal-release formulation of a short-$t_{1/2}$ opioid (usually the same drug) is often used as the rescue medication. Sustained- and normal-release formulations of oral morphine are dose equivalent; switching from one to the other is done on a milligram-for-milligram basis after the daily dose requirement is identified using a normal-release formulation.

As-needed dosing

In some limited situations, an as-needed dosing regimen alone can be recommended. This type of dosing provides additional safety during the initiation of opioid therapy in the opioid-naive patient, particularly when rapid dose escalation is needed or a long-$t_{1/2}$ drug is administered. This technique is strongly recommended when starting methadone therapy, and for patients with acute renal failure.

Patient-controlled analgesia

Patient-controlled analgesia is a technique of parenteral drug administration in which the patient controls a pump that delivers bolus doses of an analgesic according to parameters set by the physician. Use of a patient-controlled analgesia device allows the patient to titrate the opioid dose carefully to his or her individual analgesic needs. Long-term patient-controlled analgesia in cancer patients is accomplished via subcutaneous or intravenous routes using an ambulatory infusion device (Mello and Mendelson, 1980). The more technologically advanced of these devices have programmable variables, including infusion rate, rescue dose, and lock-out interval. The option for bolus dosing is typically used in conjunction with continuous opioid infusion.

Dose selection and adjustment

Initial dose selection

A patient with severe pain that is not controlled with a step 2 opioid– non-opioid combination in full dose should begin one of the opioid agonists at a dose equivalent to 10 mg oral morphine sulphate every 4 hours.

Dose titration

Inadequate pain relief should be addressed by gradual escalation of the opioid dose until adequate analgesia is reported or intolerable side effects (that cannot be managed by simple interventions) supervene. Because analgesic response to opioids increases linearly with the logarithm of the dose, dose escalations of less than 30–50% are not likely to improve analgesia significantly. Clinical experience indicates that a dose increment of this order of magnitude is safe and is large enough to observe a meaningful change in effects.

In most cases, gradual dose escalation identifies a favourable balance between analgesia and side effects which remains stable for a prolonged period. While doses can become extremely large during this process, the absolute dose is immaterial as long as the balance between analgesia and side effects remains favourable.

In a retrospective study of 100 patients with advanced cancer, the average daily opioid requirement was equivalent to 400–600 mg of intramuscular morphine, but approximately 10% of patients required more than 2000 mg and one patient required over 30 000 mg every 24 hours. Other centres have generally reported lower doses; a median dose of 60 mg/day in one centre and 120 mg/day in another (Hammersley et al., 1995).

A simple method of dose titration using oral morphine is to prescribe a dose of immediate-release morphine every 4 hours and the same dose for rescue for BTP (De Conno et al., 1991). The rescue dose can be given as often as required (e.g. every hour) and the total dose of morphine can be reviewed daily. The regular dose can then be adjusted according to how many rescue doses have been given.

Rate of dose titration

The severity of the pain should determine the rate of dose titration. Patients with very severe pain can be managed by repeated parenteral dosing every 15–30 minutes until pain is partially relieved when an oral dosing regimen should be started.

Tolerance

Patients vary greatly in the opioid dose required to manage their pain. The need for escalating doses is a complex phenomenon. Most patients reach a dose that remains constant for prolonged periods. When the need for dose escalation arises, any of a variety of distinct processes may be involved. Clinical experience suggests that true pharmacological tolerance is a much less common reason than disease progression or increasing psychological distress. Changes in the pharmacokinetics of an analgesic drug could also be implicated.

True pharmacological tolerance probably involves changes at the receptor level, and in this situation continued drug administration itself induces an attenuation of effect. Clinically, tolerance to the non-analgesic effects of opioids appears to occur commonly albeit at varying rates for different effects. For example, tolerance to respiratory depression, somnolence, and nausea generally develops rapidly, whereas tolerance to opioid-induced constipation develops very slowly, if at all. Tolerance to these opioid side effects is not a clinical problem, and indeed is a desirable outcome that allows effective dose titration to proceed.

From the clinical perspective, the concern is that tolerance to the analgesic effect of the drug will develop and that this will necessitate rapid dose escalation which may continue until the drug is no longer useful. Induction of true analgesic tolerance which could compromise the utility of treatment can only be said to occur if a patient manifests a need for increasing opioid doses in the absence of other factors (e.g. progressive disease) that would be capable

of explaining the increase in pain. Extensive clinical experience suggests that most patients who require an escalation in dose to manage increasing pain have demonstrable progression of disease. With the emergence of our understanding of opioid-induced hyperalgesia (OIH), both generalized pain and/or appearance of features of central wind-up should be assessed very carefully.

This conclusion has two important implications: concern about tolerance should not impede the use of opioids early in the course of the disease, and worsening pain in a patient receiving a stable dose of opioid should not be attributed to tolerance but taken as presumptive evidence of disease progression or, less commonly, increasing psychological distress.

Determination of an equianalgesic dose

The overriding clinical issue with an opioid switch is that it is nearly always done because a problem exists. Assessment of appropriate dose conversion is critical when switching a patient from one opioid to another. The most common reason for a switch is an unacceptable side effect profile often also associated with uncontrolled pain. It is clear that any deterioration in either side effects and/or pain control is disastrous for the patient, therefore a switch needs to find the right balance. In practice this means a very conservative equianalgesic conversion should be made (no more than 75% of the equianalgesic dose and clearly less in the case of drugs such as methadone) and appropriate breakthrough analgesia prescribed in a clear and practical way to prevent any distress due to underdosing. Failure to do this can lead to the development of opioid toxicity or worsening of existing opioid toxicity.

Management of opioid adverse effects

Successful opioid therapy requires that the benefits of analgesia clearly outweigh treatment-related adverse effects. This requires understanding of adverse opioid effects and the strategies used to prevent and manage them are essential skills for all involved in cancer pain management. The adverse effects that are frequently observed in patients receiving oral morphine and other opioids are summarized in Table 9.4.7. The most common are sedation, constipation, and nausea and vomiting, but there are other adverse effects including confusion, hallucinations, nightmares, urinary retention, multifocal myoclonus, dizziness, and dysphoria. The mechanisms that underlie these adverse effects, even the most common, are only partly understood and, as discussed earlier, appear to depend upon a number of factors including age, extent of disease and organ dysfunction, concurrent administration of certain drugs, prior opioid exposure, and the route of drug administration. Studies comparing the adverse effects of one opioid analgesic with another in this population are lacking. Similarly, controlled studies comparing the adverse effects produced by the same opioid given by various routes of administration are also lacking.

As a general rule, caution is required when using opioids in patients in acute pain with impaired ventilation, bronchial asthma, or raised intracranial pressure; the same caveats do not usually limit dose titration in chronic cancer pain management.

Factors predictive of opioid adverse effects

Drug-related

Overall, there is very little reproducible evidence suggesting that any one opioid agonist has a substantially better adverse

Table 9.4.7 Common opioid-induced adverse effects

Gastrointestinal	Nausea
	Vomiting
	Constipation
Autonomic	Xerostomia
	Urinary retention

Central nervous system	Drowsiness
	Cognitive impairment
	Hallucinations
	Delirium
	Respiratory depression
	Myoclonus
	Seizure disorder
	Hyperalgesia
Cutaneous	Itch
	Sweating

effect profile than any other. Pethidine is not recommended in the management of chronic cancer pain because of concerns regarding its side effect profile (Kaiko et al., 1983). Data from controlled studies indicate that the transdermal administration of fentanyl is associated with a lesser incidence of constipation than oral morphine (Donner et al., 1996; Ahmedzai and Brooks, 1997; Payne et al., 1998; van Seventer et al., 2003) or codeine (Mystakidou et al., 2005).

Route-related

There is very limited evidence to suggest differences in adverse effects associated with specific routes of systemic administration. Compared to oral morphine administration, small studies have demonstrated less nausea and vomiting with rectal (Babul et al., 1998) and subcutaneous administration (McDonald et al., 1991). Four studies comparing transdermal fentanyl to oral morphine demonstrated less constipation among the patients receiving transdermal fentanyl. It is not clear as to whether this is a route or drug related effect (Ahmedzai and Brooks, 1987; Donner et al., 1996; Payne et al., 1998; van Seventer et al., 2003).

Patient-related

For reasons that are not well explained, there is striking interindividual variability in the sensitivity to adverse effects from morphine and other opioid drugs. Genetic variability clearly affects the sensitivity to opioids (Somogyi et al., 2007) and it is reasonable to assume that the genetic background plays a similar important role in sensitivity to adverse effects and the pre-clinical evidence for this is discussed in the first part of this chapter (Stamer et al., 2005).

Some of this variability is related to co-morbidity. Ageing is associated with altered pharmacokinetics particularly characterized by diminished clearance and volume of distribution. This has been well evaluated for morphine (Baillie et al., 1989) and fentanyl (Bentley et al., 1982; Holdsworth et al., 1994). In a study of

morphine use in the management of chronic cancer pain in the elderly, overall elderly patients required lower doses than their younger counterparts without exhibiting an enhanced risk for opioid induced adverse effects (Rapin, 1989). In patients with impaired renal function there is delayed clearance of an active metabolite of morphine, M6G (Osborne et al., 1993). Anecdotally, high concentrations of M6G have been associated with toxicity (Osborne et al., 1986; Hagen et al., 1991; Sjogren et al., 1993), however in a prospective study of patients with opioid-induced delirium or myoclonus no relationship to renal function was observed (Tiseo et al., 1995).

Other patient-related factors that may enhance the risk of adverse effects include the co-administration of drugs which may have cumulative toxicity, especially sedation or other concurrent co-morbidity (Table 9.4.8).

Opioid initiation and dose escalation

Among adverse effects there is substantial variability in their dose response. A dose response relationship is most commonly evident with regards to the central nervous system adverse effects of sedation, cognitive impairment, hallucinations, myoclonus and respiratory depression. Even among these, however, there is very substantial interindividual variability to many of these effects. Additionally, as tolerance develops to some effects, the spectrum of adverse effects varies with prolonged use. Commonly, patients who have had prolonged opioid exposure have a lesser tendency to develop sedation or respiratory depression, and the predominant central nervous system effects become the neuroexcitatory ones of delirium and myoclonus.

Gastrointestinal adverse effects generally have a weaker dose response relationship. Some, like nausea and vomiting, are common with the initiation of therapy but are subsequently unpredictable with resolution among some patients and persistence among others. Constipation is virtually universal and it demonstrates a very weak dose relationship.

Some adverse effects appear transiently after starting an opioid or after dose escalation and spontaneously abate. This phenomenon has been well demonstrated in a prospective study on the effect of morphine dose escalation on cognitive performance (Bruera et al., 1989). This study demonstrated that opioid induced cognitive impairment commonly improved after 7 days. This phenomenon, though often described, has not been formally studied in regards to other adverse effects and needs to be repeated in relation to cognitive performance in a larger population.

Differential diagnosis

Adverse changes in patient well-being among patients taking opioids are not always caused by the opioid. Adverse effects must be differentiated from other causes of co morbidity that may develop in the treated patient and from drug interactions. Common causes of co-morbidity that may mimic opioid induced adverse effects are presented in Table 9.4.8.

Indeed, the appearance of a new adverse change in patient well-being that occurs in the setting of stable opioid dosing is rarely caused by the opioid, and an alternate explanation should be vigorously sought. Since polypharmacy is common among patients with advanced cancer, it is essential to scrutinize medication records and patient report of medication administration to evaluate for possible drug interactions or some other drug-related explanation for the reported symptoms.

Table 9.4.8 Co-morbidity that may mimic opioid induced adverse effects

Cause		Adverse effects
Central nervous system	Cerebral metastases	Drowsiness, cognitive impairment, nausea, vomiting
	Leptomeningeal metastases	Drowsiness, cognitive impairment, nausea, vomiting
	Cerebrovascular event	Drowsiness, cognitive impairment
	Extradural haemorrhage	Drowsiness, cognitive impairment
Metabolic	Dehydration	Drowsiness, cognitive impairment
	Hypercalcaemia	Drowsiness, cognitive impairment, nausea, vomiting
	Hyponatremia	Drowsiness, cognitive impairment
	Renal failure	Drowsiness, cognitive impairment, nausea, vomiting, myoclonus
	Liver failure	Drowsiness, cognitive impairment, nausea, vomiting, myoclonus
	Hypoxemia	Drowsiness, cognitive impairment
Sepsis/infection		Drowsiness, cognitive impairment, nausea, vomiting
Mechanical	Bowel obstruction	Nausea, vomiting
Iatrogenic	Tricyclics	Drowsiness, cognitive impairment, constipation
	Benzodiazepines	Drowsiness, cognitive impairment
	Antibiotics	Nausea and vomiting
	Vinca alkaloids	Constipation
	Flutamide	Constipation
	Steroids	Agitated delirium
	Non-steroidal anti-inflammatory drugs	Nausea, drowsiness
	Chemotherapy	Nausea, vomiting, drowsiness, cognitive impairment
	Radiotherapy	Nausea, vomiting, drowsiness

Overview of the alternative approaches to treating opioid adverse effects

In general, four different approaches to the management of opioid adverse effects have been described:

1. Dose reduction of systemic opioid

2. Specific therapy to reduce the adverse effect

3. Opioid switching

4. Change route of administration

Dose reduction of systemic opioid

Reducing the dose of administered opioid usually results in a reduction in dose related adverse effects. When patients have well-controlled pain, gradual reduction in the opioid dose will

often result in the resolution of dose related adverse effects whilst preserving adequate pain relief (Fallon and O'Neill, 1997).

When opioid doses cannot be reduced without the loss of pain control, reduction in dose must be accompanied by the addition of an accompanying synergist approach. Extensive experience has been reported with four accompanying approaches:

1. *The addition of a non-opioid co-analgesic.* The analgesia achieved from non-opioid co-analgesics is additive and often synergistic with that achieved by opioids. This is supported from a number of prospective studies (Nabal et al., 2012).

2. *The addition of an adjuvant analgesic that is appropriate to the pain syndrome and mechanism* (see Chapter 13.1). Adjuvant analgesics (see following) may be combined with primary analgesics to improve the outcome for patients who cannot otherwise attain an acceptable balance between relief and side effects (Lussier et al., 2004; Mitra and Jones, 2012). There is great inter-individual variability in the response to all adjuvant analgesics and, for most, the likelihood of benefit is limited. Furthermore, many of the adjuvant analgesics have the potential to cause side effects which may be additive to the opioid induced adverse effects that are already problematic (Bennett, 2011). In evaluating the utility of an adjuvant agent in a particular patient setting, one must consider the likelihood of benefit, the risk of adverse effects, the ease of administration and patient convenience.

3. *The application of a therapy targeting the cause of the pain.* Specific antitumour therapies, such as radiotherapy, chemotherapy, or surgery targeting the cause of cancer related pain can provide substantial relief and thus reduce the need for opioid analgesia. Radiotherapy is of proven benefit in the treatment of painful bone metastases, (Lutz et al., 2011) epidural neoplasm (Souchon et al., 2010; Holt et al., 2012) and headache due to cerebral metastases (Pease et al., 2005; Akhtar et al., 2012; Kong et al., 2012). In other settings there is a lack of well-established supportive data, and the use of radiotherapy is largely anecdotal (Lutz et al., 2010, 2012). Despite a paucity of evidence concerning the specific analgesic benefits of chemotherapy (Bang et al., 2005; von Gruenigen et al., 2006; Dahele et al., 2007), there is a strong clinical impression that tumour shrinkage is generally associated with relief of pain. Although there are some reports of analgesic value even in the absence of significant tumour shrinkage (Patt et al., 1985; Thatcher et al., 1995; Rothenberg 1996), the likelihood of a favourable effect on pain is generally related to the likelihood of tumour response (Bang et al., 2005; von Gruenigen et al., 2006; Dahele et al., 2007). Surgery may have a role in the relief of symptoms caused by specific problems, such as obstruction of a hollow viscus (Sartori et al., 2010; Dalal et al., 2011; Dolan 2011; Kolomainen and Barton, 2011), unstable bony structures (Ogilvie et al., 2008; Utzschneider et al., 2011), and compression of neural tissues (Dy et al., 2008; Eleraky et al., 2010; Quraishi et al., 2010).

4. *The application of a regional anaesthetic or neuroablative intervention* (see Chapter 13.2). The results of the WHO 'analgesic ladder' validation studies suggest that 10–30% of patients with cancer pain do not achieve a satisfactory balance between relief and side effects using systemic pharmacotherapy alone without unacceptable drug toxicity (Takeda, 1985; Ventafridda et al., 1987; Goisis et al., 1989; Schug et al., 1990; Grond et al., 1991).

Anaesthetic and neurosurgical techniques may reduce or eliminate the requirement for systemically administered opioids to achieve adequate analgesia. In general, regional analgesic techniques such as intraspinal opioid and local anaesthetic administration or intrapleural local anaesthetic administration are usually considered first because they can achieve this end without compromising neurological integrity. Neurodestructive procedures, however, are valuable in a small subset of patients; and some of these procedures, such as coeliac plexus blockade in patients with pancreatic cancer, may have a favourable enough risk: benefit ratio that early treatment is warranted.

Symptomatic management of the adverse effect

Symptomatic drugs used to prevent or control opioid adverse effects are commonly employed. Most of these approaches are based on cumulative anecdotal experience. With few exceptions, the literature describing these approaches is anecdotal or 'expert opinion'. Very few studies have prospectively evaluated efficacy and no studies have evaluated the toxicity of these approaches over long term. In general, this approach involves the addition of a new medication, adding to medication burden and with the associated risks of adverse effects or drug interaction.

Opioid rotation

Opioid rotation refers to an approach to reduce opioid side effects by switching to an alternative opioid (Quigley, 2004; Mercadante and Bruera, 2006; Vadalouca et al., 2008; Fine and Portenoy, 2009; Vissers et al., 2010).

Improvements in cognitive impairment, sedation, hallucinations, nausea, vomiting and myoclonus are commonly reported. This approach requires familiarity with a range of opioid agonists and with the use of equianalgesic tables to convert doses when switching between opioids. While this approach has the practical advantage of minimizing polypharmacy, outcomes are variable and unpredictable. When switching between opioids, even with prudent use of equianalgesic tables, patients are at risk for under or over dosing by virtue of individual sensitivities.

The biological basis for the observed intra-individual variability in sensitivity to opioid analgesia and adverse effects

The biological basis for the observed intra-individual variability in sensitivity to opioid analgesia and adverse effects is multifactorial (Ross et al., 2006) and is related to pharmacogenetics (Kadiev et al., 2008). The pharmacokinetic and pharmacodynamic differences among the opioids and the spectrum of proteins involved in determining response create great potential for response variability.

Heterogeneity of opioid metabolism

Different opioids have different metabolic and excretion pathways. Of the processes of metabolism and excretion, some are genetically determined and some reflect phenotypic changes particularly with regard to renal and hepatic function. The genetic factors influencing metabolism play an important role in analgesia for some opioids and similar phenomena may contribute to variability in adverse effect sensitivity (Stamer and Stuber, 2007; Kadiev et al., 2008; Kleine–Brueggeney et al., 2010).

Genetic influences of receptor function

The potential for genetic influences on opioid effects and tolerability is vast and understanding of this very complex system remains

rudimentary (Stamer et al., 2005). Still several important findings have contributed to the understanding of differences in opioid effects:

1. Genetic factors influencing opioid receptors: The mu-opioid receptor is a GPCR the signalling of which results in inhibition of neuronal transmission of painful stimuli by a complex sequence of events. Pre-clinical studies show that opioids can act on different receptors or subtype receptors and, individual receptor profiles may influence the analgesia as well as the side effects (Pasternak, 2005). More than 100 polymorphisms have been identified in the human mu-opioid receptor gene alone, and some of these variants, such as the A118G nucleotide substitution, have been shown to alter the binding affinities of different opioids (Lötsch et al., 2002b; Beyer et al., 2004) and to effect analgesic outcomes (Chou et al., 2006; Hayashida et al., 2008; Zhang et al., 2010). Furthermore other factors involved in the processes of GPCR such as desensitization, endocytosis, and down-regulation may further add to the potential for variability (Kristiansen, 2004).

2. Control of opioid receptor gene expression: There are some data to suggest that differences in signal transfer function that controls the expression of the mu-opioid receptor gene may impact on opioid responsiveness (Ross et al., 2005). Research continues to examine other transcription factors that may be important in influencing response to different opioids.

Genetic factors influencing drug transport

The membrane-bound drug transporter P-glycoprotein influences drug absorption and drug excretion as well as transport of drugs in and out of the CNS across the blood–brain barrier (Hennessy and Spiers, 2007). Furthermore the P-glycoprotein modulation of opioid CNS levels varies substantially between different opioids (Dagenais et al., 2004). To add to the potential heterogeneity of responses, these critical transporter proteins are encoded by the multidrug resistance gene *MDR-1*, which has multiple genetic variations, some of which are associated with differences in P-glycoprotein expression or function (Hoffmeyer et al., 2000).

Switching route of systemic administration

Limited data indicate that some adverse side effects among patients receiving oral morphine can be relieved by switching the route of admission to the subcutaneous route. In one small study this phenomenon was reported for nausea and vomiting (McDonald et al., 1991), in another there was less constipation, drowsiness, and nausea (Drexel et al., 1989).

Initial management of the patient receiving opioids who presents with adverse effects

Among patients receiving opioid analgesic therapy there are two key steps in the initial management of adverse effects. Firstly, the clinician must distinguish morphine adverse effects from co-morbidity or drug interactions. This step requires careful evaluation of the patient for factors outlined in Table 9.4.8. If present, these factors should be redressed. Metabolic disorders, dehydration, or sepsis should be treated; non-essential drugs that may be producing an adverse interaction should be discontinued. Symptomatic measures may be required until an effect is observed.

Secondly, if indeed it seems that this is a true adverse effect of the opioid, consideration should be given to reducing the opioid dose. If the patient has good pain control, reduce morphine dose by 25%.

Adverse drug interactions

In patients with advanced cancer side effects due to drug combinations are common. The potential for additive side effects and serious toxicity from drug combinations must be recognized. The sedative effect of an opioid may add to that produced by numerous other centrally-acting drugs, such as anxiolytics, neuroleptics, and antidepressants (Bennett 2011). Likewise, drugs with anticholinergic effects probably worsen the constipatory effects of opioids. As noted previously, a severe adverse reaction, including excitation, hyperpyrexia, convulsions, and death, has been reported after the administration of pethidine (meperidine) to patients treated with a monoamine oxidase inhibitor (Browne and Linter 1987).

Gastrointestinal side effects

The gastrointestinal adverse effects of opioids are common. In general they are characterized by having a weak dose–response relationship.

Constipation

All opioids cause constipation and tolerance to this effect is not observed over time. Importantly, the dose–response relationship to this effect is very flat and the severity does not appear to be strongly dose related. There are some data to indicate that the severity is less severe with fentanyl and, possibly, methadone (Pappagallo, 2001; Staats et al., 2004). The likelihood of opioid-induced constipation is so great that laxative medications should be prescribed prophylactically to most patients (Ahmedzai and Boland, 2010). In general, bulking laxatives are discouraged. There is some evidence from randomized controlled trials, supported by consensus, that the oral laxatives lactulose, polyethylene glycol/electrolyte solutions and senna are probably of similar efficacy in people with opioid-induced constipation and that the polyethylene glycol/electrolyte solutions may have a better adverse effect profile than the other oral laxatives (Ahmedzai and Boland, 2010).

Methylnaltrexone, a quaternary derivative of naltrexone that does not cross the blood–brain barrier in humans, is a potentially important product recently licensed in Europe. It antagonizes only peripherally located opioid receptors while sparing centrally mediated analgesic effects of opioid pain medications. There is evidence of very predictable effectiveness after administration by either oral or parenteral routes of administration with most patients achieving defecation within 90 minutes of administration (Ahmedzai and Boland 2010; Candy et al., 2011; Licup and Baumrucker, 2011).

In many countries, an oral prolonged-release preparation containing oxycodone and naloxone in a ratio of 2 to 1, is available. Efficacy in preventing and or managing opioid related constipation is based on the fact that oral naloxone binds to gut opioid receptors with a greater affinity than oxycodone, however, naloxone that undergoes metabolism in the liver where it is rendered inactive, while oxycodone passes through the liver unchanged. The preparation is administered 12-hourly. A randomized controlled trial demonstrated that prolonged release oxycodone and naloxone combination provides superior bowel function in cancer pain patients, compared with prolonged release oxycodone alone, without compromising analgesic efficacy or safety (Ahmedzai et al., 2012).

Nausea and vomiting

Opioids may produce nausea and vomiting through both central and peripheral mechanisms. These drugs stimulate the medullary chemoreceptor trigger zone, increase vestibular sensitivity and have effects on the gastrointestinal tract (including increased gastric antral tone, diminished motility and delayed gastric emptying). With the initiation of opioid therapy, patients should be informed that nausea may occur. Routine prophylactic administration of an antiemetic is not necessary, except in patients with a history of severe opioid-induced nausea and vomiting, but patients should have access to an antiemetic at the start of therapy if the need for one arises. Nausea and vomiting that persists more than a few days is likely to be a chronic problem. No antiemetic has proven superiority over another and, indeed, there is little supportive evidence for any specific agent (Laugsand et al., 2011).

Additionally, there is also limited evidence supporting use of transdermal scopolamine (Ferris et al., 1991). A 'first principle' approach is usually adopted using metoclopramide or haloperidol. Persistent nausea and vomiting often necessitates opioid switching.

Central nervous system side effects

The CNS side effects of opioids are generally dose related. The specific pattern of CNS adverse effects is influenced by individual patient factors, duration of opioid exposure, and dose.

Sedation

Initiation of opioid therapy or significant dose escalation commonly induces sedation that persists until tolerance to this effect develops, usually in days to weeks. It is useful to forewarn patients of this potential, and thereby reduce anxiety and encourage avoidance of activities, such as driving, that may be dangerous if sedation occurs (Vainio et al., 1995). Some patients have a persistent problem with sedation, particularly if other confounding factors exist. These factors include the use of other sedating drugs or coexistent diseases such as dementia, metabolic encephalopathy, or brain metastases. Limited evidence supports the potential efficacy of amphetamines and amphetamine-like agents such as dextroamphetamine, methylphenidate, donepezil, and modafinil in the treatment of opioid-induced sedation (Reissig and Rybarczyk, 2005; Stone and Minton, 2011).

Treatment with methylphenidate or dextroamphetamine is typically begun at 2.5–5 mg in the morning, which is repeated at midday if necessary to maintain effects until evening. Doses are then increased gradually if needed. Few patients require more than 40 mg per day in divided doses. This approach is relatively contraindicated among patients with cardiac arrhythmias, agitated delirium, paranoid personality and past amphetamine abuse.

Confusion and delirium

Mild cognitive impairment is common following the initiation of opioid therapy or increase in dose. Similar to sedation, however, pure opioid-induced encephalopathy appears to be transient in most patients, persisting from days to a week or two (Banning and Sjogren, 1990; Vainio et al., 1995). Although persistent confusion attributable to opioid alone occurs (Gaudreau et al., 2007), the aetiology of persistent delirium is often related to the combined effect of the opioid and other contributing factors, including electrolyte disorders, neoplastic involvement of central nervous

---

> **Box 9.4.3** A stepwise approach to the management of confusion and delirium
>
> 1. Discontinue non-essential centrally acting medications.
> 2. If analgesia is satisfactory, reduce opioid dose by 25%.
> 3. Exclude sepsis or metabolic derangement.
> 4. Exclude CNS involvement by tumour.
> 5. If delirium persists, consider:
>   - trial of neuroleptic (e.g. haloperidol)
>   - change to an alternative opioid drug
>   - a change in opioid route to the intraspinal route (± local anaesthetic)
>   - a trial of other anaesthetic or neurosurgical options.

system, sepsis, vital organ failure and hypoxaemia (Centeno et al., 2004; Gaudreau et al., 2007).

A stepwise approach to management (Box 9.4.3) often culminates in a trial of a neuroleptic drug or opioid rotation. Among the neuroleptic agents, haloperidol in low doses (0.5–1.0 mg PO or 0.25–0.5 mg IV or IM) is most commonly recommended because of its efficacy and low incidence of cardiovascular and anticholinergic effects. As an alternative strategy, there is limited anecdotal experience with the use of acetylcholinesterase inhibitors; initiated with IV physostigmine, and then maintained with oral donepezil (Slatkin and Rhiner, 2004).

Respiratory depression

When sedation is used as a clinical indicator of CNS toxicity and appropriate steps are taken, respiratory depression is rare. When, however, it does occur it is always accompanied by other signs of CNS depression, including sedation and mental clouding (Dahan 2007). Respiratory compromise accompanied by tachypnoea and anxiety is never a primary opioid event. With repeated opioid administration, tolerance appears to develop rapidly to the respiratory depressant effects of the opioid drugs, consequently clinically important respiratory depression is a very rare event in the cancer patient whose opioid dose has been titrated against pain.

The ability to tolerate high doses of opioids is also related to the stimulus-related effect of pain on respiration in a manner that is balanced against the depressant opioid effect. Opioid-induced respiratory depression can occur however, if pain is suddenly eliminated (such as may occur following neurolytic procedures) and the opioid dose is not reduced (Wells et al., 1984).

Careful observation is the best method for monitoring sedation level and respiratory status. The University of Wisconsin Hospital and Clinics Sedation Assessment Scale (Gordon et al., 2000) is a very useful aid to assessment, particularly in the sleeping patient.

When respiratory depression occurs in patients on chronic opioid therapy, administration of the specific opioid antagonist, naloxone, usually improves ventilation (Dahan et al., 2010). This is true even if the primary cause of the respiratory event was not the opioid itself, but rather, an intercurrent cardiac or pulmonary process. A response to naloxone, therefore, should not be taken as proof that the event was due to the opioid alone and an evaluation for these other processes should ensue.

Naloxone can precipitate a severe abstinence syndrome and should be administered only if strongly indicated. If the patient is bradypnoeic but readily arousable, and the peak plasma level of the last opioid dose has already been reached, the opioid should be withheld and the patient monitored until improved. If severe hypoventilation occurs (regardless of the associated factors that may be contributing to respiratory compromise), or the patient is bradypnoeic and unarousable, naloxone should be administered. To reduce the risk of severe withdrawal following a period of opioid administration, dilute naloxone (1:10) should be used in doses titrated to respiratory rate and level of consciousness. In the comatose patient, it may be prudent to place an endotracheal tube to prevent aspiration following administration of naloxone.

Multifocus myoclonus

All opioid analgesics can produce myoclonus. Mild and infrequent myoclonus is common. In occasional patients, however, myoclonus can be distressing or contribute to breakthrough pain that occurs with the involuntary movement. If the dose cannot be reduced due to persistent pain, consideration should be given to either switching to an alternative opioid (Stone and Minton, 2011) or to symptomatic treatment with a benzodiazepine (particularly clonazepam or midazolam), dantrolene, or an anticonvulsant such as gabapentin (Mercadante et al., 2001; Stone and Minton, 2011).

Endocrine effects

Hypogonadism

Chronic opioid therapy may often cause endocrine dysfunction mainly in the form of hypo function of the pituitary–gonadal axis with sexual disturbance and menstrual irregularities. Chronic opioid therapy has an inhibitory effect on the hypothalamic–pituitary axis (Katz and Mazer, 2009; Elliott et al., 2011). It interferes with the release (including its pulsatile nature) of gonadotropin-releasing hormone, resulting in lower peak values of luteinizing hormone and follicle-stimulating hormone and an inhibitory effect of the opioids on the hypothalamic–pituitary levels with secondary effects on oestradiol and testosterone levels. Clinical manifestations may include fatigue, muscle wasting, erectile dysfunction, reduced libido, vaginal dryness, and menstrual abnormalities. More subtle symptoms such as hot flushes and anxiety may occur, rarely with changes in pubic hair distribution and breast size. This may require hormone replacement therapy (Aloisi et al., 2011; Blick et al., 2012; McWilliams et al., 2014).

Adrenal hormones

Chronic use of exogenous opioids has been found in several studies to decrease adrenocorticotropic hormone (ACTH) and cortisol levels and cortisol responses to adrenocorticotropin challenges. Opioids also affect the circadian rhythms of cortisol secretion, resulting in persistently raised levels of ACTH and cortisol and eventually blunting the stress response (Katz and Mazer, 2009; Elliott et al., 2011).

Obesity and diabetes

Chronic opioid use is associated with weight gain, hyperglycaemia, and worsening diabetes. This may be a central action via the sympathetic nervous system and impaired insulin secretion (Katz and Mazer, 2009; Elliott et al., 2011).

Immune effects

No clinical data exist on the effects of opioids on the immune system, when used for chronic cancer pain, however, a significant amount of pre-clinical data exist. Some theoretical differences between opioid classes have been suggested, however, clinical studies are needed to understand if this is a clinically relevant issue (Bortsov et al., 2012).

Other effects

Urinary retention

Opioid analgesics increase smooth muscle tone and can occasionally cause bladder spasm or urinary retention (due to an increase in sphincter tone). This is an infrequent problem that is usually observed in elderly male patients. Tolerance can develop rapidly but catheterization may be necessary to manage transient problems.

Opioid-induced hyperalgesia

The phenomenon of OIH may occur, whereby there is a paradoxical increase in pain with increasing or high doses of opioids. It is important to recognize when OIH occurs, in order to manage it correctly. Chronic opioid use may result in tolerance, when a higher dose is required to achieve the same degree of analgesia (with a right shift in a standard dose–response curve). In contrast, when OIH occurs, an increase in opioid dose results in an increase in pain (see Fig. 9.4.7) (Colvin and Fallon, 2010).

Laboratory studies of OIH in both acute and chronic models show a number of changes in pain processing, due to opioid administration. There are some variations, dependent on what model is used, but the underlying mechanisms may include central sensitization involving the glutaminergic system (Haugan et al., 2008; Zhao and Joo, 2008; Minville et al., 2010; Hutchinson et al., 2011; Wang et al., 2012); activation of glial cells via opioid binding to toll-like receptors, inducing a central neuroinflammatory response (Hutchinson et al., 2011; Wang et al., 2012); or alterations in the balance between anti-nociceptive and facilitatory descending systems (Vera-Portocarrero et al. 2007; Xie et al., 2005) and spinal alpha-2 receptors (Milne et al.. 2013). Improved understanding of the mechanisms that lead to OIH should allow us to develop more effective targeted therapies to treat it.
Fig. 9.4.7 Common adverse effects of opioid medication.

There has been much debate about the clinical relevance of OIH, but the evidence from basic science studies, human volunteer studies, and emerging clinical evidence indicate that it is a real clinical phenomenon, although an area where more research is urgently needed (Angst and Clark, 2006; Eisenberg et al.. 2010; Brush, 2012). A recent systematic review of OIH in the acute setting found 27 studies that were suitable to include in a meta-analysis, with a total of 1494 patients, where those patients who had received high dose intraoperative opioids compared to lower doses, had a significant increase in postoperative pain (Fletcher and Martinez, 2014). Many of the studies of chronic opioid use have been of patients on methadone for substance misuse, with some evidence of increased pain sensitivity (Doverty et al., 2001). This has been confirmed in chronic non-malignant pain, where reduced effectiveness of descending inhibitory pathways may contribute to OIH (Baron and McDonald, 2006; Ram et al., 2008).

Management of OIH may include gradual reduction in opioid doses and assessing the analgesic effect, which should improve, as the dose is decreased. Alternatively, opioid rotation may be useful: this may be due to genetic variation in opioid response, or due to differential binding at opioid receptor subtypes (Quigley, 2004; Jensen et al., 2009). For example, there is interest in developing novel dual-action opioids, with high binding affinity to mu and delta receptors, where there is early evidence of reduced OIH and other adverse effects (Dietis et al., 2009; Parenti et al., 2013; Podolsky et al., 2013). Other management strategies may include the use of NMDA receptors, such as ketamine, alpha-2 agonists, and in the future, agents that modify TRP receptors, or glial cell activity (Ramasubbu and Gupta, 2011; Mion and Villevieille, 2013).

There are no evidence-based therapeutic algorithms for this scenario. Commonly recommended strategies include dose reduction of the causative agent and/or substitution of the causative agent with another opioid. Naloxone does not reverse this effect. Anecdotal suggestions include, as above, a NMDA receptor antagonist such as ketamine, non-opioid co analgesics, spinal opioids, and hydration.

Opioids and driving

The ability to continue driving is very important to maintaining the quality of life of many patients with advanced cancer. Many assume that they must stop driving whilst taking regular potent opioid analgesics, but this is not necessarily so. The usual advice to patients is that they should not drive or engage in other skilled activities such as operating machinery when they first start on morphine or a similar opioid, or when they increase the dose. However, once the initial sedative effects have resolved and both the patient and physician are confident that cognitive and psychomotor performance is no longer impaired, driving and other similar activities may restart.

This advice is based to a large extent on empirical experience and there have been few objective data to substantiate it. However, recent studies confirm, perhaps surprisingly, that morphine produces little measurable impairment of cognitive and psychomotor function, particularly in patients receiving continuous treatment with stable doses (Vainio et al., 1995; Fishbain et al., 2003; Byas-Smith et al., 2005). In one study, which used a battery of performance tests designed specifically to assess functions related to driving ability, chronic morphine use was associated with slower reaction times, more mistakes, and a slowing in ability to process visual information and perform motor sequences, but these changes were not statistically significant compared with a control group of cancer patients not taking morphine (Vainio et al., 1995). These data support the clinical impression that stable doses of morphine are unlikely to cause substantial impairment of the psychomotor skills required for driving, and allow us to continue to advise patients to this effect.

Patients, however, must be reminded of the responsibility of critical self-examination of their fitness to drive on a moment-by-moment basis before and during operating a motor vehicle and should desist if they are aware of any impairment of concentration or alertness (Brandman, 2005; Kress and Kraft, 2005). Clearly a physician has a duty of care to society and if he feels a patient should not drive, has to report this to the relevant driving authority, if the patient continues to drive.

'Allergy' and intolerance to morphine

Morphine and other opioids cause histamine release, and this is said to contribute to asthma or urticaria in allergic patients (Hermens et al., 1985; Warner et al., 1991; Katcher and Walsh, 1999). There is no published information on the incidence of this phenomenon and, in our experience, it is very uncommon (Woodall et al., 2008).

However, it is not uncommon for patients to claim that they are 'allergic' to morphine. This usually means that they have had a bad experience with the drug but, on investigation, what they describe are its common side effects. There is no doubt that most patients experience some adverse effects when they first start regular morphine treatment. Most commonly this is sedation, nausea, and, less often, vomiting. All patients must be warned about this and appropriate measures must be taken, as described above. If patients are not warned and experience unpleasant adverse effects they will be discouraged from continuing with the drug, and if they do not understand what is going on they may assume they that are 'allergic' to it.

Opioid misuses and addiction

Opioid misuse is a generic term for the intentional or unintentional use of a prescribed medication other than as directed (see Chapter 9.5). Misuse can include a patient taking more pain medicine than prescribed to control otherwise inadequately controlled pain as well as criminal, abusive and addictive behaviours.

Abuse refers to the intentional self-administration of a medication for non-medical purpose or the use of an illegal drug.

Addiction is a primary, chronic disease defined by one or more of the following behaviours: impaired control over drug use, compulsive use, continued use despite harm, and craving.

Addiction and substance abuse are social and medical problems of pandemic proportions which are associated with major social and human costs. Commonly, opioid drugs are the preferred substances of abuse. This association, combined with the principle of non-maleficence is the basis for concern regarding risk of addiction caused by the medical use of opioids. In recent years, the relationship between the medical use of opioids and the risk of addiction has been the focus of policy makers, medical sociologists, and pain clinicians.

Overall, this body of research has demonstrated (1) the risk of developing addictive behaviours or substance abuse as a

consequence of the medical use of opioids in a palliative care setting is low (Passik et al., 2000; Hojsted and Sjogren, 2007; Minozzi et al., 2013); (2) patient, family members, members of the health-care professions, and regulators commonly overestimate the risk of addiction; (3) patient, family members, members of the health-care professions, and regulators often confuse physical dependence and addiction; and (4) together, these concerns contribute substantially to physician reluctance to prescribe opioids and patient reluctance to use them (Goldberg, 2010).

Sadly, in the United States there is now clear evidence of an increasing problem of diversion of prescribed opioids (Epstein et al., 2007; Joranson and Gilson, 2007) as well as substance abuse and addiction among patients with chronic pain syndromes (Hojsted and Sjogren, 2007). This has generated much public discussion and anxiety about prudent opioid use and underscores the need for vigilance in patient evaluation and selection, the storage of opioid medications and the disposal of unused drugs, and used opioid patches.

To understand these phenomena as they relate to opioid treatment of cancer pain, it is useful first to present a concept that might be called 'therapeutic dependence'. Patients who require a specific drug therapy to control a symptom or disease process are clearly dependent on the therapeutic efficacy of the drugs in question. Examples of this 'therapeutic dependence' include the requirements of patients with congestive cardiac failure for cardiotonic and diuretic medication or the reliance of type 1 diabetics on insulin therapy. In these patients, undermedication or withdrawal of treatment would result in serious untoward consequences. Patients with chronic cancer pain have an analogous relationship to their analgesic therapy. This relationship may or may not be associated with the development of physical dependence, but is virtually never associated with addiction.

Psychological dependence and 'addiction'

The properties of the opioid analgesics that are most likely to lead to their being misused are effects mediated in the CNS. The term addiction refers to a psychological and behavioural syndrome characterized by a continued craving for an opioid drug to achieve a psychic effect (psychological dependence) and associated aberrant drug-related behaviours, such as compulsive drug-seeking, unsanctioned use or dose escalation, and use despite harm to self or others. Addiction should be suspected if patients demonstrate compulsive use, loss of control over drug use, and continuing use despite harm. The term addiction should not be used when physical dependence is meant.

There is a common perception that opioid use, for any reason, is associated with a high risk of iatrogenic psychological dependence and that it is best avoided or minimized. Many health-care professionals and laypersons fail to distinguish between patients with substance abuse disorder and psychologically well patients with pain, and consequently overestimate the risk of iatrogenic addiction. This skews evaluation of the therapeutic index of opioids, and impacts adversely on the likelihood of a clinician to prescribe opioids and on the patient's compliance with an opioid prescription.

Physical dependence

Physical dependence is the term used to describe the phenomenon of withdrawal when an opioid is abruptly discontinued or

an opioid antagonist is administered (Jasinski, 1981). The severity of withdrawal is a function of the dose and duration of administration of the opioid just discontinued (i.e. the patient's prior opioid exposure). The administration of an opioid antagonist to a physically dependent individual produces an immediate precipitation of the withdrawal syndrome. Patients who have received repeated doses of a morphine-like agonist to the point where they are physically dependent may experience an opioid withdrawal reaction when given a mixed agonist–antagonist. It can be shown that prior exposure to a morphine-like drug greatly increases a patient's sensitivity to the antagonist component of a mixed agonist–antagonist. Therefore, when used for chronic pain, the mixed agonist–antagonists should be tried before prolonged administration of a morphine-like agonist is initiated.

The abrupt discontinuation of an opioid analgesic in a patient with significant prior opioid experience will result in signs and symptoms characteristic of the opioid withdrawal or abstinence syndrome (Rogers, 1991b). The onset of withdrawal is characterized by the patient's report of feelings of anxiety, nervousness and irritability, and alternating chills and hot flushes. A prominent withdrawal sign is 'wetness' including salivation, lacrimation, rhinorrhoea, sneezing, and sweating, as well as gooseflesh. At the peak intensity of withdrawal patients may experience nausea and vomiting, abdominal cramps, insomnia, and, rarely, multifocal myoclonus. The time course of the withdrawal syndrome is a function of the elimination $t_{1/2}$ of the opioid on which the patient has become dependent. Abstinence symptoms generally appear within 6–12 hours and reach a peak at 24–72 hours following cessation of a short-$t_{1/2}$ drug such as morphine, while onset may be delayed for 36–48 hours with methadone, which has a long $t_{1/2}$. Therefore, it is important to emphasize that, even in a patient in whom pain has been completely relieved by a procedure (e.g. a cordotomy), it is necessary to decrease the opioid dose slowly to prevent withdrawal.

Experience indicates that the usual daily dose required to prevent withdrawal is equal to 75% of the previous daily dose. Following this rule of thumb, doses can be gradually titrated down until the drug is discontinued.

'Pseudoaddiction'

Some cancer patients who continue to experience unrelieved pain manifest intense concern about opioid availability and drug-seeking behaviour that is reminiscent of addiction but ceases once pain is relieved, often through opioid dose escalation. This behaviour has been termed 'pseudoaddiction' (Weissman and Haddox, 1989). Pain relief usually produced by dose escalation eliminates this aberrant behaviour and distinguishes the patient from the true addict. Misunderstanding of this phenomenon may lead the clinician inappropriately to stigmatize the patient with the label 'addict', which may compromise care and erode the doctor–patient relationship.

For the treating clinician, differentiating pseudoaddiction from abuse or addiction can be challenging. Evaluation requires a complete pain assessment and review the recent analgesic history: is this a pain syndrome that typically responds to opioids? Is the current opioid dose, route and schedule appropriate? If so, has a reasonable attempt at dose escalation been made? Is there any past medical history to suggest a substance abuse disorder? Complete a comprehensive addiction assessment if such a disorder is suspected

(Weissman, 2005). Ultimately, the diagnosis can only be made retrospectively, that is, pseudoaddiction improves with the provision of adequate analgesia, including opioids. In contrast, behaviours associated with a substance abuse disorder will not change.

This concept has been criticized, arguing that it is difficult to empirically demonstrate and that it can only be diagnosed ex post facto, that is, it can only be recognized when pain is adequately relieved and the pseudoaddictive behaviours disappear (Bell and Salmon, 2009).

Screening for abuse risk or abuse

Whereas opioids analgesic therapy is a safe and effective treatment for pain in many, for some it carries risk of abuse and addiction. Patients with severe chronic pain and high risk of opioid misuse should not necessarily be denied opioid therapy but should be identified and managed with a modified treatment plan and be followed under closer supervision than those patients with lower risk estimates (Hojsted and Sjogren, 2006).

Especially in the United States, authorities have been advocating the use of a screening evaluation for risk of misuse and addiction before patients are commenced on chronic opioids therapy. Although no screening tests have been developed to screen for opioid misuse specifically in cancer or palliative care patients the *Screener and Opioid Assessment for Pain Patients* (SOAPP) appears to be the best validated tool. The SOAPP predicts risk potential for aberrant drug behaviour via a 14-item self-report. Items included in the SOAPP cluster into categories of antisocial behaviour, substance abuse history, doctor/patient relationship, medication-related behaviours, and psychiatric and neurobiological need for medicine. Responses are based on a 5-point Likert scale (possible score range 0–56). Using 7 as a cut-off, this test had a sensitivity of 91%, specificity of 69%, positive predictive value of 71% and negative predictive value of 90% to predict future likelihood of aberrant drug behaviour (Butler et al., 2004). It is important to note that while a score of 7 maximizes this test's sensitivity, that is, identifies most patients with a risk of opioid misuse, it will also result in a large number of false positive tests given the lower specificity at this cut-off. In a study of 48 chronic pain patients, the sensitivity of predicting aberrant behaviour using SOAPP (73%) was very close to the sensitivity of a trained psychologist's clinical interview (77%) (Akbik et al., 2006). More recently a 24 item, revised version SOAPP-R has been developed with greater reliability (Butler et al., 2008).

Current Opioid Misuse Measure (COMM) is a 17-item, self-report questionnaire to assist clinicians identify whether a patient, currently on long-term opioid therapy may be exhibiting aberrant behaviours associated with misuse of opioid analgesics. Since the COMM examines current behaviour, it is ideal for helping clinicians to monitor patients during the course of therapy (Butler et al., 2007). In validation studies among patients with chronic pain, a COMM score of 13 had a sensitivity of 77% and a specificity of 77% for identifying patients with prescription drug use disorder (Meltzer et al., 2011).

Management of cancer pain in patients with a history of drug abuse

Patients with a history of abuse of opioid analgesics may develop cancer and severe pain (Starr et al., 2010; Kircher et al., 2011). It is important to distinguish between the patient with a previous history of abuse and one who is currently abusing or who is in the company of active abusers. In general, a multidisciplinary team approach is recommended for the management of at-risk patients. Mental-health professionals who specialize in addiction therapy may be instrumental in helping palliative care team members develop strategies for management and treatment compliance (see Chapters 4.13 and 9.5).

Conclusion

This opioid chapter reinforces that we have to remain grounded in individual patient assessment and tailored prescribing, with the background knowledge that complex disease and genomic dynamics make the patient phenotype. The ultimate response to analgesia is complex, but can be managed in an optimal way.

The consensus that opioid-based pharmacotherapy remains the mainstay of chronic cancer pain management, drives a consensus to best practice and a clinically relevant research agenda.

Opioid therapy: managing risks of abuse, addiction, and diversion

Julie R. Price, Alric D. Hawkins, and Steven D. Passik

Introduction to opioid therapy

Over the past decade, an emerging societal health issue has been the troubling increase in prescription drug abuse in the United States (National Center on Addiction and Substance Abuse of Columbia University, 2005). Given the complex and chronic medical problems that are seen in the palliative care setting, there is an increasing need for awareness of this issue, in addition to the potential for diversion of medications to others for illicit use. Traditionally, patients with substance use problems have been considered a homogenous group, but there exists a wide array of patients ranging from those with frank dependency to others with self-escalation of their medication doses without their prescribers' knowledge. Regardless of where patients may lie on the spectrum of substance-related problems, awareness of the existence of such issues is an important component to establishing an appropriate treatment plan.

However, simple awareness is only the first step in management, as these patients create a quandary for well-intentioned providers, who must balance the potential for abuse of prescribed opioids with the need to provide appropriate analgesia for patients in the palliative care setting. Nevertheless, these patients can be treated safely and effectively while addressing both of these issues.

Prevalence

Substance use in the United States is not uncommon with approximately half of the population between the ages of 15 and 24 having previously used illicit substances, while another 6–15% has met criteria for a substance use disorder (Regier et al., 1990; Colliver and Kopstein, 1991; Groerer and Brodsky, 1992; Warner et al., 1995; Kessler et al., 2005a, 2005b). Reports in the European Union from 2013 cite up to 38% of the population having a 'disorder of the brain', which includes substance use disorders. This number does include issues of alcohol and tobacco dependence as well, accounting for some of the increased prevalence rates (Effertz and Mann, 2012). Perhaps even more alarming is the increasing misuse of prescription drugs, which increased approximately 94% between 1992 and 2003 (National Center on Addiction and Substance Abuse of Columbia University, 2005). The combination of this high prevalence of use and its association with conditions such as HIV/AIDS, hepatic cirrhosis, and certain cancers (Wells et al., 1989; Blot, 1992; Thun et al., 1997; Smith-Warner et al., 1998; Room et al., 2005) means that issues surrounding substance misuse will arise in the palliative care setting, and will require increasing attention. Clinicians must be aware of the difficulties that may arise with the use of potentially abusable medications with patients who have an active or past problem with substance misuse and the potential difficulties this may cause in providing the patient with optimal care for management of their illness.

The problem of increasing prescription drug misuse is more than a complication of treatment, as it is contributing to a health care crisis where, in the United States, for the year of 2002 alone, it was implicated in approximately 30% of drug-related emergency-room deaths and at least 23% of emergency-room visits (National Center on Addiction and Substance Abuse of Columbia University, 2005). More concerning is that approximately one-third of abusers were new users with a growth of 225% in new opioid abusers between the years of 1992 and 2003. Additionally, during the same time period, there was a 150% increase in the abuse of tranquilizers, a 127% increase in the abuse of sedatives, and a 171% increase in the abuse of stimulants (National Center on Addiction and Substance Abuse of Columbia University, 2005). Given this rapid growth in the general population, new questions have to be raised about the prevalence of problematic use among those seen in the palliative care setting.

Fortunately, it appears that the prevalence of use amongst patients with cancer in tertiary care centres appears to be less than the frequency seen in society and general medical populations (Derogatis et al., 1983; Regier et al., 1984; Burton et al., 1991; Colliver and Kopstein, 1991; Groerer and Brodsky, 1992). For example, less than 1% of psychiatric consultations were requested for substance abuse concerns at Memorial Sloan Kettering Cancer Center (MSKCC) in a 6-month period in 2005 with only 3% of those patients eventually receiving a substance abuse diagnosis (Yu, 2005). A 1983 study by the Psychiatric Collaborative Oncology Group, found substance use conditions in less than 5% of 215 patients with cancer in the ambulatory care setting of several tertiary care hospitals based on structured clinical interviews (Derogatis et al., 1983). When compared to other settings, including emergency departments, general medical care providers, and society, this prevalence is fairly low (Derogatis et al., 1983; Regier et al., 1984; Burton et al., 1991; Colliver and Kopstein, 1991; Groerer and Brodsky, 1992).

However, this data must be considered carefully, due to the potential of bias, as prevalence has been found to be higher in other settings (Bruera et al., 1995). Potential contributors to lower

than expected prevalence, include potential under-reporting and underrepresentation of groups, who may have a higher likelihood of substance misuse, due to potential barriers and access to care. Ultimately, more studies are needed to sort out the true prevalence, but until then, there should remain some index of suspicion for substance use issues so that they can be adequately addressed.

Abuse, dependence, and the terminology of substance misuse

The terminology used in describing the phenomena associated with substance misuse is often problematic, given the widespread misuse amongst members of both the medical community and lay public. Nevertheless, it is imperative that this nomenclature become more standardized and be utilized appropriately in order to facilitate communication between providers and with patients. The American Psychiatric Association (2000) has outlined their criteria for substance abuse and dependence, in the *Diagnostic and Statistical Manual of Mental Disorders* (4th edition, text revision) (DSM-IV-TR), but these can be problematic when applied in the context of medical illness. One major difficulty is inconsistent use or relevant terminology, which interferes with communication between care providers. What will follow is a discussion of the relative terminology.

Tolerance

Tolerance is defined as a need for increasing doses of a medication to facilitate an effect (Martin and Jasinski, 1969; Dole, 1972). This phenomenon has been observed in a variety of opioid effects including its analgesic effects, as demonstrated in animal models (Ling et al., 1989), as well as respiratory depression and cognitive impairment (Bruera et al., 1989). Although it is often considered negative, there is limited data to support that it creates problems in the medical setting (Foley, 1991; Portenoy, 1994a). In fact, it appears that most patients can be maintained on stable doses of their medications with tolerance being primarily a side effect of the medication. It appears the increasing needs for analgesia when using opioids is more related to progression of the underlying illness (Twycross, 1974; Kanner and Foley, 1981; Chapman and Hill, 1989; Zenz et al., 1992; Aronoff, 2000; McCarberg and Barkin, 2001; Meuser et al., 2001). Moreover, clinical practice does not reliably support the notion that tolerance is a harbinger of substance dependence.

Dependence

The notion of dependence has to be considered in the context of physical dependence and the much broader substance dependence. Substance dependence, as described in the DSM, is a syndrome that requires maladaptive substance use with drug-seeking behaviour and physical indicators of use including withdrawal and tolerance (American Psychiatric Association, 2000). This is to be considered differently from physical dependence which indicates the presence of withdrawal alone with cessation of use or administration of an antagonist (Martin and Jasinski, 1969; Dole, 1972; Redmond and Krystal, 1984). Although there is some overlap, with previous speculations that physical dependence drives some of the drug-seeking behaviour associated with substance dependence (Wikler, 1980), these are completely separate entities. Physical dependence is a physiological phenomenon which may not occur

in patients taking opioids for pain relief. This is confirmed by animal studies, which have demonstrated that drug-taking behaviour can occur without physical dependence (Dai et al., 1989), and in the clinical treatment of non-malignant pain where patients who have physical dependence are able to discontinue without developing problematic substance use behaviours (Halpern and Robinson, 1985). Clinically, this is an important concept to understand in order to avoid the stigmatization of patients and inappropriate management. This stigmatization is particularly typified in the use of terms such as addiction, which has a pejorative meaning to the general public. This ill-defined term may include both components of problem drug use behaviours as well as physical dependence, and when misused may place patients in danger of having their pain undertreated by well-intentioned clinicians. In general, the label of 'addict' should rarely be used, especially when describing a patient who only has the potential for developing a withdrawal syndrome with substance discontinuation and has no maladaptive behaviours associated with their exposure to the addictive substance.

Substance abuse and dependence

Substance abuse and dependence are the terms designated in the DSM-IV-TR for problematic substance use (American Psychiatric Association, 2000), and should be utilized when discussing these issues. A key component of these designations is the idea of maladaptive behaviours associated with use that occur outside typical societal/cultural norms. However, it is important to recognize that defining normative behaviour is problematic, as evidenced by a survey of pain clinicians which demonstrated significant individual differences when defining the behaviours that were most problematic when ranking aberrant drug-taking behaviours (Passik et al., 2002). Furthermore, normative behaviours will also vary based on the circumstances under which they occur, such as in the chronic pain and medical conditions seen in palliative care.

As a result, problem drug-related behaviours are poorly defined in medically ill populations, which limit appropriate assessment. Furthermore, what defines problem behaviour may differ between provider and the patient, which could impair formation of an appropriate treatment alliance. This was demonstrated in a 2000 pilot study at MSKCC, where inpatients with cancer condoned behaviours typically considered as misuse, when it was done in the context of symptom management, while women, who were inpatients with complications of HIV frequently engaged in behaviours that would commonly be labelled as misuse (Passik et al., 2000). Further complicating the use of these terms in medically ill patients is the lack of clarity with regards to which symptoms should be attributed to the substance use and which should be attributed to the underlying illness, such as the declining physical status of the patient being due to the underlying medical illness and/or their substance dependence. For example, a patient may become less engaged with those around him/her, which may be more related to the progression of their illness than deterioration in social functioning related to their ongoing substance use. Given these and other issues, it can be seen that the use of these terms in medically ill populations are limited.

Aberrant drug-related behaviour

A concise definition of substance dependence was previously proposed by Rinaldi et al., who described it as a 'compulsive use of

a substance resulting in physical, psychological, or social harm to the user and continued use despite that harm' (Rinaldi et al., 1988). However, it could be argued that this definition is not sufficient to help in clinical decision-making. An attempt to develop a model that was more clinically useful has lent itself to the concept of 'aberrant drug-related behaviour'. The importance of this concept is that it moves away from defining and classifying the significance of behaviours that can be associated with misuse, and making it more clinically useful by defining it as an indication to assess patients for problematic substance use. Thus, in practice, a patient who presents with aberrant drug-related behaviours should be viewed as having a symptom of a potentially larger problem for which a differential should be constructed in order to fully address and provide an opportunity to manage a variety of issues that may be negatively impacting the patient's treatment including an underlying psychiatric illness or poor adaptive coping with the stressors of having a chronic medical illness.

At the core of this concept is the idea that aberrant substance use can represent more than a dependency syndrome. For example, a patient may ask aggressively for escalating drug dosage, which may be related to an intense desire to have adequate analgesia as opposed to representing true substance abuse or dependence (also known as pseudoaddiction). This, and other signs of distress, may appear to be aberrant drug-related behaviour and, if misdiagnosed, could produce a missed opportunity to help relieve patient suffering.

In using this model, the degree of aberrancy should be noted. Examples include:

◆ Mildly aberrant:
  • requests for specific pain medication
  • aggressive complaints about the need for medication
  • using drugs prescribed for a friend or family member
  • frequent prescription losses
  • hoarding drugs
◆ More highly aberrant:
  • forging prescriptions
  • obtaining drugs from non-medical source
  • sale of prescription drugs
  • crushing sustained-release tablets for snorting or injecting (Passik et al., 2002).

Less aberrant behaviours are more likely to represent patient distress whereas more aberrant behaviour is more consistent with problem substance use. However, it should be remembered that no specific behaviour should be viewed as pathognomonic for problem drug use and further exploration of any such behaviours should be undertaken if they are present. Examples include:

◆ a patient who is forging prescriptions in the context of borderline personality disorder due to their fears of abandonment instead of drug misuse
◆ a patient who self-medicates their underlying psychiatric illness, such as depression or anxiety
◆ a patient who misuses their medication due to confusion about their regimen in the context of cognitive deficits such as delirium or an underlying dementia.

In each of these examples, targets for treatment can be easily identified and would not preclude further prescribing of needed pain medications to the specific patient.

Empirical studies using the aberrant drug taking concept

The use of this model appears to have some support based on a few small studies (Dunbar and Katz, 1996; Compton et al., 1998; Passik et al., 2000) and appears to be a clinically useful tool, although larger empirical studies are needed. Dunbar and Katz (1996) examined 20 patients, with varying substance histories, who were being followed on chronic opioid therapy for 1 year. Ultimately, when compared to patients who abused their regimen, they found patients who did not abuse their opioid medications (11 of the 20 patients) were more likely to have abused alcohol alone or had a remote history of polysubstance use, were in community treatment programmes, and had strong psychosocial support. The patients who abused their regimen typically acquired opioids from more than one provider, increased their dose without permission, and made multiple phone calls or unscheduled visits to the clinic.

In another study, Compton et al. (1998) studied a group of patients who were referred to a multidisciplinary pain programme due to aberrant drug-taking behaviours. They examined these patients for a psychiatric diagnosis of substance dependence and found that those who met the criteria were more likely to have experienced a loss of control, increased their dose without permission, and received pain medications from multiple sources, compared to those without a psychiatric diagnosis.

Passik et al. (2000) examined patients with both cancer and AIDS for self-reported measures of attitudes and behaviours with regard to aberrant drug use. They found patients were not opposed either to themselves or others engaging in aberrant drug-taking behaviours if pain and other symptom management were not optimal. In addition, they found that the worry about developing substance dependence was greater than the actual risk.

These studies provide some insight into identifying potential behaviours that may be most concerning with regard to development of substance dependence syndromes with potentially abusable drugs. This is important to consider because of the potential to ascribe aberrant behaviours to substance dependence based on anecdotal evidence instead of following a more evidence-based approach. As a result, patients may be labelled inappropriately with dependence, which may jeopardize their ongoing management. Furthermore, it may lead to a missed opportunity to address the underlying needs or issues that resulted in the observed behaviour. For example, Passik et al. (2000) found that patients who had used anxiety medications that were intended for a friend appeared to have been doing so in an effort to manage undertreated anxiety instead of representing a true dependence syndrome.

Risk of substance abuse and dependence in the medically ill

Due to the growing prescription drug abuse problem in the United States, awareness has increased, which appears to have inappropriately raised the concern of both clinicians and patients with regard to the potential for developing opioid dependency when being treated for cancer pain. Contrary to this, is the increasing

concern in the palliative care community that patients are being undertreated. This is based on available data that indicates the development of a significant substance abuse issue in patients being treated for cancer pain with opioids, with no previous substance abuse history, is a rare occurrence (Health and Public Policy Committee, 1983; Ventafridda et al., 1985, 1990; Walker et al., 1988; Jorgensen et al., 1990; Moulin and Foley 1990; Schug et al., 1990, 1992; World Health Organization, 1990; Ad Hoc Committee on Cancer Pain, 1992; American Pain Society, 1992; Agency for Health Care Policy and Research, 1994; Zech et al., 1995).

Considering this issue raises questions regarding the potential risks and benefits for chronic opioid treatment in patients with non-malignant pain (Zenz et al., 1992; Portenoy, 1994b), which has traditionally been considered negative, especially when considering that a large group of patients who have drug dependence issues began abusing substances after receiving prescribed opioids (Kolb, 1925; Pescor, 1939; Rayport, 1954). In one survey, Caucasian participants with substance dependence had a previous history of medical opioid prescriptions at a rate of approximately 27% compared to only 1.2% of their African American counterparts (Rayport, 1954). This may represent a differential effect that has yet to be identified or may reflect ongoing disparities in the adequate treatment of pain in African American patients.

However, these estimates are flawed, as they do not represent a sample of medically ill patients requiring opioid therapy with no known drug abuse history. One study, which included almost 12 000 inpatients that received opioids while hospitalized, only demonstrated four cases of substance abuse or dependence issues following discharge (Porter and Jick, 1980). In a series including more than 10 000 burn patients without a history of drug abuse, no cases were identified of patients who subsequently developed new substance use disorders. Another study of patients with chronic headaches demonstrated similarly low numbers of patients who developed substance misuse concerns (Medina and Diamond, 1977). Although this does not directly support the safety of long-term opioid therapy in chronic pain patients, it seems promising with regard to their safety potential.

The other component in the ultimate development of substance use issues is potential heritability or a predisposition for developing such a disorder. Evidence now exists that supports the idea of inheritance of predispositions for substance use (Grove et al., 1990), so patients with a genetic loading for these disorders along with exposure to opioids would be expected to have a higher rate of developing a substance use disorder. However, the data currently does not support the concept that patients are likely to develop these issues when treated with drugs that have abuse potential for appropriate medical indications if they have no personal history of substance use or psychopathology, no family history of substance abuse/dependence, and/or no membership in a subculture that fosters abuse (Grove et al., 1990; Zenz et al., 1992; Gardner-Nix, 1996; Aronoff, 2000; McCarberg and Barkin 2001; Meuser et al., 2001; Potter et al., 2004).

Risk in patients with current or remote drug abuse histories

The available information about the risk of exacerbating remote or active substance abuse/dependence issues in medically ill patients who require prescriptions for substances of abuse is inadequate.

There are small reports which seem to support safety in such prescribing in patients, especially when the substance use issues are remote (Macaluso et al., 1988; Gonzales and Coyle, 1992; Dunbar and Katz, 1996). This is further supported by a study of patients, who had AIDS-related pain, who were able to be treated effectively with morphine (Kaplan et al., 2000). Ultimately, this issue needs further investigation and caution should be exercised in these patients with close follow-up and attention to aberrant behaviours.

Clinical management

The presence of aberrant drug use amongst patients with advanced illness represents a major impediment to appropriate care, regardless of the context in which it occurs. In order to maximize patient outcomes and to prescribe needed medications both safely and fairly, the clinician should work to develop appropriate controls and monitoring within their clinical practice.

Multidisciplinary approach

Multidisciplinary teams in the palliative care setting can be an important tool in optimizing treatment for patients with substance use disorders. A structured approach can minimize impediments to treatment for both the patient and the prescriber, who can develop a variety of emotions while treating these patients that may inadvertently affect the quality of pain-related care that is being offered. Teams would ideally include a psychologist, who is trained in addictions, along with adequate nursing and social work support to address the complex needs that patients often have.

Assessment

Once a member of the treatment team becomes concerned about the potential for aberrant substance use, then the other team members should be notified in order to begin a multidisciplinary intervention (Lundberg and Passik, 1997). Due to safety concerns that may arise, a physician should be involved early in the process in order to rule out life-threatening issues such as respiratory depression due to intoxication and/or life-threatening withdrawal symptoms. Once immediate safety has been assured, then an organized assessment should be conducted where information is gathered concerning the nature and extent of the problematic substance use in a non-judgemental and empathetic manner.

One technique to accomplish this is by conducting a graduated interview that proceeds from open-ended and broad questioning to more specific details about substance use, which will allow for a positive rapport to develop and potentially minimize the patients denial of his/her use. In this same manner, information should be gathered about co-occurring psychiatric disorders including anxiety, mood, and personality disorders, which are often co-morbid (Regier et al., 1990; Penick et al., 1994; Grant et al., 2004). Once this information has been gathered a more comprehensive treatment plan can be developed that will allow for the patient's need to be most effectively met.

Pre-screening patients

Much of recent research has been done on developing screening tools that allow for appropriate risk stratification of patients who will require a treatment plan that includes chronic opioid prescribing. An important component of risk stratification is to be non-judgemental

and to be mindful that aberrant substance use occurs on a spectrum that differs between recreational users and those requiring chronic pain treatment with opioids (Kirsh and Passik, 2008) (see Fig. 9.5.1). No assessment tool can diagnose substance misuse disorders alone, and some clinical acumen will need to be applied in order to identify the issues that may be leading to non-adherence.

Assessments tools are available for the purpose of identifying patients who may have problem substance use. A tool, called the Screener and Opioid Assessment for Patients with Pain (SOAPP) is a 24-item self-administered screen, which was validated in patients with chronic non-malignant pain (Butler et al., 2004). A shorter, five-item self-report tool, called the Opioid Risk Tool (ORT) was demonstrated in 2005 to be effective in identifying patients who would later develop aberrant substance use (Webster and Webster, 2005), although it is susceptible to deception. A study by Moore et al. demonstrated that a semi-structured clinical interview had the highest sensitivity alone (0.77), but this was increased to 0.90 when combined with the SOAPP (Moore et al., 2009). However, this study was done on patients primarily with chronic pain and its effectiveness in medically ill patients is unclear.

The four As for ongoing monitoring

Analgesia, Activities of daily living, Adverse side effects, and Aberrant drug-taking behaviours have been labelled the 'Four A's' of necessary monitoring for patients with chronic pain on opioids (Passik and Weinreb, 2000). Utilizing these four domains is useful in treatment planning and clinical decision-making. A checklist tool (Passik et al., 2004) has been developed:

◆ *Analgesia:* document and monitor patient's pain, using scales such as a 0–10 pain rating scale. Although listed as the first 'A,' analgesia is not necessarily to be considered the most important outcome of pain management. An alternate view is how much relief it takes for a patient to feel that their life is meaningfully changed so they can work toward the attainment of their own zgoals.

◆ *Activities of daily living:* monitor patient's typical level of daily activities and psychosocial functioning to observe increases over time. The second 'A' concerning activities of daily living refers to quality of life issues and functionality. It is necessary that patients understand that they must comply with all of their recommended treatment options so that they are better able to return to work, avocation, and social activities.

◆ *Adverse effects:* strive for the highest analgesia with the most benign side effect profile. Patients must also be made aware of the adverse side effects inherent in the treatment of their pain condition with opioids and other medications. Side effects must be aggressively managed so that sedation and other side effects do not overshadow the potential benefits of drug therapy. The most common side effects of opioid analgesics include constipation, sedation, nausea, vomiting, and dry mouth.

◆ *Aberrant behaviours:* be aware of aberrant behaviours suggestive of drug use, such as multiple 'lost' prescriptions or unauthorized dosing escalations. Patients must be educated through agreements, or other means, about the parameters of acceptable drug taking. Even an overall good outcome in every other domain might not constitute satisfactory treatment if the patient is non-adherent with the contract in concerning ways. Dispensing pain medicine in a highly structured fashion may become necessary for some patients who are in violation or constantly on the fringes of inappropriate drug taking behaviours.

Development of a treatment plan—general considerations

A treatment plan with clear goals will need to be individualized for each patient in an effort to curtail and manage aberrant drug-related behaviours. The ultimate overall goal is for 'harm reduction' as poor coping and dealing with chronic illness may interfere with adequate management (Passik et al., 1998). The key elements of this approach are:

1. Approach the patient with empathetic listening and attempt to understand their distress.

Population of Rx Opioid Users Is Heterogeneous

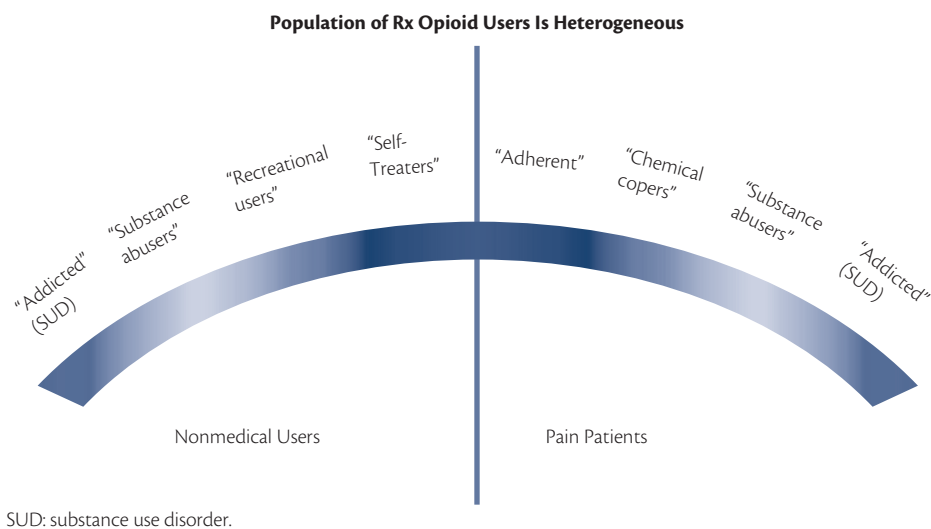
SUD: substance use disorder.


Fig. 9.5.1 The spectrum of adherence for pain patients versus the spectrum of illicit use by nonmedical users.

Reprinted with permission.

2. Utilize non-opioid interventions as part of management, but not as a substitute.

3. Utilize the patient's history of aberrant use in determining dosing and choice of medication that will offer the best outcome.

4. Frequent reassessment of the adequacy of pain and symptom control.

Urine toxicology screening

Non-adherence to treatment planning and aberrant substance use pose a variety of issues that could negatively impact prognosis. Due to this, it is imperative that appropriate monitoring be undertaken. The most useful and often easily obtained form of monitoring is the urine toxicology screening. However, one chart review in 2000 at a tertiary care centre showed that these screens were not often used by providers (Passik et al., 2000) and when used often demonstrated problems that decreased their effectiveness.

One of the difficulties in the use of urine toxicology screenings is a non-standardized approach, where clinicians make their decisions on who to test based on their own assessment of who they feel is at risk. However, this is not a reliable practice and could potentially miss problem behaviours, which would have been readily identified with testing. This unreliability was tested by Bronstein et al. (2011) who asked clinicians to identify patients who they felt were most at risk for aberrant drug use. They found that clinicians missed a significant group of patients who had no identifiable risk factors, but were able to identify patients more reliably when assessment tools were used.

Given that clinicians are not reliable in assessing those patients who do not have recognizable risk factors or problem behaviours, it is of great importance that drug screens be performed in a standardized and reliable way and performed on a randomized basis to minimize the ability of patients to predict testing in an effort to deceive screening.

The patient with advanced disease

The management of patients with advanced medical illness is a difficult task at baseline, but aberrant substance use can negatively impact efforts to offer appropriate palliative care. Ultimately the palliative care team and other treatment providers must work together to minimize risk, which may be as simple as a reduction in use, which could have a positive effect on the patient (Passik and Theobald, 2000). Box 9.5.1, lists some interventions that could be utilized in managing risk. These include screening tools for monitoring a variety of conditions, prescription monitoring programmes, which provides information on adherence to providers (Passik, 2009), and the previously mentioned urine drug screens. It is also important to remind patients to control their prescriptions carefully as studies have shown that prescription opioids are commonly diverted to family and friends for non-medical use (Passik, 2009). A final safety guard is opioid formulations and delivery strategies that minimize the potential for misuse, such as physical barriers.

Outpatient management

Outpatient management can be done safely and effectively. An important step to ensure a structure for appropriate management is to have the patient agree to a written treatment contract that is a mutually agreed upon document that establishes the boundaries

---

Box 9.5.1 Screening for substance abuse and treatment recommendations

Assessment guidelines

- Use a graduated interview approach beginning with broad questions about substances such as nicotine or caffeine and becoming more specific.

- Assess for comorbid psychiatric disorders, such as anxiety, mood, and personality disorders.

- Consider diagnostic instruments, such as the Screener and Opioid Assessment for Patients with Pain (Butler et al., 2004).

Treatment recommendations

General

- Listen and accept the patient's report of distress.

- Use behavioural and non-opioid interventions for pain when possible.

- Consider drugs with slower onset and longer duration (e.g., transdermal fentanyl and modified-release opioids). Note that higher doses may be needed for adequate pain control in patients with a history of abuse or dependence.

- Frequently assess adequacy of symptom and pain control.

Outpatients

- Limit amount of drug dispensed per prescription.

- Make refills contingent on clinic attendance.

- Consider urine toxicology screenings to assess usage.

- Involve family members and friends in the treatment plan.

Inpatients

- Consider placing the patient in a private room near the nurses' station.

- Consider daily urine collection.

---

of treatment. This may include such issues as frequency of urine drug screens, expectations in obtaining refills, expectations for outpatient substance abuse treatment, contingency plans for problem drug use, and expectations for the involvement of family and friends.

Inpatient management

In the inpatient setting, issues of misuse still remain a problem as patients may develop a variety of issues in regards to their substance use. This includes withdrawal syndromes, which may only become apparent after the patient no longer has access to the amount of medication they take at home. Aberrant substance use within the inpatient hospitalization can also be problematic and in extreme cases, visitors may need to be restricted and/or searched upon their arrival along with the patient's belonging. However, remain cognizant of the negative feelings that this may

elicit from patients who may view this as an invasion of privacy. The goal of maintaining safety should be communicated to the patient and, when possible, the patient should be included in the process in order to facilitate a more positive working relationship. Clinicians should also be aware of intravenous access in patients with a known history of intravenous drug use and of the potential for patients to leave the floor to purchase illicit substances. The patient should be monitored carefully for both safety and adequate pain management with an individual plan that is designed to meet his/her needs.

Conclusion

Aberrant drug-related behaviour is a complex phenomenon that can occur in the chronic medically ill patient and needs to be approached in a manner that allows for recognition of the biological, chemical, psychological, and social aspects of it. The spectrum of behaviours that fall within this category is broad and, unfortunately, not well defined in terms of outcome, management, and potential difficulties. Nevertheless, we must continue to approach patients with these issues in an empathic manner, with the ultimate goal of safely managing their pain, while addressing other issues that are leading to their distress and perpetuating their aberrant drug use.

Non-opioid analgesics

Per Sjøgren, Frank Elsner, and Stein Kaasa

Introduction to non-opioid analgesics

Non-opioid analgesics encompass the non-steroidal anti-inflammatory drugs (NSAIDs) and paracetamol (acetaminophen). All these drugs have analgesic and antipyretic properties. The NSAIDs include acetylsalicylic acid (ASA, aspirin), dipyrone (metamizole), and numerous other drugs in diverse classes. The advantages of non-opioid analgesics include their wide availability, familiarity to patients, effectiveness for milder pain conditions, ease of administration, additive analgesia when combined with other analgesics, and relatively low cost. The disadvantages include a ceiling effect for pain relief and the risk of side effects, including the potential for serious gastrointestinal (GI), renal, and cardiovascular toxicity (NSAIDs), and hepatotoxicity (paracetamol).

Non-opioid analgesics are widely used to manage mildto-moderate pain. In most Western societies, patients use over-the-counter formulations to treat pain related to headache and musculoskeletal ailments. In palliative medicine, they represent the first step of the analgesic ladder when used alone, or with adjuvant drugs, for mild pain and are an important supplement to opioids and adjuvant drugs at higher steps of the ladder (World Health Organization, 1996). The NSAIDs seem to be particularly useful in inflammatory pain and specific conditions such as bone pain. Paracetamol has limited anti-inflammatory effects, but is safer than the NSAIDs for long-term use. Dipyrone (metamizole) is used in some countries to treat pain, but has been removed from the market in others because of an association with life-threatening agranulocytosis.

Anti-inflammatory mechanisms

NSAIDs and paracetamol inhibit the production of prostaglandins (PGs). PGs are lipid-soluble molecules that are produced by enzymatic breakdown of arachidonic acid, which is itself produced from cell-membrane phospholipids. PGs are not stored in the body, but are produced constitutively as mediators of physiological effects in many tissues, or induced as part of the inflammatory cascade in in response to various noxious stimuli. Only 44 years ago, Vane postulated that inhibition of PG synthesis was the main effect of analgesics such as ASA (Vane, 1971). Subsequently, this led to the development of different types of drugs aiming at inhibiting the synthesis of PGs. A large number of NSAIDs were designed, and after the discovery of different isoforms of cyclooxygenase (COX), more selective COX-inhibitors became the focus of NSAID development. The selective COX-2 NSAIDs (coxibs) are the latest group to emerge from these activities.

The two isoforms of COX that have been best characterized are COX-1 and COX-2 (Fig. 9.6.1). COX-1 is largely a constitutive enzyme that produces PGs in many tissues. These PGs protect gastric mucosa, maintain normal kidney function, and promote platelet aggregation. Most COX-2 is induced as part of the complex processes that lead to inflammation, fever, and pain. All NSAIDs inhibit both COX-1 and COX-2, but there is a large variation in the relative effects on the two isozymes. Compared to conventional 'non-selective COX-1/COX-2' NSAIDs, coxibs inhibit COX-2 to a much greater extent.

The potential positive effects produced when NSAIDs inhibit PG synthesis include reduced inflammation and less pain. Serious adverse effects are possible, however, if the normal physiological effects of the PGs are disrupted (Abramson et al., 1985; McCormack, 1994; Richardson and Emery, 1995). Managing the latter risk is key to the use of these drugs in palliative care. The therapeutic benefit of the NSAIDs may be compromised if those PGs that are involved in nociception and inflammation cannot be reduced sufficiently, or adverse effects on normal physiology related to PG inhibition outweigh the therapeutic effects.

The tissue release of PGs is complex and is mediated by many types of noxious stimuli, and also by the actions of other substances like bradykinin and cytokines. The latter compounds induce nociception themselves and stimulate the synthesis of PGs and other mediators involved in nociception, such as substance P and calcitonin gene-related peptide (Burke et al., 2006).

Some of the functions affected by PGs also are mediated by leukotrienes. Leukotrienes are responsible for and involved in anaphylactic reactions, broncho-constriction, and chemotaxis, as well as vascular permeability and inflammation (Burke et al., 2006). PG synthesis inhibitors, such as NSAIDs and ASA, do not inhibit the production of leukotrienes, which to some extent may explain the limited efficacy of NSAIDs and ASA when treating pain of inflammatory origin.

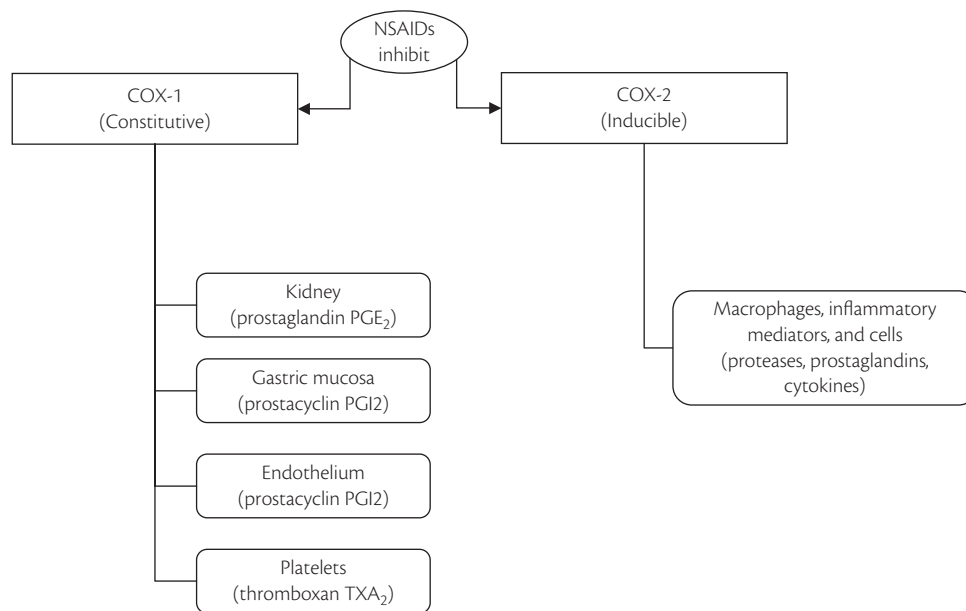
The specific mechanisms underlying the beneficial antipyretic and analgesic actions of NSAIDs are not fully understood. Mediators of the inflammatory process—especially the cytokines—induce the production of COX-2 within hours. The induction of COX-2 does not only take place in injured tissues, but also in the central nervous system (CNS). In the CNS, high concentrations of COX-2 cause increasing concentrations of PGs, which, in turn, induce central sensitization and consequently more pain (Baba et al., 2001; Samad et al., 2001). However, under normal physiological conditions, COX-2 is found only at very low concentrations in the body, including brain tissue (Breder et al., 1995; Seibert et al., 1997). In animal studies, endothelial cells


Fig. 9.6.1 Simple diagram of the influence of NSAIDs on prostaglandin synthesis.

express COX-2 mRNA in response to systemic interleukin-1 beta and the resulting production of PGs in the hypothalamus area may play an important role in producing fever (Cao et al., 1996).

In addition to COX-1 and COX-2, a COX-3 has been proposed as a variation expressed by the *COX-1* gene (Chandrasekharan et al., 2002). The existence of COX-3 in the CNS of humans has been controversial, and discussions regarding COX variants and their impact on antipyretic and analgesic effects are ongoing (Warner and Mitchell, 2002; Kis et al., 2003, 2004; Snipes et al., 2005).

COX-1 is constitutive, which means that it exists and acts continuously in many different tissues (Fig. 9.6.1). In gastric epithelial cells, COX-1 predominates and is responsible for the production of the protective PGI_2 (prostacyclin). Multiple actions of PGI_2 are involved in the protection of gastric mucosa: maintenance of mucosal blood flow, mucus production, secretion of bicarbonate, and also a positive influence on epithelial cell regeneration in order to provide a well-protected gastric mucosa. Thus, the inhibition of the production of PGI_2 by NSAIDs can upset this protective equilibrium (Scarpignato, 1995).

COX-1 is also responsible for the synthesis of PGE_2, which in addition to vasodilatation during inflammatory processes counteracts vasoconstriction in the kidneys. Under normal physiological conditions, the PG synthesis activity in the kidney is low and its role in modifying renal blood flow (RBF) is not of major importance (Ruilope et al., 1986). However, if RBF is critically lowered, glomerular filtration rate (GFR) may be partly restored by vasodilatatory effects of PGE_2. If PGE_2 production is reduced due to the use of NSAIDs, volume depletion of different aetiologies may aggravate the reduction of RBF. Moreover, inhibition of PGs may also result in a higher extracellular concentration of electrolytes such as sodium, which may cause water retention and oedema. In 10–25% of the patients treated with NSAIDs, sodium retention can be found (Burke et al., 2006).

There is growing evidence that nephrotoxicity is not only related to the influence of COX-1, but also to COX-2 activity. COX-2 is also constitutively expressed in the kidney and is regulated in

relation to changes in intravascular volume. Metabolites of COX-2 have also been discussed in the regulation of sodium excretion and renin release and the maintenance of RBF (Harris, 2006).

COX inhibition by NSAIDs also reduces platelet aggregation. Thromboxane A_2 (TXA_2) and PGI_2 are produced in platelets. PGI_2 prevents aggregation of platelets, but does not influence endothelial adherence, whereas TXA_2 is mainly responsible for coagulation. NSAIDs temporarily inhibit platelet aggregation by decreasing TXA_2 synthesis via incomplete and reversible inactivation of COX-1. The antithrombotic action of ASA is mainly due to inhibition of TXA_2-mediated platelet aggregation related to a complete and irreversible inactivation of COX-1 in platelets by acetylation of the enzyme (Patrono et al., 2004).

In an effort to minimize side-effects such as GI complications, renal impairment, and increased cardiovascular risk, efforts have been made to develop NSAIDs that selectively suppress the inducible form of COX, that is, COX-2, and also reduce the action of microsomal prostaglandin E_2 synthase (mPGES-1)-derived PGE_2. The coxibs have these effects. PGES-1 was identified as the most important PGE_2 synthase and its inhibition may lead to a relevant reduction of inflammation, fever, and pain in animal models. However, even if mPGES-1 seems to be a paramount target for inhibition resulting in a therapeutic use for any diseases related to inflammation and cancer, current knowledge about its role in clinical settings is limited (Koeberle and Werz, 2009).

NSAID-induced reduction in prostaglandin formation could potentially have other therapeutic effects, but supporting data are yet very limited. Epidemiological surveys of users and non-users of NSAIDs and ASA have shown that NSAIDs may alter the development and growth of malignancies. Clinical trials in patients with familial adenomatosis polyposis have shown the efficacy of NSAIDs in reducing the number as well as the size of colorectal polyps. However, a primary preventive effect has not yet been demonstrated. NSAIDs are also supposed to have a preventive and growth inhibitory effect in extracolonic epithelial malignancies. Pre-clinical studies show promising results with combination

treatments of either chemotherapy or radiotherapy with NSAIDs. These NSAID effects in cancer cells may be mediated not only by COX enzymes, but also by interactions with downstream effectors of inflammation (Meric et al., 2006).

NSAIDS also have been proposed to be effective in the treatment of cancer-induced cachexia. The effect can be explained through the 'cytokine pathway' in the development of cachexia. Consequently, the blocking effect of NSAIDS on cytokines may slow down the development of cancer cachexia.

In general, the inhibition of cyclooxygenase isoforms is the main mechanism of the non-opioid analgesics, especially the NSAIDs. However, there are several other effects of non-opioid analgesics beyond COX inhibition, and these too may ultimately be shown to be important in the analgesic and anti-inflammatory effects. Interactions with cholinergic, monoaminergic, and endocannabinoid systems may be responsible for anti-inflammatory effects, as well as for the reduction of pain and fever; they also may be responsible for some adverse effects (Hamza and Dionne 2009).

The pharmacology of NSAIDs

Absorption, distribution, metabolism, and excretion

Most NSAIDs are administered orally, and absorption takes place mainly in the upper GI tract; stomach mucosa may also absorb a substantial proportion of the dose, especially at low pH. If administered as suppositories, most of the NSAID crosses the mucosal membrane easily. Recommended maximum doses and pharmacokinetic data of widely used NSAIDs are shown in Table 9.6.1.

With oral administration, effects usually begin within 30 minutes and peak effects, which mirror maximum concentration, occur within 120 minutes. The rate at which effects decline depends on the half-life of each NSAID.

There is evidence that topical administration of NSAIDs can be an effective way of treating pain in special indications. The pharmacology of topical-applied NSAIDs is not well understood (Mason et al., 2004).

Several NSAIDs, such as ketorolac and ibuprofen, are available in injectable formulations, which may be administered intravenously or intramuscularly. There are only a few publications which compare possible advantages and disadvantages of the parenteral and oral routes (Tramer et al., 1998).

All systemically administered NSAIDs are highly protein-bound. Plasma protein binding ranges from 90% to 99%. NSAIDs are predominantly metabolized in the liver by conjugation to sulphate and glucuronide compounds. Hepatic metabolism, which is by the cytochrome P450 system, is subject to many sources of individual variation, including genomic factors and the influence of other drugs. There may be circadian differences as well, but the potential clinical relevance of this phenomenon remains unclear (Burke et al., 2006). Conjugation of NSAIDs in other tissues of the body occurs, but accounts for a small and insignificant percentage of the metabolism.

Most of the NSAIDs are rapidly distributed in all tissues of the body. The more lipid-soluble a NSAID is, the more it will distribute into the CNS. However, the very high plasma protein binding will retain most of the drug within the plasma compartment (Burke et al., 2006).

NSAIDs are eliminated in the urine in free and conjugated forms. The relative amounts of free and conjugated compounds are

highly dependent on urinary pH. Higher pH favours more acidic forms of elimination products. A small percentage of the drug can be found in the bile as well, which indicates that excretion also takes place via the intestines into the faeces (Burke et al., 2006).

Clinical efficacy of NSAIDs alone and in combination with opioids

Although data from populations with musculoskeletal pain or pain due to inflammatory disorders suggest that NSAIDs are likely to be efficacious in the treatment of pain associated with cancer and other advanced medical illnesses, the evidence of efficacy is very limited. A useful measure of relative efficacy is the number needed to treat (NNT), which can be calculated from data aggregated through systematic reviews. The NNT is the number of patients who need to be treated before one patient benefits at a specified level—such as 30% or 50% pain relief for a specified period of time—when compared to placebo. A systematic review of NSAID efficacy in cancer pain, alone or in combination with opioids, was unable to provide a NNT for the analysed studies because few studies reported the percentage of responders as dichotomous data (McNicol et al., 2005). Based on limited data, the authors cautiously concluded that NSAIDs seem to be

more effective than placebo for cancer-related pain. The evidence is not adequate to determine comparative efficacy or safety across NSAIDs, and the relative efficacy of NSAIDs in different cancer-related pain mechanisms cannot be established. There are no data specific to other severe illness. Given the short duration of studies, the long-term safety of NSAIDs for cancer pain also has not been established.

Side effects and toxicity of NSAIDs

NSAIDs administered alone or in combination with other analgesics should be used carefully. Potential adverse effects must be weighed carefully against potential advantages on a case-by-case basis, especially during chronic use. Given the broad role that PGs have in modifying physiological mechanisms, potential adverse effects vary widely.

Gastrointestinal effects

The most common adverse effects associated with the intake of NSAIDs occur in the GI tract (Table 9.6.2). The effects vary from symptoms without evident end-organ injury, such as nausea, pyrosis, pain, or bloating, to more serious problems, such as gastric and/or intestinal erosions followed by ulcerations. Erosions or ulceration, which can be observed in up to 30% of NSAIDs users, produce a range of associated symptoms of varying severity, and haemorrhage may range from harmless to life-threatening. Ulcers are often asymptomatic until haemorrhage occurs. Compared to non-users, patients who receive long-term treatment with a non-selective COX-1/COX-2 NSAID have an approximate fivefold higher risk of peptic ulcer disease and a fourfold higher risk of upper GI bleeding.

Patients receiving COX-2 selective inhibitors have significantly lower risk of GI toxicity than those receiving a non-selective COX inhibitor (Lanas, 2010). Although COX-1 inhibition is not the only mechanism involved in NSAID-induced GI toxicity, a systematic review of randomized controlled trials has shown that COX-2 selective inhibitors produced significantly fewer gastroduodenal ulcers and clinically important ulcer complications than non-selective NSAIDs (Rostom et al., 2007). Whether the outcome included bleeding events, symptomatic ulcers, or both, the GI risks with coxibs was consistently about half of that with traditional NSAIDs. However, there is evidence, both from this systematic review and from large controlled trials such as CLASS (Silverstein et al., 2000) and SUCCESS-1 (Singh et al., 2006), that this safety advantage is reduced in patients receiving concomitant low-dose ASA treatment. For example, in the SUCCESS-1 study, the risk of ulcer complications in patients receiving naproxen or diclofenac was significantly higher than in those receiving the COX-2 selective inhibitor celecoxib in the absence of ASA; in contrast, there was no significant difference in risk between the two groups of ASA users (Singh et al., 2006). A recent meta-analysis of all available trials including patients taking low-dose ASA combined with either non-selective NSAIDs or COX-2 selective inhibitors indicates a 28% reduction of GI risk in patients taking the combination of ASA + COX-2 (Rostom et al., 2009).

Celecoxib is the only COX-2 inhibitor currently available in the United States. Rofecoxib and valdecoxib were marketed but were withdrawn in 2004 and 2005, respectively, because of concern related to prothrombotic effects and other toxicities associated with long-term use.

The past decade has seen major advances in the prevention and management of ulcer complications, such as a decrease in the prevalence of *Helicobacter pylori* infection and improved treatment of acute ulcer bleeding. Recent evidence suggests that these developments have been reflected in a change in the pattern of NSAID-related GI complications seen in clinical practice (Lanas et al., 2009). Thus, while the incidence of complications involving the upper GI tract has decreased steadily during the last decade, perforations and bleeding in the lower GI tract have increased. Such findings suggest that, whereas attention has traditionally focused on NSAID-related complications in the stomach or duodenum, a broader perspective regarding the potential adverse effects of NSAIDs in the GI tract as a whole is needed.

Although there is a connection between NSAID use and lower GI haemorrhage, the evidence of NSAID-associated risk of lower GI bleeding is weaker than the evidence of upper GI bleeding. A systematic literature review reported that mucosal breaks or small intestinal injuries were present in up to 71% of NSAID users, and that up to 88% of patients with lower GI bleeding were NSAID users (Laine et al., 2006); the odds ratios (ORs) for upper GI and lower GI bleeding or perforation associated ranged from 1.9 to 18.4 and from 2.5 to 8.1, respectively. The risk of such problems was lower in patients receiving COX-2 selective inhibitors than in those receiving non-selective COX-1/COX-2 inhibitors (Laine et al., 2006).

The risk of GI toxicity varies among the non-selective COX inhibitors as well. Ibuprofen seems to be the least harmful drug in terms of the risk of upper GI bleeding. In comparison to non-users of NSAIDs, patients taking coxibs seem to have a low relative risk of GI bleeding followed by ibuprofen and diclofenac. A medium risk seems to be present for flurbiprofen, indomethacin, and naproxen, and a high risk has been proposed for ASA and ketorolac (Hernandez and Rodriguez 2000).

The risk of GI toxicity also varies with many other factors. The duration of the use of NSAIDs seem to be weakly associated with the risk of developing GI bleeding, whereas the incidence of haemorrhage is highly associated with high doses (Hawkins and Hanks, 2000). Specific characteristics and comorbidities also strongly influence the likelihood of adverse GI effects. Risk is related to age above 65 years; *Helicobacter pylori* infection; peptic ulceration within the last year; simultaneous intake of corticosteroids, low-dose ASA, and/or anticoagulants; far-advanced disease; cardiovascular disease, renal and hepatic impairment, and diabetes mellitus; smoking; and excessive alcohol use (Hernandez and Rodriguez, 2000).

Due to the high risks of GI side effects of traditional NSAIDs in frail patients, the use of gastroprotective strategies prevails, although the evidence is still limited. Proton pump inhibitors (PPIs) and misoprostol both reduce the incidence of gastric and duodenal ulcers, as well as recurrence in patients receiving traditional NSAIDs. Although misoprostol is slightly more effective in preventing gastric ulcers, PPIs are better tolerated, as misoprostol often causes diarrhoea (Rostom et al., 2002; Dubois et al., 2004). Patients at increased risk of GI complications should receive either a non-selective NSAID with an appropriate gastroprotective agent, such as a PPI, or a COX-2 selective inhibitor alone. These two strategies were compared in a randomized, double-blind trial involving 287 arthritis patients who received either diclofenac plus omeprazole, or celecoxib, 200 mg twice daily, for 6 months

Table 9.6.2 Side effects of NSAIDs in general

Where	What
◆ Gastrointestinal tract	◆ Pain ◆ Nausea ◆ Gastric erosion: ulceration ◆ Bleeding ◆ Perforation

◆ Kidney	◆ Water and sodium retention
	 ◆ Oedema
	 ◆ Hyperkalaemia
	 ◆ Decreased effectiveness of:
	   • antihypertensive agents
	   • diuretics

◆ Central nervous system	◆ Dizziness ◆ Headache ◆ Confusion ◆ Vertigo ◆ Depression
◆ Platelet function	◆ Inhibition of activation ◆ Increased risk of haemorrhage
◆ Special areas of hypersensitivity	◆ Rhinitis ◆ Bronchial asthma ◆ Urticaria ◆ Flushing ◆ Hypotension ◆ Shock

(Chan et al., 2002). The risk of recurrent ulcer bleeding did not differ significantly in the two groups. More recently, the combined use of a COX-2 selective inhibitor and a PPI to prevent recurrent ulcer bleeding in high-risk patients was studied. In this randomized, double-blind trial, 441 patients with upper GI bleeding received celecoxib, 200 mg twice daily, alone or in combination with esomeprazole, 20 mg twice daily, for 12 months (Chan et al., 2007)[)]. The incidence of recurrent bleeding within 12 months was significantly lower with combination therapy than with celecoxib alone, and there were no differences in discontinuation rate or the incidence of adverse events between the two groups.

Nephrotoxicity and hypertension

Non-selective NSAIDs inhibit both constitutive COX-1 and inducible COX-2, the rate-limiting enzymes involved in the production of PGs and thromboxane. In addition to their role in inflammation and pain, PGs are important mediators of vascular tone, salt and water balance, and renin release. PGE_2 is a mediator of sodium reabsorption in the distal renal tubule and acts as a counter-regulatory factor under conditions of increased sodium reabsorption by limiting salt and water reabsorption (Whelton, 2000). PGI_2 and PGE_2 increase potassium secretion, primarily by stimulating the secretion of renin and activating the renin–angiotensin system, which leads to increased aldosterone secretion. These vasodilatory PGs also increase RBF and GFR under conditions associated with decreased actual or effective circulating volume, resulting in greater tubular flow and secretion of potassium. In healthy hydrated individuals, renal PGs do not play a major role in sodium and water homeostasis (Whelton, 2002). Under conditions of decreased renal perfusion, however, the production of renal PGs serves as an important compensatory mechanism. Numerous conditions are associated with a decrease in renal perfusion, including dehydration, blood loss, congestive heart failure, cirrhosis, diuretic use, and restricted sodium intake. Under these conditions, non-selective NSAIDs may produce adverse effects, including a decrease in GFR. Conversely, in conditions of high salt intake and/or volume expansion, non-selective NSAIDs may induce salt retention, which may elevate blood pressure or make pre-existing hypertension worse.

These effects produced by the non-selective COX-1/COX-2 inhibitors also occur with the selective COX-2 inhibitors. Both types of NSAIDs can cause acute renal failure and hypertension (Cheng and Harris, 2004) during short-term or long-term use. All these drugs are especially likely to reinforce renal impairment in patients with pre-existing renal insufficiency. Patients with chronic kidney diseases, like those with heart failure, cirrhosis, dehydration, or any other co-morbidity causing activation of the sympatho-adrenergic and/or renin–angiotensin system, depend very much on a normal PG status for maintaining adequate function of the kidneys. Because the production of PGE_2 and PGI_2 depends on the activity of COX-2 (Qi et al., 2002), there is no difference in this risk between the non-selective COX inhibitors and the selective COX-2 drugs. Long-term treatment with either non-selective COX-1/COX-2 inhibitors or the selective COX-2 inhibitors also may significantly increase the risk of developing and maintaining renal failure, as may the use of NSAIDs with a long half-life (Henry et al., 1997).

Renal papillary necrosis induced by the non-selective COX-1/COX-2 inhibitors is well recognized and case reports also have described this complication with the selective COX-2 inhibitors (Whelton, 1999; Akhund et al., 2003). Recently, tubulointerstitial injury has been reported with COX-2 inhibitors (Ortiz et al., 2005). The vascular supply within the renal papillae is dependent on local renal PG production. Clinical conditions resulting in volume depletion or decreased RBF in association with NSAID ingestion may lead to elevated concentrations of NSAIDs and their metabolites within the papillae, which inhibit the vasodilatatory effect of the PGs and lead to renal papillary necrosis.

Congestive heart failure, coronary heart disease, and thrombosis

Congestive heart failure also may result from treatment with NSAIDs, particularly in medically frail and elderly patients. Patients admitted to the hospital diagnosed with congestive heart failure had a higher prevalence (17%) of recent NSAID use than patients admitted with other diagnoses (12%) (Page and Henry, 2000; Merlo et al., 2001). The risk of congestive heart failure increased with an additional history of heart disease

As mentioned earlier, TXA_2 is a potent vasoconstrictor and promotes platelet aggregation. TXA_2 is induced by the activity of COX-1 and, in effect, acts as a prothrombotic agent. On the other hand, PGI_2 causes vasodilatation, and thereby inhibits the aggregation of platelets. Selective inhibition of COX-2 increases the relative activity of TXA_2, which subsequently may facilitate the formation of thromboses. The literature relating to the risk

of prothrombotic complications from NSAIDs, including myocardial infarction and stroke, is complicated, but supports the conclusion that all NSAIDs—including non-selective COX-1/COX-2 inhibitors and selective COX-2 inhibitors—could pose a risk of these complications as a result of their effects on COX-2. There appears to be important variation across drugs, however. In patients with coronary heart disease, a reduction of COX-2 activity produced by treatment with selective COX-2 inhibitors increase the risks for acute cardiovascular events such as strokes, thromboses, and myocardial infarction (Fitzgerald, 2004; Bresalier et al., 2005; McGettigan and Henry, 2006). However, some studies do not observe these outcomes during treatment with celecoxib (McGettigan and Henry, 2006). A meta-analysis of randomized trials including coxibs and non-selective NSAIDs taken for more than 4 weeks showed that coxibs and high-dose regimens of ibuprofen and diclofenac were associated with a moderate increase in the risk of vascular events (defined as myocardial infarction, stroke, or vascular death) (Kearney et al., 2006). However, high-dose naproxen was not associated with such events. Another recent systematic review confirmed that the relative risk of myocardial infarction varied with the individual NSAIDs. An increased risk was observed for diclofenac and rofecoxib; the latter drug had a dose–response trend, with risk higher for doses greater than 25 mg/day (78%) than for lower doses (18%) (Hernandez-Diaz et al., 2006). Rofecoxib was withdrawn from the market in September 2004.

Notwithstanding the limitations in the literature, it is clinically prudent to include prothrombotic cardiovascular risk as among the potential adverse effects produced by both the selective COX-2 inhibitors (Flavahan, 2007) and the non-selective COX-1/COX-2 inhibitors (Kearney et al., 2006; Warner and Mitchell, 2008). The 'imbalance' theory alluded to previously offer a reasonable explanation: any NSAID that reduces COX-2-dependent PGI_2 in endothelium without a commensurate effect on COX-1-dependent TXA_2 in platelets will predispose to a prothrombotic state by increasing the relative activity of TXA_2. All NSAIDs may be prothrombotic because all have an inhibitory effect on COX-2 (Cheng et al., 2002).

Contraindications and drug interactions

Given the risk profile of the NSAIDs there are important relative contraindications to their use in palliative care. Treatment should be undertaken cautiously, if at all, in patients at high risk for GI haemorrhage, or those who would be unlikely to cope with bleeding should it occur. The former group includes those with a haemorrhage within the last year, a history of peptic ulcer disease or NSAID-induced gastroduodenopathy in the past, advanced age, severe medical frailty, or concurrent treatment with a corticosteroid.

Patients with clinically significant renal insufficiency usually are considered to have too high a risk for NSAID therapy, and patients with liver disease and those predisposed to adverse cardiovascular outcomes should be considered to have a relative contraindication. The latter group includes those with a history of symptomatic atherothrombotic disease in the past (myocardial infarction, angina, stroke, transient ischaemic attacks, or symptomatic peripheral vascular disease) and those with significant risk factors, such as a history of poorly controlled hypertension, hyperlipidaemia, or smoking. Patients with a history of

NSAID-induced asthma or a documented allergic reaction to any NSAID also should not generally be offered NSAID therapy. When the European Agency for the Evaluation of Medicinal Products reviewed a recent addition to the coxibs available in Europe, etoricoxib, it noted that the drug is contraindicated in cases of hypertension, severe hepatic dysfunction, inflammatory bowel disease, and congestive heart failure (European Medicines Agency, 2008).

NSAIDs also are associated with drug–drug interactions that may be particularly important in the medically ill. For example, they may reduce renal function during concomitant lithium, methotrexate, and amino-glycoside therapy, which can give rise to increased plasma concentrations. High plasma protein binding of NSAIDs can increase the concentration of free, active drug in some cases, such as phenytoin, and lead to unanticipated toxicity as a result. Patients who have a coagulopathy or are receiving anticoagulant therapy should be considered to have a strong relative contraindication to NSAID therapy. NSAIDs also may attenuate the metabolism of warfarin and thus increase its effect.

One should take into consideration that most of the studies of patients with advanced disease and short life expectancy typically involve small numbers of patients. Therefore, the studies investigating side effects are probably underestimating the frequency of such symptoms and signs. As a general rule in old and/or frail patients, polypharmacy should be limited if possible. Indications for the use of all drugs should be carefully considered by evaluating the probability of beneficial effects versus the probability of side effects. These considerations seem to be of utmost importance when using NSAIDS.

Topical NSAIDs

Topical NSAIDs, which may be applied via a rub-on solution, gel, or adhesive skin patch, offer obvious theoretical advantages by minimizing the systemic complications of these drugs. They have a relatively low bioavailability compared with oral NSAIDs and this may account for their favourable safety profile. Topical patches provide a fixed constant dose and local action. Gel formulations can be used on parts of the body that are not easily accessible by a patch, such as the fingers. Side effects tend to be localized to the site of application, such as itching and rashes.

Topical NSAIDs have been recommended for use in osteoarthritis (National Institute for Health and Clinical Excellence, 2010). After topical application, therapeutic levels of NSAIDs can be demonstrated in synovial fluid, muscles, and fasciae, and this finding suggests that they may have their pharmacological effects on both intra- and extra-articular structures. Although it is assumed that their mechanism of action is similar to that of oral NSAIDs, the topical drugs produce a maximal plasma NSAID concentration of only 15% of that achieved following oral administration of a similar dose (Lin et al., 2004). There have been no studies of topical NSAID therapy in palliative care and their efficacy for localized pain associated with non-musculoskeletal causes is unknown. The potential role of topical NSAIDs needs to be explored in palliative care.

Acetylsalicylic acid

ASA and its derivatives are the prototypes of NSAIDs and have been known since ancient times. In the mid-eighteenth century,

Edward Stone, an English clergyman, wrote the first scientific description of the effects of willow bark.

ASA covalently and irreversibly inhibits both COX-1 and COX-2. This is an important feature of ASA, as the duration of the effects are related to the turnover rate of COX in the different tissues. Platelets are particularly susceptible to ASA-mediated irreversible inhibition of COX, because they have limited capacity for protein synthesis and thus cannot regenerate COX enzymes. This means, that a single and small dose of ASA will inhibit the COX enzymes for the lifetime of the platelets (Patrono et al., 2004).

The prevalent use of low-dose ASA for cardioprotection must be considered when NSAIDs are administered for pain. The combination of a non-selective COX-1/COX-2 inhibitor and low-dose ASA increases the risk of GI toxicity. The combination of a selective COX-2 inhibitor and low-dose ASA reduces the relative benefit of the coxib on GI risk, particularly if treatment lasts more than 6 months. Some NSAIDs, such as ibuprofen, may attenuate the antithrombotic effects of ASA and reduce its cardioprotective effects. Because the latter interaction would be less likely to occur if the NSAID is taken after (perhaps 2 or more hours) the dose of ASA, patients should be instructed to do so. Paracetamol has no adverse interaction with low-dose ASA therapy (Gaziano and Gibson, 2006).

The results of systematic reviews of single-dose studies confirm ASA's efficacy as an analgesic. Analysis of the analgesic dose–response tells us that higher doses give more analgesia, and comparing ASA with paracetamol the analgesia produced by the two drugs are very similar. One gram of ASA gives the same analgesia as 1 g of paracetamol (Gaziano and Gibson, 2006; McQuay and Moore, 2007). Furthermore, significant benefit of ASA over placebo was shown for ASA 600–650 mg, 1000 mg, and 1200 mg, with NNT values for at least 50% pain relief of 4.4, 4.0, and 2.4, respectively. However, in single-dose studies even low doses of ASA 600/650 mg produced significantly more gastric irritation and drowsiness than placebo (Edwards et al., 1999). The GI side effects of ASA are the main reason for the limited use of ASA in palliative care.

Paracetamol (acetaminophen)

Paracetamol (acetaminophen; *N*-acetyl-p-aminophenol) is one of the most commonly used analgesic and antipyretic drugs worldwide, and it is widely available by prescription and over the counter. Paracetamol, a so-called coal-tar analgesic, was discovered by accident as an active metabolite of phenacetin. The site of action seems to be in the brain; however, the mechanism of action is still poorly understood. In a double-blind, placebo-controlled study in healthy volunteers, Piletta and colleagues obtained some evidence for a central analgesic action of paracetamol. Application of a transcutaneous electrical stimulus to the sural nerve caused a flexion reflex and a subjective sensation of pain. In contrast to ASA, paracetamol raised the threshold to both types of pain, indicating an analgesic action both at the spinal cord level and in higher centres (Piletta et al., 1991).

Although there is considerable overlap in the actions of paracetamol, NSAIDS, and ASA regarding inhibition of COX, *in vitro* studies show that paracetamol is not a highly potent inhibitor of COX-1 and COX-2 (Ouellet and Percival, 2001). As mentioned earlier, a third form of COX has been proposed, which has been referred to as COX-3 (Ayoub et al., 2006). However, cloning studies have failed to confirm the existence of COX-3 in humans and the search for a convincing mechanistic explanation of the therapeutic activity of paracetamol continues (Qin et al., 2005).

Paracetamol also possesses antipyretic activity and the brain is likely to be the site of its antipyretic effects. The antipyretic activity of the compound resides in its aminobenzene structure and the effect seems to be caused by inhibition of COX-2 or a variant of this enzyme (Simmons, 2003). Because of the association between ASA and Reye's syndrome in children, paracetamol is the antipyretic drug of choice in children, and when used in recommended doses, has few side effects, and is remarkably well tolerated.

Pharmacokinetics and metabolism

Paracetamol is commercially available in a considerable number of products, both alone and in combination with other drugs. It can be administered orally as tablets (conventional, sustained release, effervescent), capsules, powders, and elixirs, and can be given rectally as suppositories. Paracetamol is rapidly and almost completely absorbed from the GI tract. Gastric emptying rate rather than the diffusion across the intestinal mucosa is the rate-limiting step in paracetamol absorption after oral administration. Therefore, any drug, disease, or other condition that alters the rate of gastric emptying will influence the rate of absorption. Although paracetamol is rapidly absorbed from the GI tract, it is incompletely available to the systemic circulation due to hepatic first-pass metabolism accounting for a 10% loss in therapeutic doses. Intestinal metabolism also contributes to decreased bioavailability (Tone et al., 1990). In adults, the bioavailability of paracetamol after administration of suppositories is approximately 60% (Beck et al., 2000). After oral administration of therapeutic doses, the concentration in plasma reaches a peak in 30–60 minutes, and the half-life in plasma is about 2 hours. Paracetamol is relatively uniformly distributed throughout most body fluids (Prescott 1996). The proportion of paracetamol bound to plasma proteins is small and varies from 5% to 20% (Milligan et al., 1994). Biotransformation takes place primarily in the liver and the oxidative reactions via the cytochrome P450 system are followed by conjugation. After therapeutic doses, 90–100% of the drug may be recovered in urine within the first day, primarily after hepatic conjugation with glucuronic acid (about 60%), sulphuric acid (about 35%), or cysteine (about 3%); small amounts of hydroxylated and deacetylated metabolites also have been detected (Steventon et al., 1996).

Pharmacodynamics

The lack of dichotomous data in randomized trials, and a lack of trials in medically ill populations, largely precludes calculation of a NNT for paracetamol use in patients with serious illness. Studies also have not evaluated long-term efficacy. Nonetheless, evidence suggests the use of non-opioids alone is superior to placebo for mild pain in cancer and medical illness, at least during short-term treatment (McNicol et al., 2005).

The efficacy of paracetamol compared to NSAIDS has not been thoroughly investigated (Ventafridda et al., 1990) and the combination of paracetamol and NSAIDS has not been investigated in cancer-related pain. Most studies have assessed paracetamol in combination with other analgesics, and these studies do not give any information on the analgesic effect that paracetamol provides

on its own (Carlson et al., 1990; Chary et al., 1994). Only one randomized, double-blind, placebo controlled study indicated that the addition of paracetamol to ongoing oral opioid therapy improved pain relief and general well-being in cancer patients (Stockler et al., 2004).

Side effects and toxicity

At therapeutic doses of paracetamol, side effects are rare, and the clinical advantage during long-term treatment is that the side effects are less severe than with the NSAIDS. Allergic reactions have been described, and during long-term treatment chronic headache may occur (Meskunas et al., 2006). Toxicity from paracetamol usually is due to either accidental or deliberate overdose. A small proportion of paracetamol undergoes P450-mediated N-hydroxylation to form N-acetyl-benzoquinoneimine, a highly reactive intermediate metabolite. This metabolite normally reacts with sulfhydryl groups in glutathione. At large doses of paracetamol (usually considered in those without liver disease to be a single dose > 10 g), the metabolite is formed in sufficient amounts to deplete liver cells completely of glutathione, which seems to trigger hepatotoxicity and a prolonged rise in liver-derived transaminase and alkaline phosphatase levels in the serum. Intervention to sustain hepatic glutathione is an effective treatment for paracetamol overdose and administration of N-acetyl-L-cysteine, which replenishes glutathione stores, remains the treatment of choice (Josephy, 2005).

Dipyrone (metamizole)

Dipyrone is a popular medicine for pain relief in many countries and is used to treat postoperative pain, colic pain, cancer pain and migraine. In other countries (e.g. United States, United Kingdom, and Japan), however, the drug has been removed from the market, or not approved, due to concerns about serious adverse effects. Although the data are insufficient to draw any conclusions about the influence of dose or route of administration, dipyrone has been associated with potentially life-threatening blood disorders, such as agranulocytosis.

A single 500 mg oral dose of dipyrone provides at least 50% pain relief to adults with moderate or severe postoperative pain, with efficacy similar to ibuprofen 400 mg. A single 2.5 g intravenous dose is equivalent to 100 mg intravenous tramadol for at least 50% pain relief. In efficacy studies, no serious events or adverse event withdrawals were reported (Edwards et al., 2010). A small controlled trial indicated that dipyrone adds significantly to the analgesic effect of morphine in patients with cancer-related pain (Duarte et al., 2007).

Conclusions and recommendations

NSAIDs have important risks and should be used cautiously in the medically ill. There are many factors that increase the risk of GI, renal, or cardiovascular toxicity, and populations with serious or life-threatening illness are likely to have one or more of these factors. Caution must be exercised in elderly or medically frail patients and those with significant disorders affecting liver or kidney. Risk factors for GI haemorrhage, such as peptic ulcer disease or *Helicobacter pylori* infection, and risk factors for cardiovascular disease, such as prior coronary artery disease, uncontrolled

hypertension, diabetes, and others, present relative contraindications to the long-term use of NSAIDs. The risk of these drugs increases when the potential for pharmacokinetic or pharmacodynamic drug–drug interactions occur, and co-treatment with corticosteroids, low-dose ASA, or anticoagulants, for example, should further increase caution in the use of these drugs.

Patients at high risk for adverse effects during long-term oral NSAID therapy should be considered for other strategies, such as paracetamol, topical NSAIDs, adjuvant analgesics, and opioids. When treatment with NSAIDs is indicated and effective, it is strongly recommended to use the lowest effective dose for the shortest period of time, and to combine the treatment with a gastroprotective agent (usually a PPI; misoprostol and higher-dose H_2 antagonists are alternatives). Unless otherwise contraindicated for other reasons, a COX-2-inhibitor, such as celecoxib, should be strongly considered. Patients with advanced illnesses are often at high risk and either lowest effective dose of an NSAID combined with PPI or the lowest effective dose of a coxib should be considered.

Cardiovascular risks are associated with COX-2 inhibition, and consequently, are concerns during treatment with all NSAIDs. Although the data are inconclusive, there do appear to be important drug-selective effects; naproxen, for example, may pose a lesser risk than other NSAIDs, and some studies suggest a low risk for celecoxib. Both relatively higher doses and longer treatment durations seem to increase the cardiovascular risks. Based on current evidence, patients at high cardiovascular risk should be treated with either naproxen (plus PPI) or celecoxib, and the use of the lowest effective dose for the shortest possible duration of time is recommended.

Generally, the efficacy and side effects of NSAIDs should be monitored and evaluated during long-term treatment. If effectiveness is doubtful, the drug should be discontinued.

Future trends

There remains a need for a substantial increase in the number of high-quality trials of non-opioid analgesics in patients with serious or life-threatening illnesses, such as cancer. Studies that specifically address the question of whether addition of a non-opioid to an opioid analgesic regimen actually increases efficacy and/or reduces side effects are required. In addition, the safety and efficacy of chronic use of non-selective COX-1/COX-2 inhibitors versus the coxibs needs to be established. Emerging questions about the selective COX-2 inhibitors, such as their potential anti-angiogenic properties, remain unanswered (Steinbach et al., 2000). Translation of emerging preclinical insights into distinct mechanisms for pain of different aetiologies (e.g. bone metastases) would be another step towards more rational pharmacotherapy (Davar, 2002).

Due to the potential for adverse effects encountered during NSAID therapy, combined with a very economically lucrative market, this is an area of continuing major investment in research. The COX-inhibiting nitric oxide donors (CINODs) are a new class of agents designed for the treatment of pain and inflammation. CINODs have a multi-pathway mechanism of action that involves COX-inhibition and nitric oxide donation. The anti-inflammatory and analgesic effects of COX-inhibition are reinforced through inhibition of caspase-1 regulated cytokine production, while nitric

oxide donation provides multi-organ protection. The CINODs are devoid of hypertensive effects in animal models and their mechanism of action suggests that they may not cause oedema. CINODs also have other renal-sparing effects, being better tolerated than NSAIDs in models of kidney failure. CINODs have been shown to prevent platelet activation *in vitro* and exhibit antithrombotic activity *in vivo*. In animal models of ischaemia/reperfusion treatment with CINODs results in improved recovery of heart contractility and reduced left ventricular end-diastolic pressure, in contrast to the effects of NSAIDs and ASA. Naproxcinod has been the first, and so far the only, CINOD investigated in clinical trials. These studies have shown a slight improvement in GI tolerability in comparison to naproxen in surrogate endpoints (number of gastric and duodenal ulcers) and a significant reduction in the risk of destabilization of blood pressure control in patients with osteoarthosis taking antihypertensive medications in comparison to either naproxen and rofecoxib (Baerwald et al., 2010; White et al., 2011). The lack of outcome studies, however, has precluded the approval of naproxcinod by the US Food and Drug Administration.

NSAIDs that release H_2S as a mechanism may have greater GI and cardiovascular safety, and are being investigated in preclinical models. Both naproxen and diclofenac hybrids have been reported to cause less GI injury than parent NSAIDs. These novel chemical entities exert a variety of beneficial effects in rodent models of cardiovascular and metabolic disorders through a mechanism that might involve the release of H_2S and/or by exerting antioxidant effects. The beneficial role these mechanisms in clinical settings await a proof-of-concept study (Fiorucci and Distrutti, 2011).

The short-term use and benefits of topical NSAIDs have been reflected in guidelines for the treatment of osteoarthritis. The evidence with regards to efficacy of these drugs is predominantly limited to the osteoarthritis and rheumatoid arthritis populations (National Institute for Health and Clinical Excellence, 2010). Their efficacy needs to be further investigated in chronic cancer pain conditions of musculoskeletal origin.

Adjuvant analgesics

David Lussier and Russell K. Portenoy

Introduction to adjuvant analgesics

The term 'adjuvant analgesic' has been defined as any drug that has a primary indication other than pain, but is analgesic in some painful conditions. As drugs in this category have begun to be used in the treatment of diverse chronic pain disorders, the term itself, and its definition, have become outmoded. There are now drugs in this category that are approved in many countries as primary analgesics for selected pain disorders. The evolution of this group of non-traditional drugs has been rapid and a strongly positive development in the search for a more effective pharmacological armamentarium for chronic pain.

In the palliative care literature, the term 'adjuvant analgesic' also is often used synonymously with 'co-analgesic'. These labels refer to drugs that may be administered with a primary analgesic, usually an opioid, to enhance pain relief, treat pain that is refractory to the analgesic, or allow reduction of the analgesic dose for the purpose of limiting side effects. In this context, adjuvant analgesics should be distinguished from other adjuvant drugs that are co-administered with analgesics for the specific purposes of treating side effects produced by the analgesic or managing symptoms other than pain. In the latter sense, laxatives and antiemetics are adjuvant drugs.

Given this imprecise terminology and the expanding use of adjuvant analgesics as non-traditional primary analgesics, it is important to understand the pharmacology of these drugs and their therapeutic role in varied patient populations. In this way, the use of the adjuvant analgesics can be optimized, both as 'add-on' therapy to an opioid regimen and as distinct, primary therapy in those painful disorders that are likely to demonstrate a good response.

General considerations

Several principles guide the administration of all adjuvant analgesics. These emphasize the importance of a comprehensive patient assessment and a broad foundation in analgesic pharmacotherapy.

Comprehensive assessment

The selection of a drug and optimal dosing regimen depends on a systematic assessment of the patient. This assessment requires a careful history and review of records, physical examination, and appropriate laboratory and imaging studies (Box 9.7.1).

The need for systematic assessment continues during the course of therapy. Over time, changes in pain, side effects, or any of the broader quality of life concerns may impel a shift in therapeutic strategy. The use of adjuvant analgesics in the management of pain may be a 'labour intensive' endeavour, which requires frequent contact with the patient to ensure continuous, appropriate administration of the drug.

Positioning of treatment

Adjuvant analgesics are, as a group, less reliable analgesics than opioids. This characteristic may be determined by a smaller proportion of treated patients who respond adequately, a higher likelihood of troublesome side effects, or a slower onset of analgesic effect for most drugs (perhaps due to the need to initiate therapy at low doses to avoid side effects). For example, in contrast to survey data that demonstrate a favourable outcome within days for 70–90% of cancer patients who receive opioid therapy (Schug et al., 1990; Grond et al., 1999) studies of the tricyclic antidepressants show that these drugs require treatment for weeks to obtain optimal results and offer 50%, or greater, relief to fewer than 50% of patients with neuropathic pain (Max et al., 1987; Kishore-Kumar et al., 1990).

This observation suggests that most patients with moderate or severe pain related to serious medical illness who have no relative contraindications to opioid therapy should not receive an adjuvant analgesic until opioid therapy has been optimized. Although some clinicians attempt to improve patient response by initiating therapy with an opioid and an adjuvant analgesic concurrently, this approach increases the risk of additive toxicity. Unless another indication for an earlier trial exists (e.g. a comorbidity that may also respond to the drug, a history of problems with opioids, or a type of pain that may be particularly responsive to a specific adjuvant), the safest and most efficient approach usually involves the addition of an adjuvant analgesic to an opioid regimen that is yielding inadequate analgesia despite dose escalation to limiting side effects. In the absence of data from comparative clinical trials, the decision to use an adjuvant analgesic drug instead of an alternative therapy, such as a trial of spinally administered opioids or a nerve block, is usually a matter of clinical judgement.

The selection of a specific adjuvant analgesic may be suggested by the characteristics of the pain (see 'Pharmacological characteristics') or, in some instances, by the existence of another symptom concurrent with pain that may be amenable to a non-analgesic effect of the drug. In many situations, multiple options exist and priorities for therapeutic trials must also be developed on the basis of a comprehensive assessment of the patient and best clinical judgement.

Pharmacological characteristics

Safe and effective prescribing requires familiarity with a drug's actions, approved indications, unapproved indications accepted in medical practice, likely side effects and potential serious

1. Characteristics of the pain, including severity, location, temporal features, quality, and syndrome

2. Aetiology of the pain and its relationship to the underlying disease

3. Inferences about the predominating type of pain pathophysiology, for example, nociceptive or neuropathic

4. Impact of pain on function and quality of life

5. Presence of associated factors (comorbidities), including physical and psychological symptoms, functional impairments, psychiatric disorder, family or social disruption, financial problems, and spiritual or religious concerns, and their effects on quality of life.

adverse effects, usual time–action relationship, pharmacokinetics, specific dosing guidelines for pain, and interactions with other drugs. Very few of the adjuvant analgesics have been studied in populations with serious illness and this information is usually extrapolated from other patient populations.

Caution is appropriate when prescribing to the medically ill. Low initial doses and gradual dose escalation may avoid early side effects and identify dose-dependent analgesic effects that can be explored to optimize the balance between pain relief and adverse effects. The use of low initial doses and dose titration may delay the onset of analgesia, however, and patients must be forewarned of this possibility to improve adherence with the therapy.

Interindividual and intraindividual variability

There is great variability in the response to all adjuvant analgesics. The inability to reliably predict the outcome of therapy underscores the potential utility of sequential trials of adjuvant analgesics. The process of sequential drug trials, like the use of low initial doses and dose titration, should be explained to the patient at the start of therapy to enhance adherence and reduce the distress that may occur as treatments fail.

Risks and benefits of polypharmacy

The potential for additive side effects and unpredictable adverse effects must be anticipated by the practitioner whenever an adjuvant is added to an existing drug regimen. The decision to add, or continue, a therapy must be based on a careful assessment of outcomes and a clear understanding of the goals of care. If a treatment yields demonstrable benefit without serious risk, and without cumulative side effects that otherwise impair function or quality of life, there is ample justification for continuing. Additional pain relief at the price of somnolence or mental clouding is not acceptable for patients whose goals include restoration of function, but may be completely appropriate for those who seek comfort as the only goal.

The risks of additive toxicity from polypharmacy derive from both pharmacokinetic and pharmacodynamic changes. For example, the addition of a tricyclic antidepressant to a morphine regimen may produce somnolence due to an increase in morphine plasma concentration or a pharmacodynamic interaction independent of changes in drug concentration.

Adjuvant analgesics

The adjuvant analgesics comprise an extraordinarily diverse group of drug classes (Box 9.7.2). A generally useful, broad classification distinguishes those that may be considered non-specific, multipurpose analgesics from those used for more specific indications. A review of the evidence supporting the analgesic efficacy of agents in each class provides the foundation for the development of clinical guidelines.

Multipurpose analgesics

The data supporting the analgesic efficacy of some drug classes derive from numerous studies of very diverse syndromes. The range of positive outcomes for these drugs suggests that they can

Multipurpose adjuvant analgesics

◆ Antidepressants

◆ Corticosteroids

◆ Alpha-2 adrenergic agonists.

Adjuvant analgesics used for neuropathic pain

◆ First-line:
  • gabapentinoid anticonvulsants
  • antidepressants
  • corticosteroids

◆ Other drugs:
  • oral and parenteral sodium channel blockers
  • *N*-methyl-D-aspartate receptor blockers
  • cannabinoids
  • baclofen.

Topical analgesics

◆ Capsaicin

◆ Local anesthetics

◆ NSAIDs

◆ Tricyclic antidepressants.

Adjuvant analgesics used for bone pain

◆ Calcitonin and bisphosphonates

◆ Radiopharmaceuticals

◆ Corticosteroids.

Adjuvant analgesics used for bowel obstruction

◆ Anticholinergics

◆ Octreotide

◆ Corticosteroids.

Adjuvant analgesics used for musculoskeletal pain

Table 9.7.1 Multipurpose adjuvant analgesics

Class	Examples
Antidepressants:	
Tricyclic antidepressants	Amitriptyline, nortriptyline, desipramine, doxepin, imipramine
Serotonin/norepinephrine reuptake inhibitors	Venlafaxine, duloxetine, milnacipran
Selective serotonin reuptake inhibitors	Paroxetine, citalopram, escitalopram
Others	Bupropion
Alpha-2-adrenergic agonists	Clonidine
	Tizanidine
Corticosteroids	Dexamethasone, prednisone,
	methylprednisolone

be considered multipurpose analgesics, fundamentally similar in this respect to the opioid and non-opioid analgesics (Table 9.7.1).

Antidepressant drugs

The analgesic efficacy of antidepressant drugs has been shown in diverse types of chronic pain (Table 9.7.2).

In the palliative care setting, antidepressants can be used to improve pain control when a favourable balance between analgesia and side effects cannot be attained with an opioid, or to treat comorbid depression or anxiety. Along with the gabapentinoids (see below), specific antidepressants are usually considered first-line medications for the treatment of neuropathic pain (Dworkin et al., 2007). However, very few clinical trials have evaluated analgesic efficacy of antidepressants for cancer-related pain, and none have been approved by the US Food and Drug Administration for this use. Recommendations for their use in this setting are therefore derived from observational studies, clinical experience or shown efficacy for pain of a non-malignant origin.

Anecdotal observations suggest that there is substantial variability in the analgesic response to the different antidepressants. Failure of a drug due to inefficacy, therefore, might reasonably be followed by a trial of an alternative drug. There are no guidelines for drug selection during these sequential trials and the process usually proceeds by trial and error. In those patients with refractory pain that has responded in part to one antidepressant, combination antidepressant therapy using drugs in different classes is sometimes considered, as it is for treatment-refractory depression. The latter option is based on anecdotal observation and usually involves the combination of a tricyclic and a serotonin-norepinephrine reuptake inhibitor (SNRI), or bupropion (see later).

Given evidence of dose-dependent analgesic effects, at least for the tricyclic antidepressants, it is reasonable to continue upward dose titration beyond the usual analgesic doses in patients who

Table 9.7.2 Antidepressants

Drug	Starting dose	Usual effective dose[a]	Precautions and contraindications	Selected potential drug interactions	Commonly reported adverse effects
Tricyclics					
Amitriptyline Nortriptyline Desipramine	10–25 mg HS	50–150 mg HS	Caution in elderly and medically ill, patients with cardiovascular disorders, urinary hesitancy or seizure history. Contraindicated with narrow angle glaucoma, recent MI	Caution with MAOIs, SSRIs, anticholinergic agents, antiarrhythmics, clonidine, lithium, and tramadol. Combination with beta blockers or agents which prolong QTc interval may increase risk for cardiac arrhythmia	Sedation, confusion, orthostatic hypotension, heart block, weight gain, tachycardia, seizure, arrhythmia, anticholinergic effects (e.g. dry mouth, blurred vision, urinary retention, constipation)
Noradrenaline and serotonin reuptake inhibitors (NSRIs)					
Duloxetine	20 mg bid or 30 mg qd[b]	60 mg qd	Caution in patients with hypertension (for venlafaxine) or seizure disorders	Venlafaxine: increased risk of serotonin syndrome with MAOIs, TCAs, bupropion, SSRIs, buspirone, sibutramine, ritonivir	Nausea, headache, somnolence, tremor, nervousness, hypertension, dry mouth, diaphoresis, constipation, sexual dysfunction.
Milnacipran	25 mg bid	100 mg bid	Should be tapered down progressively when discontinued. Rapid discontinuation may lead to agitation, anxiety, insomnia		
Venlafaxine XR	37.5 mg qd	150–300 mg qd	Dose should be reduced by 25% in mild-moderate renal impairment and by 50% in dialysis patients		Duloxetine: dizziness, fatigue
Noradrenaline and dopamine reuptake inhibitor					
Bupropion	75 mg qd	75–150 mg bid–tid	Contraindicated with seizure disorder, anorexia/bulimia, use of MAOI within 14 days	Toxicity of bupropion is increased by levodopa and amantadine. Seizure risk increased with agents that lower the seizure threshold	Agitation, tremor, insomnia, nausea, decreased appetite, weight loss, headache, dry mouth, somnolence, hypertension, tachycardia

[a] These doses are the ones shown analgesic in RCTs, or suggested by clinical experience, if the patient responds to that drug; if there is no response with that dose, the medication can be titrated up to the maximum tolerated or recommended dose.

[b] In United States, duloxetine is available in 20-mg dosing, whereas the lowest dose is 30 mg in other countries.

fail to achieve benefit and have no limiting side effects. This course is clearly justified in patients with a coexistent depression, but should be considered even in patients without evidence of this disorder. There is currently no justification for increasing doses beyond the levels associated with antidepressant effects.

A favourable analgesic effect is usually observed within a week after achieving an effective dosing level and, in some patients, maximal effect appears to evolve over days or weeks thereafter. This delay, combined with the many days required to increase the dose to a therapeutic level, may result in a prolonged period during which patients experience unsatisfactory effects from the therapy, and sometimes experience uncomfortable side effects. To reduce non-adherence, the patient should be well informed about this potential.

Tricyclic antidepressants

There is evidence that the tricyclic compounds have analgesic efficacy in a variety of chronic pain syndromes (Dworkin et al., 2007). The evidence is stronger for the tertiary amine compounds, mainly amitriptyline. The secondary amines, desipramine and nortriptyline, are often preferred, however, because of a lower toxicity than the tertiary amines.

Although evidence is limited to a few partially controlled trials (Walsh, 1986; Ventafridda et al., 1987) and one randomized controlled trial with amitriptyline (Mishra et al., 2012), tricyclics are actually the only antidepressants for which there is some evidence of analgesic potential in the cancer population. Use of tricyclic antidepressants is often limited by their frequent association with adverse effects. Although they can be minimized by starting with a very low dose and titrating up slowly, adverse effects, especially mental clouding, often limit the use of tricyclics in this population.

SNRIs

SNRIs are the only antidepressants, along with the tricyclics, for which there is clear evidence of analgesic efficacy, with pain relief reported in several types of neuropathic pain, as well as in fibromyalgia.

In patients with breast cancer, venlafaxine prevented the development of chronic post-mastectomy pain when started the night before surgery and administered for 2 weeks (Reuben et al., 2004). A randomized trial also showed that venlafaxine, administered for 2 weeks during chemotherapy, reduced acute neurosensory symptoms and chronic oxaliplatin neurotoxicity (Durand et al., 2012). The analgesic efficacy of duloxetine and milnacipran has been established in several conditions and in the United States and several other countries, these drugs have been approved for the treatment of fibromyalgia and varied types of neuropathic pain.

Evidence has also started to accumulate for an analgesic effect of duloxetine in cancer-related neuropathic pain. In an open label study of 39 patients with colon cancer and chronic oxaliplatin-induced peripheral neuropathy, 63.3% of those who could tolerate duloxetine experienced improvement of their pain (Yang et al., 2012). Similar results were observed in a retrospective case series of patients who could not tolerate pregabalin (Matsuoka et al., 2012). A recent randomized controlled trial found that duloxetine significantly reduced pain associated with chemotherapy-induced peripheral neuropathy (Smith et al., 2013).

SSRIs

Although there is limited evidence that some selective serotonin reuptake inhibitors (SSRIs)—paroxetine, citalopram, and escitalopram—may have analgesic efficacy (Lee and Chen, 2010), drugs in this class appear to be less analgesic than other antidepressants. They are therefore not preferred when pain is the primary indication.

Others

Bupropion provided substantial pain relief in a randomized study of patients with neuropathic pain (Semenchuk et al., 2001). Although this finding has not been replicated, bupropion has favourable characteristics that may support a trial for pain. It has a low risk of somnolence and sexual dysfunction, side effects that may be limiting with other antidepressants. Anecdotally, patients may report increased energy that appears to be unrelated to mood effects, which has led to empirical use for fatigue. Bupropion should be considered as a potential treatment for pain in selected patients, especially those who are sedated, fatigued, or apathetic.

Whereas mirtazapine was shown to improve sleep, anxiety and depression in cancer patients diagnosed with depression, it did not improve pain (Cankurtaran et al., 2008).

Corticosteroids

Numerous studies have suggested that corticosteroids may improve appetite, nausea, malaise, and overall quality of life in populations with advanced illness (Tannock et al., 1989; Farr, 1990). Although concern about toxicity has generally limited the primary analgesic use of these drugs to those with short life expectancies, there is a substantial anecdotal experience with both short-term and long-term administration for a variety of clinical problems, including pain.

Data from controlled trials and clinical series support the classification of corticosteroids as multipurpose analgesics. Analgesic efficacy has been suggested in diverse types of cancer pain, including bone pain, neuropathic pain from infiltration or compression of neural structures, headache due to increased intracranial pressure, arthralgia, and pain due to obstruction of a hollow viscus (e.g. bowel or ureter) (Tannock et al., 1989; Fainsinger et al., 1994). Patients who present with these pain syndromes commonly have other symptoms that could potentially be improved by steroid therapy, such as nausea or malaise, and corticosteroid therapy may be considered earlier if primarily indicated by these other symptoms.

The relative risks and benefits of the various corticosteroids are unknown. In the United States, dexamethasone is usually selected, a choice that gains theoretical support from the relatively low mineralocorticoid effects of this drug. Prednisone and methylprednisolone have also been used.

On the basis of clinical experience, corticosteroids are usually administered either in a high-dose regimen or a low-dose regimen. A high-dose regimen (empirically ranging from an initial dose of dexamethasone of 20–100 mg followed initially by 32–96 mg per day in four divided doses, which is usually tapered concurrent with the initiation of other analgesic approaches) has been used for patients who experience an acute episode of very severe pain that cannot be promptly reduced with opioids, such as that associated with a rapidly worsening malignant plexopathy. The higher range of this regimen has been widely used in the setting of emerging spinal cord or cauda equina signs related to epidural metastasis and may also be appropriate when treating other oncological emergencies, such as superior vena cava syndrome.

A low-dose corticosteroid regimen (e.g. dexamethasone 1–2 mg once or twice daily) has been used for patients with advanced medical illness who continue to have pain despite optimal dosing of opioid drugs. Although a randomized controlled study of low-dose oral dexamethasone (8 mg daily) combined with an opioid failed to show any benefit on pain or most other symptoms in a sample of patients with far advanced illness, (Mercadante et al., 2007) gastrointestinal side effects of the opioid were diminished and the drug produced short-lasting improvement of weakness, drowsiness and well-being. In most cases, long-term therapy is planned when a low-dose regimen is initiated.

Well-recognized adverse effects are associated with short-term and long-term administration of corticosteroids, and with the withdrawal of these drugs following chronic use. The risk of serious toxicity increases with the dose of the drug, the duration of therapy, and predisposing factors associated with the medical condition of the patient. These risks are balanced by the need for enhanced comfort. Repeated assessments are required to ensure that benefits occur and are sustained. Ineffective regimens should be tapered and discontinued, and in all cases, the lowest dose that yields the desired results should be sought.

Alpha-2 adrenergic agonists

Reports suggest that clonidine can be analgesic in diverse pain syndromes, including cancer pain (Eisenach et al., 1995; Tumber and Fitzgibbon, 1998). A controlled trial of transdermal clonidine in diabetic painful polyneuropathy demonstrated that fewer than one-quarter of patients are potential responders, but that those who do respond can experience analgesia that is both substantial and sustained (Byas-Smith et al., 1995). A 14-day epidural infusion of clonidine (30 micrograms/hour) in cancer patients reduced pain in 45% of patients, compared to 21% with placebo, but did not reduce opioid consumption (Eisenach et al., 1995); neuropathic pain responded relatively well (56% vs only 5% with placebo). The most common adverse effects associated with systemic or epidural clonidine administration have been somnolence, hypotension (usually orthostatic), and dry mouth.

Tizanidine is another centrally acting alpha-2 agonist and is commercially available in the United States as an antispasticity agent (Nance et al., 1994). Although the evidence of analgesic efficacy is limited to a few open-label studies in myofascial pain syndrome, the mechanism of this drug and a favourable clinical experience has supported its use as a multipurpose analgesic. The most frequent side effects are somnolence and dry mouth. This drug has less affinity for the alpha-1 adrenergic receptor and therefore produces hypotension less often than clonidine.

Given limited experience with the adrenergic agonists in those with advanced illness, trials of these drugs are usually considered after other adjuvant analgesics, such as the antidepressants and anticonvulsants, have failed.

Neuroleptics

In the palliative care setting, neuroleptics are used commonly in the management of delirium or nausea. A systematic review suggested that the second-generation 'atypical neuroleptics' may have analgesic properties (Fishbain et al., 2004). According to a case series, olanzapine could decrease opioid-unresponsive cancer pain by potentiating the effect of opioids, thereby allowing a significant decrease of the opioid dose (Khojainova et al., 2002).

Nonetheless, there is relatively little evidence of analgesic activity for most neuroleptic compounds and their role as adjuvant analgesics is limited by this lack of definitive data and the potential for adverse effects (Fishbain et al., 2004). They should therefore only be considered for pain when treatment with many other drugs has proved unsuccessful, or there is concomitant delirium or nausea.

Adjuvant analgesics used for neuropathic pain

Although neuropathic pain may be relatively less responsive to opioid drugs than other pains (Portenoy et al., 1990; Mercadante et al., 1992; Cherny et al., 1994), combination therapy with an opioid and adjuvant analgesics can yield analgesic outcomes in cancer-related neuropathic pain that mirror those obtained during treatment of nociceptive or mixed pain syndromes (Grond et al., 1999). One survey found that absent and mild pain can be obtained in 53.2% and 41.9% of patients, respectively, after 6 months (Mishra et al., 2008).

Guidelines for the management of neuropathic pain recommend selected antidepressants (tricyclics and SNRIs) and the gabapentinoid anticonvulsants as the first-line drugs (Table 9.7.3). In the context of advanced illness, a corticosteroid also may be first-line drug. Drugs in many other classes are tried in refractory cases, despite limited data.

Anticonvulsant drugs

The analgesic potential of anticonvulsant drugs has been recognized for decades for the management of neuropathic pains. The older drugs, such as phenytoin and carbamazepine, are now complemented by a rapidly increasing number of newer agents (Table 9.7.4).

There is evidence that the gabapentinoids—gabapentin and pregabalin—are analgesic in diverse neuropathic pains (Caraceni et al., 2004; Mishra et al., 2012). Given good tolerability and no known drug–drug interactions, they are first-line agents for the

Table 9.7.3 Adjuvant analgesics used for neuropathic pain

Class	Examples
Antidepressants	See Table 9.7.1
Anticonvulsants	Gabapentin, pregabalin, topiramate, carbamazepine, phenytoin, valproate, oxcarbazepine, lamotrigine, levetiracetam
Topical agents	Capsaicin, lidocaine patch, EMLA*
Oral sodium channel blockers	Mexiletine, tocainide, flecainide
Alpha-2 adrenergic agonists	Clonidine, tizanidine
N-methyl-D-aspartate receptor antagonists	Dextromethorphan, ketamine
GABA agonists	Baclofen
Cannabinoids	Tetrahydrocanninol (THC), nabilone, THC:cannabidiol mixture
Miscellaneous	Calcitonin

Table 9.7.4 Anticonvulsants

Drug	Starting dose	Usual effective dose	Precautions and contraindications[a]	Selected potential drug interactions[b]	Commonly reported adverse effects
Gabapentin	100–300 mg daily; titrate by 100–300 mg every 1–3 days to an effective dose	300–1200 mg tid	Decrease dose in patients with renal dysfunction (avoid in severe renal dysfunction). Rapid discontinuation may result in headache, nausea, insomnia, and diarrhoea.	None	Sedation, dizziness, tremor, peripheral oedema, weight gain, nausea, headache
Pregabalin	25–75 mg qd–bid	150–300 mg bid			
Lamotrigine	25 mg qd; titrate by 25 mg every 7 days to an effective dose	100–200 mg bid	Black box warning: severe and potentially life threatening skin rashes have been reported	May increase carbamazepine levels	Headache, dizziness, ataxia, somnolence, tremor, nausea, diarrhoea, blurred vision, insomnia
Carbamazepine	100–200 mg qd–bid	300–800 mg bid	Contraindicated in bone marrow depression, or within 14 days of MAOI use. Caution in patients with cardiac disease, hepatic or renal dysfunction. Potentially fatal blood dyscrasias have been reported; monitor CBC, platelets, renal and liver function, and serum sodium. Potentially fatal severe dermatologic reactions (e.g. Stevens–Johnson syndromes) are rare	May decrease levels of drugs metabolized by CYP3A4	Somnolence, dizziness, blurred vision, headache, confusion, speech and memory difficulties, cardiovascular abnormalities (e.g. arrhythmia, bradycardia, hypertension, AV block), rash, SIADH, nausea, urinary retention, hematologic abnormalities (e.g. aplastic anaemia, bone marrow suppression, thrombocytopenia), increased liver enzymes, hepatic failure
Oxcarbazepine	150 mg qd; titrate by 150–300 mg every 3–5 days to an effective dose	150–600 mg bid	Clinically significant hyponatremia can develop: monitor serum sodium at baseline, during the first 3 months and periodically	May decrease levels/effects of CYP3A4 substrates and increase levels/effects of CYP2C19 substrates	Dizziness, somnolence, headache, ataxia, nausea, tremor, diplopia, nystagmus
Topiramate	25–50 mg qd; titrate by 25 mg every 5–7 days to an effective dose	100–400 mg bid	May significantly decrease serum bicarbonate; monitor serum bicarbonate at baseline and periodically. Often poorly tolerated: high rate of withdrawal due to adverse effects	Administration with anticholinergics may increase risk of hyperthermia and oligohydrosis	Somnolence, dizziness, ataxia, psychomotor slowing, speech and memory difficulties, decreased serum bicarbonate, metabolic acidosis, nausea, paraesthesia, tremor, abnormal vision, nystagmus, diplopia, weight loss, nephrolithiasis, secondary angle closure glaucoma
Lacosamide	50 mg bid	200–400 mg bid	—	—	Dizziness, fatigue, nausea/vomiting
Levetiracetam	250–500 mg bid	500–1500 mg bid		None	Somnolence, dizziness
Zonisamide	100 mg qd	100–300 mg bid	Use in patients with severe sulfonamide allergy is contraindicated; potentially fatal sulfonamide reactions (including Stevens–Johnson syndrome and toxic epidermal necrolysis) are rare. Use cautiously in patients with renal or hepatic dysfunction	CYP3A4 inhibitors may increase zonisamide levels/effects	Somnolence, dizziness, headache, confusion, ataxia, insomnia, tremor, nausea, weight loss, diplopia, nystagmus

[a] Avoid abrupt withdrawal of any anticonvulsant as this may increase the risk for seizure. Although the actual incidence of seizure following abrupt withdrawal of anticonvulsants in patients without seizure disorders, is unknown to discontinue over 1–2 weeks.

[b] CNS depressants (e.g. alcohol, benzodiazepines, barbiturates, opioids) may increase the CNS side effects of all anticonvulsants.

treatment of neuropathic pain of diverse aetiologies (Dworkin et al., 2007). Gabapentin is the most commonly used adjuvant analgesic in cancer patients with neuropathic pain and on palliative care units (Oneschuk and al-Shahri, 2003).

Although one controlled study of gabapentin failed to demonstrate any benefit in chemotherapy-induced peripheral neuropathy (Rao et al., 2007), others have been positive (Keskinbora et al., 2007; Rao et al., 2007). Another study found that low-dose gabapentin (200 mg twice daily) and imipramine (10 mg twice daily) produced good pain control with fewer adverse effects than high-dose gabapentin alone (Arai et al., 2010) and yet another demonstrated that treatment with oral gabapentin and local anaesthetics in the wound decreased acute and chronic pain after breast surgery for cancer (Fassoulaki et al., 2005). Controlled trials have similarly confirmed that pregabalin is analgesic in neuropathic pain (Sabatowski et al., 2004), including neuropathic cancer pain (Saif et al., 2010; Mishra et al., 2012), and also is analgesic in non-neuropathic conditions such as fibromyalgia (Crofford et al., 2005) and irritable bowel syndrome (Houghton et al., 2007). The onset of analgesic activity is faster with pregabalin (significant difference in pain on second day) than with gabapentin (Sabatowski et al., 2004).

A recent systematic review found insufficient evidence to conclude that other anticonvulsants have analgesic efficacy (Wiffen et al., 2013). It acknowledged, however, that decades of experience provided support for some agents and called for more research to assess effectiveness in clinical practice. Carbamazepine has been used for many years and is approved in the United States for trigeminal neuralgia. This drug raises concern about adverse effects, particularly leucopenia, and has been largely supplanted by others, including oxcarbazepine, which is a metabolite of carbamazepine and is better tolerated. A small, randomized open-label study has suggested that oxcarbazepine might significantly decrease the risk of oxaliplatin-induced painful neuropathy (31.2 vs 75%) (Argyriou et al., 2006). Both topiramate and lamotrigine are used empirically for refractory neuropathic pain; although case reports suggested possible efficacy for neuropathic cancer pain (Devulder, 2000) and chemotherapy-induced peripheral neuropathy (Durand et al., 2005), a randomized controlled crossover trial failed to show any pain relief with lamotrigine for the latter condition (Rao et al., 2008). Although some observational data supported the potential for analgesic effects from levetiracetam, recent controlled trials have yielded negative results (Holbech et al., 2011). Zonisamide has been shown to be effective in one randomized controlled trial of painful diabetic neuropathy (Atli and Dogra, 2005) and further evaluation of this drug is warranted. Similarly, recent studies of the newest anticonvulsant, lacosamide, suggest potential for analgesic effects in some situations (Wiffen et al., 2013). There is very scarce evidence related to other anticonvulsants, such as tiagabine and felbamate, and despite a large clinical experience, similarly limited data about several older drugs such as clonazepam, valproate, and phenytoin.

In sum, the first-line drugs for neuropathic pain remain the gabapentinoids followed by the analgesic antidepressants (the order may be reversed when the patient is depressed), in addition to the corticosteroids. Those who do not respond to any of the several drugs in these two classes may be considered for empirical trials of other anticonvulsants, notwithstanding the lack of evidence, or trials of one or more of the drugs described below. Drug selection is by trial and error. The preferred anticonvulsant drugs based on limited evidence, safety considerations and experience are usually considered to be oxcarbazepine, topiramate, lamotrigine, lacosamide and zonisamide; clonazepam may be considered as well, particularly when there is comorbid anxiety. The older anticonvulsants (carbamazepine, valproate, and phenytoin) usually are considered if access to other drugs is limited or patients have been highly refractory to treatment

Oral and parenteral sodium channel blockers

Several sodium channel blockers possess analgesic activity, including some anticonvulsants and anaesthetics/anti-arrhythmics. Although studies suggest that these drugs may be multipurpose analgesics, a large clinical experience has focused on their use for neuropathic pain. While controlled trials have demonstrated efficacy of a brief intravenous infusion of lignocaine (lidocaine) for diverse types of non-malignant neuropathic pain, several studies in neuropathic cancer pain have yielded negative results (Bruera et al., 1992; Chong et al., 1997).

Prolonged relief of pain following a brief intravenous infusion of a local anaesthetic is nevertheless possible. On the basis of clinical experience, a trial of a brief local anaesthetic infusion is sometimes implemented in patients with severe neuropathic pain that has not responded promptly to an opioid and requires immediate relief. Repeated infusions with escalating doses can be performed over a period of hours and may be a useful approach to the acute management of severe neuropathic pain even in those with advanced illness. If pain recurs, long-term subcutaneous administration of lignocaine also has been used anecdotally to yield sustained relief of refractory neuropathic pain in cancer patients (Brose and Cousins, 1991).

Oral formulations of sodium channel blockers (mexiletine, flecainide) are available and long-term systemic therapy can be accomplished simply using these drugs. A survey of cancer patients suggested that flecainide can be effective in the treatment of pain due to tumour infiltration of nerves (Dunlop et al., 1989). One study showed that the response to an intravenous infusion of lidocaine is a good predictor of the response to oral mexiletine treatment (Galer et al., 1996). It may therefore be useful to consider a brief infusion as a means to guide the selection of an oral therapy after trials of anticonvulsants and antidepressants have proved unhelpful.

N-methyl-D-aspartate receptor blockers

Excitatory amino acids, such as glutamate and aspartate, are released by primary afferent neurons in response to noxious stimuli and are important in the central processing of the pain-related information. Interactions at the *N*-methyl-D-aspartate (NMDA) receptor are involved in the development of central nervous system changes that may underlie chronic pain and modulate opioid mechanisms—specifically tolerance (Mao et al., 1995). Preclinical studies have established that the NMDA receptor is involved in the sensitization of central neurons following injury and the development of the 'wind-up' phenomenon, a change in the response of central neurones that has been associated with neuropathic pain (Dickenson and Sullivan, 1987).

Although there is evidence that antagonists at the NMDA receptor may be multipurpose analgesics, which could potentially ameliorate acute pain (Weinbroum et al., 2003) and diverse types

Table 9.7.5 NMDA antagonists

Drug	Starting dose	Usual effective dose	Precautions and contraindications	Selected potential drug interactions	Commonly reported adverse effects
Ketamine	Different intravenous or SC regimen, e.g. continuous infusion (0.05–1.5 mg/kg/h), IV boluses (0.25–0.5 mg/kg), IV 'burst' doses (100–500 mg/kg/d × 2-3 days) or oral doses (0.2–0.5 mg/kg bid–tid)	Unclear	Contraindicated with hypertension, heart failure, angina, aneurysms, cerebral trauma, recent myocardial infarct Caution with psychotic disorders, thyrotoxicosis, tachycardia, seizures	Increased levels/effects with CYP3A4 inhibitors	Hypertension, tachycardia, tremor, nystagmus, diplopia, airway resistance, myocardial depression, hallucinations, vivid dreams, tonic–clonic movements
Dextromethorphan	15–20 mg tid	Unclear		Increased levels/effects with CYP2D6 inhibitors	Dizziness, nausea, vomiting, confusion, hallucination, respiratory depression

of chronic pain (Graven-Nielsen et al., 2000), the most intense interest has focused on their role as new therapies for neuropathic pain. At the present time, there are four commercially available drugs in the United States that have primary effects at the NMDA receptor and have been explored as potential analgesics: ketamine, dextromethorphan, memantine, and amantadine (Table 9.7.5).

There is some evidence that ketamine is analgesic for non-malignant neuropathic pain (Schwartzman et al., 2009), and despite the negative results of a recent large and well controlled clinical trial evaluating subcutaneous ketamine infusion in cancer patients, (Hardy et al., 2012) a recent systematic review concluded that there is sufficient evidence to support the use of this drug in treatment-refractory cancer pain (Hardy et al., 2012). The drug can be used orally, as well as parenterally (Lauretti et al., 1999).

The side effect profile of ketamine can be daunting, particularly in the medically frail. Concurrent treatment with a benzodiazepine or a neuroleptic commonly is used to blunt or prevent these adverse effects. These side effects are unlikely to be problematic when low subanaesthetic doses are used. In the palliative care setting, ketamine may be a valuable strategy for severe refractory pain, particularly neuropathic pain, for pain emergencies and for pain that occurs in the context of a decision to offer sedation.

Evidence in favour of analgesic efficacy for the other commercially available NMDA receptor antagonists is very limited. One trial suggested that the antitussive dextromethorphan is analgesic in non-malignant neuropathic pain (Weinbroum et al., 2003), but a randomized trial of a mixture of morphine and dextromethorphan failed to show better analgesia than morphine alone (Galer et al., 2005). There is very little evidence on analgesic efficacy of memantine or amantadine.

The D-isomer of the opioid methadone also blocks the NMDA receptor (Davis and Inturrisi, 1999). In most countries, methadone is commercially available as a racemate containing 50% of the D-isomer. The contribution of this non-opioid molecule to the analgesia produced by methadone is uncertain, but the greater-than-anticipated potency of methadone in patients who undergo a switch to this drug from another mu agonist suggests that it can play a clinically important role. There are no data, however, to support the conclusion that methadone is better than other opioids for the treatment of neuropathic pain.

Cannabinoids

There are several cannabinoids now available and others in development. Clinical trials have established the analgesic efficacy of some of these drugs. Nabiximols, a cannabinoid oromucosal spray formulation primarily comprising delta (9)-tetrahydrocannabinol (THC) and cannabidiol, is approved in some countries for spasticity related to multiple sclerosis and opioid-refractory cancer pain. A recent large randomized graded-dose trial in cancer patients with persistent pain despite opioid treatment showed that the overall proportion of patients reporting analgesia was greater for nabiximols than placebo in the low-dose and medium-dose groups, but not the high-dose group (Portenoy et al., 2012). Other studies have demonstrated positive results in pain due to multiple sclerosis, cancer, peripheral nerve lesions, and rheumatoid arthritis (Rog et al., 2005; Russo et al., 2007).

The oral synthetic cannabinoid nabilone has been shown to be analgesic in spasticity-related pain from chronic upper motor neuron syndrome (Wissel et al., 2006) and fibromyalgia (Skrabek et al., 2008). An observational study of nabilone in patients with advanced cancer suggested significant benefit for pain and other symptoms (Maida et al., 2008).

The most common side effects associated with the cannabinoids are dizziness, somnolence, and dry mouth. An older study of THC for cancer pain noted a narrow therapeutic window and a relatively low efficacy, comparable to codeine at conventional doses (Noyes et al., 1976). Studies of the plant extracts suggest that better outcomes occur with drugs that include a combination of cannabinoid compounds. Additional studies will provide new agents for clinical use and hopefully clarify the relative benefits and burdens.

The existing data suggest that the newer cannabinoid drugs, such as the oromucosal spray containing THC and cannabidiol, ultimately will be characterized as multipurpose analgesics, potentially appropriate for a trial in the medically ill whenever pain is refractory to opioid therapy. At this point, however, both experience and available agents are limited, and most of the data in relation to this class has been collected in neuropathic pain populations. A trial of a commercially available cannabinoid usually is considered only in those patients who are refractory to opioids and other appropriate adjuvant analgesics; most of these patients will have neuropathic pain. Nabilone should be started at 0.5–1 mg at night and titrated up to 3 mg twice daily, or higher if

tolerated. THC usually is started at a dose of 2.5 mg once or twice daily, and titrated. The oromucosal spray containing THC and cannabinol has been initiated with an 'as needed' schedule and effectively titrated by the patient to an effective dose.

Baclofen

Baclofen, an agonist at the gamma-aminobutyric acid type B (GABA$_B$) receptor, is efficacious in trigeminal neuralgia (Fromm et al., 1984). Intrathecal baclofen also is very effective in relieving pain related to spasticity. Although there have been a few observations that suggest a broader analgesic potential for systemically administered baclofen, the data are too limited to recommend a trial for non-neuropathic pain.

Topical analgesics

Topical therapies have the potential to deliver low doses of analgesic compounds directly to a site responsible for pain. There is a potential for benefit with a very low risk of systemic toxicity. Topical analgesics are used for many types of focal pain and commercially available agents include capsaicin preparations, formulations of aspirin or non-steroidal anti-inflammatory drugs (NSAIDs), creams, and patches containing local anaesthetics, and preparations containing tricyclic preparations. Other formulations compounded by pharmacies may include opioids, selected anticonvulsants, or other drugs.

Capsaicin is the naturally occurring constituent of the chili pepper that produces its pungent taste. When applied topically, it inhibits polymodal primary afferent nociceptive neurons by binding to the transient receptor potential vanilloid type 1 (TRPV1) receptor, and inhibiting the release of substance P and other compounds. The presumed analgesic mode of action is depletion of substance P from the terminals of afferent C-fibres, which occurs with regular use. Low-dose topical capsaicin (0.1%) has been demonstrated to be effective in both painful mononeuropathies and polyneuropathies, including peripheral painful mononeuropathies following cancer surgery (post-mastectomy, post-thoracotomy, post-amputation) (Fromm et al., 1984). A controlled trial in HIV-associated painful peripheral neuropathy, however, failed to show any analgesic effect (Paice et al., 2000). A high-dose capsaicin patch (8%), which is applied for only an hour and is available in some countries, has shown efficacy in post-herpetic neuralgia and HIV-associated painful peripheral neuropathy, with a duration of effect in responders that can last several months (Baranidharan et al., 2013).

Topical formulations of NSAIDs (e.g. diclofenac, aspirin) are widely available and used to treat common musculoskeletal pains, such as sprains and strains. The use of these creams, fluids, and patches to manage focal pains in those with serious illness is empirical; given the potential for some systemic absorption, they should not be given to patients with strong contraindications to systemic NSAID therapy, such as renal insufficiency.

There is ample evidence that topical local anaesthetics are analgesic. Given the observation that the lidocaine 5% patch may reduce pain and allodynia from diverse types of neuropathic pain and some presentations of osteoarthritis, a trial of this formulation can be considered for all patients with relatively small areas of pain unrelated to local skin injury. Topical local anaesthetic creams and gels also are available. A commercially available

mixture of local anaesthetics, which contains a 1:1 mixture of prilocaine and lignocaine, is capable of penetrating the skin and producing a dense local cutaneous anaesthesia; this product, known as eutectic mixture of local anaesthetics (EMLA®), is widely used to prevent the pain of needle puncture or incision, as well as pain from debridement of leg ulcers. Although there is a very remote risk of toxicity from systemic absorption of a topical local anaesthetic, careful monitoring is needed if the anaesthetic is applied repeatedly to mucous membranes or open wounds.

Topical administration of tricyclic antidepressants sometimes is considered for focal neuropathic pain, despite conflicting data. There are favourable clinical observations pertaining to topical amitriptyline 2% cream, given alone or in combination with ketamine 1%, for the treatment of neuropathic pain (Lynch et al., 2005b), but randomized trials have not confirmed the efficacy of topical amitriptyline (Lynch et al., 2005a; Ho et al., 2008).

Compounded topical preparations also are used, based mostly on anecdotal observations. A topical gel made of amitriptyline, ketamine, and baclofen lessened tingling, cramping, and shooting/burning pain in patients with chemotherapy-induced peripheral neuropathy, without any systemic toxicity (Barton et al., 2011).

A topical gel of amitriptyline, ketamine, and lidocaine, used three times daily during radiation therapy and up to 2 weeks after, appeared to help pain caused by radiation skin reaction (Uzaraga et al., 2012).

Adjuvant analgesics used for bone pain

Radiation therapy is usually considered when bone pain is focal and poorly controlled with an opioid, or is associated with a lesion that appears prone to fracture on radiographic examination. Anecdotally, multifocal bone pain has been observed to benefit from treatment with a NSAID or a corticosteroid. Other adjuvant analgesics that are potentially useful in this setting include calcitonin, bisphosphonate compounds, gallium nitrate, and selected radiopharmaceuticals (Table 9.7.6). There have been no comparative trials of these adjuvant analgesics for bone pain and the selection of one over another is usually based on convenience, patient preference, and the clinical setting.

Calcitonin and bisphosphonates

Although evidence of its analgesic efficacy is mostly limited to case studies, clinical experience suggests that calcitonin may relieve pain from bone metastases (Hindley et al., 1982; Szanto et al., 1992; Mystakidou et al., 1999).

While calcitonin was most commonly administered intranasally, which was very convenient since less invasive, the intranasal formulation has recently been withdrawn from the European and Canadian markets because of poor evidence of analgesic efficacy and possible increased cancer risk when used on a long-term basis to treat osteoporosis (Overman et al., 2013). The only remaining route of administration is therefore subcutaneously, usually administered daily. Continuous subcutaneous administration also has been described (Mystakidou et al., 1999).

There is much more evidence that the bisphosphonates are analgesic for metastatic bone pain and one of these drugs typically is used first. The bisphosphonates are analogues of inorganic pyrophosphate and inhibit osteoclast activity. Studies have demonstrated that pamidronate is analgesic in breast cancer

Table 9.7.6 Adjuvant analgesics for cancer-related bone pain

Drug	Starting dose	Usual effective dose	Precautions and contraindications	Selected potential drug interactions	Commonly reported adverse effects
Corticosteroids	c.f. above text				
Calcitonin	100 IU SC daily	Dose can be progressively increased up to 200 IU SC daily	SC administration should be preceded by skin testing with 1 IU SC to screen for hypersensitivity, especially in patients with a history of allergy to salmon or seafood	None	Nausea/vomiting
Bisphosphonates		60–90 mg SC q 4 weeks, can increase up to 120 mg if well tolerated and not effective	Renal function should be checked prior to initiation and monitored during course of therapy		Renal toxicity
Pamidronate	30 mg SC q 4 weeks				Acute-phase (flu-like) reactions, usually transient and well controlled with acetaminophen and NSAIDs
Zoledronic acid	4 mg IV in 15 minutes, q 3 weeks		Adherence to dosing instructions decrease risk of GI toxicity		Gastrointestinal toxicity, only with oral administration
Ibandronate	6 mg IV in 1–2 h, q 3–4 weeks or 50 mg po qd				Osteonecrosis of the jaw (worrisome but uncommon)

(Hortobagyi et al., 1996) and multiple myeloma (Berenson et al., 1996); zoledronic acid decreases bone pain from breast, prostate, and lung metastases, and multiple myeloma (Vogel et al., 2004; Wardley et al., 2005); and ibandronate reduces pain and analgesic use in patients with breast cancer (Body et al., 2004; Mancini et al., 2004; Pecherstorfer et al., 2006). Ibandronate was shown to be helpful in opioid-resistant bone pain (Mancini et al., 2004) and to be safe for up to 4 years of use (Pecherstorfer et al., 2006). The bisphosphonates also reduce other skeletal morbidity, including pathological fractures, need for bone radiation or surgery, spinal cord compression, and hypercalcaemia (Berenson et al., 1996; Hortobagyi et al., 1996; Rosen et al., 2003).

Radiopharmaceuticals

Radionuclides that are absorbed at areas of high bone turnover have been evaluated as potential therapies for metastatic bone disease. Strontium chloride-89, rhenium-186 hydroxyethylene diphosphonic acid, and samarium-153 ethylene-diaminetetramethylene phosphonic acid have been most promising thus far. The data suggest that treatment with a radiopharmaceutical yields meaningful pain relief in approximately 80% of patients, 10% of whom attain complete relief (Robinson et al., 1995). Initial clinical response occurs in 7–21 days and peak response may be delayed for a month or more. Approximately 5–10% of patients experience a transitory pain flare immediately after treatment. The usual duration of benefit is 3–6 months, after which retreatment may regain a favourable effect. Following treatment, clinically significant leucopenia or thrombocytopenia peak a few weeks after treatment and occurs to a clinically significant degree in approximately 10% and 33% of patients, respectively. Bone marrow effects usually wane by 12 weeks after treatment. Given the effects on bone marrow and delayed onset, treatment with a radiopharmaceutical should not be considered in patients awaiting cytotoxic chemotherapy and those with a life expectancy of greater than 3 months. This delay also implies that treatment should not be considered as the sole approach for patients with severe pain.

Adjuvant analgesics used for bowel obstruction

The management of symptoms associated with malignant bowel obstruction may be challenging. If surgical decompression is not feasible, the need to control pain and other obstructive symptoms, including distension, nausea, and vomiting, becomes paramount. The use of opioids may be problematic due to dose-limiting toxicity (including gastrointestinal toxicity) or the intensity of breakthrough pains. Anecdotal reports suggest that anticholinergic drugs, the somatostatin analogue octreotide, and corticosteroids may be useful adjuvant analgesics in this setting. The use of these drugs may also ameliorate non-painful symptoms and minimize the number of patients who must be considered for chronic drainage using nasogastric or percutaneous catheters.

Anticholinergic drugs

Anticholinergic drugs theoretically relieve the symptoms of bowel obstruction by reducing propulsive and non-propulsive gut motility and decreasing intraluminal secretions. Some patients appear to benefit from the administration of hyoscine (scopolamine) (Baines et al., 1985).

In some countries, hyoscine is only commercially available as the hydrobromide salt, which readily crosses the blood–brain barrier. Although this formulation can be delivered via a transdermal system, which simplifies treatment in patients with bowel obstruction, it is likely to be associated with a relatively higher incidence of central nervous system side effects, such as somnolence and confusion, than an anticholinergic drug with less penetration through the blood–brain barrier. Hyoscine butylbromide, which is less likely to pass the blood–brain barrier due to low lipid solubility, can be effective for obstructive symptoms, including pain (Ripamonti et al., 2000). Glycopyrrolate has a pharmacological profile similar to hyoscine butylbromide, but has not been systematically evaluated in a population with symptomatic bowel obstruction.

Octreotide

The somatostatin analogue octreotide inhibits the secretion of gastric, pancreatic, and intestinal secretions and reduces gastrointestinal motility. These effects probably underlie the analgesic effects that have been reported in case series of symptomatic treatment of bowel obstruction (Ripamonti et al., 2000). The benefits of this drug may occur more rapidly than hyoscine (Mercadante et al., 2000).

Octreotide has also been used to manage severe diarrhoea due to enterocolic fistula, high output jejunostomies or ileostomies, or secretory tumours of the gastrointestinal tract. A newer long-acting formulation, administered intramuscularly once monthly, can provide sustained reduction of bowel obstruction symptoms (Massacesi et al., 2006).

Octreotide has a good safety profile but is expensive. In some settings, however, the cost may be balanced by an excellent clinical response or the avoidance of the costs involved in the use of a gastrointestinal drainage procedure.

Corticosteroids

As discussed previously, the symptoms associated with bowel obstruction may improve with corticosteroid therapy. The mode of action is unclear and the most effective drug, dose, and dosing regimen are unknown. A broad range of doses have been described anecdotally. For example dexamethasone has been used for this indication in a dose range of 8–60 mg/day (Fainsinger et al., 1994) and methylprednisolone has been administered in a dose range of 30–50 mg/day (Farr, 1990). The potential for complications during long-term therapy, including an increased risk of bowel perforation, may limit this approach to patients with short life expectancies.

Adjuvant analgesics used for musculoskeletal pain

Although pains that originate from injury to muscle or connective tissue are prevalent in the medically ill, there has been no systematic evaluation of analgesic therapies for this problem. In the management of acute traumatic sprains or strains in the non-medically ill, non-opioid and opioid analgesics are commonly supplemented by treatment with so-called muscle relaxant drugs or benzodiazepines. The role of the latter drugs for opioid-refractory musculoskeletal pains in populations with advanced medical illness remains ill defined.

Muscle relaxants

The so-called muscle relaxants include drugs in a variety of classes, all of which are marketed for the treatment of acute musculoskeletal pain. In the United States, this group includes drugs that are also administered as antihistamines (e.g. orphenadrine), tricyclic compounds structurally similar to the tricyclic antidepressants (e.g. cyclobenzaprine), and other types of drugs (e.g. carisoprodol, chlorzoxazone, metaxalone, and methocarbamol).

The efficacy of the muscle relaxant drugs in common musculoskeletal pains has been established in placebo-controlled studies (Bercel, 1977; Gold, 1978).

Some studies have demonstrated analgesic effects that are superior to either aspirin or acetaminophen, and others have shown that the combination of a muscle relaxant and one of the latter drugs provides better analgesia than does aspirin or acetaminophen alone. There have been no controlled comparative trials or studies that have directly compared the efficacy and side effect profiles of these drugs with either NSAIDs or opioids.

Although muscle relaxant drugs can relieve musculoskeletal pains, these effects may not be specific and do not depend on relaxation of skeletal muscle. The label 'muscle relaxant' notwithstanding, there is actually no evidence that these drugs relax skeletal muscle in the clinical setting. They should not be administered in the mistaken belief that they relieve muscle spasm. If muscle spasm is believed to be related to the pain, it may be justifiable to consider a trial of a drug with established effect on skeletal muscle, such as diazepam or another benzodiazepine, the alpha-2 adrenergic agonist tizanidine, or the $GABA_B$ agonist baclofen.

Conclusions

Although the use of adjuvant analgesics in palliative care remains largely guided by anecdotal experience, controlled clinical trials have begun to provide a scientific rationale for many therapies. Future investigations of nociceptive processes and pain pathophysiology will undoubtedly lead to the development of novel drugs. For example, the adjuvant analgesics may one day include drugs that modulate peripheral nociceptive processes, such a substance P or bradykinin antagonists, or drugs that alter central processing by interacting with gangliosides or second messenger systems activated by excitatory amino acids. Although opioid drugs continue to be the major approach to the treatment of pain in the palliative care setting, adjuvant analgesics offer opportunities for improved outcomes in the substantial group of patients who cannot attain an acceptable balance between pain relief and side effects.

Interventional approaches for chronic pain

Robert A. Swarm, Menelaos Karanikolas, Lesley K. Rao, and Michael J. Cousins

Introduction to interventional approaches for chronic pain

Severe, uncontrolled pain remains common in populations with serious or life-threatening illness. Despite the availability of oral opioid therapy in most developed countries, an estimated 10–30% of people with advanced cancer have inadequate pain control (Hoskin 2006). Published guidelines endorse the view that these patients should be considered for procedural, or so-called interventional, pain therapies (Ripamonti et al., 2012; National Comprehensive Cancer Network, 2013). These therapies are best used within a multimodal strategy for symptom management, including appropriate systemic pharmacological, non-pharmacological, and psychosocial therapies.

Generally accepted indications for interventional pain therapies include (a) uncontrolled pain despite systemic analgesics and (b) unacceptable systemic analgesic adverse effects. In practice, if pain is not adequately controlled with systemic analgesics, doses are increased until pain is controlled or dose-limiting adverse effects occur; therefore, analgesic adverse effects are common indications for procedural pain therapies. Procedural pain therapies potentially improve pain control and/or allow opioid dose reduction.

Disease and patient characteristics that limit the effectiveness of systemic opioid analgesics should be recognized as factors that also increase the likelihood that procedural pain therapies will be needed. These characteristics include neuropathic pain, somatic pain that is sharp and severe, and pain that fluctuates markedly. Some patients are poorly responsive because of adverse effects that cannot be adequately controlled. Opioids may cause sedation, constipation, pruritus, urinary dysfunction, or neuroendocrine abnormalities (Katz and Mazer, 2009). Research in the future may indicate other risks, such as opioid-related immune suppression (Odunayo et al., 2010) and proliferative effects (Lennon et al., 2012). Some patients develop aberrant patterns of drug use or addiction (Ballantyne and LaForge, 2007). Finally, a reluctance to use high-dose systemic opioid therapy may be justified by concerns related to facilitation of pain transmission (or opioid-induced hyperalgesia) (Ossipov et al., 2005; Angst and Clark, 2006). Although the importance of the latter phenomenon is uncertain, it occurs in humans (Chu et al., 2008), and anecdotally,

may compromise some high-dose systemic or spinal therapies (De Conno et al., 1991; Bruera and Pereira, 1998); management approaches have included interventional pain therapies (Carr and Cousins, 2009; Deer et al., 2012c), opioid rotation, and adjuvant drugs such as systemic lignocaine (lidocaine) (Tremont-Lukats et al., 2005) or ketamine infusions (Mercadante et al., 2000).

There are numerous interventional pain therapies. In populations with advanced illness, these techniques may be used to address acute pain, perioperative pain, exacerbations of chronic pain, and pain from diagnostic or therapeutic procedures, as well as chronic pain.

Injection therapies

Peripheral injections for muscular and arthritic pain

Trigger point injections

Myofascial pain syndromes (MPS) are common, can involve any muscle, and can be the primary problem, or a secondary manifestation of underlying pathology, such as infection, intervertebral disc disease, vertebral compression fracture, or bone metastasis. MPS diagnosis requires thorough physical examination for muscular 'trigger points' (TPs). A TP is a hyperirritable nodule in skeletal muscle that may be palpable, is painful on compression, and can cause characteristic referred pain and/or autonomic phenomena (Simons et al., 1999). Physical therapy alone may suffice, but many patients benefit from local anaesthetic TP injections. Other therapies comprise both interventional (e.g. dry needling, acupuncture, pulse radiofrequency, botulinum toxin (BTX) injection) and non-interventional (e.g. spray and stretch) approaches.

Intra-articular injections

Arthritis and joint-related pain are common in populations with advanced illness. Corticosteroids are most commonly used for intra-articular injections, although data comparing various agents are limited (Bliddal et al., 2006). Possible complications include infection, bleeding, nerve injury, or joint destruction.

Botulinum toxin injection

BTX is a potent neuroparalytic agent produced by the bacterium *Clostridium botulinum*. It irreversibly inhibits acetylcholine release at the neuromuscular junction, thereby causing localized

chemodenervation at the target organ (e.g. muscle, glands), with minimal systemic adverse effects. More relevant to pain, BTX-A also may block peripheral sensitization and indirectly reduce central sensitization (Aoki, 2005).

In addition to its use in spasticity and movement disorders, BTX is used as an analgesic in migraine, interstitial cystitis, and chronic myofascial pain (Foster et al., 2001; Gobel et al., 2001). Evidence in the latter condition is inconclusive (Soares et al., 2012), but it is generally safe and well tolerated, and may be repeated. When effective, its effects usually become evident approximately 1 week after injection; benefit lasts 3–4 months and then fades. Repeated administration may lead to diminishing benefit due to the development of neutralizing antibodies. To limit this, an interval of at least 12 weeks between injections is recommended, and if positive effects are lost, they may be regained by using an alternative formulation. There are at least four commercially available BTX-A preparations, one BTX-B preparation, and recent report of a BTX-F preparation.

Regional administration of agents that modify neural transmission

Peripheral nerve blocks and catheters

Regional local anaesthetic neural blockade is best used for pain in the distribution of a peripheral nerve or plexus. It is most frequently used perioperatively and also is applied to the treatment of acute pain caused by tumour, pathological fractures, and/or ischaemia. Occasional patients with chronic pain are candidates for repeated or continuous local anaesthetic blockade, which may be facilitated by placement of a catheter near the peripheral nerve (Vranken et al., 2001; Okell and Brooks, 2009). Almost any somatic nerve can be blocked and ultrasound techniques have been developed to improve the accuracy of needle or catheter placement (Hadzic, 2012). Long-term catheters may be complicated by infection, local anaesthetic toxicity, catheter displacement, or technical difficulties such as catheter knotting. With good care and strict attention to sterility, however, peripheral nerve catheters can be maintained for several weeks.

Spinal corticosteroid injection techniques

Although efficacy data are inconclusive, broad experience suggests that selected patients with neck, back, and/or spinal radicular pain unrelated to serious illness may benefit from translaminar (Abram, 1999), transforaminal (Riew et al., 2000), or caudal epidural steroid injections. These and related injection techniques may be used to treat comorbid spinal pain or radiculopathy in populations with advanced illness. Despite limited data suggesting efficacy, subarachnoid steroid injection for intractable pain remains controversial because of concern about neurotoxicity, and should be considered experimental.

Neural destructive techniques: neurolytic blockade, surgical techniques

Chemical neurolysis: alcohol and phenol

Phenol and ethyl alcohol (ethanol) are the agents most frequently used for neurolytic blocks (Burton et al., 2009). Phenol has both local anaesthetic and neurolytic effects, resulting in nearly painless injection. Excessive doses or accidental intravascular phenol injection may cause convulsions, central nervous system depression, or cardiovascular collapse. In contrast, ethanol has few significant adverse effects from systemic absorption but may cause pain on injection. There are few comparative data for choosing a neurolytic agent.

Radiofrequency (RF) techniques: RF ablation and pulsed RF treatment

RF neurotomy is the destruction of neural tissue with heat generated by a high-frequency electrical current (Niemisto et al., 2003). Conventional (thermal) RF, which creates a thermal lesion at the tip of the wire probe, has been used to denervate painful spinal facet joints, ablate trigeminal or dorsal root ganglia, and lesion thoracic or lumbar sympathetic ganglia. RF is rarely used to lesion somatic nerves supplying the skin due to risk of generating neuropathic pain.

In contrast to thermal RF, pulsed radiofrequency (PRF) applies radiofrequency current in short, high-voltage bursts. The time between bursts allows heat to dissipate. Although sufficient heat to damage tissue may occur, the mechanism by which PRF yields pain relief is not clearly understood, and is thought to involve a neuromodulatory effect rather than neurodestruction. The relatively non-destructive nature and good safety profile of PRF make it attractive for treating pain, but its role in pain management remains unclear (Gofeld et al., 2012). The technique may be useful in cases where conventional RF has limited indications, such as peripheral neuropathies, arthrogenic pain, painful trigger points, and modulation of dorsal root ganglion (Chua et al., 2011). There is no published experience in the treatment of pain related to serious illness.

Sympathetic nervous system block

Sympathetic blockade, with local anaesthetic or neurolytic solutions, can be used for a variety of pain problems, including neuropathic, ischaemic, and/or visceral pain, complex regional pain syndrome (CRPS), and pain from other acute processes (e.g. renal colic, or ischaemic crises in Raynaud's disease or obliterative arteriopathies) (Breivik and Cousins, 2009). Local anaesthetic sympathetic block has been used to predict response to sympathetic neurolysis, but response to local anaesthetic blockade should be interpreted with caution because of the analgesic effect of absorbed (systemic) local anaesthetic and/or placebo response.

In advanced malignancy, neurolytic sympathetic blocks are used for abdominal (coeliac plexus block), pelvic (superior hypogastric plexus block), and perineal (ganglion impar block) pain of visceral origin (Table 9.8.1). These blocks are generally done with fluoroscopic or computed tomography (CT) imaging to guide needle placement; ultrasound guidance may also be an option (Bhatnagar et al., 2012). Although patients with mixed somatic (from tumour invasion of somatic structures) and visceral pain may experience incomplete relief, even partial relief from sympathetic blockade may allow reduction in opioid doses and fewer side effects as a result.

Coeliac plexus/splanchnic nerve block

Neurolytic coeliac plexus block (NCPB) and or neurolytic splanchnic block are used for upper abdominal pain from unresectable pancreatic or other upper abdominal malignancies (Burton et al., 2009). NCPB produces good to excellent relief in 85–90%

Table 9.8.1 Neurolytic sympathetic blockade by location and clinical indication

Location	Clinical use	Results
Stellate ganglion block[a]	Angina, inoperable coronary artery disease Upper extremity pain: ◆ complex regional pain syndrome ◆ peripheral vascular disease ◆ Raynaud's disease ◆ brachial plexus infiltration by tumour ◆ herpes zoster ◆ phantom pain	Rarely indicated[a] Upper thoracic (T2–3) paravertebral sympathectomy (surgical or radiofrequency ablation) is the preferred technique of cervicothoracic sympathectomy when needed
Coeliac plexus block[b]	Visceral pain from: ◆ pancreatic cancer ◆ other upper abdominal tumours	Partial to complete pain relief in 90% of patients alive after 3 months. Results similar for pancreatic cancer and other abdominal malignancies (Eisenberg et al., 1995)
Lumbar sympathetic block[b]	Kidney pain (including 'phantom kidney pain') Intractable lower extremity pain: ◆ inoperable peripheral vascular disease ◆ chronic painful leg ulceration ◆ complex regional pain syndrome ◆ phantom pain ◆ herpes zoster ◆ diabetic neuropathy Testicular pain	Variable, depending on pain condition Peripheral vascular disease: 50–80% of patients experience partial or complete relief of pain at rest (Breivik and Cousins, 2009)
Superior hypogastric plexus block[b]	Pelvic visceral pain from gynaecological, colorectal, or genitourinary cancer	Long-lasting relief in 70% of patients with positive response to diagnostic block (Burton et al., 2009)
Ganglion impar block[b]	Intractable perineal pain	Case series suggest efficacy but little data available (Burton et al., 2009)

[a] Neurolysis of the stellate ganglion is controversial, due to risk of complications. In some cases, persistent relief can be achieved from a series of local anaesthetic blocks (Breivik and Cousins 2009).

[b] Some clinicians do a local anaesthetic block before proceeding with neurolytic block to assess the effect of neurolysis.

of patients and pain relief persisting until death in 70–90% of responders (Eisenberg et al., 1995). A recent Cochrane review concluded that NCPB reduces opioid consumption and side effects (Arcidiacono et al., 2011). Given a favourable risk:benefit ratio, this approach is widely accepted as the next step for patients with pain due to upper abdominal malignancy that fails to respond promptly to systemic opioid therapy. Although NCPB was associated with longer survival in patients with significant preoperative pain (Staats et al., 2002), a subsequent study failed to confirm a survival benefit (Wong et al., 2004).

Both NCPB and neurolytic splanchnic block may be accomplished percutaneously, typically under fluoroscopic control, or by endoscopic ultrasound-guided transoesophageal injection. Extant data are not sufficient to determine whether any of these procedures is better than any other (Arcidiacono et al., 2011). Outpatient treatment is possible, but frail patients or those living far away may be best served by overnight observation. Immediately following the procedure, many patients have diarrhoea and/or orthostatic hypotension, which are typically transient; patients may rarely need oral ephedrine (30 mg three times daily) for orthostatic hypotension or an oral opioid for diarrhoea. Major catastrophic complications are rare: a survey of 2730 patients reported four cases of paraplegia (incidence 1:683)

(Davies, 1993). It is postulated that paraplegia after NCPB is due to ischaemic spinal cord injury from injury or spasm of the artery of Adamkiewicz. Other rare complications include aortic dissection, generalized seizures, and circulatory arrest (Burton et al., 2009). It is unclear if complication risk is affected by the technique or imaging used. Paralysis has even been reported after open, intraoperative NCPB (Abdalla and Schell, 1999).

Lumbar sympathetic block

Intractable lower extremity ischaemic pain due to inoperable peripheral vascular disease is the most common indication for neurolytic lumbar sympathetic block (NLSB). In such settings, NLSB appears to increase cutaneous blood flow, reduce rest pain, and enhance healing of chronic ischaemic ulceration (Breivik and Cousins, 2009). NLSB may also reduce neuropathic lower extremity pain, especially in CRPS. Less common indications are visceral pain from lower abdominal or pelvic structures, such as renal pain, testicular pain, and tenesmus. Serious complications from NLSB are rare when radiographic imaging is used. Lumbar sympathectomy done by NLSB or surgery has comparable results: most peripheral vascular disease patients experience partial or complete relief of pain at rest, and mean duration of effect is approximately 6 months. Compared to surgical sympathectomy,

NLSB is less invasive; has lower morbidity, mortality, and cost; and can be repeated.

Neuraxial neurolysis: spinal neurolytic injection techniques

The aim of neuraxial neurolysis is to produce a chemical posterior rhizotomy, interrupting pain signal transmission. Although use is decreasing, clinical experience supports the approach in selected patients with advanced cancer. Subarachnoid neurolysis should be restricted to patients with advanced malignancy and pain limited to a few dermatomes (Candido and Stevens, 2003), for example, perineal pain in patients with colostomy and permanent bladder catheter or in those with relatively localized (unilateral) chest wall or trunk pain (Burton et al., 2009). Pain relief may last for 6–12 months, with a rate of reported complications between 1% and 14%, which is acceptable to some patients. The approach also is considered for non-ambulatory, incontinent patients with severe lower-extremity spasticity that has not responded to systemic medications or spinal baclofen (Jarrett et al., 2002). Very rarely, extreme cases of lower-body and/or lower-extremity pain in bedbound, terminally ill patients with significant nerve root or spinal cord tumour involvement is managed with chemical cordectomy at the upper-lumbar or lower-thoracic dermatomal level (Burton et al., 2009).

Spinal analgesics: epidural and subarachnoid

Administration of analgesic drugs into either the epidural or subarachnoid (or intrathecal) space is the most common interventional pain therapy for patients with advanced malignancy whose pain cannot be controlled with systemic analgesics (Carr

and Cousins, 2009). These approaches allow one or more drugs to be delivered close to relevant spinal receptors (see Fig. 9.8.1) and will provide some patients with analgesia that could not be obtained with systemic therapies, and others with comparable analgesia but fewer side effects. A randomized controlled trial that compared an implantable subarachnoid drug delivery system to best medical management in patients with advanced cancer found that the spinal analgesic approach reduced pain and analgesic-related adverse effects, and perhaps increased 6-month survival (Smith et al., 2002). Spinal analgesics are included in widely accepted guidelines for the management of cancer pain that is poorly responsive to systemic analgesics (Ripamonti et al., 2012; National Comprehensive Cancer Network, 2013).

Morphine is the most frequently used spinal analgesic for chronic pain, but other opioids (hydromorphone, fentanyl, and sufentanil) are also used. When spinal opioid monotherapy is ineffective, opioids can be combined with other analgesics, most commonly local anaesthetics (bupivacaine, ropivacaine) and/or clonidine. Best practices for these and other drug combinations are outlined in the 2012 Polyanalgesic Consensus Conference report (Deer et al., 2012c). In the United States, morphine (epidural and subarachnoid), clonidine (epidural), baclofen (subarachnoid), and ziconotide (subarachnoid) are the only drugs approved for chronic spinal administration, and other drugs are used off-label. Due to concern about neurotoxicity, and the safety of compounded 'custom' preparations, great caution is needed when considering analgesics not approved for spinal administration, including non-standard drug preparations, concentrations, doses, or multiple-drug combinations of approved analgesics (Deer et al., 2012c).
Fig. 9.8.1 Presynaptic primary afferent neurons (peripheral nociceptor) release neurotransmitters such as glutamate (Glu) and substance P (SP). These neurotransmitters stimulate secondary neurons in the dorsal horn (spinal neuron post synaptic membrane), sending pain signals to the brain. Inhibition of ion channel permeability decreases neurotransmitter release and decreases responsiveness of dorsal horn neurons to reduce transmission of noxious stimuli to the brain. Activation of inhibitory receptors (μ and δ opioid; GABA (γ-aminobutyric acid); α_2-adrenergic) also is a means by which pain transmission may be modulated. The drugs shown reduce pain transmission, and are believed to be active at the sites indicated (arrows). Some agents exert their effect presynaptically, others act on postsynaptic receptors, and many act on both.

Spinal opioid administration

Spinal administration delivers opioid close to the opioid receptors within the dorsal horns of the spinal grey matter, where they reside on both presynaptic (peripheral afferent nociceptor) and post-synaptic (second-order spinal neuron) nerve terminals. Opioid binding inhibits synaptic transmission between primary afferent nociceptors and second-order spinal neurons, and reduces the firing of the second-order neurons. Following spinal administration, cerebrospinal fluid (CSF) opioid concentrations are far in excess of plasma concentrations, and the time course of analgesia correlates with CSF opioid concentration rather than with plasma concentrations (Carr and Cousins, 2009).

Adverse effects of spinal opioids

Most common spinal opioid adverse effects are those of opioid therapy in general. The incidence of these effects is not high when spinal opioids are used in patients with advanced illness because these patients usually have developed opioid tolerance during prior systemic administration. When adverse effects occur, they are often self-limiting or can be successfully managed by dose adjustment. While the opioid dose is being adjusted, adverse effects due to excess opioid may be managed with small naloxone doses, often without reducing opioid analgesia. In this setting, naloxone is best administered as an intravenous loading dose, given in 40-microgram increments, followed by intravenous infusion (approximately 1–5 micrograms/kg/hour) titrated to effect. Constipation is a problem to which tolerance may not develop; therefore, it should be anticipated and managed.

Although respiratory depression from spinal opioid therapy is uncommon, it can occur at initiation of treatment or with subsequent spinal catheter or pump adjustments (Scherens et al., 2006; Deer et al., 2012b). Occasionally, delayed respiratory depression (onset 3–20 hours) occurs, presumably as a result of cephalad opioid migration within the CSF (Carr and Cousins, 2009). These risks require that opioid dosing adjustments be made cautiously. Other, more common adverse effects, such as endocrine abnormalities, sweating, and peripheral oedema, are associated with both systemic and spinal chronic opioid therapy (Katz and Mazer, 2009). In one study of spinal opioid for non-malignant pain (Winkelmuller and Winkelmuller, 1996), most male and all female patients developed hypogonadotropic hypogonadism, and other endocrine abnormalities were also common. Peripheral oedema associated with chronic spinal opioid, related to opioid antidiuretic effect, is usually managed with diuretics, but may require opioid rotation or change to non-opioid analgesics (Deer et al., 2012c). Analgesic tolerance and likely associated hyperalgesia also may accompany chronic systemic or spinal opioid administration (Angst and Clark 2006; Chu et al., 2008). Very high doses of either systemic or spinal opioid may cause an opioid-induced toxicity syndrome, potentially including delirium, myoclonus, and hyperalgesia (De Conno et al., 1991). The best way to avoid these effects is to limit opioid dose by optimizing non-opioid analgesics, and non-pharmacologic therapies; more severe toxicity may be managed with opioid rotation.

Non-opioid spinal analgesics

When spinal opioids do not provide adequate analgesia, addition of a local anaesthetic may help (Carr and Cousins, 2009; Deer et al., 2012c). Bupivacaine is most commonly used, whereas lignocaine (lidocaine) and tetracaine are generally avoided due to concern for neurotoxicity. Local anaesthetics may both decrease nociceptive input and reduce sensitization of spinal cord neurons. Blockade of pain transmission without loss of sensory or motor function is usually possible, and may be more readily obtained with epidural than with subarachnoid use. Subarachnoid local anaesthetic requires low (less than 20–30 mg bupivacaine per day) and carefully adjusted doses. Refractory pain in non-ambulatory terminally ill patients sometimes is managed with high-dose subarachnoid local anaesthetic (> 48 mg bupivacaine per day), which produces spinal anaesthesia, with dense sensory and motor block.

Clonidine, an α_2-adrenergic agonist, is well accepted as a spinal analgesic and typically is administered along with an opioid and/or local anaesthetic. Analgesic efficacy was demonstrated in randomized controlled trials that evaluated effects in cancer pain (Eisenach et al., 1995) and spinal cord injury pain (Siddall et al., 2000). Adverse effects, including hypotension, bradycardia, and sedation, are dose related and generally manageable. However, a case report of spinal cord damage after 3 years of uneventful subarachnoid clonidine-bupivacaine administration (Perren et al., 2004) is a reminder that there are few safety data on long-term administration of custom compounded combination spinal analgesic solutions.

Chronic subarachnoid baclofen infusion via an implanted pump is useful for severe spasticity in patients unresponsive to, or intolerant of, oral baclofen. There also may be some efficacy as a co-analgesic for CRPS, musculoskeletal pain related to spasticity, and neuropathic pain (Deer et al., 2012c). Spinal administration, which results in significantly higher CSF concentrations than oral administration (despite doses 100–1000 times lower), is generally well tolerated and no significant neurotoxicity has been identified.

Ziconotide, a synthetic analogue of an omega-conotoxin derived from the marine snail *Conus magus*, produces analgesia by blocking N-type calcium channels in the superficial dorsal horn of the spinal cord. Subarachnoid dosing starts from 0.5 to 1.5 micrograms/day and is slowly titrated to an average dose of 7 micrograms/day. There is a narrow therapeutic window as a result of neuropsychiatric adverse events, including depression (perhaps with increased risk of suicide), cognitive impairment, hallucinations and depressed level of consciousness; rare adverse effects include creatine kinase level elevation and meningitis (perhaps due to infusion device contamination). Because of its narrow therapeutic window, ziconotide is rarely used as a single agent, but has been combined with morphine to improve intractable pain (Deer et al., 2012c), with documented efficacy in advanced cancer pain (Alicino et al., 2012).

Indications for spinal analgesics in palliative care

Spinal analgesics are used to manage chronic cancer pain (Carr and Cousins, 2009; Deer et al., 2011) and non-cancer pain in populations with serious illness. Limited life expectancy should not deter consideration of this approach, but is a factor in selecting among spinal administration systems. Spinal opioids work best for deep, constant somatic pain, whereas other types of pain (e.g. cutaneous, intermittent somatic such as pathologic fracture, intermittent visceral from intestinal obstruction, and coexistent cancer and non-cancer pain) are variably responsive. Neuropathic pain may respond but often requires trials of drug combinations,

including clonidine, local anaesthetic, or ziconotide). Patients with extreme opioid tolerance are unlikely to have good pain control with spinal opioid alone, and will likely require coadministration of non-opioid spinal analgesic(s). In general, a spinal analgesic trial through a temporary catheter is recommended before permanent spinal delivery system implantation.

Contraindications to spinal analgesic therapy are similar to those for any regional anaesthetic technique, with additional concerns due to chronicity of spinal analgesia. Coagulopathy increases risk and anticoagulation therapy should be withheld before implementing therapy. Specific recommendations vary depending on the anticoagulant and the indication for its use; consensus statements by anaesthesiology professional societies are a useful guide (Gogarten et al., 2010; Horlocker et al., 2010). Septicaemia is an important contraindication due to the risk of spinal delivery system infection, and local infection is a contraindication if a site free of infection cannot be found for spinal catheter system implantation. Immunosuppression is generally only a relative contraindication for implantable devices. Ongoing chemotherapy or radiation therapy is not a contraindication to spinal analgesic therapy, and radiation therapy is a concern only if the portal includes a surgical site. In the latter situation, a simple percutaneous spinal catheter may be used until the effects of radiation are clear; percutaneous spinal catheters have been utilized for prolonged periods with appropriate sterile technique (Nitescu et al., 1995; Aprili et al., 2009).

Spinal metastasis is not a contraindication for spinal therapy. To avoid trauma to a friable tumour mass or neural injury caused by needle or catheter placement into a stenotic spinal canal, catheters should be inserted away from metastases, under fluoroscopy. If CSF circulation may be impeded by an expanding tumour, the catheter should be placed cephalad to the lesion.

Technical considerations and complications in spinal drug administration

The system used to deliver intraspinal drug may be as simple as a 'low-tech', percutaneous catheter for intermittent injection or as sophisticated as a totally implanted high-tech infusion pump system. No single system is appropriate for all cases, and any system can result in complications, such as infection, catheter dislodgement, or other failures (Table 9.8.2) (Aprili et al., 2009; Carr and Cousins, 2009). Before initiating long-term spinal analgesia, adequate medical, nursing and social support to assist with maintenance of the specific system and address any complications should be confirmed.

'High-tech' implantable pump systems have long battery life, need refills at regular intervals (typically 1–2 months), and may have capacity for patient-activated bolus dose administration, in addition to continuous infusion (Brogan and Winter, 2011). They are generally reserved for patients with a life expectancy of at least a few months, because of high start-up costs. Because they have small medication-reservoir volume (20–50 mL), the use of commercially available (dilute) bupivacaine and/or clonidine preparations is impractical and custom-compounded solutions are needed (Deer et al., 2012c). Compounds pose a risk of contamination and infection, or potential overdose if high-concentration solution is inadvertently injected into the subcutaneous tissue surrounding the pump ('pocket fill') or into the spinal catheter injection port (allowing direct access to the spinal fluid) (Deer et

al., 2012b). Pump refill, accomplished by placing a needle through the skin into the pump refill port, is usually technically straightforward, but may be associated with devastating drug overdose if the refill solution is not correctly injected into the refill port; therefore, refills require physician or skilled nursing personnel.

'Low-tech' spinal infusion systems usually consist of an epidural or subarachnoid catheter connected to an implanted or externalized injection port (Carr and Cousins, 2009). Spinal analgesics are then administered by intermittent injection or external pump. Advantages of subarachnoid analgesia are efficiency and potency, which may translate into improved analgesia with lower drug cost. Therapy requires adequate skilled nursing assistance and/or physician evaluation. Percutaneous catheters or implanted injection port systems with or without external infusion pumps may be managed by some patients and/or family members, but still require periodic nursing support. It is possible to initiate and maintain percutaneous subarachnoid analgesia at home for terminally ill, homebound patients, if physician home visits can be arranged (Mercadante 1994).

Infection (meningitis, epidural abscess, or encephalitis) may occur with any delivery system but is more of a concern with the 'low-tech' spinal infusion systems (Aprili et al., 2009). Experience has shown that the risk is low if aseptic technique during placement is followed by careful maintenance and medication administration. Risk is further reduced by use of bacterial filters (0.2 micrometres) and a sterile technique that strictly minimizes changing external infusion pump reservoirs and tubing (Nitescu et al., 1995; Aprili et al., 2009). Infections are usually superficial, localized to skin at the catheter insertion or implantation site. Cultures of any drainage can guide antibiotic therapy. Epidural abscess and meningitis are rare, but must be treated aggressively because they may cause permanent neurological deficit or death. Although an epidural system usually is removed as part of epidural abscess management, the catheter may temporarily serve as a drainage conduit from the epidural space. Antibiotics may be delivered via the epidural catheter (Du Pen, 1999), but if infection does not rapidly improve, the catheter should be removed. Meningitis associated with subarachnoid catheter systems should be treated with intravenous antibiotics, but treatment may also include antibiotics delivered via the subarachnoid system (only antibiotics suitable for subarachnoid administration, such as vancomycin, should be administered through the spinal catheter). If the infection does not rapidly clear with antibiotics, the subarachnoid catheter system should be removed (Mercadante, 1999). In end-of-life care, attempts to contain the infection without removal of the system may be appropriate.

Any spinal catheter system may malfunction. Malfunction typically is signalled by abrupt or gradual worsening of pain (which may be difficult to distinguish from disease progression) or the development of withdrawal. Infusion device function can be evaluated using epidurography or myelography to verify catheter location and patency, and plain radiographs to help confirm the structural integrity of the spinal system.

The efficacy of epidural infusion also may be compromised by epidural fibrosis, that is, formation of scar tissue around the catheter within the epidural space (Cherry and Gourlay, 1992). Epidural fibrosis is a variable process and may develop as early as 2 weeks after epidural catheter placement. It limits analgesic solution spread, resulting in pain on injection and/or loss of analgesic

Table 9.8.2 Evaluation and management of spinal catheter complications

Catheter system	Symptoms	Complication	Prevention	Evaluation	Management
Epidural	Back pain Paraesthesias on injection Loss of analgesic effect No signs of infection	Epidural fibrosis (Cherry and Gourlay, 1992)	Unknown	Epidurography	Replace epidural or insert subarachnoid catheter
	Back and extremity pain Weakness Sensory abnormalities Fever, Leucocytosis	Epidural infection or abscess	Sterile technique, bacterial filters (Du Pen, 1999)	Catheter aspirate for Gram stain, culture; spine MRI	Catheter aspiration for decompression Intravenous antibiotics Remove catheter
Epidural or subarachnoid	Loss of analgesic effect Opioid withdrawal	Catheter dislodgement or disconnection	Implanted rather than percutaneous system; subarachnoid catheter anchored to fascia	Plain radiographs with contrast injection via catheter	Revise or replace catheter
		Pump malfunction	Pump maintenance; utilize low volume and low battery alarm	Pump analysis; technical support from manufacturer	Revise or replace pump

	Erythema, tenderness at catheter insertion point or incision site	Infection at catheter insertion site	Sterile technique
			Catheter care
				Culture:
				    catheter exit site
				    catheter aspirate
					Antibiotics
					Local site care
					Remove catheter system if no rapid improvement

Subarachnoid	Meningeal irritation: severe headache, cervical stiffness, photophobia, fever	Meningitis	Sterile technique Bacterial filters for pump refill or on percutaneous catheters	Catheter aspirate (CSF) for cell count, Gram stain, glucose, culture	Systemic (and possibly subarachnoid) antibiotics Remove catheter system if no rapid improvement

	Spinal cord compression:
	    paraesthesias, weakness
		Subarachnoid granuloma	Unknown
			Avoid excessive doses, concentrations of spinal opioid
				Spine imaging:
				    MRI or CT myelogram
					Discontinue spinal analgesics
					Surgical consultation if significant sensory or motor deficits present

effect. Management requires repositioning the epidural catheter or replacing it with a subarachnoid catheter.

Although scarring around subarachnoid catheters rarely occurs, these systems may be complicated by catheter-tip granuloma formation. These lesions are rare, may develop slowly over several weeks, and can present with loss of pain control, sensory abnormality, or weakness progressing to paralysis. Most granulomas occur with chronic opioid administration and may be related to activation of opioid receptors on inflammatory cells. Consideration should be given to evaluating for catheter-tip granuloma whenever a patient reports worsening pain control, or the new onset of back pain, radicular pain, or sensory or motor abnormalities. Spine magnetic resonance imaging (MRI) is the preferred imaging technique (patients with spinal pumps can undergo MRI), but CT myelography is a good alternative. Surgical resection of a granuloma is only indicated if significant neurologic deficit is present. Otherwise, discontinuation of spinal analgesics may be followed by shrinkage of the granuloma and symptomatic improvement. Careful monitoring is required to ensure that improvement occurs (Deer et al., 2012a, 2012d).

Patients with worsening pain as a result of a technical problem or complication often require systemic analgesics to relieve pain and prevent opioid withdrawal. Subarachnoid morphine doses are approximately 10% of epidural doses, and 1% of systemic (parenteral) doses, but these estimations are just starting points, and must be used cautiously in order to prevent significant under or over-dosing. Lignocaine (lidocaine), 50–100 mg/hour, or ketamine 10–20 mg/hour, by intravenous or subcutaneous infusion, may temporarily control intractable pain unresponsive to opioids (Tremont-Lukats et al., 2005). If intravenous ketamine is utilized, a benzodiazepine should be administered also to control possible dysphoric hallucinations.

Neurosurgical interventions for intractable pain: intracerebroventricular opioid and neuro-destructive interventions

Catheter techniques are rarely used for opioid administration directly into the cerebral ventricles (Raffa and Pergolizzi, 2012). Data suggest that intracerebroventricular opioid is a reasonable option for intractable pain (usually cancer related) in the following settings: inadequate analgesia through conventional techniques, inaccessible spinal epidural and subarachnoid spaces, known obstruction of spinal CSF circulation, and/or intractable head and neck pain. A Cochrane review (Ballantyne and Carwood, 2005) concluded on the basis of case series that intracerebroventricular opioid may have efficacy similar to spinal analgesics, with

a lower incidence of complications, but no comparative studies are available.

In recent years, with increasing use of systemic and spinal analgesics, there has been a reduction in use of destructive neurosurgical procedures for control of intractable pain. Nonetheless, these techniques are potentially valuable in selected pain syndromes (Raslan and Burchiel, 2010). These procedures most commonly target the spinal cord, but may target the brainstem or brain. Percutaneous, image-guided ablation techniques potentially limit the need for open surgical interventions. Spinothalamic cordotomy, the most common, is best used for intractable unilateral somatic pain in the lower body (or at least below the level of the neck) (Raslan et al., 2011). Rarely, midline myelotomy (for midline visceral pain) and dorsal root entry zone lesioning (for localized neuropathic pain such as brachial plexopathy) are considered (Romanelli et al., 2004). Neurosurgical procedures to disrupt pathways involved in emotional processing (e.g. cingulotomy) are very rarely utilized.

Miscellaneous techniques for pain control

Vertebroplasty and kyphoplasty

Vertebral compression fractures are an important cause of pain and morbidity in patients with serious illnesses and can be caused by metastatic cancer, multiple myeloma, or bone loss after radiotherapy, hormonal treatment, steroids, and poor overall medical status (Aghayev et al., 2011) (see also Chapter 12.5). Osteoporotic vertebral compression fractures not only are painful, but increase mortality (Bliuc et al., 2009). Percutaneous vertebroplasty and kyphoplasty are similar minimally invasive procedures, in which a fractured vertebra is stabilized by injection of polymethylmethacrylate bone cement into the vertebral body via large-bore needles (Burton et al., 2005; Nairn et al., 2011). Both procedures provide good to excellent pain relief to 80–90% of people with painful vertebral compression fractures due to osteoporosis, and 50–60% of those with painful neoplastic vertebral fractures. In vertebroplasty, bone cement is injected through needles into the interstices of the vertebral body marrow space. Kyphoplasty includes inflation of a high-pressure balloon in the vertebral body to create a cavity, which is subsequently filled with bone cement. The balloon expansion may partially restore vertebral height, but the degree of height restoration may be modest and is of unclear significance. There are no comparative studies between these techniques. A randomized, controlled trial comparing kyphoplasty with non-interventional, conservative management strongly favoured kyphoplasty in terms of pain, disability, quality of life, and decreased analgesic use (Berenson et al., 2011). Rapid pain relief from percutaneous vertebroplasty or kyphoplasty may improve patient tolerance of needed antitumor therapies, such as positioning for radiation therapy (Aghayev et al., 2011).

Both vertebroplasty and kyphoplasty requires neuraxial imaging (MRI or CT) to evaluate vertebral anatomy, with attention to possible extension of bone fragments or tumour into the spinal canal. MRI is especially useful for detecting acute vertebral compression fractures because vertebral marrow oedema (indicating acute fracture) is readily identified. Bone scintigraphy is less useful because it will identify increased activity at a fracture site for up to 2 years, long after the fracture may have spontaneously stabilized.

Absolute contraindications for vertebral augmentation are spinal cord compression with clinical myelopathy, overt spinal instability (i.e. subluxation), and osteomyelitis. Relative contraindications include posterior vertebral defects, epidural tumour spread, and cervical fractures. The overall complication rate for these procedures is low, but cement extrusion into the spinal canal can result in neural compromise, and cement venous embolism can cause pulmonary embolism (Burton et al., 2005; Nairn et al., 2011).

Spinal cord stimulation

Spinal cord stimulation (SCS) is a minimally invasive and readily reversible approach to neuropathic and nociceptive pain, most frequently used for post-laminectomy syndrome and CRPS (for detailed discussion see Chapter 9.9). It can be efficacious for intractable angina (Yu et al., 2004), peripheral neuropathic pain (e.g. diabetic or chemotherapy-induced neuropathy), abdominal visceral pain (Tiede et al., 2006), and ischaemic pain from peripheral vascular disease (Ubbink and Vermeulen, 2013). Its analgesic mechanism has not been fully elucidated.

SCS involves placing stimulating electrode arrays in the epidural space overlying the posterior aspect of the spinal cord. Current is delivered by an internal, battery-powered pulse generator. SCS stimulation paraesthesias are generally perceived as warm, soothing sensations associated with pain relief. A trial using temporary leads can help determine patient response prior to permanent placement. As many as 50–60% of patients who undergo a SCS trial experience meaningful pain relief (defined as reduction of pain by at least 50%). Although some stimulator systems have limited MRI compatibility, most are not MRI compatible; therefore, compatibility must be determined from the manufacturer for each specific stimulator and MRI study.

Palliative sedation: management of intractable pain when all else fails

Despite advances in palliative care, a few patients still experience distressing end-of-life symptoms, including pain or delirium (Maltoni et al., 2012). To address intractable pain and suffering, 'anaesthetic' rather than 'analgesic' interventions may be considered. Palliative sedation is a medical intervention, clearly different than euthanasia, and accepted guidelines for proper use have been proposed (Cherny and Radbruch, 2009). Appropriate use requires a clinician to distinguish symptoms that are merely difficult to control from symptoms that are truly refractory to standard treatments, including interventional pain therapies. This distinction will protect patients with refractory symptoms from futile interventions, and avoid unnecessary sedation in patients with difficult but controllable symptoms (Cherny and Radbruch, 2009). Obtaining 'second opinion' from a pain specialist or multidisciplinary palliative care team, may help determine if effective symptom management therapies are yet available. For detailed discussion of this issue see Chapter 18.2.

Conclusion

There have been important advances in the therapies used to control pain in populations with serious illness. In developed countries, systemic opioid and adjuvant analgesics are widely available and are used with increasing sophistication and improved effect, although cost and other barriers (Fisch et al., 2012) continue to limit analgesic access. Unfortunately, poor access to analgesics in developing nations often denies people their fundamental human right to pain treatment (Cousins and Lynch, 2011). Across

the globe, there is increasing scrutiny on health-care institutions and providers, which is intended to encourage the delivery of patient-centred care that efficiently and effectively improves outcomes, including quality of life. In addition to assured access to systemic analgesics, the availability of selected interventional pain therapies should be viewed as a goal to optimize pain management.

The need for access to interventional pain therapies has become more certain with increasing recognition that opioid analgesia has significant limitations. For many patients, systemic opioids cannot provide satisfactory analgesia with acceptable side effects, and poor outcomes combined with emerging concerns about adverse effects such as neuroendocrine and sleep disturbances underscore the need to evaluate and manage risk when opioids are used. Interventional pain therapies are key components of this strategy and are now incorporated into best practices for cancer pain management (Ripamonti et al., 2012; National Comprehensive Cancer Network 2013). These therapies, especially spinal analgesics, NCPB, and vertebroplasty, have become essential components of palliative care, to control pain that cannot be safely and effectively managed with systemic analgesics. Most patients now suffering from uncontrolled pain need not await clinical application of new developments but could benefit from well-coordinated and consistent application of available techniques, including interventional pain management therapies.

Neurostimulation in pain management

Joy Hao, Rae Lynne Kinler, Eliezer Soto, Helena Knotkova, and Ricardo A. Cruciani

Introduction to neurostimulation in pain management

Pain is highly prevalent and exerts a huge toll on individuals, families and society. A 2011 review conducted by the US Institute of Medicine exemplifies the scope of the problem. It found that 100 million American adults have chronic pain and estimated the annual cost burden to society at US$560–635 billion plus US$100 billion spent by the federal government (Institute of Medicine of the National Academies, 2011). Pain prevalence is likely to rise in most countries as age-related chronic illnesses increase and the long-term effects of HIV/AIDS evolve. Both health systems and individual health professionals face enormous challenges in providing safe and effective care for diverse populations with chronic pain.

Pain is a major factor in the burden associated with serious or life-threatening illnesses, and both the prevalence and the adverse consequences increase in advanced illness. Most studies have focused on populations with cancer and have determined that the prevalence of pain associated with varied solid tumours is 39–50% (Deandrea et al., 2014). The adverse effects of unrelieved pain on physical functioning, mood, coping and adaptation, and caregiver distress justify the widely-held view that pain management is a moral imperative in the clinical management of patients with advanced illness.

There is a strong international consensus that the first-line treatment for pain associated with serious or life-threatening illnesses is opioid therapy. Although broad experience with opioid therapy indicates that it is usually safe and effective, patients may not be able to access optimal therapy or may be unable to obtain satisfactory relief even when treatment is available. Indeed, some studies indicate a relatively high rate of inadequate pain relief (Nekolaichuk et al., 2013), the reasons for which are likely to be multifactorial and variable across settings.

Both non-opioid pharmacological therapies and non-pharmacological interventions are needed to optimize analgesic outcomes. If opioid therapy does not yield a favourable balance between analgesia and side effects, the patient should be considered to be poorly responsive to the current regimen and an alternative strategy should be selected. There are many options. Some, such as opioid rotation, the use of non-opioid or adjuvant analgesics, and varied interventions like neural blockade and neuraxial analgesia, are considered routinely.

Neurostimulation is another important strategy for pain. The term includes an array of interventions that involve precisely targeted stimulation of peripheral nerve, spinal cord, or the brain (Table 9.9.1). Some of these treatments, such as transcutaneous electrical nerve stimulation (TENS) and spinal cord stimulation (SCS), have been available for decades. Others, such as peripheral nerve stimulation (PNS) and transcranial stimulation techniques, have emerged more recently as viable options in pain management. Neurostimulation techniques are seldom used in the management of pain related to serious illness. A better understanding of the available treatments and the emergence of newer technologies, may increase access and use in the future.

Neurostimulation techniques

The treatments categorized as neurostimulation techniques are highly variable. They target different tissues with different stimulation modalities and use varied technologies to accomplish intended effects.

Transcutaneous electrical nerve stimulation

TENS is a non-invasive technique that uses electrodes on the skin to deliver electrical stimulation to peripheral nerves. The site selected for stimulation usually is in the region of the painful site, but may be at a distance, usually along the course of the peripheral nerves innervating the site (Atamaz et al., 2012). The approach is sometimes considered a rehabilitative modality comparable to heat, cold, vibration, or ultrasound; when used in this way, it may be directed by physical therapists as part of a programme intended to reduce symptoms and improve function. In some countries, however, TENS units may be acquired by patients for home use and applied primarily for the purpose of pain management.

TENS was developed after publication of the gate control theory, which suggested that stimulation of large-diameter, non-nociceptive primary afferent nerves may be able to modulate pain due to interactions with nociceptive pathways in the spinal cord (Johnson et al., 1991; Sluka and Walsh, 2003). Later studies demonstrated that stimulation of nerves can produce dose-dependent (80 Hz vs 30 Hz) segmental inhibition of

Table 9.9.1 Neurostimulation techniques

Strategy	Type of stimulation	Complexity and burden	Mechanism
Spinal cord stimulation (SCS)	Implantation of electrodes in the epidural space at the level of the posterior columns of the spinal cord	Invasive; outpatient surgical procedure; mid level of burden to patients	Modulation of pain signals at the level of the spinal cord and central modulation of the pain response
Transcutaneous electrical stimulation (TENS)	Electrodes are placed at the level of the painful region and stimulate the underlying area	Non-invasive; low level of burden to patients	Based on the 'gate theory' by Melzack and Wolf in which vibration closes the gate for pain information at the spinal cord level; also evidence for supraspinal mechanisms
Peripheral nerve stimulation (PNS)	Implantation of electrodes in the subcutaneous tissue over the peripheral nerve that innervates the affected area	Invasive; outpatient surgical procedure; intermediate level of burden to patients	Impulse interruption by collision; gate control within the spinal cord or supraspinal locations; inhibition of neuroma spontaneous activity
Transcranial direct current stimulation (tDCS)	Placement of electrodes on the scalp and forehead creating an electrical field between the two electrodes	Non-invasive; minimal burden to patients	Subthreshold modulation of neuronal resting membrane potential with subsequent changes of N-methyl-D-aspartate receptor
Transcranial magnetic stimulation (TMS)	Magnet placed on the scalp and stimulate the underlying brain tissue	Non-invasive; delivery can be painful; low burden to patients.	Modulation of brain neuronal excitability under the magnet and connections to other parts of the brain
Deep brain stimulation (DBS)	Leads placed in deep brain structures	Invasive; inpatient surgical intervention; high level of burden to patients	Modulates the activities of certain brain areas like the hypothalamus, thalamus, periaqueductal grey area
Motor cortex stimulation (MCS)	Grid placed on the motor cortex	Invasive; inpatient procedure; high level of burden to patients	Modulates the activity of the underlying cortex and connections to other brain areas

pressure-pain thresholds mediated by second-order neurons in the dorsal horn of the spinal cord (Chen and Johnson, 2009). Adenosine pathways are responsible, at least in part, for the TENS analgesia, as caffeine and adenosine antagonists can block the effect (Marchand and Charest, 1995). In addition, the endogenous opioid peptides, encephalins and dynorphins, may play a role and may actually mediate differential responses to low versus high TENS frequencies. Specifically, low-frequency TENS stimulation causes met-encephalin release (Han et al., 1991), implicating mu opioid receptors, and high-frequency TENS induces dynorphin A release that activates delta receptors (Kalra et al., 2001) at supraspinal and spinal levels (Sluka et al., 1999; Leonard et al., 2010).

The extent to which the effects of TENS is influenced by the placement of electrodes in the dermatome affected by injury has suggested the possibility that the effects of TENS in the spinal cord may be augmented or modified by more direct actions on peripheral nerves (Walsh et al., 1998). TENS can ameliorate chronic pain when applied to a region innervated by a specific peripheral nerve territory (Gersh et al., 1980; Engholm and Leffler, 2010) and TENS application to dermatomes can increases local pain threshold (Bjordal et al., 2007) and reduce postoperative pain (Chen et al., 1998; Yeh et al., 2010). The potential efficacy of TENS placed at traditional acupuncture points also suggests the importance of peripheral localization of the electrical stimulation (Ng and Hui-Chan, 2007, 2009).

The clinical use of TENS is largely based on favourable anecdotal experience. There have been few high-quality studies capable of determining safety and efficacy in different patient populations. Of the 43 studies in a recent systematic review of TENS treatment

for cancer pain, only two were randomized controlled trials (RCTs), 16 were non-randomized, 19 were educational articles, five were on non-cancer related pain, and one was on acute pain (Robb et al., 2009).

The two RCTs were too small to account for variability in settings and patients characteristics, and were considered yield inconclusive results. One of these studies randomly assigned 49 breast cancer patients with thoracic pain due to mastectomy to receive TENS, sham TENS, or transcutaneous spinal electro-analgesia (TSE) (Robb et al., 2007). Treatment for 3 weeks at the intensity recommended by the manufacturers produced no difference among the three arms in terms of the primary outcomes (pain intensity, anxiety, mood, and function); there was, however, less pain interference in the patients randomized to the TENS arm, and at study end, twice as many TENS than TSE patients decided to continue treatment. The second RCT randomized 15 cancer patients with advanced illness to sham, acupuncture-like TENS, or no treatment and found that 30-minute treatment periods for 5 consecutive days produced no difference in pain intensity among the groups (Gadsby et al., 1997).

A systematic review of TENS in patients with advanced illness who were receiving palliative care also noted that conclusions about efficacy are not possible given the limited data available (Pan et al., 2000). Most published experience is in the form of case series (Loh and Gulati 2013). More research is needed to determine whether TENS is efficacious and safe for pain associated with cancer or other serious illnesses.

The ability of TENS to increase blood flow at the site of high-frequency stimulation has raised concerns about the safety of TENS in patients with pain caused by tumour masses.

Theoretically, the application of TENS near a tumour could increase angiogenesis or tumour spread. Although recent studies indicate that the elevated blood flow at the TENS stimulation site is the result of increased muscle activity, and that high-frequency or low-frequency TENS below motor threshold has no clinically significant effect on blood flow in tumours (Cooperman et al., 1975; Cata et al., 2004), the limited data on safety may justify caution in the use of high-frequency TENS in those with metastatic disease.

Peripheral nerve stimulation

PNS for the management of pain is a strategy that became available in 1970s but has received more attention since the 1990s when more sophisticated leads and stimulators were developed (Verrills et al., 2009). Patients receiving PNS undergo implantation of one or more percutaneous leads adjacent to the peripheral nerves innervating a painful region (Long et al., 1981; Hassenbusch et al., 1996; Johnson and Burchiel, 2004). Nerve dissection is not required and the risk of nerve injury is minimal. Although the literature in support of this approach is mostly characterized by retrospective reviews and case series, the potential for this technology may be significant.

PNS has been utilized for a variety of pain syndromes, including occipital neuralgia, headache, and regional pains in the abdominal, pelvic, axial low back, and cervical regions. In a typical report, PNS was used to address pain in the distribution of sensory nerves that was part of a failed back surgery syndrome; all six patients experienced improvement in pain scores, decreased the utilization of pain medications, and experienced an improvement in function (Paicius et al., 2007). There have been no confirmatory controlled trials and no published experience in populations with serious medical illnesses.

Recently, a variation of PNS has been introduced, which is known as 'PNS cross- talk' (PNSCT). By creating an electrical circuit between leads, a larger area can be covered than would be possible using conventional PNS (Burgher et al., 2012). PNSCT has been proposed as an alternative to treat chronic regional and axial pain in patients refractory to conventional therapy (Falco et al., 2009). Controlled trials are needed to evaluate whether this approach is better than PNS and could be applied to the treatment of chronic pain in the medically ill.

Spinal cord stimulation

SCS is achieved by applying an electrical current to a specific area of the spinal cord (Shealy et al., 1967). Stimulation is accomplished using electrodes placed in the epidural space that deliver a current to the underlying posterior columns. Patient who are candidates for this therapy typically undergo an initial trial using percutaneous leads to determine whether stimulation can be provided to the painful area, and if so, whether it is associated with meaningful analgesia (Ghoname et al., 1999). Those who report benefit are offered subcutaneous implantation of the entire system, which includes the electrodes, connecting wires, and a radiofrequency transmitter. The system is equipped with an alarm that alerts when the batteries need to be replaced; newer systems are rechargeable.

The mode of action of SCS has not been elucidated, but like TENS and PNS, the approach was developed based on predictions developed from the gate control theory (Melzack and Wall, 1965). Specifically, stimulation of large-diameter afferents in the posterior columns may be able to segmentally inhibit transmission of impulses originating in small diameter nociceptive afferents. Ongoing research also suggests that SCS may inhibit transmission in the spinothalamic tract through the activation of central descending inhibitory mechanisms, influencing sympathetic efferent neurons, and releasing various inhibitory neurotransmitters (Oakley and Prager, 2002).

Stancak et al. tested patients with failed back surgery syndrome to determine the area of the central nervous system (CNS) where SCS has its effect. Functional magnetic resonance imaging (fMRI) technology showed that during SCS, there was a signal increase in the somatosensory cortex, primary motor cortex, and insula of the leg area and vicinity, while there was a concomitant signal decrease in the primary motor cortex corresponding to the shoulder. Applying a standardized suprathreshold heat stimulus to the lower leg of study subjects produced increases in the secondary somatosensory cortex, insula, thalamus, and cingulate cortex. During simultaneous spinal cord and painful heat stimulations, the left and right temporal poles and the ipsilateral cerebellar cortex were activated more strongly compared with the sum of the activations of the separate stimulations, suggesting modulation of pain-related activation by ongoing SCS.

In another study of SCS mechanisms, Nihashi and colleagues utilized fluorodeoxyglucose (FDG) positron emission tomography (PET) scanning to study metabolic/glucose uptake information in seven patients with complex regional pain syndrome (CRPS) and 13 controls (Nihashi et al., 2004). They found an increase of FDG metabolism in the left thalamus, secondary somatosensory cortex, anterior cingulate cortex, bilateral insula, dorsolateral prefrontal cortex, and bilateral superior temporal gyrus in the six patients where SCS was effective (defined by > 50% pain reduction). However, FDG uptake decreased in the posterior cingulate cortex.

Most reports of SCS have described case series of patients with neuropathic pains, such as radiculopathies, arachnoiditis (De La Porte and Siegfried, 1983), phantom limb pain, CRPS (Taylor 2006; Taylor et al., 2006), deafferentation syndromes (Sanchez-Ledesma et al., 1989), non-specific neuropathic pain (Kumar et al., 2008), brachial and lumbosacral plexopathies, and post-herpetic neuralgia (Tasker, 1998). Positive effects also were reported in 18 patients with visceral syndromes, such as interstitial cystitis, chronic abdominal pain, chronic pancreatitis, mediastinal pain (Guttman et al., 2009), and intractable angina (Kemler et al., 2000).

A systematic review of the literature on the use of SCS in cancer patients identified only four trials, all of them small observational or retrospective studies (Lihua et al., 2013). In one study, three of 11 patients reported greater than 50% analgesia and underwent implantation (Meglio et al., 1989). Another study of 14 lung cancer patients who underwent SCS implantation for the treatment of chest pain after surgical or radiological interventions noted a mean 71% decline in opioid use after implantation and a reduction in mean visual analogue score from 7.43 at baseline to 3.07 after 1 month and 2.07 after 12 months (Yakovlev et al., 2010). A survey of 15 patients with intractable, cancer-related, low back pain observed similar benefits after SCS implantation (Yakovlev and Resch, 2011).

A retrospective study of 454 patients undergoing SCS implantation for a variety of pain diagnoses observed that 71% of the patients reported partial to complete pain relief, 58% decreased analgesic use, and 11% stopped using analgesics completely

(Shimoji et al., 1993). Fifty-two of these patients had cancer-related pain, and 45 also experienced greater than 50% pain reduction. These retrospective data, like the case series, cannot confirm efficacy or establish the benefits of SCS relative to other treatments used for refractory pain. Nonetheless, the observational data are promising and suggest that a trial of SCS should be considered in patients who have pain related to serious illness that has not responded to conventional pharmacological management.

Central nervous system stimulation

Widespread use of neuroimaging techniques such as fMRI has shown that patients with chronic pain syndromes develop changes in the brain. For example, imaging shows changes in the excitability and/or somatotopic organization within specific cortical and subcortical regions, including structures generally considered to be part of a pain processing network or 'pain matrix' (e.g. areas of the motor and somatosensory cortices and parts of the thalamus) (Cohen et al., 1991; Elbert et al., 1994; Flor 2003). The observation that modulation of these neuroplastic changes may be accompanied by pain relief (Pleger et al., 2005; Birbaumer et al., 1997) has provided a physiological justification for trials of CNS neurostimulation for the treatment of chronic pain.

Both non-invasive and invasive techniques of neuromodulation have been studied in different types of chronic pain syndromes. Results have been promising and suggest that CNS neurostimulation could play a role in the treatment of pain related to serious medical illness.

Transcranial direct current stimulation

Transcranial direct current stimulation (tDCS) is a non-invasive technique that applies low-intensity direct current to the scalp (Nitsche and Paulus, 2000). The current penetrates the brain and modulates neuronal excitability by altering the firing rate of individual neurons. There are two modalities depending on current direction: anodal (excitatory) tDCS increases cortical excitability and cathodal (inhibitory) tDCS decreases excitability (Nitsche and Paulus, 2001).

Studies have shown that the analgesic effect of tDCS may be elicited by the application of anodal tDCS over the primary motor cortex (Fregni et al., 2006a, 2006b) or cathodal tDCS over the somatosensory cortex (Antal et al., 2008, Knotkova et al., 2009). Two randomized, sham-controlled studies showed that anodal stimulation improved pain in patients with fibromyalgia (Fregni et al., 2006b; Roizenblatt et al., 2007), and another sham-controlled trial showed promising results of tDCS for the treatment of central pain in patients with traumatic spinal cord injury (Fregni et al., 2006a). A case study suggested that cathodal tDCS over the somatosensory cortex also may be able to relieve chronic neuropathic pain (Knotkova et al., 2009).

Two recent sham-controlled studies evaluated the analgesic efficacy of tDCS for the treatment of chronic migraine headache: Antal et al. found that cathodal tDCS applied to the visual cortex resulted in a significant reduction in pain intensity when compared with the sham group (Antal et al., 2011), and Dasilva et al. showed that anodal tDCS applied over the primary motor cortex resulted in a delayed reduction in pain intensity four months after stimulation (Dasilva et al., 2012). Furthermore, tDCS was successfully applied in two patients with trigeminal neuralgia and neuropathic facial pain due to surgical disturbance

of the trigeminal nerve, resulting in greater than 50% reduction in pain scores and decreased use of pain medications (Knotkova 2009). A small observational study suggests that tDCS may be useful for the treatment of cancer pain (Silva et al., 2007).

Both studies and clinical experience with tDCS suggest that the analgesic properties are cumulative and that the duration of the analgesic effect outlasts the stimulation but is transitory. Pain usually returns to prestimulation levels. Independent investigators have shown greater pain relief with tDCS over 5 consecutive days as compared to a single session, and demonstrated a time course of the analgesic response that can outlast the last stimulation session by over 9 weeks (Fregni et al., 2006a, 2006b; Roizenblatt et al., 2007). However, the duration of the effect varies greatly from patient to patient, and predictions on the magnitude of the response and duration of the effect cannot be made based solely on the underlying pain syndrome, concomitant medications (opioids or adjuvants), co-morbidities like depression or anxiety, or other patient characteristics (e.g. age and gender). Indeed, a recent negative study in a group of patients with painful spinal cord injury suggested that time since the injury may affect the magnitude of the analgesic response (Wrigley et al., 2013).

TDCS may yield benefits for symptoms other than pain. One study showed that tDCS treatment in patients with fibromyalgia increased sleep efficiency by 11.8% and decreased arousal by 35% (Roizenblatt et al., 2007). Others have shown improvement in quality of life and a decrease in the use of pain medications (Fregni et al., 2006a, 2006b).

In summary, tDCS has been shown to be effective in relieving pain in a variety of chronic pain syndromes, with potential secondary benefits in sleep, quality of life, and use in pain medications. It is relatively inexpensive, easy to implement, and can be portable so that patients can be educated to self-administer the stimulation at home. These characteristics suggest that tDCS could play a useful role in the treatment of pain in populations with serious medical illness. Studies are needed to confirm these positive outcomes in medically ill populations.

Transcranial magnetic stimulation

Like tDCS, transcranial magnetic stimulation (TMS) is a non-invasive technique applied directly on the scalp. This technology entails the generation of a powerful magnetic field perpendicular to the brain cortex. This field induces the formation of electrical currents that are parallel to the cortex (similar to tDCS) and can modulate the neuronal excitability in underlying brain structures. The electrical field is relatively restricted in space due to the conical shape of the magnetic field, and as a result, TMS can produce more selective regional neuromodulation than tDCS.

TMS can be delivered as a single stimulation (sTMS) or a train of repetitive stimulations (rTMS). It was first explored for the treatment of pain in 1995 and numerous studies since then have been conducted to test various parameters of frequency, duration and width of the wave. The range of frequencies that have been tested is wide and is divided into high- and low-frequency stimulation based on efficacy.

In general, studies involving patients with various types of neuropathic pain suggest that high-frequency rTMS is more effective in eliciting long-lasting pain relief than low-frequency rTMS. For instance, André-Obadia et al. performed a double-blind study comparing the analgesic effect of a single session of

1 Hz and 20 Hz rTMS with sham stimulation in 14 patients with treatment-resistant neuropathic pain, including trigeminal, central post-stroke, and peripheral brachial plexus neuropathic pain. Although pain relief was achieved immediately after stimulation with both, the analgesic effect was maintained 1 week after stimulation in the 20 Hz group only (André-Obadia et al., 2006). Another sham-controlled study of 48 patients with trigeminal neuralgia or post-stroke pain syndrome reported that 20 Hz rTMS yielded significantly greater improvement in pain after five consecutive daily sessions of stimulation; the positive effect persisted for 2 weeks after treatment, suggesting that repeated rTMS sessions also can result in long-lasting pain relief (Khedr et al., 2005).

Other studies suggest that the outcome of TMS is influenced by the cause and location of the pain, and the somatotropic area where stimulation is applied. Lefaucheur et al. conducted a study in 60 patients with intractable pain secondary to a variety of causes, including thalamic stroke, brainstem stroke, spinal cord lesion, brachial plexus lesion, and trigeminal nerve lesion. The overall pain reduction was significantly greater in rTMS as compared to sham stimulation, but rTMS was less effective in patients with brainstem stroke than with other lesions. The best results were obtained in patients with facial pain, rather than those with pain in the upper or lower limbs (Lefaucheur et al., 2004). In a later study, the same authors evaluated the relationship between the cortical stimulation site and pain site in 36 patients with chronic neuropathic pain located on the face or the hand. Interestingly, patients with facial pain experienced significantly better analgesic effects after stimulation to the hand rather than to the face. Similarly, patients with hand pain had greater pain relief after stimulation to the face rather than to the hand. The authors concluded that rTMS was the most effective for pain relief when stimulation was applied to an area adjacent to the cortical representation of the painful zone rather than to the motor cortical area corresponding to the painful zone itself (Lefaucheur et al., 2006).

Recent research in volunteers also has suggested that targets for rTMS treatment of pain may include brain regions that process pain perception, such as prefrontal cortex (Martin et al., 2013).

Some studies suggest that there are limitations in the use of rTMS in pain management. A randomized double-blind, sham-controlled, crossover study of patients with painful diabetic polyneuropathy demonstrated only a transient and modest improvement in pain scores following ten daily 5 Hz rTMS (500 pulses/session) of primary motor cortex (M1) (Hosomi et al., 2013). However, it has been proposed that a modification of the magnet (H-coil) would result in better stimulation of areas that otherwise are not easily accessible, like the lower limbs in diabetic neuropathy, hence achieving better pain relief (Onesti et al., 2013).

TMS may be efficacious in the treatment of headache. One evaluated sTMS as an abortive strategy for migraine and observed that pain relief occurred in 69% of the patients in the sTMS group as compared to 48% in the sham-controlled group (Mohammad et al., 2008). The second did not find a difference between the treatment and placebo groups (Clarke et al., 2006). Lipton et al. conducted a large multicenter, double-blind, sham-controlled study to evaluate the efficacy of a portable, self-administered sTMS device for the treatment of acute migraine, and found that 39% of the patients treated with sTMS were pain-free at 2 hours post-treatment, as compared to 22% of the sham controlled group (Lipton et al., 2010).

Four studies have evaluated the efficacy of rTMS for the treatment of frequent migraines. A small randomized study (Brighina et al., 2004) and an observational study Misra et al., 2012) suggested benefit, but this was not confirmed in two placebo-controlled studies (Teepker et al., 2010; Conforto et al., 2012).

There have been no studies of TMS in populations with acute or chronic pain related to serious illnesses. Extant data suggests that the strategy can be efficacious in some types of neuropathic pain and acute headache. Studies have shown that high-frequency stimulation is more effective in achieving long lasting pain relief than low-frequency stimulation, and that the outcome of TMS is influenced by the origin and location of the pain, and the somatotropic area where stimulation is applied. The best results have been obtained with facial pain, and when applied to an area adjacent to the cortical representation of the painful zone rather than to the motor cortical area corresponding to the painful zone itself. Like tDCS, TMS may prove to be a feasible, non-invasive alternative to pharmacological therapy for the treatment of refractory chronic pain.

Deep brain stimulation

Deep brain stimulation (DBS) is an invasive neurostimulatory technique that involves stereotactic implantation of electrodes directly into subcortical areas. It was first used for the treatment of chronic pain in the 1950s by placing electrodes in the hypothalamus (Pool et al., 1956), but later on, other brain areas were also considered to be good targets, including the thalamic nuclei and adjacent structures (Hosobuchi et al., 1973), subthalamic nucleus (Marques et al., 2013), the internal capsule (Adams et al., 1974; Hosobuchi et al., 1975), anterior cingulate cortex (Pereira et al., 2013), and the periventricular and periaqueductal grey area (Richardson and Akil, 1977a, 1977b). The analgesic mechanism of action of DBS for chronic pain is unclear and still debated, but the evidence favours modulation of brain activity (Kringelbach et al., 2007, Montgomery and Baker, 2000; McIntyre et al., 2004) over synaptic depression, synaptic inhibition (Dostrovsky et al., 2000), or depolarization blockade (Beurrier et al., 2001). DBS has been successfully used for the management of facial and head pain such as post-herpetic trigeminal neuralgia (Green et al., 2003), anaesthesia dolorosa (Green and Owen et al., 2006), multiple sclerosis (Hamani et al., 2006), genital pain, brachial plexus injuries, and malignancy (Nandi et al., 2003).

Although the recommendation of DBS for the management of headaches should be made with caution due to the limited evidence of its efficacy, there are reports of successful use of DBS for the management of cluster headaches. Leone et al. published the first case report of DBS in which a single patient with cluster headache underwent stereotactic implantation of an electrode in the posterior ipsilateral hypothalamic grey matter. The headaches stopped after 48 hours of stimulation, and the patient remained pain-free 13 months after implantation (Leone et al., 2001). Since then, multiple studies have been published evaluating the efficacy of DBS for the treatment of cluster headaches, most of which are case series. The largest study was a prospective, open-label study which included 16 patients, 13 of whom reported improvement in pain with DBS, and ten achieved a persistently pain-free state at 23 months' follow-up (Leone et al., 2006). The underlying mechanism seems to involve down-regulation of the increased regional blood flow in the posterior hypothalamus that occurs during an

acute attack, as seen with both PET and fMRI techniques (May et al., 2006).

Kringelbach et al. published a case series comparing DBS with other invasive techniques for the management of chronic pain. Approximately 70% of the 65 patients who underwent DBS in the thalamus and/or periventricular or periaqueductal grey (PVG/PAG) experienced pain relief after 1 week post-implantation, and pain relief persisted more than 1 year in 60% of these patients (Nandi et al., 2002). Another study found very good efficacy of DBS for stroke patients complaining of burning hyperaesthesia (Owen et al., 2006) but less efficacy in patients with stroke overall.

Although the advent of the non-invasive CNS neurostimulation approaches may supplant DBS for pain, rare patients with severe treatment-refractory neuropathic pain still may be considered for a trial of invasive brain stimulation. Patient selection for DBS should be done by an experienced team, including a mental health professional experienced with this type of evaluations (Saint-Cyr and Trepanier, 2000; Lang et al., 2006). Medical contraindications to DBS include ventriculomegaly large enough to impede direct electrode passage to the surgical target (Kringelbach et al., 2010) and uncorrectable coagulopathy. The current recommendation is to utilize DBS as the last resort for patients who do not respond to standard of care.

Although the use of DBS is limited to a highly selected group of patients, the number of DBS implantations is greater than that for other invasive strategies such as motor cortex stimulation (MCS). According to a recent report, at least 1300 patients have been implanted with electrodes for DBS for the treatment of chronic neuropathic pain conditions (Kringelback et al., 2007), while only 400 patients have been implanted with motor cortex stimulators during a comparable period (Brown et al., 2003). The goal is to improve patient selection and thus outcomes. One intriguing possibility is the use of autonomic measures as potential objective markers, as shown by stroke patients' subjective preference for PVG/PAG stimulation over ventral posterolateral nucleus/ventral posteromedial nucleus, and correlations between analgesic efficacy and cardiovascular effects or burning hyperaesthesia (Green and Wang et al., 2006).

There are several types of complications that can occur as a result of the electrode implantation for DBS, including complications related to surgical procedures, complications due to the implanted devices, and side effects that result from the stimulation itself (Hariz 2002). According to Beric et al., 6.5% of the implantations can result in device-related complications, including infections, electrode fracture or dislocation, and hardware failure (Beric et al., 2001). Infrequent life-threatening complications can also occur and include intracranial haemorrhage (Benabid et al., 1996), haematoma, and paralysis (Beric et al., 2001). In addition, other complications like perioperative haemorrhage, occurred in 2.3% of patients undergoing DBS implantation (Beric et al., 2001). Stimulation-related side effects are the most frequently encountered problems in DBS. The symptom tends to correlate with the anatomical structure being stimulated (Hariz 2002), and can include paraesthesias, dysarthria, dyskinesia, gait disturbances, imbalance, confusion, depression, inappropriate laughter (Krack et al., 2001), and mood or personality changes (Bejjani et al., 2002).

Motor cortex stimulation

MCS is another invasive neurostimulation method, in which electrodes are surgically implanted in the epidural space to deliver an electric current to the motor cortex. This strategy requires the assistance of neuronavigation, most commonly fMRI or somatosensory evoked potentials, to localize the motor cortex. During the neurosurgical procedure, a lead with four electrodes is positioned above the dura and under the periosteum so that all four contacts are over the precentral gyrus of the motor cortex (Rasche et al., 2006). To verify the positioning of the electrodes, a suprathreshold stimulus is delivered that produces a contralateral motor response in the absence of concomitant sensory sensations (Brown and Barbaro, 2003). After the operation, a trial is performed to determine the best electrode combination and stimulation parameters that elicit the maximum response without significant side effects. A variety of settings have been proposed, but the most commonly utilized are an intensity of 2–3 V (range 0.5–9.5 V), with a frequency of 25–50 Hz (range 15–130 Hz), and a pulse width of 200 microseconds (range 60–450 microseconds). The stimulation can be tailored to the individual patient's needs by programming alternating cycles of stimulation with periods of no stimulation.

As noted, experience with MCS is far more limited than experience with DBS, and there have been no published trials of MCS in medically ill patients (Nguyen et al., 1998; Cioni and Megglio, 2007; Friedland et al., 2007; Arle and Shils, 2008; Lima and Fregni, 2008). Favourable case reports (Nguyen et al., 2000; Esfahani et al., 2011) are now supplemented by a few clinical trials suggesting positive outcomes from this approach. A randomized trial of MCS in 16 patients with chronic neuropathic pain following peripheral nerve lesions reported that 60% of patients had satisfactory levels of pain relief after 1 year (Lefaucheur et al., 2009).

The potential role of MCS is ill-defined. If non-invasive neurostimulation strategies are available, they will likely be tried first. If an invasive CNS neurostimulation treatment is considered for refractory chronic pain associated with serious illness, the choice between DBS and MCS is likely to revolve around the experience of the clinician.

Conclusions

Stimulation of the peripheral or central nervous systems for the management of chronic pain has been done for many years and the results have been mixed. Over the years, technology has improved and the delivery of current has become more sophisticated, allowing stimulation of discrete areas with a variety of intensities and frequencies that can be tailored to the underlying condition. The most efficacious parameters, stimulation targets, and devices have evolved with the improvement in technology, but selection of the proper stimulation strategy and patient population continues to be based on limited data and clinical experience. Studies are needed to confirm efficacy and illuminate those factors that predict a high likelihood of a favourable response. Further research also may reveal additional innovations, such as the potential utility of combinations of stimulations (e.g. SCS and DBS) (Chodakiewitz et al., 2013).

Rehabilitation medicine approaches to pain management

Andrea L. Cheville and Jeffrey R. Basford

Introduction to rehabilitation medicine approaches to pain management

Pain is a frequent but poorly controlled aspect of cancer and other medical conditions which may, in part, stem from the clinician's lack of understanding of its severity or impact. However, even with the best of care, our current approaches are associated with poorly tolerated side effects and frequently fall far short of complete control. All pain is limiting, but bone pain from metastatic disease is particularly problematic in that it is provoked by movement or weight bearing and has profound effects on an individual's mobility, activities, and independence.

Rehabilitation medicine, with its focus on optimizing patient function irrespective of their symptom burden or impairments, has developed strategies that may reduce pain in general, but are particularly targeted to movement-related pain. For the most part, these approaches serve as adjuncts to, rather than replacements for, conventional analgesic approaches. Some may have a limited evidence base and most have not been validated in the palliative setting. Nevertheless, common sense and extensive experience argue persuasively for their clinical effectiveness. In addition, with few exceptions, they are patient controlled and largely free of side effects.

These approaches can be grouped into four general categories: (1) modulating nociception, (2) stabilizing and unloading painful musculoskeletal structures, (3) influencing pain perception, and (4) alleviating musculotendinous pain. This latter section is included since 'benign' pain related to the overloading or maladaptive use of muscles and connective tissues occurs with sarcopenia in the late stages of many diseases. This chapter will review each of these categories in detail and offer examples to illustrate their clinical application. It will be noted that the majority are focused on minimizing pain during periods of mobility and the performance of activities of daily living (ADLs).

Modulation of afferent nociceptive activity

Rehabilitation uses two approaches to modulate the input of nociceptive signals into the central nervous system (CNS). The first, the use of heat and cold, is traditionally associated with rehabilitation medicine and still has a role. The second, rather than trying to block the input of painful stimuli, uses benign afferent sensory input to reduce nociceptive activity. This approach, introduced and named by Melzack and Wall in the 1960s has been termed the 'gate theory of pain' (Melzack and Wall, 1965). The concept has been challenged but not disproved or seriously debunked even though the precise neural pathways and biochemical reactions continue to be studied.

Heat and cold

Heat and cold have powerful effects on the body. Metabolic and enzymatic processes may be markedly accelerated or slowed by temperature elevations of only a few degrees with changes of 3–7°C capable of altering nerve conduction, blood flow, and collagen extensibility (Knight, 1985; Guyton, 1986; Denys, 1991; Lehmann et al., 1966). Effects can be local or systemic: immersions of the body at robust but tolerable temperatures can alter core temperatures by 0.3–0.4°C with local effects being more pronounced (Doering et al., 1999). Ice massage over the knee can reduce intra-articular temperatures by as much as 6°C (Oosterveld and Rasker, 1994), and agents such as hot paraffin and diathermy can markedly raise local skin and intra-articular temperatures (Oosterveld and Rasker, 1994). Although the heating agents differ, most gain their effects by inducing analgesia, hyperaemia, or reducing muscle tone. Cold, while reducing perfusion, is also used for its analgesic and tone reduction capabilities.

Heat and cold have clear effects on a variety of physiological processes. As such, their main use has been primarily for the control of pain. Use is typically focused on the musculoskeletal system where there is support for its benefits as an adjunct to exercise (Brosseau et al., 2002; Lin, 2003; French et al., 2006; Chou et al., 2007).

Electrical stimulation

Electrical stimulation is used for a variety of indications that range from moving and strengthening limbs to analgesia and even the healing of soft tissue injuries and fractures (see Chapter 9.9). Here we will restrict ourselves to its analgesic applications. Rehabilitation has developed and discarded a great many approaches to stimulating benign, sensory afferents for physiological effect. Those that have withstood the test of time, though not necessarily the scrutiny of randomized controlled trials, as well as newer approaches whose use seems more predicated on novelty than empirical support are discussed in this section.

Transcutaneous electrical nerve stimulation

Transcutaneous electronic nerve stimulation (TENS) is one of the most thoroughly studied and widespread of the modalities

used to modulate nociceptive drive. Its introduction provided a non-invasive means to provide the afferent sensory stimuli posited by the 'gate theory' as necessary to block nociceptive signals (Melzack and Wall, 1954). A few successful trials ensured its acceptance. Acceptance and use has not, however, completely clarified its best application or the complete characterizing of how it, or close relatives such as interferential current, achieve their effects

TENS units are typically small, programmable within limits, and consist of a power source, a set of electrodes, and one or more signal generators. The devices can produce a variety of stimuli with currents of less than 100 mA, pulse rates ranging from a few to 200 Hz, and pulse widths from 10 to a few hundred microseconds. Varying waveform modulations and stimulation parameters are chosen to increase effectiveness, improve comfort and lessen tachyphylaxis.

Electrodes are often placed over the painful area but positioning on the vicinity of afferent nerves, acupuncture points, and other sites is often assessed. Stimulation settings are similarly idiosyncratic. Two options, however, are the most common. The first ('low-intensity' or 'conventional' TENS) stimulation occurs at frequencies of about 40–80 Hz and is set at a level that is barely perceptible. The second is in many ways the reverse: frequencies are relatively slow (1–8 Hz) and intensities are set at a mildly uncomfortable level.

Response is not guaranteed and difficult to predict, and TENS studies range in quality from well-designed, prospective, randomized, controlled trials to, particularly in the earlier days, small and poorly blinded trials. Even today, trials with TENS compared with active controls are far rarer than ideal.

A number of studies in the 1970s and 1980s focused on postoperative incisional and early labour pain and found that TENS usage resulted in benefits were comparable to limited amounts of analgesics including narcotics (Chen et al., 1998; Hamza et al., 1999; Philadelphia Panel, 2001a).

Research over the subsequent years has had mixed results with more recent evidence-based clinical guidelines and systematic reviews finding that no or insufficient evidence that TENS can lessen neck or back pain (Philadelphia Panel, 2001b; Pengel et al., 2002; Khadilkar et al., 2005; Vernon et al., 2005). The situation may be somewhat more positive for knee osteoarthritis.

Cancer-related pain has, thus far, received only limited attention. As a result, while there are suggestions that TENS is capable of improving movement/weight bearing-associated cancer pain, a recent Cochrane review, despite casting a wide net for admissible studies, found that only three met its criteria for inclusion. Issues with design heterogeneity and quality were noted and while treatment was well tolerated by the subjects, the authors were unable to conclude that the evidence was strong enough to support the use of TENS (Pengel et al., 2012).

TENS relies on repetitive stimuli. As a result, a number of units have tried to avoid this issue by producing waveforms of varying shapes and frequencies. This concept has now been carried to the extreme by the introduction sof a device that is similar to conventional TENS in that its analgesic effects are mediated through transcutaneous electrical input but it differs in that its wave form randomly varies and its electrode placement can be more complex (Marineo et al., 2012). Anecdotal experience suggests benefits in mixed neuropathic and nociceptive syndromes.

TENS has few safety issues other than skin irritation and mild discomfort during use. Cardiac pacemakers appear relatively resistant to TENS signals but reasonable concerns about real or apparent introduction of dysrhythmias/malfunction restricts TENS use in this setting. It also seems prudent to avoid treatment near the carotid sinus, epiglottis, and abdomen/low back of pregnant women.

Why have TENS units continued to be used despite equivocal evidence of effectiveness? The reasons may help clinicians in deciding whether to consider TENS for their patients. First, TENS studies are heterogeneous in terms of the conditions assessed, parameter settings, and outcome measures. Thus, while systematic reviews have found limited evidence of effectiveness, they have been unable to state that the approach is ineffective. Second, side effects are minimal. Third, efficacy in both nociceptive and neuropathic pain syndromes—most patients with cancer experience a mixture of both (Zech et al., 1995; Caraceni and Portenoy, 1999)—is anecdotally and weakly empirically supported in reducing patients' numerical rating scale ratings. Fourthly, a TENS trial can be incorporated into a course of physical therapy (PT) without significantly interfering with other potentially beneficial activities, such as therapeutic exercise. Lastly, the prolonged use of TENS by a subgroup of patients suggests that it may benefit certain individuals. In all, reasonable candidates are patients whose localized pain is inadequately controlled by conventional treatments, who experience untenable medication side effects, or who prefer to trial non-pharmacological approaches. Depending on the pain syndrome, a PT-based TENS trial can be combined with counter-stimulation, myofascial release techniques, and therapeutic exercises during a single treatment session.

Counterstimulation and desensitization techniques

Other rehabilitation techniques increase benign afferent sensory drive in order to attenuate pain intensity. Some, such as desensitization, have this as their sole objective. Others, such as massage or compression garments, increase afferent sensory drive in conjunction with other treatment goals such as the control of oedema or muscle tone. Desensitization techniques warrant particular mention since they are a first-line rehabilitation medicine treatment for complex regional and neuropathic pain. Tolerance for increasingly intense and unpleasant stimuli is systematically cultivated by gently applying stimuli in an incremental fashion to steadily shift a patient's threshold for experiencing a stimulus as noxious. Desensitization techniques can be coupled with other modalities during a treatment session.

Stabilization and unloading strategies

Cancer is often associated with a decreased ability of the body to bear weight, move, or tolerate the forces placed on it by even routine activities of daily living. As a consequence, the limbs, spine, and muscles frequently become pain generators, particularly with movement. The most prevalent example is bone pain in the face of metastatic cancer. For example, a cervical vertebra with metastatic involvement may produce pain since the neck not only supports the weight of the head but also its positioning in space. Even intact musculoskeletal elements can become inflamed, hypertonic, or frankly compromised as a consequence of the biomechanical changes induced by cancer and cancer treatment (Cheville

and Tchou, 2007). Suffice to mention that virtually any distorting force, such as contracted soft tissue from radiation fibrosis, pectoralis muscle tension from breast implants, or compromised core muscle strength from extensive abdominal surgery, has the potential to alter normal biomechanical relationships in a manner that stresses other musculoskeletal elements to the point that they become independent pain generators.

Stabilizing and unloading strategies are designed to reduce the forces placed upon painful bony or connective tissues. Four approaches are utilized:

1. displacing loads onto external supports

2. improving the load bearing capacity of intact anatomic elements

3. immobilizing painful joints, or

4. reducing the work required by a painful activity.

The information in the following sections is organized by therapeutic approach similar to the manner in which a therapy prescription would be structured. As will become clear, more than a single modality can be applied to each of the four listed approaches.

Assistive devices for mobility and ADL performance

A wide range of devices to assist patients with safe and autonomous mobility are available. Fig. 9.10.1 includes a single point cane, quad cane, platform walker, and rolling walker. Each has its fitting requirements as well as its strengths and weaknesses. The need for the guidance of a physical therapist and the importance of professionally supervised trials and fitting cannot be overstated if patients are to effectively utilize and incorporate these devices into their lives. Mechanized or electrical assistive devices may be required to substitute for entire activities if pain renders their performance intolerable. For example, a Hoyer lift, scooter or wheelchair may free the patient from pain during transfers and locomotion.

A mind-boggling array of assistive devices can be used to protect inflamed or otherwise vulnerable structures from ADL-related forces. Fig. 9.10.2 shows a variety of possibilities. In contrast to assistive devices for mobility, these for ADL performance generally reduce the amount of reaching, bending, or twisting required to complete a painful activity. Occupational therapists (OTs) can trial a range of ADL assistive devices during an initial evaluation on an out- or inpatient basis.

The efficacy of assistive devices for ADLs has not been well assessed in clinical trials since a strong experiential base (e.g. the use of elastic shoe laces and a long-handled shoe horn permitting a patient to don his/her shoes when they had previously been unable to do so) supports their use. Several excellent reports have quantified the off-loading achieved by various mobility assistive devices, particularly canes, and found this to exceed 30% (Blount, 1956).

Compensatory strategies

The pain-relieving benefits of compensatory strategies stem from the same theoretical basis as assistive devices: relief of forces applied to painful structures. In fact, compensatory strategies so often rely on assistive devices that it becomes almost contrived to separate them. Nonetheless, there are important distinctions that, if appreciated, may help clinicians to produce more effective and comprehensive PT and OT prescriptions.

Our daily activities consist of an orchestrated combination of coordinated and isolated movements. Often, not all the movements required to execute an activity produce pain. By deconstructing painful activities to their constituent movements, PTs and OTs can isolate those that are painful and devise alternative, 'compensatory', strategies to achieve the patient's goal. Simply helping a patient to recognize the movements that trigger pain frequently enable them to develop their own strategies. Activities that can be deconstructed in this manner vary widely from transferring into or out of a vehicle to toileting and other hygiene-related activities. Engaging caregivers, using architectural supports and durable medical equipment, as well as altering the home environment can be combined to optimize patients' non-painful functioning.

Therapeutic exercise

Muscles are dynamic and often provide the most effective means of stabilization and immobilization. There are obvious limitations to this approach (e.g. the unstable spine) but the approach, often
Fig. 9.10.1 Devices to assist patients with safe and autonomous mobility. (A) Single point cane; (B) quad cane; (C) platform walker and (D) rolling walker.
Fig. 9.10.2 Assistive devices used to protect inflamed or vulnerable structured from ADL-related forces.

termed dynamic stabilization, has been a mainstay in the treatment of low back and knee pain for years. As a result, therapeutic exercises aimed at enhancing the strength and stamina of muscles capable of splinting a painful body part can be a remarkably effective adjunct to conventional analgesia. Further consideration of the translation of the techniques of sports and musculoskeletal medicine into the realm of cancer rehabilitation seems warranted given the benefits of unloading painful areas and mobilizing the patient with metastatic disease.

Though conceptually simple, therapeutic exercises should be chosen and implemented by a PT with the skills and time to identify the painful structures or movements and to design a strengthening programme that can effectively splint or constrain the movement of a pain-generating structure. For the most part, muscles should be strengthened in a fixed position through isometric contractions that avoid pain-producing changes in muscle length or in the angle of the joint on which the muscle is acting. Common examples of isometric exercises used to stabilize pain-generating bony structures include strengthening of the abdominal and hip abductor muscles to deweight painful vertebrae and hip joints, respectively.

Orthotics

Orthotics, often referred to as braces, can be used to stabilize, deweight, and protect compromised musculoskeletal structures. Stabilization is the most common application among patients with cancer and the orthotics that perform this function typically either (a) immobilize the entire affected body part or (b) apply pressure at selected points to restrict motion. Orthotics come in myriad forms. Many are commercially available while others may require custom construction. Those used with the goal of avoiding pain in cancer care are, in large part, directed at stabilizing the neck, trunk, and low back. However, orthotics for the extremities such as moulded ankle foot orthoses '(AFOs') and spica or resting wrist splints may benefit patients with distal limb pain.

Spinal braces warrant specific mention. Often their prescription is initiated and coordinated by an orthopaedic surgeon when a patient's spine is deemed unstable. Moulded body jackets, also referred to as clam shell braces, which require custom fabrication are most frequently prescribed because of their superior immobilizing properties. While body jackets unquestionably limit motion better than other spinal orthoses, they are costly, hot,

uncomfortable, and poorly tolerated. In these cases it may be necessary to consider a less ideal alternative such as the semi-rigid braces that are often commercially available and are also capable of restricting spinal motion (Utter et al., 2010).

Less expensive, and more tolerable, alternatives include prefabricated orthoses that encompass different segments of the spine. Thoracolumbosacral orthoses such as the CASH and Jewett braces (Fig. 9.10.3) are widely available and generally well tolerated. These 'three-point braces' apply pressure at two anterior points on the upper and lower trunk and at a third point on the mid-back in between the two anterior points. A nice attribute of such off-the-shelf orthoses is that they can be trialled to assess patients' tolerance and pain control without making an expensive investment in either purchase or custom fabrication. It should be noted that while these braces do limit spinal flexion, they do little or nothing to constrain truncal extension. Fortunately, the anterior vertebral column is the most common site of metastatic involvement and pain generation. As a result, in the absence of spinal instability, the limitation of spinal flexion is the goal. If the spine is unstable, however, surgical stabilization or a body jacket should be considered.

Lumbosacral orthoses (LSOs), while most effective at the mid-lumbar level, control spinal motion from roughly the epigastrium to the lower gluteal area. LSOs are, for the most part, variations on the abdominal corset with rigid struts and other support. The off-the-shelf Bell Horn Brace, for example, is a lightweight LSO. Like abdominal binders, the Bell Horn and other LSOs are believed to alleviate pain by deweighting the spine through compression of the abdominal contents to generate a load-bearing fluid column. This sounds potentially uncomfortable, but LSOs are generally well tolerated. An advantage of most LSOs is that as they can be easily trialled without financial outlay by the patient. A number of LSOs have adrawstring or one-handed cinching mechanism which facilitates easy donning, doffing, and adjustment.

Cervical orthoses also offer a continuum from the fixed immobilization of the halo brace to the essentially tactile feedback and limited support of the soft cervical collar (Sandler et al., 1996). Between the two extremes are a range of pre-fabricated orthoses including the Miami J, Philadelphia, and sterno-occipital mandibular immobilizer brace. All are variably uncomfortable and are used principally to restrict cervical motion. If pain control,

(a)

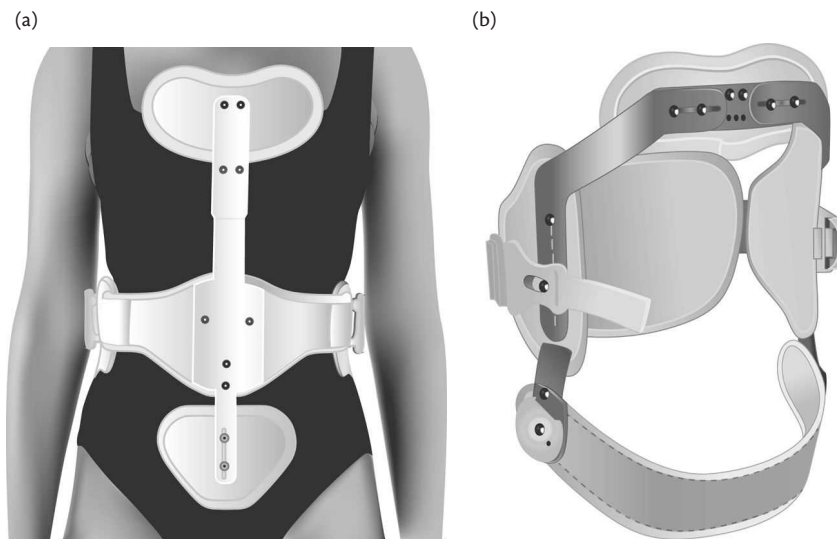
(b)


Fig. 9.10.3 Examples of CASH and Jewett braces.

rather than stabilization, is the impetus for considering a cervical orthotic, a trial of the differing options as well as a soft collar, is warranted since patients' preferences and degree of benefit can vary in unexpected ways.

Coordinating an orthotic trial is generally straightforward and within the practice scope of most OTs and PTs. Patients can also be sent directly to an orthotist, but this may require prior determination of which brace should be dispensed. Many medical centres have established alliances with orthotic suppliers. Orthotists may be available to evaluate and fit patients while hospitalized or during their outpatient oncology visits. Payers may restrict the providers from which patients may obtain their orthotics and coverage should be explored prior to initiating a trial.

Positioning

The strategic use of pillows, bolsters, the built environment, hospital beds, and adaptive equipment to support patients and constrain them to a pain-free range of motion is so common sense that it almost does not warrant mention. However, these effective approaches receive little attention in the formal guidance given to both professional and lay caregivers. For patients with severe motor deficits and weakness, stabilizing their painful areas at rest by positioning can not only reduce pain, but also protect vulnerable skin over bony prominences. Like orthotics, pillows and bolsters can be used to reduce the forces placed on compromised muscles and tissue. For example, use of pillows, arm rests, or padded bed rails to support the arms of people with treated head and neck cancers with weakened cervical and shoulder stability following neck dissections can radically reduce painful hypertonicity and myofascial pain in the residual musculature.

Modalities with physiological effects that influence nociception

Light and laser therapy

Laser therapy had been widely taken up to treat to a wide variety of soft tissue injuries and conditions. With time, the evolution of

their use has grown to include a large number of non-laser monochromatic light sources and a tendency for treatments to take place with 30–150+ mW devices and with a limited number of joules/cm^2. As such, tissue temperatures are not elevated more than a few tenths of a degree Celsius and the theoretical support for their effectiveness lies in research findings that irradiation at these intensities and energies can produce a variety of effects that range from the modulation of metabolic processes and DNA synthesis to improving the healing and function of damaged nerves. These devices have been approved for use by the US Food and Drug Administration, typically as an adjunct to the treatment of pain, for the last 10 years or so.

As is true for many modalities, evaluation of clinical benefits has been difficult. A large number of clinical trials have evaluated the efficacy of laser therapy over the years with those done more recently typically having better designs and power than their earlier counterparts. While many are quite encouraging, the variety of conditions and parameter settings (e.g. wavelength and intensity) has limited systematic, evidenced-based analysis. Thus, recent evidence-based reviews on non-specific low back pain and venous stasis ulcers have been unable to support benefits (Flemming and Cullum, 2000; Yousefi-Nooraie et al., 2008). The situation is somewhat better for patients with cancer receiving treatment for oral mucositis and rheumatoid arthritis where systematic reviews have found 'limited benefits' (Brosseau et al., 2000; Clarkson et al., 2010). Even, here, however, concern is voiced for the need for additional trials to ensure an adequate evaluation.

In summary, evidence for the benefits of low-level light sources remains mixed but with some level of support above the individual study. Treatment is associated with minimal side effects.

Manual lymphatic drainage

Manual lymphatic drainage (MLD), 'lymphatic massage', or 'Vodder-type massage' is a highly specialized technique designed to enhance the sequestration and transport of lymph (see Chapter 11.3). Specific stroke duration, orientation, pressure, and sequence characterize MLD. MLD stimulates the smooth muscles in the lymph vessel walls to enhance their contractility, leading to increased

removal of potentially inflammatory and pro-nociceptive macro-molecules from the interstitium (Casley-Smith, 1988). Through gentle and rhythmic skin distention, congested lymph is directed to intact lymph vessels and nodal beds. Thereby, MLD permits removal of congested lymph and reduction of its adverse local effects. The massage is very light and superficial, limited to finger or hand pressures of around 30–45 mmHg. MLD treatments are initiated proximal to lymphostatic regions. Lymph is constantly directed towards functional lymphatics with strategic hand movement. Treatments gradually progress distally to terminate in the regions farthest removed from intact lymphatics, and presumably most congested.

MLD's analgesic properties have been recognized through its extensive use in the management of lymphoedema. Consequently, MLD is increasingly applied to pain syndromes in which congested lymph is thought to play a role (Ekici et al., 2009; Ebert et al., 2013). Because it is remarkably low pressure, MLD tends to be well tolerated, even among patients with moderate to severe allodynia. MLD is a cultivated skill and its clinical benefit highly practitioner dependent.

Rehabilitation approaches to managing musculoskeletal pain

The overwhelming majority of analgesic modalities utilized in rehabilitation medicine are directed towards pain arising from the soft tissues of the musculoskeletal system. These structures may contribute importantly to cancer pain syndromes through four principal mechanisms: (1) direct tumour invasion, (2) maladaptive changes induced by cancer treatment or local tumour effects, (3) exacerbation of pre-existing musculoskeletal pain and (4) secondary hypertonicity and spasm related to (2), and (3). The third, exacerbation of pre-existing pain, may be the most common across all cancer populations, though this, to the best of our knowledge, has never been subjected to epidemiological scrutiny. However, common sources of musculoskeletal pain, such as knee osteoarthritis or rotator cuff tendonitis, affect over 70% of the population. Common approaches to the treatment of musculoskeletal pain are outlined below. Often, multiple approaches are integrated in a unified treatment plan. Pain arising from tumour invasion is far more likely to definitively respond to treatment with antineoplastic therapies; however rehabilitation medicine approaches may be trailed once tumour control has been optimized.

Principals of rest, ice compression and elevation (PRICE)

PRICE, though simple, continues to be widely used because of its effectiveness and safety in controlling acute inflammation. Musculoskeletal pain of abrupt onset or with a clear precipitant, such as overuse or trauma, warrants a trial of PRICE with or without NSAIDs. Twice daily, 20-minute immersion of the affected body part, when feasible and tolerated, in a slurry of crushed ice and water will be more effective than ice packs.

Injections

Injections all share a common goal of delivering an analgesic or anti-inflammatory agent at high concentration to a pain generator in order to maximize therapeutic effects while minimizing systemic toxicity. An impressive array of pharmaceuticals is injected, but steroids and local anaesthetics remain the most common. Ultrasound guidance is increasingly used to optimize localization; however, the benefits of this approach, particularly with lipophilic injectates, have not been clearly established. Inflamed tendons, bursae, and synovium are the most common targets

When the long-term benefits of steroid injections have been subjected to high-quality and rigorous scrutiny, they appear to be less effective than PT alone, although benefits are slower to accrue with PT. To date, some of the best work has been done in lateral epicondylitis or tennis elbow (Coombes et al., 2013). There seems to be a rebound effect following the near-term anti-inflammatory benefits of the injection (Bisset et al., 2006). This is relevant to patients with cancer since their prognoses and involvement with cancer treatments vary radically. For a disease-free survivor with a good prognosis, PT in conjunction with or independent of an injection may offer greater collective benefit than an injection alone. In contrast, patients with far advanced cancer need near-term relief and may not survive to experience the more delayed and sustained benefits offered by PT.

Injections are relatively safe and toxicity free. Patients should not receive more than three per year to a single joint. Most physiatrists, orthopaedists, rheumatologists, as well as many primary care practitioners perform these procedures. However, for more specialized injections, such as those involving the smaller structures of the hand, the involvement of specialists who frequently target these joints is recommended.

Myofascial release techniques and trigger points

Myofascial pain is a painful syndrome that is most commonly located in upper back musculature and affects millions of people (Gerwin, 2001; Alvarez and Rockwell, 2002). Its most salient findings include tenderness on palpation and the presence of 'taut bands' of increased muscle tone and tenderness in association with trigger point (small areas of increased tenderness that when pressed, generate repeatable patterns of referred pain). While the nature and cause of the syndrome remains controversial, its effects on patients can be large. Massage, exercise, and trigger point/botulinum injections are the mainstays of myofascial pain treatment.

Massage, often accompanied with heat, which builds in intensity according to the patient's tolerance along with muscle tension release techniques and relaxation exercises are frequently employed. 'Spray and stretch,' a massage variant in which a cooling spay (often pentafluoropropane or tetrafluoroethane in place of the environmentally outlawed fluoromethane) is applied briefly to the trigger point and then along a line that follows the pattern of its pain radiation. Several sweeps with the spray are typically applied, followed by a gentle, sustained stretch for 30–60 seconds. The cycle of spray and stretch is repeated several times. Like most approaches to myofascial pain, multiple treatment sessions are required for sustained benefit.

Trigger point injections and dry needling mechanically stimulate the discreet taut bands that are the hallmark of myofascial pain. Controversy persists as to the benefits of introducing an injectate, such as local anaesthetic, botulinum toxin, or steroid, versus simply penetrating taut bands with a needle. No direct comparisons offer an empirical basis to choose one over the other. However, since positive benefits have been reported for approaches utilizing very narrow gauge (> 30), needles that inflict less trauma

and discomfort, these may be preferred for initial trials of invasive myofascial techniques.

Therapeutic exercise plays a critical role in normalizing the biomechanical derangements that predispose patients to develop myofascial pain. Chronic muscle overuse is the most common source of myofascial pain among patients with cancer and occurs when muscles, whether through surgical alterations, radiation-induced contractures, or focal neurological/myogenic weakness, must work harder or differently than they were designed to. It may not be possible to reverse the injuries produced by the inciting trauma through stretching and strengthening activities. However, the forces on the affected muscles, as well as the intensity and chronicity of their associated pain, can generally be improved through therapeutic exercise approaches. Evaluation by a physician or therapist familiar with cancer treatment-related changes, as well as comprehensive myofascial pain management, offers the best chance of developing an appropriate and individualized exercise programme targeting all implicated muscle groups.

Therapeutic exercise

In addition to its role in the optimal control of myofascial pain and enhancing splinting capacity, therapeutic exercise is a cornerstone of all rehabilitative approaches to pain arising from muscles, tendons, and ligaments. The structured application of specific demands to muscle and connective tissues reliably elicits desirable physiological changes. Such demands may be resistive, aerobic, or tensile depending on the desired alterations in muscle anatomy and physiology. In the palliative setting, therapeutic exercise is used most commonly to strengthen painful muscle, as tolerated, to improve their resistance to over use.

Conclusion

Rehabilitation medicine offers a range of pain management approaches that may serve as beneficial adjuncts to conventional systemic and interventional analgesia. These approaches may be particularly beneficial to patients with movement-associated pain and those who are ambivalent about pharmacoanalgesia.

Psychological and psychiatric interventions in pain control

Julie R. Price, Alric D. Hawkins, Michael L. Adams, William S. Breitbart, and Steven D. Passik

Introduction to psychological and psychiatric interventions in pain control

Pain is a common problem in populations with advanced illness and has been best characterized in those with cancer or AIDS. The causes, presentation, and impact of pain may be highly complex in some patients, and effective management may require the expertise of multiple specialties, including neurology, neurosurgery, anaesthesiology, and rehabilitation medicine (Foley, 1975, 1985; Breitbart, 1990b). Psychiatric and psychological interventions are integral to the comprehensive treatment of pain and distress in these populations (Breitbart, 1989, 1990b; Massie and Holland, 1987).

The scope of the problem

Approximately 70% of cancer patients experience severe pain at some time in the course of their illness (Foley, 1985) and nearly 75% of those with advanced cancer have chronic pain (Fitzgibbon, 2001). Overall, approximately 50% of terminally ill patients are in moderate to severe pain (Weiss et al., 2001) and 25% of cancer patients may die in severe pain (Twycross and Lack, 1983). Pain prevalence varies among different types of cancer, ranging from a low of approximately 5% in leukaemia to 50–75% in cancers of the lung, gastrointestinal tract, and genitourinary system, and to 85% in cancers of the bone or cervix (Foley, 1975).

Pain is frequently under-diagnosed and inadequately treated (Twycross et al., 1973). This phenomenon presumably has multiple causes, one of which is the complex presentation of pain in populations with advanced illness. In those with cancer, this complexity is partly determined by the common experience of symptoms other than pain, one or more of which may contribute to symptom distress. In one survey, cancer patients had an average of three additional troubling physical symptoms (Grond et al., 1994) and another study observed that patients with advanced disease reported a median of 11 symptoms (Walsh et al., 2000). A global evaluation of the symptom burden allows for a more complete understanding of the impact of pain (Achte and Vanhkonen, 1971).

Pain also is a significant and often neglected problem in patients with AIDS. Although its epidemiology has likely changed in the era of antiretroviral therapy, it also is likely that earlier prevalence data continue to apply to those with poorly controlled or advanced disease. Estimates of the prevalence of pain in AIDS generally range from 30% to 90%, with prevalence increasing as the disease progresses (Breitbart et al., 1996; Norval, 2004). The incidence of pain may be as high as 88%, and 69% of patients may experience moderate to severe pain-related impairment in activities of daily living (Frich and Borgbjerg, 2000). A retrospective chart review of hospitalized patients with AIDS revealed that pain heralded the onset of the illness in 30% and was second only to fever (Lebovits et al., 1989). More than 50% required treatment for pain, including chest pain in 22%, headache in 13%, oral cavity pain in 11%, abdominal pain in 9%, and peripheral neuropathy in 6%. Another retrospective study reported that abdominal pain, peripheral neuropathy, and Kaposi's sarcoma were the three most frequent pain problems, together affecting 15% of patients (Newshan, et al., 1989). Other studies report that between 5% and 30% of AIDS patients have painful peripheral neuropathy (Snider et al., 1983; Levy et al., 1985; Cornblath and McArthur, 1988; Schofferman and Brody, 1990); this disorder has many determinants and it is likely that the prevalence is changing as the use of neurotoxic treatments declines. In a hospice setting, pain was observed in 53% of patients and the main diagnoses were peripheral neuropathy, abdominal pain, headache, and skin pain due to Kaposi's sarcoma (Schofferman and Brody, 1990). Prior to the advent of effective therapies, pain was highly prevalent even in the ambulatory AIDS population, with 43% of patients reporting pain of at least 2 weeks' duration (Rosenfeld et al., 1996); painful neuropathy accounted for 50% of pain diagnoses and lower extremity pain related to Kaposi's sarcoma was found in 45%.

The aetiologies of pain in populations with cancer, AIDS or other advanced illnesses are heterogeneous. For example, a study of ambulatory patients with AIDS before the widespread availability of antiretroviral therapy observed that 33% of pain syndromes were somatic, 35% were visceral, and 33% were neuropathic (Hewitt et al., 1997). Patients often experience different types of pain concurrently.

Multidimensional concept of pain in terminal illness

In populations with serious illness, pain often involves a complex interplay between physical causes and other aspects of human

functioning, including personality, affect, cognition, behaviour, and social relations (Breitbart et al., 1993). An enlightened description of pain in terminal illness—known as 'total pain'—was proposed by Cecily Saunders (Saunders, 1967). This label describes the all-encompassing nature of pain, helps explain the inadequate effects of analgesic drugs in some patients (Hanks, 1991), and underscores the importance of psychological factors as determinants of both pain intensity and distress (Syrjala and Chapko, 1995).

The interaction of cognitive, emotional and socio-environmental factors with nociceptive aspects of pain (Fig. 9.11.1) illustrates the multidimensional nature of pain and suggests a model for multimodal intervention (Breitbart, 1990). The challenge of untangling and addressing both the physical and psychological issues involved in pain is essential to developing rational and effective management strategies. Psychosocial therapies directed primarily at psychological variables may have an impact on pain intensity or distress, while somatic therapies directed at nociception may reduce the adverse psychological aspects of pain. To manage complex chronic pain problems, both somatic and psychosocial therapies should be used in a multimodality approach (Breitbart, 1989).

Psychological factors in pain experience

Pain-related distress is complex and may be influenced by stressors faced by patients with advanced disease, such as loss of independence, disability, and fear of painful death. Distress may be influenced by medical factors, cognitions, coping capacity, personality, and social support. Daut and Cleeland (1982) showed that cancer patients who attributed a new pain to a benign cause reported less interference with their activity and pleasure than cancer patients who believed that their pain represented progression of disease. Spiegel and Bloom (1983) found that women with metastatic breast cancer experienced more intense pain if they were depressed and believed that their pain represented spreading of their cancer. The presence of a mood disturbance and beliefs about the meaning of pain are better predictors of pain levels than is the site of metastasis.

The variables that affect pain-related quality-of-life may be categorized in three domains: (1) physical well-being, (2) psychological well-being (consisting of affective factors, cognitive

Fig. 9.11.1 The multidimensional nature of pain in terminal illness.

factors, spiritual factors, communication, coping, and meaning of pain or cancer), and (3) interpersonal well-being (focusing on social support or role functioning) (Padilla et al., 1990). The heterogeneity and prominence of these variables have been revealed in studies linking higher levels of pain or pain-related distress to impairment in activities of daily living, the experience of unpredictable painful episodes, negative thoughts about personal or social competence, cognitions about the cause of pain, greater anxiety or depressed mood, and more existential concerns such as fears about the future (Bond and Pearson, 1969; McKegney et al., 1981; Payne et al., 1994; Payne, 1995; Strang, 1997; Smith et al., 1998; Portenoy et al., 1999). A prospective study of cancer patients found that maladaptive coping strategies, lower levels of self-efficacy, and distress specific to the treatment or disease progression were modest but significant predictors of reported pain intensity (Syrjala and Chapko, 1995).

These data highlight the broad variation in the response to pain. A classification that was developed in populations with chronic pain and focuses on adaptation (described as 'dysfunctional', 'interpersonally distressed', or 'adaptive coping') also describes the population with cancer pain, further suggesting the importance of psychosocial factors in the pain experience (Turk et al., 1998). Psychological distress is strongly associated with the number of concerns reported by patients and concerns about pain and treatment have been particularly associated with depression (Heaven and Maguire, 1998).

Most of the aforementioned studies have been performed in the cancer population. Similar findings have been found in patients with AIDS. The perception of control over pain, emotional associations and memories of pain, fear of death, depression, anxiety, and hopelessness—all contribute to the experience of pain and increase suffering in this population (Breitbart et al., 1994). In ambulatory populations with AIDS, pain was associated with depression, functional impairment, and disability (Rosenfeld et al., 1996), and negative pain-related thoughts were associated with greater pain intensity, psychological distress, and disability (Payne et al., 1994). Patients with pain were twice as likely to have suicidal ideation (40%) than those without pain (20%), and those who felt that pain represented a threat to their health reported more intense pain than those who did not see pain as a threat (Rosenfeld et al., 1996). Singer and colleagues (Singer et al., 1993) also reported an association among the frequency of multiple pains, increased disability, and higher levels of depression.

Although these data underscore the importance of psychological variables in explaining continued pain or lack of response to therapy, it must be emphasized that the diagnosis of the physical factors responsible for pain is essential to treatment. It also is important to emphasize that the nature of psychological distress cannot be accurately determined when pain is severe. The psychologist or psychiatrist consulted on a patient with pain must review the medical evaluation of the pain and the adequacy of the analgesic management provided. If medical options for therapy are available, they always should be considered. Pain control should be considered a prerequisite to both the assessment and management of other sources of distress. Indeed, personality factors may be quite distorted by the presence of pain, and relief of pain often results in the disappearance of a perceived psychiatric disorder (Marks and Sachar, 1973, Cleeland and Tearman, 1986).
Psychiatric disorders and pain in the terminally ill

In cancer populations, the prevalence of psychiatric disorders is associated with chronic pain (Ahles et al., 1983; Derogatis, 1983; Woodforde, 1989). For example, the Psychosocial Collaborative Oncology Group Study (Derogatis, 1983) found that 39% of the patients who received a psychiatric diagnosis (Table 9.11.1) reported significant pain, compared to 19% without a psychiatric diagnosis. The psychiatric disorders in those with pain were largely adjustment disorders with depressed or anxious mood (69%) and major depression (15%).

The prevalence and patterns of psychiatric disorders may vary systematically in subgroups of patients. For example, a study of patients receiving high-dose dexamethasone for epidural spinal cord compression (as much as 96 mg a day for up to a week, followed by a tapering course for up to 3 or 4 weeks) noted that the incidents of depression (22%) and delirium (24%) were much higher than a comparison group (4% and 10%, respectively) (Breitbart et al., 1993). Although there is limited information about patterns of disorders in other subpopulations, it is apparent that advanced disease itself, at least among patients with cancer, is associated with a relatively high prevalence of depression and delirium (Bukberg et al., 1984). The prevalence of severe depressive symptoms increases from approximately 25% among all cancer patients to 77% in those with advanced illness, and the prevalence of organic mental disorders (delirium) requiring psychiatric consultation increases from the range of 25% to 40% to as high as 85% during the terminal stages of illness (Massie et al., 1983). The latter finding is presumably multifactorial and partly related to the use of opioids and other drugs that can cause confusional states, particularly in the elderly and terminally ill (Bruera, 1989).

Rosenfeld, Breitbart, and colleagues (Rosenfeld et al., 1996) described the psychological impact of pain in an ambulatory AIDS population. AIDS patients with pain reported significantly greater depression and functional impairment than those without pain. Psychiatric disorders, in particular the organic mental disorders such as AIDS dementia complex, can occasionally interfere with adequate pain management. The use of an opioid in this setting may worsen dementia or cause treatment-limiting sedation, confusion, or hallucinations. This observation has suggested the judicious use of psychostimulants to diminish sedation and neuroleptics to clear confusional states. Other psychiatric disorders that have an impact on pain management in the AIDS population include substance abuse and personality disorders.

Pain and suicide

Uncontrolled pain is a major factor in suicide and suicidal ideation in the medically ill (Breitbart, 1987, 1990a; Sison et al., 1991), confirming a US public opinion survey in which 69% agreed that cancer pain could cause a person to consider suicide (Levin et al., 1985). Although relatively few cancer patients commit suicide, they are at increased risk overall (Farberow et al., 1963; Levin et al., 1985) and the majority of suicides involve patients who have severe, inadequately controlled or poorly tolerated pain (Bolund, 1985). Patients with advanced illness, who are most likely to have pain, depression or delirium, are at highest risk. A review of the psychiatric consultation data at Memorial Sloan Kettering Cancer Center showed that one-third of hospitalized cancer patients who were seen for evaluation of suicide risk received a diagnosis of major depression, approximately 20% met criteria for delirium, and more than 50% were diagnosed with an adjustment disorder (Breitbart, 1987).

Thoughts of suicide probably occur quite frequently, particularly in the setting of advanced illness (Massie et al., 1994). For many patients, these thoughts actually may be reassuring, acting as a 'steam valve' for feelings: 'If it gets too bad, I always have a way out'. Patients who have a trusting and safe relationship with a health professional commonly admit to occasional thoughts of suicide as a means of escaping the threat of being overwhelmed by pain. Persistent suicidal ideation is relatively infrequent, however, and is limited to those who are significantly depressed. Silberfarb et al. (1980) found that only three of 146 breast cancer patients had suicidal thoughts, whereas none of the 100 cancer patients interviewed in a Finnish study expressed suicidal thoughts (Achte, 1971). A study conducted at St Boniface Hospice in Winnipeg, Canada, demonstrated that only ten of 44 terminally ill cancer patients were suicidal or desired an early death, and all ten were suffering from clinical depression (Brown et al.,

Table 9.11.1 Rates of DSM-III psychiatric disorders and prevalence of pain observed in 215 cancer patients from three cancer centers

Diagnostic category	Number in diagnostic class	Percentage of psychiatric diagnoses	Number with significant pain[a]
Adjustment disorders	69	32	68
Major affective disorders	13	6	13
Organic mental disorders	8	4	8
Personality disorders	7	3	7
Anxiety disorders	4	2	4
Total with psychiatric diagnosis	101	47	39 (39%)
Total with no psychiatric diagnosis	114	53	21 (19%)
Total patient population	215	100	60 (28%)

[a] Score greater than 50 mm on a 100 mm VAS pain severity.

1986). At Memorial Sloan Kettering Cancer Center, suicide risk evaluation accounted for 8.6% of psychiatric consultations, usually requested by staff in response to patients verbalizing suicidal wishes (Breitbart, 1987); all 71 patients who had suicidal ideation with serious intent had a psychiatric disorder (mood disturbance or organic mental disorder) and 30% had significant pain (Breitbart, 1987).

In the cancer population, pain has been associated with the desire for hastened death. In multivariate analyses, depression and hopelessness provided independent and unique contributions to the prediction of the desire for hastened death, while social support and physical functioning added significant but smaller contributions (Breitbart et al., 2000). In a study at Memorial Sloan Kettering Cancer Center, 17% of 185 patients with pain expressed suicidal ideation, with the majority reporting suicidal ideation without intent to act (Saltzburg, 1989). Interestingly, in this population of cancer patients who had significant pain, suicidal ideation was not directly related to pain intensity, but was strongly related to the degree of depression and mood disturbance. Pain was related to suicidal ideation indirectly in that patients' perception of poor pain relief was associated with suicidal ideation. Perceptions of pain relief may have more to do with aspects of hopelessness than pain itself.

Although pain may play an important role in vulnerability to suicide in populations with advanced cancer, these data suggest that factors other than pain, such as mood disturbance, delirium, loss of control and hopelessness, contribute to cancer suicide risk (Bolund, 1985). Frequency of suicidal ideation in one study was associated with poor well-being, depression, anxiety, and shortness of breath, but not with other somatic symptoms such as pain, nausea, and loss of appetite (Suarez-Almazor et al., 2002).

Although work in other populations has been limited, studies of patients with advanced AIDS also have found complex and variable relationships among pain, depression, hopelessness, and suicidal ideation, and suggest that the findings in cancer studies may be more universal. A study of men with AIDS in New York City (Marzuk et al., 1988) demonstrated a relative risk of suicide 36 times greater than that of males in the general population. Many of these patients had advanced AIDS, with Kaposi's sarcoma and other potentially painful conditions. However, the role of pain in contributing to increased risk of suicide was not specifically examined. In a study at Memorial Sloan Kettering Cancer Center (Rabkin et al., 1993), suicidal ideation in ambulatory AIDS patients was found to be highly correlated with the presence of pain, depressed mood (as measured by the Beck Depression Inventory), and low T4 lymphocyte counts. While 20% of ambulatory AIDS patients without pain reported suicidal thoughts, more than 40% of those with pain reported suicidal ideation. Only two of the 110 patients in this study reported suicidal intent. One of these two men was in the pain group; both scored highly on measures of depression. No correlations were observed between suicidal ideation and pain intensity or pain relief. The mean visual analogue scale measure of pain intensity for the group overall was 49 mm (range 5–100 mm), thus falling predominantly in the moderate range. Similar to cancer patients, suicidal ideation in AIDS patients with pain is more likely to be related to a concomitant mood disturbance than to pain intensity. Although AIDS patients are frequently found to have suicidal ideation, these thoughts are more often context-specific, occurring almost exclusively during exacerbations of the illness, when pain is severe, or at times of bereavement (Rabkin et al., 1993).

Inadequate pain management

The adequacy of pain management can be best judged when there is consensus about best practice and data that illuminate the likelihood of satisfactory pain control when treatment is optimal. From this perspective, studies in the cancer population and AIDS population may illuminate the prevalence and causes of undertreatment and suggest the seriousness of the problem in other medically ill groups. Studies suggest that pain in cancer is undertreated (Cleeland et al., 1994) and pain in AIDS is dramatically undertreated (Lebovits et al., 1989; McCormack et al., 1993; Breitbart et al., 1996). In one study of a cohort of AIDS patients treated in New York City (Breitbart et al., 1996), only 6% of patients reporting pain in the severe range (8–10 on a numerical rating scale) received a strong opioid, such as morphine. This degree of undermedication far exceeds published reports of undermedication of pain in cancer populations (Cleeland et al., 1994). Similar to the cancer population, undertreatment of AIDS-related pain may be more likely in women, those with limited education or a substance abuse history, and those who express a variety of patient-related barriers to opioid treatment (Breitbart et al., 1996, 1998). It is also clear that adjuvant agents such as the antidepressants are also dramatically underused (Lebovits et al., 1989; McCormack et al., 1993; Breitbart et al., 1996). Only 6% of patients in a sample of AIDS patients reporting pain received an adjuvant analgesic drug (i.e. an antidepressant).

Inadequate management of pain often is due to the inability to properly assess pain in all its dimensions (Foley, 1985; Breitbart 1989; Twycross and Lack, 1983). Psychological variables may be ignored, or contrariwise, may be proposed to explain pain when in fact medical factors have not been adequately appreciated. Other causes of inadequate pain management include lack of knowledge about pharmacological interventions, focus on prolonging life rather than alleviating suffering, lack of communication between doctor and patient, limited expectations of patients to achieve pain relief, patients' limited capacity to communicate, unavailability of opioid drugs, doctors' fear of opioid toxicity, and doctors' fear of amplifying addiction and substance abuse. In advanced cancer, several related factors have been noted to predict the undertreatment of pain, including a discrepancy between physician and patient in judging the severity of pain; the presence of pain that physicians did not attribute to cancer, better performance status, age of 70 or over, and female sex (Cleeland et al., 1994).

The pharmacological risks associated with opioid drugs, including respiratory depression, are too often overestimated and also can limit appropriate use of opioid analgesics. Non-specialists may not appreciate the safety of opioid therapy when careful dose selection and titration are employed. The widely accepted use of morphine to treat dyspnoea in populations with serious cardiopulmonary disease, without causing a significant deterioration in respiratory function, may be useful to cite when educating colleagues about these drugs (Bruera et al., 1990).

The adequacy of cancer pain management also can be adversely influenced by other misapprehensions. Persistent cancer pain is often ascribed to a psychological cause when it does not respond to treatment attempts. Clinical observation suggests that the

complaint of 'severe' pain is relatively more likely to be viewed as having a psychological contribution. Indeed, staff members' ability to empathize with a patient's pain complaint may be limited by the report of high intensity. Grossman et al. (1991) found that while there is a high degree of concordance between patient and staff ratings of patient pain intensity at the low and moderate levels, this concordance broke down at high pain levels; specifically, the clinicians' ability to assess a patient's level of pain became unreliable when pain intensity was greater than 7 on a 0–10 scale. Physicians must be educated about the limitations of their ability to objectively assess the severity of a subjective pain experience. Additionally, patient education may be useful given the observation that patients are more likely to be believed and adequately treated if they are taught to request pain relief without behaviours that would be interpreted as emotional over-reaction.

A history of drug abuse has been repeatedly associated with the undertreatment of pain. Clinicians may overestimate the prevalence of drug abuse in populations with serious medical illness. At Memorial Sloan Kettering Cancer Center, for example, only eight (1.7%) of 468 inpatients referred for cancer pain had a history of intravenous drug abuse, and none had been actively abusing drugs during the previous year. All eight of these patients were intentionally undermedicated because of concern by staff that drug abuse was active or would recur, and adequate pain control was ultimately achieved in these patients by using appropriate analgesic dosages and intensive staff education. Although populations in other settings may have far higher prevalence of substance use disorders—for example, the base rate of substance use disorders is clearly higher in the younger HIV population (Breitbart, 2003)—clinicians should be able to reassure colleagues and others through knowledge of the true prevalence rates. Derogatis et al. (1983) assessed 215 ambulatory cancer patients for psychiatric diagnoses and found that fewer than 5% met the criteria for a substance use disorder.

Limited knowledge about the presentation, assessment, and management of tolerance, physical dependence, drug abuse and addiction may contribute to an overestimation of risk, which may, in turn, discourage the appropriate use of opioids to treat pain (Charap, 1978; Kanner and Foley, 1981; Twycross and Lack, 1983; Macaluso et al., 1988; Breitbart, 1990). For example, a patient's request for a higher dose to treat worsening pain may be perceived as a strong indicator of, tolerance, abuse, or addiction. In populations with advanced illness, however, most patients stabilize on a dose for a prolonged period, and when dose escalation is needed, it usually is linked to observable progression of disease. If pain increases as a result of disease progression, the loss of drug effect cannot be ascribed to the development of tolerance; in the absence of other findings, it should not be attributed to abuse or addiction. Like physical dependence, which is defined as the potential for abstinence if the dose is abruptly reduced or an antagonist is administered, tolerance usually is not perceived to be a clinical problem unless there is repeated loss of analgesic efficacy in the absence of disease progression.

Addiction is a neurobiological disease with a strong genetic basis, which is defined by the occurrence of craving, loss of control over drug use, compulsive use, and continuing use despite harm. Understanding the assessment strategies needed to identify these characteristics, and acknowledging the key differences between addiction and both tolerance and physical dependence,

are essential to accurately judge the true risks of opioid therapy in an individual patient.

Patients who require pain treatment with opioids or other potentially abusable drugs and either have a history of significant alcohol or drug abuse or meet criteria for a substance use disorder do pose a challenge for clinicians. This is exemplified by the management of pain in the growing segment of the AIDS population that is actively abusing intravenous drugs (Breitbart, 2003). Active drug use, particularly intravenous opioid abuse, may compromise pain therapy through (a) high tolerance to opioid analgesics needed for disease-related pain, (b) drug-seeking and manipulative behaviour, (c) lack of adherence or reliability of patient history, and (d) the risk of spreading HIV. Because subjective report may be the only indication of the presence and intensity of pain, or the degree of pain relief achieved by an intervention, patients who are assumed to lie as an element of addictive disease are at high risk to generate concern among clinicians, whose reluctance to believe the patient may lead to anger and limited pain therapy. Undertreatment is clearly a risk in this context.

Most clinicians experienced in working with medically ill patients with substance abuse history recommend clear and direct limit setting. To the extent possible, clinicians should attempt to eliminate the issue of drug abuse as an obstacle to pain management by dealing directly with the problems of opioid withdrawal and drug abuse treatment. Often, specialized substance abuse consultation services are available to help manage such patients and initiate structured drug administration, or other elements of drug treatment, at the same time that pain management is occurring. If analgesic drugs are the focus of a battle for control between the patient and physician, therapy will be compromised, especially in terminal stages of illness. In this setting, it is appropriate for clinicians to err on the side of believing a patient when they complain of pain, and present a bias toward treatment, as long as there is no clear evidence of self-destructive behaviours or drug diversion to the illicit market (see Chapter 9.5).

Psychiatric and psychological management of pain in advanced disease

Optimal treatment of pain associated with advanced illness often requires a multimodality strategy, including pharmacological, psychological, rehabilitative, and interventional approaches. The numerous psychological approaches include psychotherapeutic, cognitive behavioural, and psychopharmacologic interventions, usually in combination.

Psychotherapy and pain

When patients experience pain in the context of serious medical illness, the goals of psychotherapy are to provide support, knowledge, and skills (Table 9.11.2). Short-term supportive psychotherapy focused on the crisis created by the medical illness is a common strategy, through which the therapist provides emotional support, continuity and information, and assists in adaptation. The therapist has a role in emphasizing past strengths, supporting previously successful coping strategies, and teaching new coping skills. These new skills may include relaxation training, cognitive behavioural approaches to improve coping, self-monitoring skills, and assertiveness and communication skills. Patients can be taught about documentation, such as the effective use of a pain diary, and

Table 9.11.2 Goals and forms of psychotherapy for pain in patients with advanced disease

Goals	Form
Support—provide continuity	Individuals—supportive/crisis intervention
Knowledge—provide information	Family—patient and family are the unit of concern
Skills—relaxation, cognitive coping, communication, use of analgesics	Group—share experiences, identify successful coping strategies

about the safe and effective use of analgesics. In some cases, existential issues arise and require exploration. Communication skills are of paramount importance for both patient and family, particularly around pain and analgesic issues. The patient and family is the unit of concern, and there is a need to support a more general, long-term supportive relationship within the health-care system, in addition to providing specific psychological approaches.

Psychotherapy with the patient who has advanced illness and pain consists of active listening with supportive verbal interventions and the occasional interpretation (Cassem, 1987). Despite the seriousness of the patient's plight, it is not necessary for the psychologist or psychiatrist to appear overly solemn or emotionally restrained. Often, the relationship is strengthened by the ability of the psychotherapist to converse lightheartedly and allow the patient to talk about his life and experiences, rather than focus solely on impending death. The patient who wishes to talk or ask questions about death and pain and suffering should be allowed to do so freely, with the psychotherapist maintaining an interested, interactive stance. This work may ensue in parallel with discussions between the patient or family and other members of the treatment team, including the chaplain.

As the illness progresses, psychotherapy with the individual patient may become limited by cognitive or speech deficits. It is at this point that the focus of supportive psychotherapeutic interventions shifts primarily to the family. A common issue for the family at this point is the level of alertness of the patient. Attempts to control pain are often accompanied by sedation that can limit communication between patient and family. This can sometimes become a source of conflict, with family members disagreeing among themselves or with the patient about what constitutes an appropriate balance between comfort and alertness. It can be helpful for the physician to clarify the patient's preferences as they relate to these issues early so that conflict can be avoided and work related to bereavement can begin.

Group interventions with individual patients (even in advanced stages of disease), spouses, couples, or families are a powerful means of sharing experiences and identifying successful coping strategies. The limitations of using group interventions for patients with advanced disease are primarily pragmatic. The patient must be physically comfortable enough to participate and have the cognitive capacity to be aware of group discussion. It is often helpful for family members to attend support groups during the terminal phases of the patient's illness.

Family caregivers often assist in pain management and interventions may be targeted to enhance these efforts. In an novel intervention, Keefe (2005) tested the efficacy of a partner-guided cancer pain management protocol consisting of a three-session intervention conducted in patients' homes that integrated educational information about cancer pain with systematic training of patients and partners in cognitive and behavioural pain coping skills (see 'Cognitive behavioural techniques'); this approach produced significant increases in the partners' ratings of their self-efficacy for helping the patient control pain and self-efficacy for controlling other symptoms.

Psychotherapeutic interventions that have multiple targets may be the most useful. Based upon a prospective study of cancer pain, cognitive behavioural and psychoeducational techniques based upon increasing support and self-efficacy, as well as providing education, may help patients deal with increased pain (Syrajala et al., 1992). Distress related to the illness, self-efficacy, and coping may be associated with pain and be specifically addressed by these interventions.

Psychotherapy to diminish symptoms of anxiety and depression, factors that can intensify pain, also may be an important strategy. In a randomized controlled study, Spiegel and Bloom (1983) demonstrated that both supportive group therapy and training in hypnotic pain control exercises benefited patients with pain related to metastatic breast cancer. The supportive group focused not on interpersonal processes or self-exploration, but rather on a series of themes related to the practical and existential problems of living with cancer.

While psychotherapy in populations with advanced illness is primarily non-analytical and focuses on current issues, exploration of reactions to illness often involve insights into earlier, more pervasive life issues. Some patients choose to continue a more exploratory psychotherapy during extended periods of stable disease, or during survivorship.

Cognitive behavioural techniques

Cognitive behavioural techniques can be useful as adjuncts to the management of pain in the setting of serious medical illness (Box 9.11.1). The goal of these techniques is to guide the patient towards a sense of control over pain. Some of the specific interventions are primarily cognitive in nature, focusing on perceptual and thought processes, and others are directed at modifying patterns of behaviour that may help patients cope with pain. Specific strategies include passive relaxation with mental imagery, cognitive distraction or focusing, progressive muscle relaxation, biofeedback, hypnosis, and music therapy (Cleeland, 1987; Fishman and Loscalzo, 1987; Loscalzo and Jacobsen, 1990; Singer et al., 1993). Behavioural techniques may seek to modify physiologic pain reactions, respondent pain behaviours, or operant pain behaviours (see Table 9.11.3 for definitions).

The cognitive interventions that are used to reduce pain intensity or associated distress may attempt to modify the thoughts about the pain, introduce more adaptive coping strategies, or provide instruction through various types of relaxation techniques. Cognitive modification (cognitive restructuring) is an approach derived from cognitive therapy for depression or anxiety and is based on how one interprets events and bodily sensation. It is assumed that patients have dysfunctional automatic thoughts that reflect underlying assumptions and beliefs. In both cancer and AIDS populations, negative thoughts about pain have been shown to be significantly related to pain intensity, degree of psychological distress, and level of interference in functional

Box 9.11.1 Cognitive behavioural techniques used by pain patients with advanced disease

- ◆ Psychoeducation:
  - preparatory information
  - self-monitoring
- ◆ Relaxation:
  - passive breathing
  - progressive muscle relaxation
- ◆ Distraction:
  - focusing
  - controlled by mental imagery
  - cognitive distraction
  - behavioural distraction
- ◆ Combined techniques (relaxation and distraction):
  - passive/progressive relaxation with mental imagery
  - systematic desensitization
  - meditation
  - hypnosis
  - biofeedback
  - music therapy
- ◆ Cognitive therapies:
  - cognitive distortion
  - cognitive restructuring.

Behavioural therapies:

  Modelling

  Graded task management

  Contingency management

  Behavioural rehearsal

Table 9.11.3 Cognitive behavioural techniques: definitions and descriptions

Behavioural therapy	The clinical use of techniques derived from the experimental analysis of behaviour, i.e. learning and conditioning for the evaluation, prevention, and treatment of physical disease or physiological dysfunction
Cognitive therapy	A focused intervention targeted at changing maladaptive beliefs and dysfunctional attitudes. The therapist engages the patient in a process of collaborative empiricism, where these underlying beliefs are challenged and corrected
Operant pain	Pain behaviours resulting from operant learning or conditioning. Pain behaviour is reinforced and continues because of secondary gain, i.e. increased attention and caring
Respondent pain	Pain behaviours resulting from respondent learning or conditioning. Stimuli associated with prior painful experiences can elicit increased pain and avoidance behaviour
Cognitive restructuring	Redefinition of some or all aspects of the patient's interpretation of the noxious or threatening experience, resulting in decreased distress, anxiety, and hopelessness
Self-monitoring (pain diary)	Written or audiotaped chronicle that the patient maintains to describe specific agreed-upon characteristics associated with pain
Contingency management	Focusing the patient and family member responses that either reinforce or inhibit specific behaviours exhibited by the patient. Method involves reinforcing desired 'well' behaviours
Grade task assignments	A hierarchy of tasks, i.e. physical, cognitive, and behavioural, are compartmentalized and performed sequentially in manageable steps ultimately achieving an identified goal
Systematic desensitization	Relaxation and distraction exercises paired with a hierarchy of anxiety-arousing stimuli presented through mental imagery, or presented *in vivo*, resulting in control of fear

---

activities (Payne et al., 1994; Payne, 1995). By identifying and challenging dysfunctional automatic thoughts and underlying beliefs by restructuring or modifying thought processes, a more rational response to pain can occur (Fishman and Loscalzo, 1987). Examples of such automatic thoughts that have been shown to worsen pain experience are: 'The intensity of my pain will never diminish' or 'Because my pain limits my activities, I am completely helpless.' Patients can be taught to recognize and interrupt such thoughts and proceed to develop a view of the pain experience as time-limited and themselves as functional despite periods in which they are limited.

The use of cognitive restructuring may shift as the goals change in the palliative care context. In the setting of advanced illness, the goal may not be to change the patient's maladaptive thoughts, but rather, to utilize techniques designed to diminish the patient's anxiety, frustration, and anger. Helping patients to employ more adaptive coping strategies, allowing for decreased catastrophization and increase problem-solving skills, may be helpful at this stage (Fishman, 1990; Turk and Fernandez, 1990; Jensen et al., 1991).

Aside from modifying dysfunctional thoughts and attitudes, the most fundamental behavioural technique is self-monitoring. The development of the ability to monitor one's behaviours allows a person to notice their dysfunctional reactions to the pain experience and learn to control them.

Another approach, systematic desensitization (see Table 9.11.3), may be useful in extinguishing the anticipatory anxiety that can lead to avoidant behaviours, and in remobilizing inactive patients. Graded task assignment may be viewed as a type of systematic desensitization, by which function is improved by teaching patients to take small steps gradually and thereby initially avoiding the anxiety associated with the specific task until more effective coping mechanism and self-efficacy is achieved. Finally, contingency management is a method of reinforcing 'well' behaviours only; this may modify dysfunctional operant pain behaviours associated with secondary gain (Cleeland, 1987; Loscalzo and Jacobsen, 1990).

The range of cognitive behavioural interventions that may be useful in the setting of advanced illness is very broad (Breitbart

and Holland, 1988) and there is some evidence that all methods are not equally effective. Cognitive strategies, including relaxation, suggestion, and distracting imagery, appear to hold the greatest promise, although research on the usage of these techniques to control pain is scant (Sellick and Zaza, 1998; Montgomery et al., 2002). The mechanisms by which these techniques relieve pain are not known and it widely accepted that a favourable response to a psychological technique should not be viewed as evidence that pain is psychogenic. All these techniques share the elements of relaxation and distraction, and this common pathway may help reduce awareness of pain, muscle tension and sympathetic arousal (Cleeland, 1987). Although studies of these interventions in populations with advanced illness are limited, the recommendation to consider a combined non-pharmacological and pharmacological pain management strategy is common, and is especially promoted with paediatric populations (Kazak et al., 1998). These interventions may be a particularly attractive part of a multimodality approach because they produce no side effects.

Patient selection for cognitive behavioural interventions for pain

The selection of patients with advanced illness and pain for trials of cognitive behavioural strategies should take into account the intensity of pain and the mental clarity of the patient. Ideal candidates have mild to moderate pain, either at baseline or as a result of analgesic drug therapy. Confusional states interfere dramatically with a patient's ability to focus attention and thus limit the usefulness of these techniques (Loscalzo and Jacobsen, 1990). Occasionally, however, these techniques can be modified so as to include mildly impaired patients. This may involve the therapist taking a more active role by orienting the patient, creating a safe and secure environment, and evoking a conditioned response to the therapist's voice or presence.

Barriers to engaging patients in cognitive behavioural therapies can be divided into physician/nurse-based barriers and patient-based barriers. Many health professionals are uncomfortable with the use of behavioural therapies. Pharmacotherapy is highly effective in the management of pain and seems simpler and easier to use than labour-intensive and time-consuming non-pharmacological interventions. Physicians and nurses have typical concerns about the practice of behavioural interventions such as: 'What if the patient laughs, doesn't buy it?' or 'It seems too theatrical, unscientific, non-medical; too New Age!' Overcoming such obstacles may yield gratifying results. Physicians working with patients with advanced illness should become aware of the effective non-pharmacological interventions and be able to make appropriate referrals to practitioners who can provide them.

Patients may be uncertain about the utility of these therapies. Some may ask, 'How can breathing take away my pain?' They may be frightened by the word 'hypnosis' and its connotations. Although hypnosis is often associated with powerful and magical properties, some patients become frightened at the prospect of losing control or being under the influence of someone else. It generally is best to introduce cognitive behavioural interventions after some rapport has been established with a patient. Although some patients may benefit from a discussion of the theoretical basis of these interventions, it is important to stress that an understanding of the mechanism is not needed for effectiveness and the outcome is most important. Apprehensions must be addressed, and

patients must feel in control of the process at all times and be reassured that they can stop at any time.

Practical considerations in the use of cognitive-behavioural approaches

A general approach to using cognitive behavioural interventions with patients with advanced illness and pain involves the following: (1) assessment of the symptom, (2) choosing a cognitive behavioural strategy, and (3) preparing the patient and the setting.

The main purpose of conducting a cognitive behavioural assessment of pain is to determine what, if any, interventions are indicated (Kanner and Foley, 1981). One must initially engage the patient and establish a therapeutic alliance. A history of the pain symptom must be taken. One should review previous efforts to treat the patient's pain, and collect data regarding the nature of the pain and its impact on the patient and their family. Choosing the appropriate behavioural strategy should consider the patient's medical condition, physical and cognitive limitations, time constraints, and practical matters. For instance, patients with cognitive impairment or delirium will probably be unable to keep a pain diary or employ techniques that involve cognitive manipulation.

Muscular tension, autonomic arousal, and mental distress exacerbate pain (Cleeland, 1987; Loscalzo and Jacobsen, 1990), and a variety of techniques can be used to achieve a state of relaxation. These include passive relaxation through the focusing of attention on sensations of warmth and decreased tension in various parts of the body, progressive muscle relaxation involving active tensing and relaxing of muscles, and meditation. Other techniques that employ relaxation, as well as other cognitive therapies, include hypnosis, biofeedback, and music therapy (discussed later). Although studies of relaxation do not confirm a positive effect on chronic pain, but indicate that relaxation training can reduce some pain scores and more clearly has a positive effect on anxiety (Wallace, 1997; Carroll and Seers, 1998; Luebbert et al., 2001).

Passive relaxation, focused breathing, and passive muscle relaxation exercises involve the focusing of attention systematically on one's breathing, on sensations of warmth and relaxation, or on release of muscular tension in various body parts. Verbal suggestions and imagery are used to help promote relaxation. Muscle relaxation is an important component of the relaxation response and can augment the benefits of simple focused breathing exercises, leading to a deeper experience of relaxation and self-control.

Progressive or active muscle relaxation involves the active tensing and relaxing of various muscle groups in the body, focusing attention on the sensations of tension and relaxation. Clinically, in the hospital setting, relaxation is most commonly achieved through the use of a combination of focused breathing and progressive muscle relaxation exercises. Once patients are in a relaxed state, imagery techniques can then be used to induce deeper relaxation and facilitate distraction from or manipulation of a variety of cancer-related symptoms.

Script for passive relaxation (focused breathing)

The following script is a generic relaxation exercise, utilizing passive relaxation or focused breathing, that is based on and integrates the work of Erickson (1959), Benson (1995), and others (Loscalzo and Jacobsen, 1990).

'Why don't you begin by finding a comfortable position. Slowly allow your body to unwind and just let it go. That's it . . . I wonder if you can allow your body to become as calm as possible . . . just

let it go, just let your body sink into that bed (or chair) . . . feel free to move or shift around in any way that your body needs to, to find that comfortable position. You need not try very hard, simply and easily allow yourself to follow the sound of my voice as you allow your body to find itself a safe, comfortable position to relax in.

If you like, you can gently allow your eyes to close, just let the lids cover your eyes . . . allow your eyes to sink back deeply into their sockets . . . that's it, just let them go, falling back gently and deeply into their sockets as your lids begin to feel heavier and heavier. As you allow your head to fall back deeply into the pillow, feeling the weight of your head sinking into the pillow as you breath out, just breath out, one big breath. Slowly, if you can begin to turn your attention to your breathing. Notice your breath for a few moments, how much air you take in, how much air you let out, and just breath evenly and naturally, and with the sound of my voice I wonder if you can begin to take in more air, breathing in and out, in and out, that's it, gradually breathing in and out . . . in and out . . . breathing in calmness and quietness, breathing out tiredness and frustration, that's it . . . let it go, it's not important to you now . . . breathing in quietness and control, breathing out fear and tension . . . breathing in and out . . . in and out . . . you can enjoy breathing in this relaxed way for as long as you need to. You are peaceful now as you continue to observe your even and steady breathing that is allowing you to feel gentle and calm, breathing that is allowing you to feel a gentle calm, that's it, breathing relaxation in and tension out . . . in and out . . . breathing in quietness and control, breathing out tiredness and tension . . . that's it (patient's name here) as you continue to notice the quietness and stillness of your body, why don't you take a few quiet moments to experience this process more fully.'

It may be helpful for the clinician to mark the end of an exercise by increasing the pace, raising the volume of voice, and shifting position. Additionally, it is helpful for the clinician to both pace and model for the patient. This includes positioning yourself as similarly to the patient as possible (e.g. closing eyes, assuming a position of relaxation, and breathing at the same rate). If the patient exhibits any visible anxiety or agitation, this can be briefly explored verbally, and then, if appropriate, the exercise can be continued.

Script for active or progressive muscle relaxation

This exercise involves the patient actively tensing and then relaxing specific body parts. Once again, it may be helpful if the clinician paces and models for the patient.

'Now, I wonder if you can tense up every muscle in your body . . . that's it, squeeze in the muscles . . . hold it, and then just let it go . . . once more, tense up your muscles . . . make them very tight and tense, hold it, hold it . . . and then breath out, and let your muscles relax, just let them go . . . Now, as your body begins to feel more and more relaxed, clench your jaw, squeeze it tight, clench it and then let it go . . . now open your mouth wide, as wide as it will go, stick out your tongue, stick it way out, hold it and then let it go. Feel your head becoming more and more relaxed, as it sinks down into the pillow, allowing all the tension and tightness to drift out of it . . . Now, I wonder if you can lift up your shoulders, lift them up, up to your ears, hold them there, squeezing them tightly, squeeze, and then let them drop down, just let them go . . . and then once more lift them up . . . hold it . . . then let them go . . . as you feel all the tightness and tension in your shoulders begin to drain away . . . Now, I wonder if you can clench your hands into a fist, make a tight fist as your whole arm tightens, tense your arms as you squeeze in your fingers tighter and tighter . . . and now just let them go, once more now make a fist, a tight fist, hold it, and then let it go.'

As with passive muscle relaxation, the clinician guides the patient through the exercise, requesting the patient to tense and release specific muscles in a progressive order.

Imagery/distraction techniques

Clinically, relaxation techniques are most helpful in managing pain when combined with distraction or pleasant imagery. The use of distraction or focusing involves control over the focus of attention and can be used to make the patient less aware of the noxious stimuli (Broome et al., 1992). Keeping oneself busy is a form of behavioural distraction. Mental distraction can be used and is similar to the practice of counting sheep to aid sleep. Imagery—using one's imagination while in a relaxed state—can be used to transform pain into a warm or cold sensation. One can employ imaginative inattention by picturing oneself on a beach. One can also imaginatively transform the context of pain; for example, one could imagine oneself in battle on the football field instead of the hospital bed. Dissociated somatization, which can be employed by some patients, involves imagining that a painful body part is no longer part of their body (Fishman and Loscalzo, 1987; Breitbart, 1989, 1990; Loscalzo and Jacobsen, 1990). It is important to note that not every patient finds these techniques acceptable, and the therapist must try out a number of approaches to determine which are consistent with the patient's style.

Imagery (often referred to as guided imagery) is most effective when the specific image is obtained from the patient. The clinician may ask the patient to close his or her eyes and think of a place, an activity, or an experience where the patient felt most safe and secure. The clinician may provide suggestions for the patient such as a favourite beach scene, or a room in a house, or riding a bicycle in a state park. Once the patient identifies the scene, the clinician may ask the patient to elaborate upon the scene, asking for specific details such as the temperature, season, time of day, type of ocean (calm, or with big waves), etc. The clinician then utilizes this information and describes an image for the patient in detail. The clinician should be as flexible and as creative as possible, and elaborate upon the scene, utilizing all aspects of the senses and bodily sensations such as 'feel the suns rays touch your skin, allow your skin to feel warm and tingly all over . . . ' or, 'breath in the fresh, clear air, allow it to fill your lungs with its freshness . . . ' or, 'feel the fresh dew of the grass under your feet'. The clinician can focus on 'aromas in the garden' or the 'sounds of birds singing', always reminding the patient to breath evenly and steadily as he or she feels more and more relaxed and more and more in control. If possible, the clinician should avoid volunteering an image or scene for the patient because the clinician is unaware of the association or meaning the image may have for the patient. For example, a patient may have a fear of the water, and therefore a beach scene may invoke feelings of fear and loss of control.

Script for pleasant distracting imagery

The following is a generic script for a imagery exercise:

'Once you are in a comfortable position, I wonder if you can continue lying there with your eyes closed, continuing to breath in

out . . . in and out to the sound of my voice. Let your mind wander . . . just let it go . . . and if any unwanted thoughts come into your mind, you can allow then to pass out as easily as they came in . . . You don't need them now . . . they are not important to you now. You have the ability to control your thoughts. You have the ability to be in control.

Slowly, I wonder if you can allow your mind to travel . . . to travel far away to your favourite beach. The beach that you have many fond memories of. I wonder if you can imagine that it's almost the end of the day and the beach is deserted . . . and the sun, while setting, is still warm, as it beats down . . . and makes your skin feel tingly and warm all over. As you begin to walk on the sand, you can feel the granules underneath your feet. Step evenly and steadily along the sand. As you look around, you can see the different colours in the sky. You can see for miles off into the distance and you feel exhilarated and free because no one is around you. You are alone and in control. As you walk closer to the edge of the ocean the sand is becoming a little damp and you can feel the dampness underneath your feet—it feels refreshing. As you continue walking, you may notice a few odds and ends on the sand maybe something that the ocean brought in . . . some shells perhaps. They may be broken from being knocked against the rocks . . . or there may be a few bits of seaweed or some jellyfish. You stop to notice them as you walk past . . . marvelling at the wonders of nature. As you get to the edge of the ocean, you can feel the tiny little ripples of water washing over your feet . . . bouncing over your feet making you feel light and fresh. The water is warm—it soothes your feet. Washing back and forth . . . back and forth. As you keep walking you see your rubber raft. This is your old dependable rubber raft. You get to the raft and you secure it in your hands and lie down on it letting your whole body sink into the raft—just let it go . . . that's it. Slowly you kick off as the raft begins to take you away. The ocean is very calm and very gentle. Your whole body begins to unwind and sink deeper and deeper into the raft as you feel more and more relaxed. This raft allows you to drift off . . . and underneath you can feel the ripples of the ocean . . . rocking back and forth . . . back and forth as you continue to float away evenly and gently. You can become aware of the sun beating down on your skin. You are aware of the sounds around you—you can hear the ocean washing against the rocks as the waves rock back and forth . . . back and forth. You can hear the gulls crying in the distance. There is a very tiny protected bay that you are floating away in. It is a very calm and peaceful day, and you are feeling more and more relaxed. You are in control now . . . and as you continue to sail away, all your troubles and problems wash right out of you. They're not important to you now. You don't need them now. What's important is that your whole body, from the tip of your toes all the way up to the top of your head, is relaxed and calm in this very safe and private place that is your own. You can continue to lie here as you rock back and forth . . . back and forth for as long as you need to.

When you are ready, you can slowly readjust yourself to the sound of my voice and I am going to count slowly backwards from ten and with each count backwards, you can become more and more familiar with where you are. Perhaps when I get to number five you may want to open your eyes or you can keep then closed for as long as you need to. Ten, nine . . . —become aware of the sounds around you . . . eight, seven . . . become aware of the temperature of the room—how does it feel?, how does your body

feel? . . . six, five . . . —you can open your eyes now if you want to or you can keep them closed . . . four, three, two, one. You can stay in this relaxed position for as long as you need to. When you feel ready you may slowly prepare to sit up.'

Hypnosis

The American Society of Clinical Hypnosis defines hypnosis as 'a state of inner absorption, concentration, and focused attention' (American Society of Clinical Hypnosis., 2013). Hypnosis can foster a way of processing information in which analytic cognition and peripheral awareness is suspended. This can lead to involuntary changes in the perception of mood and memory, which in turn can lead to biological and behavioural changes (Wickramaskera, 2003).

The hypnotic trance is essentially a state of heightened and focused concentration, and thus it can be used to manipulate the perception of pain. The depth of hypnotizability may determine the effectiveness of this approach, as well as the strategies employed during hypnosis. One-third of patients are not hypnotizable, and it is recommended that other techniques be employed for them. Of the two-thirds of patients who are identified as being less, moderately, and highly hypnotizable, three principles underlie the use of hypnosis in controlling pain (Broome et al., 1992): (1) use self-hypnosis, (2) relax, do not fight the pain, and (3) use a mental filter to ease the hurt in pain. Patients who are moderately and highly hypnotizable can often alter sensations in a painful area by changing temperature sensation or experiencing tingling. Less hypnotizable patients can often utilize an alternative focus by concentrating on a sensation in a non-affected body part or on a mental image of a pleasant scene.

Hypnosis can be a useful adjunct in the management of pain (Spiegel and Bloom,1983; Spiegel,1985; Levitan,1992; Syrajala et al.,1992; Tan, 1997; Douglas, 1999; Liossi and Hatira, 1999; Montgomery et al., 2000; Rajasekaran et al., 2005) including acute pain from mucositis, procedures, or surgery (Syrajala et al., 1992; Liossi and Hatira, 1999; Montgomery et al., 2000, 2002; Floryn et al., 2007; Wobst, 2007) and pain related to wounds, burns, and various chronic conditions (Jensen and Patterson, 2006; Hammond, 2007; Neron and Stephenson, 2007; Gevirtz, 2009; Abrahamsen et al., 2011). In 1996, the National Institutes of Health in the United States assembled a Technology Assessment Panel that reviewed the evidence to date and concluded that relaxation and hypnosis are effective in reducing chronic pain (NIH Technology Assessment Panel, 1996). The main disadvantage of hypnosis for cancer patients is that the technique frequently requires more attentional capacity than these patients generally have.

Biofeedback

Biofeedback is a behavioural therapy that teaches patients how to gain awareness and control over physiological functions for the purpose of improving health and performance. Instruments are used to measure physiological activity, such as heart function, breathing, skin temperature, muscle activity, carbon dioxide partial pressure (PCO_2), or brainwave pattern. This information is then presented, rapidly and accurately, back to the patient. Patents use this information to change their thinking, emotions, and behaviours, which in turn support the desired physiological changes. Over time, these changes can be continued without the use of the biofeedback instruments.

Myrvik et al. studied single-session biofeedback-assisted relaxation training in patients with sickle cell disease. Ten participants completed a 1-hour session and showed changes in body temperature after the training session and at 6-week follow-up. Reductions in pain frequency, even though very small, were also reported (Myrvik et al., 2012). Shapiro and Shanani showed that six of nine participants who underwent biofeedback treatment for 1–4 years showed significant improvements in functional chest pain compared with those who were not treated (Shapiro and Shanani, 2012). In a meta-analysis, reductions in frequency, duration, and intensity of tension type and migraine headaches was accomplished in children with biofeedback techniques (Trautmann et al., 2006). Fotopoulos et al. (1979) noted significant pain relief in a group of cancer patients who were taught electromyographic (EMG) and electroencephalographic (EEG) biofeedback-assisted relaxation. However, only two of 17 were able to maintain analgesia after the treatment ended. The latter finding suggests that this biofeedback technique may lack generalization to other settings, and this is viewed as a problem with biofeedback techniques. Although physical condition may make a prolonged training period impossible, especially for the terminally ill, most cancer patients could utilize EMG and temperature biofeedback techniques for learning relaxation-assisted pain control (Kazak et al., 1998).

Music, aroma, and art therapies

Music is often used to enhance well-being, reduce stress, and distract patients from unpleasant symptoms. Munro and Mount (1978) have written extensively on the use of music therapy with cancer patients, documenting clinical examples and suggesting mechanisms of action. Although there are wide variations in individual preferences, music appears to exert direct physiologic effects through the autonomic nervous system and can be particularly helpful in managing the discomfort associated with procedures (Chlan et al., 2000). Music can often capture the focus of attention like no other stimulus, offers patients a new form of expression, and helps patients distract themselves from their perception of pain, while expressing themselves in meaningful ways (Schroeder-Sheker, 1993; Magill, 2001). Some studies suggest that music may decrease the overall intensity of the patient's pain when used with analgesics, and although studies have shown mixed results, music can result in a decreased need for pain medicine in some patients (Cepeda et al., 2006).

As a general relaxation technique, aromatherapy may have an application for pain management, but studies are limited and the technique warrants further investigation.

Utilizing the scent, heliotropin, Manne et al. (1991) reported that two-thirds of the patients found the scent especially pleasant and reported much less anxiety than those who were not exposed to the scent during magnetic resonance imaging. Wilkinson et al., (2007) found short-term but not persistent benefits from aromatherapy in a group of cancer patients with depression, and Anderson and Johnson found that aromatherapy did not significantly change perineal discomfort after childbirth (Anderson and Johnson, 2005)

Art therapy can be used to reduce fear, anxiety, stress and pain, and help enhance overall sense of well-being (Nainis et al., 2006). Palliative care clinicians may use art therapy to explore issues relating to loss of control, helplessness, and hopelessness (Trauger-Querry, 2001). In addition, art therapy allows the less verbally skilled adult or children to express the fears and concerns that they have in a more comfortable fashion. The creative experience can be used as both an important means of providing support and also as an avenue for providing patients with psychological insights into their experience (Connell, 1992).

Psychotropic adjuvant analgesics for pain in the patient with advanced illness

Although randomized controlled trials of psychotropic medications have largely been done in subjects who are generally healthy, there appears to be increasing evidence that they may offer some benefit for patients requiring palliative care in the advanced stages of illness.

Antidepressants

Antidepressants may improve depression in patients with advanced cancer (Holland et al., 1998). Some of these drugs are established analgesics. Although positive effects on mood, should they occur, may be beneficial for pain, the analgesic effects produced by the latter drugs may be independent of their mood-enhancing potential (Dharmshaktu et al., 2012).

Serotonin selective reuptake inhibitors (SSRIs)

SSRIs inhibit serotonin reuptake into the presynaptic neuron, which ultimately increases synaptic concentrations of serotonin. This group includes a number of commonly used agents, such as fluoxetine, citalopram, and paroxetine. They are generally considered first-line treatments for depression, anxiety, and eating disorders. This is largely related to tolerability when compared to other agents, although they are capable of causing significant gastrointestinal side effects (which tend to be a time limited side effect), as well as increased anxiety and sexual side effects. A recent meta-analysis demonstrated the efficacy of these agents in the management of mood symptoms in palliative care patients but found limited evidence to support the superiority of any one agent when compared to others within the class (Rayner et al., 2011). There are few data supporting their efficacy as analgesics (Otto et al., 2008; Dharmshaktu et al., 2012). The SSRIs are not preferred when the primary goal of treatment is to mitigate pain.

Serotonin norepinephrine reuptake inhibitors (SNRIs)

SNRIs inhibit the neuronal reuptake of both serotonin and norepinephrine (noradrenaline), similar to the tricyclic antidepressants. Among others, they include venlafaxine and duloxetine, which are widely used as first-line agents in the treatment of depression and anxiety disorders. These drugs are generally well tolerated and have a side effect profile comparable to the SSRIs. Venlafaxine may worsen hypertension, however, and is more likely to produce withdrawal symptoms when discontinued than other drugs. In contrast to the SSRIs, this antidepressant class has substantial evidence of analgesic efficacy (Sindrup et al., 2003; Eisenberg, 2007; Attal et al., 2010; Bachman et al., 2011; Kaur, 2011); both duloxetine and another agent in this group, milnacipran, are approved in the United States as analgesics for specific disorders. Although large studies are lacking in the use of these agents in patients with pain related to cancer, there are some smaller studies that demonstrate efficacy of these agents in the treatment of neuropathic syndromes following chemotherapeutic and surgical interventions for

patients being treated for cancer (Tasmuth et al., 2002; Amr and Yousef, 2010; Henry et al., 2011; Durand, 2012; Yang et al., 2012).

Tricyclic antidepressants (TCAs)

TCAs also inhibit the reuptake of serotonin and norepinephrine. The various agents in this group differ in their potency at each of these sites, as well by their affinity at the receptor sites for other neurotransmitters. There are two broad categories: the tertiary amine drugs, such as amitriptyline and imipramine, tend to cause more side effects (particularly anticholinergic effects) than the secondary amine drugs, such as nortriptyline and desipramine. All the TCAs now tend to be used as second-line agents due to the relatively better side effect profiles of the SSRIs and SNRIs. Nevertheless, there is substantial evidence that these drugs have primary analgesic effects for diverse painful conditions (Raja et al., 2002; Sindrup et al., 2003; Rahimi et al., 2009; Attal et al., 2010; Bachman et al., 2011; Kaur, 2011; Brian et al., 2012; Dharmshaktu et al., 2012). Specific evidence in populations with cancer or other serious illnesses is limited, however (Kautio et al., 2009; Arai et al., 2010; Mishra et al., 2012).

Some TCAs have been employed in non-oral formulations. An oral doxepin rinse is available that appears to offer some benefit for pain related to mucositis, although studies have been small (Epstein JP et al. 2001; Epstein JB et al. 2008). Topical doxepin is used for itch.

Monoamine oxidase inhibitors (MAOIs)

MAOIs inhibit the enzyme monoamine oxidase and include such drugs as phenelzine and selegiline, which has a transdermal preparation. These agents have largely been relegated to the treatment of refractory depression due to their potential complications, including orthostatic hypotension, interactions with other serotonergic agents leading to serotonin syndrome, and the potential for hypertensive crisis if exposed to certain medications and tyramine-containing foods. There is no support for their use as analgesics.

Other antidepressants

Mirtazapine is an antagonist at presynaptic alpha-2 receptors on noradrenergic neurons and has gained some popularity in medically ill populations due to its propensity to enhance appetite and promote sedation at lower doses (effects that tend to decrease as the dose increases), and its potential for reducing nausea. There is little evidence to support its use as an adjuvant treatment for pain.

Bupropion enhances the effects of norepinephrine and dopamine. It has current indications for the treatment of depression, smoking cessation, and attention deficit/hyperactivity disorder. It is usually activating and is well tolerated as compared to other antidepressants; it has fewer sexual side effects than the SSRIs and SNRIs. However, there is evidence of dose dependent increases in seizures, especially in patients with eating disorders. There is little evidence of analgesic efficacy, but it is sometimes tried when its profile of effects would be beneficial.

Trazodone's primary mechanism of action involves antagonism of the serotonin receptor. It has indications for the treatment of depression and anxiety, but has been relegated to the treatment of primarily insomnia due to its tendency to cause sedation. There is limited evidence supporting its use as an adjuvant for pain management.

Stimulants

Stimulant drugs such as methylphenidate and dextroamphetamine/amphetamine, are typically used in the treatment of conditions such as attention deficit/hyperactivity disorder. However, in the medically ill, they do have a role in the treatment of depression (Kaufmann et al., 1982; Bruera et al., 1987; Fernandez et al., 1987) and they be beneficial for fatigue (Bruera et al., 1987, 1989). They are not used for pain.

Mood stabilizers

Mood stabilizers describe a group of medications typically intended to treat bipolar spectrum disorders. Broadly, this group consists of lithium, antiepileptic drugs, and medications generally utilized in the treatment of psychotic disorders. The mechanisms by which these medications are effective are not entirely known. Lithium is a first-line treatment for mania and bipolar disorder, notwithstanding a narrow therapeutic window and the need for close follow-up to avoid potentially fatal toxicities, particularly in the elderly and those with chronic medical illness. It also has limiting side effects including tremor, gastrointestinal disturbance, and nephrotoxicity, amongst other issues. It is not used for the purpose of pain management.

Some antiepileptics are approved for bipolar disorder and may have utility in the treatment of neuropathic pain. These include the gabapentinoids, gabapentin (Arai et al., 2010) and pregabalin (Bril et al., 2011), and topiramate (Attal et al., 2010; Howard et al., 2011; Callaghan et al., 2012). The gabapentinoids are considered first-line agents for neuropathic pain. Other antiepileptic medications used for psychiatric indications also are occasionally considered for pain. Valproic acid and its derivatives, such as divalproex sodium, are older drugs with well-established indications for a range of neurological and psychiatric conditions. Although they are generally considered to be a first-line treatment for mania, their broader use is limited by a side effect profile that includes gastrointestinal disturbances and the potential for hepatotoxicity and hyperammonaemia. There is evidence of efficacy in neuropathic pain syndromes (Howard et al., 2011; Callaghan et al., 2012). Carbamazepine also has efficacy in the treatment of mania, but generally is not considered first line because of the potential for bone marrow suppression and hepatotoxicity, and concern about drug–drug interactions. It, too, may have efficacy in neuropathic pain, and is indicated for the treatment of trigeminal neuralgia (Eisenberg, 2007; Howard et al., 2011). Oxcarbazepine is similar to carbamazepine, but has less risk of toxicity; evidence in bipolar disorder is limited, as is evidence in pain syndromes such as trigeminal neuralgia (Eisenberg, 2007). Lamotrigine has demonstrated efficacy primarily in the management of depressive symptoms in bipolar disorder, but its use is hindered by the risk of cutaneous hypersensitivity syndromes, which necessitate a slow increase in the dose when starting therapy and avoidance of the drug in children. There is limited evidence for efficacy in neuropathic pain (Howard et al., 2011; Shaikh et al., 2011; Smith and Argoff, 2011).

Anxiolytics

Medications used for anxiety include antidepressants (as mentioned previously) and drugs that modulate the function of gamma-aminobutyric acid type A (GABA$_A$) receptors, most

importantly the benzodiazepines. The latter drugs include alprazolam, clonazepam, lorazepam, diazepam, and others. Buspirone is a non-benzodiazepine serotonin agonist also indicated for anxiety. The only anxiolytic used commonly for pain in some countries is clonazepam. Evidence of efficacy is very limited, and it is reasonable to consider this agent primary for those circumstances in which anxiety complicates significant neuropathic pain.

Antipsychotics

Antipsychotic drugs are used to manage psychotic disorders, such as schizophrenia; problems such as agitation and aggression that may be complicating other psychiatric disorders; and manifestations of organic brain disorders, including frank delirium. Broadly, the group can be divided into low-potency typical, high-potency typical, and atypical. The low-potency typical drugs are typified by chlorpromazine. These drugs have low affinity for the D_2 receptor, which is seen as their primary site of action. As a result, they have a decreased likelihood of causing extrapyramidal side effects, but are more likely to cause anticholinergic side effects, which limit their utility in many chronically ill patients. The high-potency typical drugs are typified by haloperidol. They have a high affinity for the D_2 receptor and as a result tend to cause more difficulties with extrapyramidal side effects. However, they tend to cause fewer anticholinergic side effects than the low-potency agents, and fewer metabolic side effects than the atypical antipsychotics. The atypical drugs, including olanzapine and risperidone, have a variety of mechanisms and generally cause fewer extrapyramidal side effects than the typical agents. However, as a group, they tend to cause more metabolic side effects, such as glucose intolerance.

The antipsychotic drugs have a variety of indications that are beneficial in medically ill populations, including nausea (Patt et al., 1994) and delirium (Patt et al., 1994; Grover et al., 2011a, 2011b) although additional studies are needed to better support the latter (Lonergan et al., 2007; Flaherty, 2011). Their benefit in the management of pain, including cancer-related pain, is not well supported by available data (Lonergan et al., 2007; Lussier et al., 2004; Seidel et al., 2008, 2010). The exception is methotrimeprazine, which has been used as adjuvant therapy for pain with some demonstrated benefit (Patt et al., 1994).

Complementary therapies in pain management

Gary Deng and Barrie R. Cassileth

Introduction to complementary therapies in pain management

Pain is one of the most important symptoms that compromise patients' quality of life (QOL). Appropriate and adequate pain management remains challenging because pharmacologic treatment, the mainstay of pain management, does not always meet patients' needs and may produce difficult side effects. Interventional approaches, such as neuraxial analgesia and neuroablative techniques, and disease-modifying therapies, such as radiotherapy, are sometimes useful, but often are unavailable or contrary to the goals of care (Cherny, 2004).

The medical treatment of pain requires continuing effort to balance analgesic effects while minimizing adverse effects (Cherny, 2000; Paice and Ferrell, 2011).Opioid side effects are very common, particularly gastrointestinal effects (e.g. constipation, nausea, and emesis) and somnolence or cognitive impairment. Despite the many strategies that may be used to improve the balance between analgesia and side effects, such balance may not always be achievable (Cherny and Portenoy, 1994; McNicol et al., 2003).

Complementary therapies offer additional treatment options that are not traditionally part of Western medical care but can be incorporated into a multimodality care plan. Some of these therapies have demonstrated a favourable benefit:risk ratio in recent research and are increasingly used as adjunct therapies integrated into mainstream care. Clinicians who manage pain in populations with serious or life-threatening illness should understand the current state of evidence for complementary modalities, such as mind–body therapies, acupuncture, and massage therapy, and should be able to make recommendations for clinical practice.

Types of pain and analgesic mechanisms of complementary therapies

In general, complementary therapies reduce pain by interfering with the processing of pain signals. Mind–body therapies reduce the perception of pain by affecting psychological factors, such as anxiety or depressed mood, that can increase pain intensity or worsen the impact of pain on QOL. Neurophysiology and neuroimaging studies since the 1970s provide evidence that the analgesic effect of acupuncture is likely mediated via modulation of endogenous opioid and other neurotransmitter pathways,

activities in the limbic system of the brain, and the processing of pain signals in the central nervous system (Napadow et al., 2008; Han, 2011). The array of symptoms relieved by massage therapies points to both positive local effects on soft tissue, as well as subconscious mechanisms that control the experience of pain and emotions (Sagar et al., 2007).

Mind–body therapies

Mind–body therapies are defined as practices that focus on the interactions among the brain, mind, body, and behaviour, with the intent to use the mind to affect physical functioning and promote health (National Center for Complementary and Alternative Medicine, 2012). The most common symptoms that people turn to these therapies for are pain, dyspnoea, and fatigue (Wells et al., 2007). Mind–body therapies encompass a wide variety of specific therapies, such as hypnosis, meditation, yoga/qigong (which also has physical movement components), and music therapy.

Hypnosis is a practice by which a therapist induces, or instructs the patient on how to self-induce, a mental state of focused attention or altered consciousness between wakefulness and sleep. In this state, distractions are blocked, allowing the patient to concentrate intently on a particular subject, memory, sensation, or problem. Patients may receive suggestions, or self-suggest, changes in perceptions toward sensations, thoughts, and behaviours. In a systematic review of 21 studies (11 randomized controlled trials (RCTs), two non-RCTs, and eight case series), self-hypnosis provided pain relief in cancer patients and dying patients (Pan et al., 2000). However, a subsequent systematic review of 27 reports (one RCT, 24 case studies, and two other types of studies) concluded that the poor quality of studies evaluated, and the heterogeneity of study populations, limited further evaluation (Rajasekaran et al., 2005). More recently, a meta-analysis of 37 studies ($N = 4199$) on psychosocial interventions, including hypnosis, concluded that these modalities have a significant medium-size effect on both pain severity and pain interference with functioning, and that quality-controlled psychosocial interventions should be considered in multimodal approaches to pain management for cancer patients (Sheinfeld Gorin et al., 2012).

Importantly, there appears to be a widespread acceptance among the general public to consider the use of hypnosis to control side effects associated with cancer treatment (Sohl et al., 2010). This willingness to participate may in fact have an added impact. In a RCT evaluating a hypnotherapy intervention in a sample of

patients with metastatic breast cancer (N = 124), the intervention group had significantly less increase in the intensity of pain and suffering over time, and highly hypnotizable participants reported greater benefits from hypnosis, employed self-hypnosis more often outside of group therapy, and used it to manage other symptoms in addition to pain (Butler et al., 2009).

Meditation involves practices that invite heightened awareness and attention to one's own sensations, surroundings, and/ or inner mental processes. A particular type of meditation, mindfulness-based stress reduction (MBSR), provides the practitioner with the opportunity to develop an objective 'observer role' for emotions, feelings, and perceptions, and to create a non-judgemental 'mindful state' of conscious awareness. A meta-analysis of four RCTs and six observational studies totalling 583 participants showed that MBSR is beneficial for mood, anxiety, depression, and QOL in general, although not so much for pain specifically (Ledesma and Kumano, 2009). Several systematic reviews show similar findings (Smith et al., 2005; Matchim and Armer, 2007; Shennan et al., 2011).

Yoga and qigong are practices that combine physical movement, breath control, and meditative components. Yoga has been found to significantly improve anxiety, depression, distress, and stress in a meta-analysis of ten RCTs (Lin et al., 2011). RCTs evaluating pain as the primary end point in a palliative care setting are lacking. Similarly, qigong was found promising for stress reduction and improving QOL, but no strong data support its efficacy in treating pain specifically (Chan et al., 2012).

Music therapy takes advantage of the profound effect of music on a patient's emotional and spiritual state. Patients may listen to or participate in the performance of music and singing. There are a large number of qualitative studies demonstrating the benefit of music therapy in reducing pain and anxiety (Hilliard, 2005). A recent RCT that tested music therapist-guided autogenic relaxation and live music in 200 palliative care patients showed a significant decrease in pain scores (Gutgsell et al., 2013).

In general, mind–body therapies have the most benefit in reducing psychological complications from pain, or anxiety and distress that exacerbate the impact of pain on patients, rather than the pain itself. The side effect risk is low and most of these practices can be taught to patients for self-practice. Mind–body therapies should be considered for palliative care patients who are experiencing anxiety, distress, or sleep and mood disturbance in addition to pain.

Acupuncture

Acupuncture, a modality originating from Traditional Chinese Medicine, involves the insertion of needles into certain points on the body followed by stimulation of the needles using manual manipulation, electrical pulses, or heat. Its effects on pain are supported by numerous RCTs.

The strongest data for the analgesic effects of acupuncture comes from studies targeting pain in the absence of a serious illness. Systematic reviews and meta-analyses support its benefit in the management of joint pain (Collins et al., 2012), labour pain (Smith et al., 2011a), migraine (Linde et al., 2009a), tension headache (Linde et al., 2009b), dysmenorrhoeal (Smith et al., 2011b), and chronic pain in general (Vickers et al., 2012). For the treatment of cancer pain, a systematic review of 15 RCTs showed that

acupuncture did not generate a better effect than drug therapy (risk ratio (RR), 1.12; 95% confidence interval (CI) 0.98– 1.28; p = 0.09); acupuncture plus drug therapy demonstrated a significant improvement when compared with drug therapy alone (RR, 1.36; 95% CI 1.13– 1.64; p = 0.003) (Choi et al., 2012).

One study of particular interest is an RCT in which auricular acupuncture demonstrated superiority over sham treatment in the control of cancer pain (Alimi et al., 2003). Many of the patients in that study had persistent neuropathic pain that had not responded to other treatments. In the management of chemotherapy-induced peripheral neuropathy, both a controlled pilot study and a case series using acupuncture showed some benefit, but with very small sample sizes (Wong and Sagar, 2006; Schroeder et al., 2012). Acupuncture's effect on post-thoracotomy pain syndrome is mixed, with one study using embedded tiny needles showing no benefit (Deng et al., 2008) and another using electro-acupuncture demonstrating a reduction in opioid requirement (Wong et al., 2006).

The strongest support from clinical trials supports the efficacy of acupuncture for nausea and vomiting. A high-quality Cochrane systematic review of 11 trials (N = 1247) concluded that electro acupuncture has demonstrated benefit for chemotherapy-induced acute vomiting (Ezzo et al., 2006). In non-chemotherapy settings, another systematic review of more than 40 RCTs supports the effect of acupuncture in preventing or attenuating nausea and vomiting (Streitberger et al., 2006). Because the use of opioid analgesics may be associated with nausea and vomiting, acupuncture may be considered among approaches to address a common opioid toxicity.

In summary, the analgesic effect of acupuncture is supported by preclinical and clinical studies. Although its analgesic effects are better established in musculoskeletal pain and headache, and less well established for chronic pain due to cancer or other medical illnesses, the relative safety of acupuncture suggests that it should be considered in populations receiving palliative care—for both pain and nausea. Acupuncture is not associated with common opioid side effects, such as sedation, constipation, and nausea, and combining the use of both modalities appears warranted in order to manage pain in patients who do not respond favourably to opioids alone.

Massage therapy

Massage therapy involves applying pressure to muscle and connective tissue with the intent to reduce tension and pain, improve circulation, and encourage relaxation. Massage techniques most commonly used in oncology include Swedish massage, aromatherapy massage, reflexology, and acupressure. All involve manual manipulation of soft tissues of the body by a trained therapist. However, the methods of applying touch, degree of educational preparation, regulatory requirements, and underlying theoretical frameworks vary widely among these modalities.

Clinical studies show that massage therapy can reduce anxiety, depression, and pain in cancer patients. A 2009 systematic review of massage therapy for cancer palliation and supportive care examined 14 RCTs, which studied anxiety (seven RCTs; N = 514), depression (three RCTs; N = 107), or pain (six RCTs; N = 718) (Ernst, 2009). It concluded that massage can alleviate a wide range of symptoms: pain, nausea, anxiety, depression, anger, stress, and

fatigue. However, poor methodology among the studies makes the benefits encouraging but not compelling.

An earlier systematic review focusing on cancer patients included 12 RCTs, which also used anxiety (five RCTs; N = 236), depression (two RCTs; N = 63), and pain (three RCTs; N = 144) as end points (Wilkinson et al., 2008). The trials used standard care, attention, or low-intensity bodywork as control interventions. The reviewers concluded the data support massage therapy as an effective adjunct in cancer supportive care to reduce anxiety, depression, and pain, with stronger evidence for its effect on anxiety than depression or pain. However, the methodological quality of most included trials was poor.

Among non-randomized trials, results from an observational study (N = 1290) showed that massage improved pain scores for both inpatients and outpatients by 40%, and reduced other cancer-related symptoms by approximately 50% (Cassileth and Vickers, 2004). More recently, a pilot study comparing reflexology and Swedish massage therapy for cancer survivors aged 75 or older in nursing homes found that both interventions resulted in significant declines in salivary cortisol and pain, as well as improvements in mood. Further, both interventions were well tolerated in an elderly population of cancer survivors typically excluded from trials (Hodgson and Lafferty, 2012). Another randomized pilot study found that a combination of massage and other physiotherapy can reduce pain and improve mood in patients with terminal cancer (Lopez-Sendin et al., 2012).

In palliative care, precautions must be paid to the safety of massage therapy, as some patients may have a large tumour burden or bone metastases, and could be at risk for an exacerbation of pain, fracture, bruising, or bleeding. Strong pressure should not to be applied over areas of disease involvement. In these cases, gentle light touch massage or reflexology (hand or foot massage) can still be used.

Application in clinical practice

In summary, evidence supporting the use of complementary therapies in pain management is encouraging but not definitive. In considering various treatment options for clinical practice, the strength of the evidence in favour of efficacy must be weighed against the risks and burdens to patients, and the potential alternatives or the lack thereof. From this perspective, the mind–body therapies, acupuncture, and massage therapy have a favourable record. They may improve symptoms, and the medical risk and burden they pose usually is negligible. They also encourage patient self-care and empowerment, making patients active participants in their care.

The use of complementary approaches may present financial concerns, as most of the time they are not covered by health insurance, but coverage for these therapies is expanding and reflects consumer demand along with managed care efforts to control costs. Financial barriers also may be partially overcome. Patients can be taught to practice mind–body interventions themselves, and yoga/qigong or meditation classes can be given to groups. Acupuncture also can be given in a group setting to lower unit costs, or patients can be taught to do acupressure (application of pressure, usually with a finger, on acupuncture points). Family members or caregivers can be taught to safely give massages.

The origin of pain, and the factors complicating it, should be considered when selecting from among the complementary modalities for pain. If the pain is augmented by anxiety, fear, depression, or sleep disturbance, or if the pain exacerbates psychological distress, mind–body therapies and massage therapy should be considered. If opioid therapy creates undesirable effects, such as sedation, constipation, fatigue, nausea, and emesis, the addition of acupuncture has the potential of lowering the required dose of pain medications.

Each patient's belief system and cultural background should be taken into consideration. Patients who have a strong spiritual need, who wish a more naturalistic approach to health, and patients who have experienced benefit from these therapies previously, are more open to complementary therapies and appreciate their availability as an integrated component of mainstream care. Only by considering what is truly important to a patient as an individual can we provide optimal patient-centred palliative care, improve the quality of pain management, and comfort the patient to the best of our ability.

9.13

Paediatric pain control

Renée McCulloch and John J. Collins

Introduction to paediatric pain control

Pain is common in children requiring palliative care. It is one of the most prevalent and also the most feared symptoms (Wolfe et al., 2000; Jalmsell et al., 2006; Hechler, 2008; Feudtner et al., 2011). A child in pain can be a very distressing experience for the child, the family, and the clinician. As health-care professionals, we have a responsibility to respond, either through direct support or by seeking appropriate help.

Children treated by palliative care teams usually have pain that is a result of multiple aetiologies rather than a single cause. Pain is multidimensional, involving the emotional and sensory experience of the child within their developmental and social framework. Professionals working in the field need to be competent in the management of acute pain, chronic pain, recurring pain, procedure-related pain, and pain at the end of life. Pain is often a combination of nociceptive (visceral and/or somatic) and neuropathic pain. The expectation must be for exemplary pain control through meticulous assessment and treatment, using the skills of the multidisciplinary team. Essential to success are the development of effective communication and a trusting relationship between professionals, parent/carer, and child. An open and honest approach will allow dialogue about anxieties and misconceptions, which, if not addressed, may compromise successful treatment.

The study of pain in children started with recognition that pain is undertreated in this population (Schechter, 1989; Schechter et al., 1993). The last quarter of a century has seen unprecedented advances in the understanding and management of pain in children.

We know:

- infants can experience pain and failure to alleviate pain causes adverse physiological consequences and needless suffering
- children can experience many different types of acute, recurrent, and persistent pain
- children can describe their pain
- children's pain must be regularly monitored, evaluated, and assessed
- children may suffer prolonged pain due to disease, trauma, and psychological factors
- children in severe pain require strong analgesics for relief
- administration of opioids in children does not lead to addiction (McGrath, 1998).

Much research focus has been upon the assessment and management of acute pain and the neurophysiological basis of pain in the newborn and infants. These important strides are at the beginning of a long road to understanding and implementing evidence-based, effective pain management across the spectrum of paediatrics. Lack of resources and the significant challenge of undertaking research in children, hamper progress (McGrath and Ruskin, 2007; Berde et al., 2012). This lack of evidence extends to include children's pain during the palliative phase of illness.

Although pain is an area receiving significant attention in the literature, clinical practice is currently influenced by extrapolation of evidence from studies in acute pain in children and adult palliative care. Clinicians must be cautious about extrapolating data from different populations. Paediatric patients represent a variable and diverse subset of individuals from the premature neonate to the fully-grown, sexually mature young adult. Anatomy, physiology, cognitive responses, disease types, along with social, psychological, and environmental factors all differ. However, in spite of these concerns and the lack of 'robust evidence', a sensible and empirical approach with thorough assessment and good understanding of the disease process will enable a safe and effective therapeutic approach.

This chapter sets out some of the background and principles of pain management in children's palliative care. For the purposes of this chapter the term 'child' will include all children and adolescents up to the age of 16 years.

World Health Organization 2012 guidelines for a global strategy to improve pain management in children

Persisting pain in children is a global phenomenon recently highlighted by the World Health Organization (WHO) as 'duration of pain lasting beyond what one would expect from an acute injury'. This definition intends to cover longer-term pain related to medical illness and has no defined time frame. The latest initiative *WHO Guidelines on the Pharmacological Treatment of Persisting Pain in Children with Medical Illness* has taken the best available evidence and developed a new guideline to improve the management of persisting pain in children (WHO, 2012). As such it replaces the previous guideline *Cancer Pain and Palliative Care in Children* (WHO, 1998). The new guidelines are based upon the principle that, irrespective of whether an underlying cause can be identified, pharmacological and non-pharmacological techniques should be used to treat pain in children.

Importantly, the WHO recognizes that universal application and implementation of clinical recommendations will only occur through health system change; the significant barriers to delivering effective pain management in children are due to poor education and rigid health-care systems.

The child, pain, and palliative care

Why are children different?

Although there is no doubt that the core principles of pain management in palliative care can be shared between the adult and paediatric specialties, there are many differences that determine quite distinct practice.

Firstly, there is considerable variation in disease type and trajectory compared to adult palliative care. Approximately 60% of the paediatric palliative care team's patients have non-malignant conditions (Fraser et al., 2012; Hain et al., 2012). In developed countries, there is a range of diagnostic categories: congenital, genetic, neuromuscular, respiratory, cancer, and gastrointestinal conditions with a high prevalence of cognitive impairment (Feudtner et al., 2011). In sub-Saharan Africa overwhelming numbers of HIV-related illnesses in children are treated by paediatric palliative care teams (Amery, 2012). Long and unpredictable disease trajectories have necessitated combining efforts for proactive disease modification with palliation of symptoms.

One of the main differences between children and adults is communication. Communication is the cornerstone of effective pain management and can be a major challenge in children. Understanding and interpreting pain in verbal and non-verbal children with a range of developmental and cognitive abilities needs a different psychotherapeutic approach. Additionally, continuing cognitive and physical development throughout illness requires an informed and responsive team.

The variation and complexity of ethical dilemmas in children may offer the palliative care team significant challenge not seen in adult medicine (Nolan, 1993; McGrath, 2005). For example, although children cannot legally consent, their compliance and 'assent' are important requirements for treatment. Children should be involved in the decision-making process as much as possible (Bioethics Committee, Canadian Paediatric Society, 2004). Overprotective attitudes of health-care professionals and parents/carers can underestimate the ability of children to make informed decisions (American Academy of Pediatrics, 1995; Rylance, 1996).

Many of the medications used routinely in adult palliative medicine are not licensed for use in the paediatric population and are frequently prescribed outside the terms of the product licence. Although there are some weight-related profiles for dosing analgesic medications, many have not been studied for longer-term dosing (Hain et al., 2005). Factors that may influence prescribing include pharmacokinetics and pharmacodynamics, particularly drug clearance, changing size and surface area, mode of delivery of medication, and compliance.

When considering pain in infants and children, it is important to acknowledge how situational and social factors impact upon achieving optimal pain control. Infants and children are vulnerable as they depend upon the response of an adult to alleviate their pain. Dependence on proxy reporting and interpretation of symptoms is influenced strongly by the child's family and social structure, their culture, and beliefs. When unwell, this dependence extends to the health-care professional who also has their own social basis for understanding and interpreting the child's pain.

Finally, the role of the parents and family when a child is getting progressively worse is quite different to that of the family of the dying adult, necessitating a distinctive skill set and approach from the paediatric palliative care team. Parents often carry a particularly heavy burden due to the long-term nature of many conditions. This can result in increased incidence of depression and other psychosocial issues such as divorce and unemployment with extra burden placed upon siblings. Supporting the extended family of grandparents, parents, and siblings is an important part of the holistic care offered by the palliative care team (Davies et al., 2007).

Myths and misconceptions

It is important to address the myths and misconceptions surrounding pain in children. Unfortunately the entrenchment of these attitudes and beliefs has not only been in the general population but is frequently found within the clinical fraternity (Table 9.13.1).

Misconceptions regarding pain in the child with advanced disease abound. One of the most prevalent findings in clinical practice is the child or family or another professional questioning the use of opioid analgesia. Any combination of the misconceptions listed in Table 9.13.1 may be involved in forming this barrier and care must be taken to explore and counter these barriers.

Impact of persisting pain on the child

A child's individual experience of, and response to, pain is unique and depends upon the interplay of multiple factors. Pain behaviour is a reflection of age, gender, developmental level, previous pain experiences, family learning, and cultural background. These characteristics shape the child's interpretation and experience of pain.

There is little evidence that pain perception is modified by cultural or ethnic factors but the expression of pain by children and its subsequent interpretation by a caregiver may be affected by the sociocultural context of the patient or the caregiver (Finley et al., 2009). Therefore the meaning attributed to the pain might be governed by culture (Koffman et al., 2008).

Some of these characteristics are relatively fixed: age, developmental level, and family and cultural background. Others, such as emotional, behavioural, and cognitive factors can change dynamically, reflecting the particular circumstances when the child experiences pain (Fig. 9.13.1). These 'situational' factors represent an individual and specific interaction between the context in which the pain is experienced and the child's individual response (McGrath, 1990).

What children think, what they do, and what they might sense or feel, influences their pain experience deeply. The combination of situational factors (worsening physical function associated with disease progression, sleep deprivation, upset parents, and feeling worried and scared) that influence the meaning and context of the pain experience for the child, impacts upon the physiological response of the body (Palermo et al., 2006). The ability of the central nervous system (CNS) to respond in such a flexible and varied way, influenced by internal and external factors, both conscious and subconscious, is due to plasticity. Change in situational factors may indicate why the same pain insult, or tissue damage, can result in a varied response in different children and within the same child. It would also explain why analgesic efficacy can vary both in the same child and across groups of children with the same injury.

Pain can be caused, exacerbated, maintained, or reduced as a consequence of behavioural factors. Behaviours such as crying,

Table 9.13.1 Common myths and the scientific evidence

Myth	Scientific evidence
1. Newborns do not have a mature nervous system to experience pain	By 26 weeks, a fetus *in utero* is capable of experiencing pain. Pain pathways and the cortical and subcortical pain centres are well developed. At birth, a newborn is highly sensitive to pain (Anand, 1999) Response to pain in young infants has been well documented in behavioural and physiological studies and the newborn is well able to feel pain (Fitzgerald et al., 1988; Fitzgerald and McIntosh, 1989; Fitzgerald, 1991)
2. Children do not feel as much pain as adults	Children feel as much pain as adults, and perhaps even more (McGrath, 2005)
3. Children will get used to pain. If a young child experiences pain, they have no memory and it will have no lasting effect	Continuing pain has deleterious effects and causes long-term changes in the nervous system (Schmelzle-Lubiecki et al., 2007) Data suggest that early pain experience may produce permanent reorganization of developing neural pathways, which in turn may impact negatively on future pain experience (Anand and the International Evidence-Based Group for Neonatal Pain, 2001; Fitzgerald and Walker, 2009)
4. Children cannot explain their pain reliably	If asked, children are capable at a very young age (even at 20 months) of saying where it hurts, how much it hurts, and what makes the hurt feel better Children can report pain intensity at the age of 3 years Children as young as 4 years old can indicate pain on a body chart without being able to name their body parts (Craig and Korol, 2008)
5. If a child can be distracted, the child is not in pain	Children use distraction and play as a coping mechanism for pain (Kuttner, 1996)
6. If a child says that he/she is in pain but does not appear in pain, the child does not need relief	The child is the authority on whether or not he or she is in pain Adults and medical professionals: ◆ consistently and significantly under-rate children's pain ◆ often have concern that children exaggerate pain which causes them to discount pain ◆ diminish the seriousness of the pain and suffering as the pain may be difficult to treat (Craig et al., 1996; Pillai Riddell et al., 2008)
7. A sleeping child is a comfortable child	Sleep may be due to exhaustion from pain. Disturbed sleep patterns are common, this does not mean the child never sleeps (Long et al., 2008)
8. Opioid analgesics are dangerous for children and may result in addiction	Opioid analgesics are powerful pain-relieving medications that are invaluable for children in pain Children are no more at risk of addiction than adults Addiction is not experienced in patients with true pain on therapeutic doses (Schechter et al., 1993)

Fig. 9.13.1 The situation factors that modify children's pain perception.

Reproduced from PA McGrath and LM Hillier, Modifying the Psychological Factors that Intensify Children's Pain and Prolong Disability, in NL Schechter et al., (Eds.), *Pain in Infants, Children and Adolescents*, Second Edition, Lippincott, Williams and Wilkins, Copyright © 2002, by permission of Lippincott, Williams and Wilkins.

withdrawal, or becoming very distressed can impact negatively upon the pain experience. Emotional factors are known to have a direct impact upon the pain complaint, the persistence of pain, and the further development of pain. The emotional response of the child to pain depends upon the nature of the pain and the impact that it has on their everyday life. Feeling worried, fearful, cross, sad, and irritated will affect behaviours and therefore the ability of the child to cope with pain. Usually, increased emotional distress leads to a more intense pain experience.

It is important to try and understand the child's perception of their illness, what meaning they have attached to the pain, what their expectations are regarding the quality and severity of the pain, and what coping strategies have been tried in the past. Being able to provide accurate, age-appropriate information increases a child's sense of control and has a direct impact on their experience of pain. Offering children reasonable options and choices (e.g. 'Would you like tablets or liquid?' 'Would you like a heat pack or a massage?') with explanations about how treatments work and what to expect (e.g. 'This medicine might make you feel a bit sleepy, but this feeling should get better in a couple of days' and so on) also supports this process. Knowing how a child 'makes sense' of their pain, in terms of being linked to an internal or external causes, enables the team to understand how the child is projecting their pain and respond appropriately with pain reducing strategies.

Emotional and cognitive factors tend to feature most prominently in children receiving palliative care.

Case history

Ahmed, an 11-year-old boy with a brain tumour became more withdrawn and had aggressive mood swings. Ahmed's parents report that he often refused to take prescribed oral analgesic medications but are not sure whether he has any headaches, as he never complains of pain. Ahmed ultimately discloses that he has continuous pain from headaches with several severe episodes per day and that he often wakes from sleep with pain. He thinks that the tumour and therefore the pain, is a punishment from God that he has to bear in order to be forgiven for past wrong doings. Ahmed's pain management plan includes regular meetings with the family's spiritual advisor who clarifies the religious and existential meaning of Ahmed's illness. Ahmed is then able to comply with his analgesic regimen.

Impact of a child's pain on parents

Parents are the experts on their children. They act as an essential source of information for the health-care professional in the observation, assessment, and reporting of pain. Not only this, they are often the main carer and the most important resource for managing pain. They may guide and direct the health-care professional towards strategies that 'work' for their child.

Attitudes towards pain and behaviour patterns are often absorbed and learnt through parental role-modelling. Part of a child's response to pain stems from an inherited belief system and a familial approach to pain. Increased awareness of this can enable the health-care professional to influence the role of the parent in developing new and improving existing coping strategies.

Parents who encourage their children to engage in normal, everyday activities and support behaviours that encourage as much 'familiarity and routine' as possible, enable their child to maintain 'normality'. Children who lose their normal environment and adopt a passive role, tend to become more isolated and inevitably pain is heightened. Inadvertently, as children get sicker, the family becomes more insular and isolated from friends and relatives. As play and social interaction can help to lesson anxiety and offer some distraction from the situation, isolation can contribute to the experience of pain.

Parental education of pain mechanisms and management is important in ensuring that parents are not only able to comprehend and comply with a pain management plan, but are also equipped with the correct information to pass on to their child. Educating parents regarding rationale for treatments, how disease processes and situational factors impact upon pain, what to expect from medication in terms of benefits and side effects, and non-pharmacological pain control techniques, is absolutely vital. Parents have described the need to be 'enabled in their caring' for their child at the end of life and that this is central to coping with the stress and uncertainty of living through the death of a child (Price et al., 2011).

How parents respond to their child in pain is critically important to how both parent and child attempt to cope with pain (Palermo and Chambers, 2005). Response from carers that offer a calm and consistent approach, or encouragement to use an effective pain coping strategy will influence the experience of pain (Mitchell et al., 2007). Studies have shown that parental characteristics, such as gender and likelihood for catastrophic thoughts, as well as the threatening context of pain, play an important part in regulating parental response (Schneider et al., 2011; Caes et al., 2012).

Evaluating pain in children

Evaluation of pain is the cornerstone of good pain management in children. This process includes a detailed pain history, examination, diagnosis of the causes, and subsequent measurement of pain. The consequence of pain upon the child's activity and daily routine needs to be established. In children, understanding the impact of pain upon behaviour, relationships, development level, emotional state, sleep, and physical function is essential (Palermo, 2009).

Box 9.13.1 shows a summary of questions that are pertinent in the evaluation of childhood pain (WHO, 2012).

Level of cognitive development and expression of pain by children

How pain is perceived and expressed is modulated by various factors including the age and cognitive development of the child. Over the course of child development, change can be observed in the way pain is expressed and communicated (von Baeyer and Spagrud, 2003).

Infants

The infant is totally helpless and dependent upon the carer/parent to recognize pain behaviours. As infants have no language, facial expression and pitch of cry are the characteristics used to assess pain in infants (Grunau and Craig, 1987). Moreover, there is no single behaviour that indicates pain; more a deviation from the norms of behaviours that indicate the baby is experiencing pain. Most babies cry when they experience pain or may attempt to pull away from a painful experience or 'guard' or protect the painful limb or area (Hadjistavropoulos et al., 1994). By 6 months of age,

a baby will be fearful of anticipated painful situations if they have previously experienced pain in the same context (Lilley et al., 1997). Gibbons et al. have found that extremely premature babies have a similar pain response compared to babies born at older gestational ages but their responses are damped down (Gibbins et al., 2008).

Toddlers

As a baby grows and develops it starts to learn how to communicate discomfort through speech and body language. Frank reports that children rapidly develop an extensive pain language between the age of 12 and 30 months. Difference in verbal expressions make a cognitive distinction between the origins and sensory aspects of pain (Franck et al., 2010). If the child has the right descriptive language and uses terms to describe their pain ('sore', 'ouch') then they can often indicate a part of their body that is in pain. Children in this age group display fear of painful situations and often demonstrate anger, upset, and sadness if they experience pain.

Preschool children

Children aged 2–5 years can understand vocabulary for both positive and negative emotional experience (Azize et al., 2011). They think in concrete terms and as they grow, start to distinguish between the cause and the consequence of pain, particularly if they have some memory of previous painful experiences. Although they may find pain distressing, they are usually able to express themselves and may use their own specific words and terminology that can describe pain (Craig et al., 2006). With prompting they are able to understand and learn words that help describe their pain.

Children in this age group experience 'magical thinking' with blurring of boundaries between fantasy and reality. They create explanations for pain and may regard the pain as a punishment or a consequence of an unrelated event or behaviour. Creative play can be a helpful way to discover a child's understanding and interpretation of pain.

The preschool child with chronic pain may stop thinking of their pain as an abnormal perception, stop reporting the pain and become 'withdrawn'. Gauvain-Piquard has described this as the child being 'too well behaved' and becoming overwhelmed by their pain (Gauvain-Piquard, 1997). The clinician must be watchful for this observation.

School-aged children

Children between the ages of 6 and 12 years are more adept at abstract conceptualization. At 6 years old a child can define pain intensity and children from 7 to 10 years can explain why it hurts (McGrath and Craig, 1989). They are able to link cause and effect more easily and understand concepts of time. Children in this group are able to learn more detail about their pain and explanation of facts can assist understanding and allay fears and misconceptions. Younger children in this age group may perceive their pain as a punishment. Negative emotions and feelings of persecution may arise with chronic pain and internalization resulting in withdrawal and a label of 'depression' can be a feature.

Adolescents

Teenagers are able to think in an abstract way about pain. They understand the psychological element of the pain experience as well as the physical aspect. They have insight and are able to reflect upon their pain experiences in a more systematic and flexible way, drawing upon their individual coping strategies to support this process. Most adolescents shift from strategies focused upon emotion to strategies focused upon the causative problem around the age of 15 years.

Adolescence is a time of personal growth and independence. Pain, as a consequence of a persisting or progressive disease, can undermine this natural evolution. Pain can therefore become an injustice and an aggressor. Some teenagers may show signs of regression in their ability to cope with pain, particularly when there has been longer-term disease treatment and previous pain-related learned behaviours might emerge. It is important to address adolescents on an individual basis. If questioned in front of parents or peers there is often a tendency to 'play down' or deny pain in these situations. Teenagers can be very receptive to being taught coping strategies for pain management.

Response to pain in adolescents is based upon understanding (of disease, prognosis, and treatments), emotional (fear, anxiety, sorrow, and frustration) and cognitive factors (personality, beliefs, and culture). Trembly and Sullivan have shown that attachment style and cognitive-affective factors might increase vulnerability for problematic pain outcomes in adolescents. In a group of 382 high school students preoccupied and fearful attachment styles were associated with heightened pain severity, depression, pain catastrophizing, and anxiety (Tremblay and Sullivan, 2010). Worry is prevalent in youth and develops early in adolescents. Catastrophizing about pain usually can be thought of as extreme worry involving repeated thought about threat as uncontrollable and likely to have 'awful' consequences (Eccleston et al., 2012).

The child with severe cognitive impairment

There has been a growing awareness of the pain experiences of children with cognitive impairment and how pain perception may be affected in this cohort (Hunt and Burne 1995; Oberlander, 1999; Breau et al., 2003; Malviya et al., 2005). Understanding pain in a child with profound cognitive impairment is recognized as challenging, as the usual verbal and behavioural cues may not be reliable (Hunt et al., 2003). This group of children has an increased incidence of pain in their everyday lives but is reliant on parents and caregivers to recognize a problem (Breau, and Burkitt, 2009; Herr et al., 2011). Parents and carers develop a refined skill set that recognizes their child's individual emotional and behavioural cues that are suggestive of pain (Carter et al., 2002; Hunt et al., 2003). Pain is seen as an inextricable part of everyday life (Oberlander, 2001). Parents often report that pain is something that children with severe cognitive impairment learn to live with and tolerate (Fanurik et al., 1999).

The malnourished child

Attention must be paid to children with severe malnutrition as they are often developmentally delayed, perhaps through under stimulation or as a complication of an associated chronic condition. This group expresses pain in a markedly different way with lack of facial expression and verbalization and limited physical response. Under- development and indifference may instead result in whimpers or faint moans (Albertyn, 2007).

Pain severity measures

Several pain assessment measures have been developed and validated specific to the paediatric population. There is no single tool that is appropriate across all ages or all types of pain. The choice of a scale is dependent on developmental age, cognitive ability, and the necessity for carer report. Most pain scales have been developed and validated for acute pain. A significant amount of work has been published on scales for those children who cannot communicate verbally. There is no scale specifically for children receiving palliative care.

Pain measures must have well-established reliability and validity and have been used to measure pain outcome (in clinical trials) and improve clinical practice (efficacy) (Franck and Bruce, 2009). The best available evidence informing current practice is from systematic reviews by the Society of Pediatric Psychology Pain Assessment Task Force and the Paediatric Initiative on Methods Measurement and Pain Assessment in Clinical Trials (Stinson et al., 2006; von Baeyer and Spagrud, 2007; Cohen et al., 2008a, 2008b; McGrath et al., 2008; Huguet et al., 2010).

There are three approaches for measuring pain in children: self-report, observational or behavioural, and physiological. Physiological changes such as heart rate and respiratory rate are only loosely correlated to painful events and do not distinguish between pain and anxiety (Hain, 1997). The most commonly used tools rely on the quantification of pain intensity by self-report and are based upon counting or 'grading' pain severity in acute pain. Scales recommended for the quantification of acute pain and persisting pain in children over 3 years are the Faces Pain Scale –Revised, Poker Chip Tool, the Visual Analogue Scale, and the Oucher Photographic and the Numeric Rating Scale (WHO, 2012).

Table 9.13.2 Behavioural responses to pain

Behavioural indicators of acute pain	Behavioural indicators of chronic pain
Facial expression	Abnormal posture
Body movement and posture	Fear of being moved
Inability to be consoled	Lack of facial expression
Crying	Lack of interest in surroundings
Groaning	Undue quietness
	Increased irritability
	Low mood
	Sleep disruption
	Anger
	Changes in appetite
	Poor school performance

Observation of behavioural cues is a valid approach to acute pain severity assessment in children under 3 years old and those with impaired cognitive and verbal ability. Methods for observational measurement of acute pain are much more established than methods for longer lasting or chronic pain.

The absence of visible signs in a child with persisting pain is common. However, these observational signs may be present during an exacerbation of pain, such as on moving or on perceiving a social cue, for example, someone asking about the pain (von Baeyer and Spagrud, 2003).

There are no validated scales in children for chronic or persisting pain. Only the Douleur Enfant Gustave Roussy (DEGR) (Gauvain-Piquard et al., 1999) attempts to distinguish between acute and chronic cancer pain in children. However the DEGR takes some time to perform and further validation is required (von Baeyer and Spagrud, 2007).

Overt signs of pain tend to dissipate if pain is present longer term. There is also great variability as to the expression of persisting chronic pain in different individuals (von Baeyer and Spagrud, 2007). More complex changes in behaviour are likely to be manifest in chronic pain states, for example, low mood, increased irritability, sleep disturbance, being aggressive, and changes in appetite, all of which require knowledge of the child's baseline temperament (Palermo, 2000). Generally, sleep is of poor quality (Long et al., 2008; Palermo et al., 2008). Children with chronic pain may have negative thinking or may catastrophize about pain and experience increased pain severity and physical symptoms. Catastrophic thinking also contributes to psychological distress and functional disability (Vervoort et al., 2006).

Children who have persisting pain may display a variety of behaviours including being withdrawn, silent, and passive, and are often labelled as 'depressed' or even 'very well behaved' (Gauvain-Piquard, 1997). This psychomotor inertia has been well described and is a sign of untreated or undertreated, chronic pain. Other children may be seen as 'difficult' patients with aggressive behaviour and mood swings. Again this must be considered as pain-related behaviour if it is not the norm for the child.

Recognition of these signs and prescription of appropriate analgesia is the most appropriate approach to these issues.

Children may decide not to disclose information or under report pain if they associate the outcome as having a negative impact; for example, requiring a hospital visit or inpatient stay, necessitating an unpleasant intervention such as an injection, or causing upset or worry to their parents. Absence of signs and absence of reporting does not equate to absence of pain.

The literature is currently replete with studies regarding acute pain assessment in children. However, there has been concern in more recent publications regarding what is advocated by pain experts and researchers and what is actually delivered in clinical practice (Taylor et al., 2003; Franck and Bruce, 2009; Wadensten et al., 2011; Voepel-Lewis et al., 2012). Over the past decade, questions have been raised as to the efficacy of current interpretation of pain measurement in paediatric clinical practice (Hodgins, 2002; Mularski et al., 2006; Voepel-Lewis et al., 2011; von Baeyer et al., 2011). Franck (2009) states that 'poor compliance with pain assessment in children may not be the result of a "theory to practice gap" but may indicate unspoken resistance to methods that are overly simplistic, burdensome to patients, often inaccurate and perhaps even disrespectful of clinical expertise and experience'. Many experts acknowledge the complex influence of multiple intervening factors that influence children's pain expression and expose the challenges in interpreting individual pain scores in clinical practice (Schiavenato and Craig, 2010).

Hajistavropoulos and Craig (2002) have described the social communication model of pain for understanding pain in children. This conceptual model integrates biological, psychological, and social perspectives at the level of interaction between the child in pain and the person present (parent, carer, or professional). It presents a framework for the numerous and complicated interactions among psychological and social determinants of pain through the process of pain communication (Hadjistavropoulos et al., 2011).

This model describes four domains: the child's *experience* and *expression* of pain, together with the adult's *assessment* and *action* taken. Identification of these domains, and importantly the intra- and interpersonal factors that influence each step, enables appreciation of the complexity of assessment and organization of thought around the process. Acknowledging the social context of pain in infants and children enables identification of barriers that may prohibit adequate pain management (see Fig. 9.13.2).

Despite these areas of concern that simply highlight the complexity of the issue, the available tools for pain assessment can be used effectively in palliative care, particularly during exacerbation of pain symptoms. Rating pain before and after analgesic or non-pharmacological intervention, in addition to assessment of situational factors, can be used to assess efficacy of management.

As persisting pain in serious illness affects physical and social functioning and consequently quality of life, measures that incorporate a broader assessment may be more suitable in palliative care patients rather than single-pain intensity measures.

Pain management

Optimal pain relief in children's palliative care is achieved through the holistic assessment of the child. An integrated pharmacological and non-pharmacological approach for controlling a child's pain is shown in Fig. 9.13.3.

The pharmacological management of pain in children: the 2012 WHO approach

The 2012 guidelines have been developed by an expert working group using the best available evidence and aim to cover 'persistent' pain in children with medical illness (WHO, 2012). It is important to highlight that the WHO guidelines act as a framework and pharmacological point of reference for those working with children. The guidelines do not attempt to address the non-pharmacological approach to pain. This is relevant to palliative care teams as management of pain in children is always inclusive of the psychological, emotional and existential domains of 'total' pain.

The guidelines reiterate the key principles of pain management in children:

1. Ensure that detailed assessment has occurred.

2. Dose analgesia at regular intervals when pain is constant ('by the clock').

3. Make sure medication is available for 'break through' pain episodes.

4. Use the simplest route of administration ('by the appropriate route').

5. Tailor treatment to the individual ('by the child').

Using a two-step strategy

Modifications of the original WHO guidelines have included moving from the 'three-step analgesic ladder' (mild vs moderate vs severe pain) to a 'two-step analgesic approach' (mild pain vs moderate to severe pain).

A strong recommendation by the expert group but with very low-quality evidence, this decision-making was centred on a more effective strategy for analgesic management in children and various concerns regarding the 'weak' opioids Tramadol and codeine have been excluded from the guidelines based upon the safety and efficacy of these medications in children. There is no available evidence for the effectiveness and safety of tramadol in children. Codeine has varied metabolism across the population and in neonates and children it has a very low analgesic effect but a significant side effect profile (Williams et al., 2002; Tremlett et al., 2010). Concern regarding the use of strong opioids in children is offset by poor efficacy and unknown response to the weak opioids. In effect the 'weak' opioids are not recommended for use in paediatrics and have been replaced with a low dose of a 'Step 3' or strong opioid. The 'level' of approach is determined by severity of pain.

Step one: mild pain

Paracetamol and ibuprofen are the medicines of choice in children over the age of 3 months with mild pain.

Paracetamol

Paracetamol (acetaminophen) provides effective relief from mild pain and is widely available and well tolerated. It is also one of the few analgesics that can be used safely in neonates and children under the age of 3 months. Available in syrup, tablets, and parenteral formulations, it has a low adverse effect profile when used in appropriate doses. Doses of intravenous paracetamol for children and neonates should be based upon body weight rather than age (Van Den Anker et al., 2011; Mohammed et al., 2012).

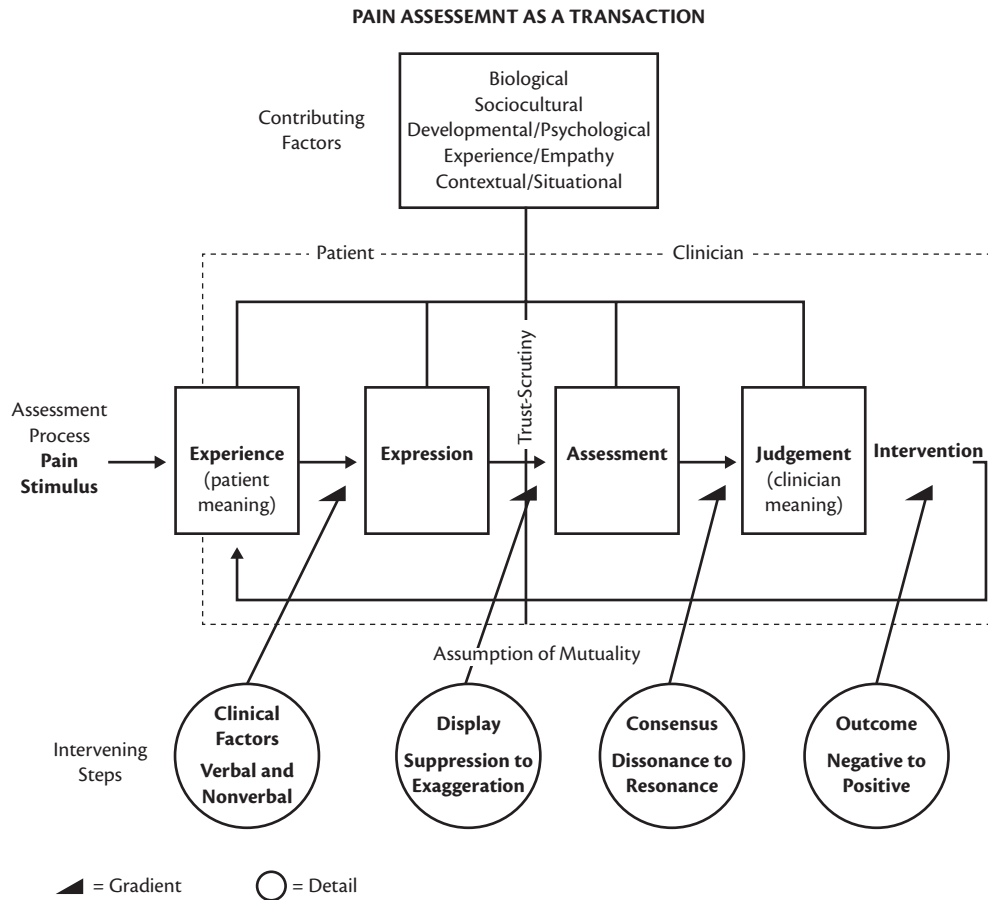
PAIN ASSESSEMNT AS A TRANSACTION


Fig. 9.13.2 Pain as a social transaction.

Hepatotoxicity is rare but can occur in vulnerable children at therapeutic doses (Haun et al., 2002). Risk factors that increase toxicity are those that can frequently be present in the paediatric palliative care population: hepatic or renal disease, malnutrition, and enzyme induction with various drugs (including carbamazepine; rifampicin and phenobarbitone amongst others). There are no data on the safety of long-term paracetamol administration in children.

Ibuprofen

Prescribing of ibuprofen is common in paediatric practice. Ibuprofen is safe to use in children and the risk of renal, gastrointestinal, and cardiovascular side effects is low, although care must be taken in children who are dehydrated (Southey et al., 2009). Ibuprofen must also be used cautiously in children with cancer due the increased risk of platelet dysfunction and subsequent bleeding.

Step two: moderate to severe pain

Children assessed with moderate to severe pain should have an opioid analgesic administered. The second step recommends the use of low-dose opioids for moderate pain. Risks regarding the use of strong opioids in children can be offset by effective risk management systems and importantly pain management education. The WHO guidelines reiterate that fear and lack of knowledge regarding the use of opioids in children should not be a barrier for effective analgesia (WHO, 2012).

Opioid analgesics

It has been estimated that 60–80% of children who die require opioids for the management of pain (Zernikow et al., 2009). The palliative care physician should have confidence and familiarity with the range of opioids availability, their scientific basis for action, and side effect profile. There are occasions when children who could benefit from opioid therapy are, or their family is, unwilling to take opioids. This is usually based on misconceptions about their use and the perception that opioids mark 'the beginning of the end'. These fears need to be explored and correct information provided. Many parents need support in understanding the difference between physical dependence, tolerance, and addiction. There is no empirical evidence that children receiving opioid analgesics are at risk for addiction. Significant time and educational investment is often needed, usually on repeated consults, to allay fears and misconceptions and ensure adequate understanding for adherence to pain management plans.

There is a great variety of opioids available to the paediatric palliative care physician in some countries; however, there are no proven benefits of using alternatives to morphine in children. Morphine is well established as a first-line opioid in children as it is inexpensive and has a wide range of formulations; however,

Assess the child with pain

- Assess sensory characteristics of pain
- Conduct medial examination and appropriate diagnostic tests
- Evaluate involvement of peripheral and central mechanisms
- Evaluate contributing situational factors

Differential Diagnosis

Diagnosis based on primary and secondary sources of nociceptive activity

Develop treatment plan

Analgesics
- Non opioids
- NSAIDs
- Opioids

OR

Anaesthetics
- Neurolytic blockade
- Epidural anesthesia
- Regional block
- Topical anesthetic

PLUS

Cognitive
- Psychotherapy
- Hypnosis
- Imagery
- Distraction and attention
- Choices and control
- Information

and/or

Phycical
- TENS/acupuncture
- Thermal stimulation
- Physiotherapy
- Massage

and/or

Behavioural
- Behavioural modification
- Biofeedback
- Relaxation therapy
- Exercise

Implement plan

- Provide feedback on cause and contributing factors to child and parents
- Provide rationale for integrated treatment plan
- Measure child's pain regularly
- Evaluate effectiveness of treatment plan
- Revise plan as necesary

Fig. 9.13.3 A model of integrated pharmacological and non-pharmacological approach for controlling children's pain.
Adapted with from PA McGrath, Pain Control in Children, pp. 32–43, in RS Weiner (Ed.), *Innovations in Pain Management: A Practical Guide for Clinicians*, Paul M. Deutsch Press, Copyright © 1992, with permission of DC Press.

alternative strong opioids can be considered based upon scientific evidence, pain pathophysiology, safety, and availability.

Effective analgesia is achieved through gradual increase in opioid until pain relief is achieved. High-dose opioids may be needed at times (Collins et al., 1995).

Dosing at regular intervals: by the clock

When pain is severe and constant, opioid analgesia must be prescribed on a regular basis rather than 'as needed'. Theoretically the dosage interval of morphine is shorter than that of adults as the half-life of morphine in children is reduced compared to adults (Zernikow et al., 2009) Nonetheless there is wide inter-individual variability. In practice, a 4-hourly dosing schedule for immediate-release opioid works well. Some children may benefit from an 8-hourly dose of long-acting opioid preparations rather than the standard 12-hourly regimen (Hunt et al., 1999).

The exception to this 'rule' is when the half-life of the opioid is increased. This occurs in neonates and infants up to the age of 12 months who, amongst other pharmacokinetic differences, have reduced renal clearance of morphine. Neonates and infants (under 12 months) are, therefore, prescribed a lower starting dose of opioid at longer intervals, for example, 6- or 8-hourly.

Impaired renal function is another indication to approach opioid dosing cautiously. It is sensible to use immediate release opioids at a dosing schedule of 8- or 12-hourly or even as needed initially until titration of dose interval to requirements in the individual patient is established. Effectively the immediate release opioid has a longer acting duration as excretion is delayed.

Using the appropriate route of administration: by the mouth

The least invasive route, the oral route, is usually preferable in children. As such, palatability, availability of oral solutions, size of tablets, and frequency of dosing become factors to consider to ensure compliance and, consequently, good symptom management. Unless these factors are reviewed regularly, administering medication in children can become a major issue and may be a source of conflict between child and parent/carer. Endless drug regimens with poor planning and lack of individual consideration can create 'battles and barriers', affect relationships and impact on quality of life.

Some manufacturers have developed concentrated oral solutions to facilitate administration of medication for children who are unable (or unwilling) to take tablets. It is also common in

paediatric practice to open capsules, to crush tablets, or to dissolve medication into solution and then to mix the powder or solution with more palatable food and drink. Consequently there may be issues regarding accuracy of dosing.

Many children with complex neurological disease, or those receiving cancer treatment, may have a gastrostomy *in situ*. Although these devices can be incredibly helpful, negating palatability and dose frequency issues, other problems may arise as several commonly used medications cannot be given via gastrostomy due to interaction between the medication and the device.

There are several situations when the enteral route might not be suitable and an alternative route must be sought, for example:

- poor absorption: vomiting, disordered gastrointestinal motility
- inability to comply: unconscious; severe nausea, poor swallow; risk of aspiration, medication refusal
- pain crisis requiring rapid titration of opioids.

The choice of alternative routes of administration when the oral route is not possible should be based on clinical judgement, availability, feasibility, and patient preference.

Other routes of medication administration in children

Alternative routes of administration of analgesics in children include the subcutaneous, intravenous, or transdermal routes. The intramuscular route is practically obsolete in children as the injection itself is a cause of pain and may result in under-reporting of pain.

The availability of short-gauge, indwelling, non-metallic needle systems has been very useful and made the subcutaneous route popular in paediatric practice. Ease of insertion, the possibility of numerous sites for access, and avoidance of recurrent intravenous cannulation offer obvious benefit. Drugs, and if necessary, fluid can be delivered effectively via this route.

Indwelling percutaneous intravenous catheters or central venous access devices are used frequently for children requiring long-term therapy, recurrent blood product transfusion, and/or parenteral nutrition. They can be useful in the palliative setting towards the end of life for delivery of analgesia and other medications, particularly if higher-volume infusions are needed. The risk of sepsis and the impact of the catheter on the child's activities of daily living and quality of life must be measured against the benefits and ease of intravenous access. The successful use of patient (or proxy) controlled analgesia has been reported in children at the end of life (Schiessl et al., 2008; Anghelescu et al., 2012).

The development of 'transdermal' medication patches has been particularly advantageous to children with chronic, stable opioid requirements (Hunt et al., 2001). Although the minimum quantity of opioid required for use might provide a barrier in smaller children, the more recent manufacture of lower-dose, matrix-based patches has enabled more children to gain from the clear advantages offered by this route.

Medication delivered by the rectal route may be advantageous in some instances but many children dislike this way of giving medications. It can be a very useful route in the infant and younger child to avoid parenteral routes in the short term. Additionally some immediate and sustained release opioid preparations can be readily absorbed from the rectal mucosa. Anticonvulsants have also been reported to be given via this route in special circumstances (Anderson and Saneto, 2012).

The transmucosal route has become an increasingly popular means to deliver medication in children. Drugs absorbed through the transmucosal membrane of the nose or buccal cavity avoid the first-pass metabolism of the gastrointestinal tract and are absorbed rapidly. This mode of delivery is particularly effective for drugs such as midazolam, which is now available for this use in a concentrated buccal form. Diamorphine has also been used very effectively via this route for breakthrough pain although intranasal fentanyl has received more attention in the literature (Crellin et al., 2010; Mudd et al., 2011; Harlos et al., 2013). Although alternative opioids are available for sublingual, transmucosal, and nasal use, there are often issues regarding the practicalities of appropriate dosing, particularly in younger children when lower doses of opioid preparations for nasal, sublingual, or buccal use may be very helpful for rapid relief of symptoms. End-of-life symptoms including pain, dyspnoea, agitation, and seizures have been controlled successfully via the transmucosal routes but unfortunately literature supporting this is scarce.

Adapting treatment to the individual: by the child

This principle promotes individualized treatment according to the assessed need of the child. Finding the right dose of opioid for a child involves three phases:

Initiation: the initial starting dose of medication in an opioid naïve child is usually calculated per kilogram of body weight (up to a maximum dose of 50 kg). The WHO guidelines have added a specified age range to allow for changes in pharmacokinetics in the growing child. In a child already receiving opioids the current dose of opioid should be used as a basis for calculation.

Titration: the dose of analgesia is titrated on an individual basis. Opioid analgesics must be increased in steps until the correct dose, based on the child's response to medication. The correct dose of opioid is determined in partnership with the child and carers until the best possible pain relief is achieved, with the fewest side effects. Generally the maximum dose increase is approximately 50% of the previous total opioid dose in non-naïve opioid patients, however in an inpatient setting, with careful monitoring and repeated assessment, experienced practitioners may increase doses more rapidly (WHO, 2012).

Maintenance: is established once a dose that provides adequate relief of pain is achieved. A long-acting opioid is commenced at this point, if available. For many children, long-acting morphine preparations (granules) are convenient and offer flexible dosing. A minimum total daily dose of oral morphine 30–40 mg is required prior to commencing the lowest available dose of a fentanyl 12-microgram patch, which can prohibit use in many small children.

Internationally the availability of child appropriate dosage formulations is often very limited and prohibits optimal analgesia. Efforts to ensure availability are supported through the *WHO Model List of Essential Medicines for Children* (WHO, 2013).

Opioid switching

Opioid switching should be considered in children who have opioid dose limiting side effects. A reduction in the equianalgesic dose of the new opioid by approximately 25–30% is recommended to reduce toxicity and counter the possibility of incomplete cross-tolerance.

Opioid side effects

Children may not report adverse effects voluntarily, for example, constipation, nausea, and itching, so careful attention must be paid to these problems when assessing opioid efficacy.

Sedation is usually one of the first side effects that occur when opioids are commenced in the opioid naïve patient or when the dose is increased significantly. Drowsiness may last for a few days but then usually subsides. Warning parents and carers avoids any unnecessary worry about sedation.

If opioids are titrated appropriately, respiratory depression is a very rare occurrence. In palliative care patients, opioid toxicity is more likely to occur when there is sudden removal of a pain stimulus, such as following radiation therapy to a bone metastasis or the insertion of an intrathecal pump for metastatic spinal disease. In these situations it is helpful to revert to short-acting opioids, or an opioid infusion, to enable close monitoring of opioid requirements. The onset of renal failure and an inability to excrete opioid metabolites is another potential reason for respiratory compromise, as is the inadvertent administration of higher doses of opioid than those prescribed, such as ingestion of sustained-release medication in the place of short-acting opioids.

If sedation persists, and renal or hepatic and CNS disease are excluded, an opioid switch should be considered. Sedation may be caused by an accumulation of morphine's centrally acting metabolite, morphine-6-glucaronide, hence a different opioid such as fentanyl may have a more favourable ratio of analgesia to side effects. Rarely, paradoxical agitation can be seen in children taking opioids. Treatment is reduction in dose or switching of opioid.

If respiratory depression occurs then small, frequent doses of naloxone (an opioid antagonist) may be necessary at a starting dose, in opioid-tolerant patients, of 1 microgram per kilogram, titrated over time (e.g. every 3 minutes) until the child is breathing spontaneously. A low-dose infusion of naloxone may be required until the adverse effect of the opioid resolves. Administration of naloxone must be done with caution as reversal of analgesia will precipitate extreme pain and opioid withdrawal syndrome. Assisted ventilation for respiratory depression may be indicated in palliative care patients in this situation.

Psychostimulants such as methylphenidate have been used in adults to reverse opioid-induced sedation, despite a recent review stating that robust data are lacking (Stone and Minton, 2011). A small study in adolescents in cancer and various case reports describe use in younger populations, however concomitant adverse effects such as delirium, psychosis, and hallucinations might deter use (Yee and Berde, 1994).

The incidence of nausea seems relatively rare in paediatric palliative care and, in contrast to adult medicine, most physicians do not prescribe antiemetics automatically in conjunction with an opioid. However, its incidence may well be overlooked in children (Mashayekhi et al., 2009), as it is not a symptom children find easy to describe.

Constipation is very common in children prescribed opioids. Regular stimulant and softening laxatives should accompany all opioid therapy. There is good evidence in adults that the opioid antagonists naloxone and methylnaltrexone are effective in opioid-induced constipation without causing opioid withdrawal (Sykes, 1996; Portenoy et al., 2008; Chamberlain et al., 2009; Candy et al., 2011). There is no such evidence in children, although

there are now published paediatric cases which report successful management with these drugs (Lee and Mooney, 2012). Fentanyl has been reported as causing less constipation than other opioids (Finkel et al., 2005; Zernikow et al., 2007).

Pruritus as a side effect of opioids is not uncommon in infants and children and occurs frequently around the nose and face. Standard management for pruritus can be trialled, however if it persists an opioid switch may be required (Drake et al., 2004; Mashayekhi et al., 2009).

Myoclonus is an involuntary muscle contraction that occurs as a consequence of either opioid toxicity or long-term use of opioids. It is not infrequent in children and usually prompts opioid switching or treatment with a benzodiazepine or muscle relaxant, depending upon the circumstances.

Urinary retention is seen in children particularly after rapid dose escalation and spinal or epidural opioids. Anecdotally, children seem to experience urinary symptoms (usually hesitancy) not infrequently; however, a small case series indicated that one in seven children (14%) had overt symptoms of retention (Mashayekhi et al., 2009). External bladder massage/pressure, heat packs, voiding in a warm bath, and, if necessary, intermittent catheterization or cholinergic agent may be required. Opioid rotation is also an option.

Non-malignant pain and use of opioids

Data on the use of opioids in children with severe pain due to non-malignant conditions are limited. One retrospective review studied opioid prescription for chronic, severe non-malignant pain in a multidisciplinary paediatric pain clinic. During a 12-month period, 104 patients were seen in the clinic, of whom 49 received an opioid as part of their pain management; 11 received an opioid for more than 3 months, and five of these were still receiving an opioid at the end of the study period. Overall, there appeared to be better pain control and improved function in patients receiving opioid therapy in the context of prescription in a multidisciplinary pain clinic with close review and a multisystem approach to pain management. More data are needed to know if such therapy is safe and beneficial on a longer-term basis (Slater et al., 2010).

Adjuvant analgesics

An adjuvant analgesic is a medication that has a primary indication other than pain, but is analgesic in some painful conditions. The WHO recently reviewed the evidence for the use of adjuvant analgesic medicines in pain management for children (WHO, 2012). The use of corticosteroids as adjuvant medicines is not recommended for the treatment of persisting pain in children with medical illnesses, nor is the use of bisphosphonates for the treatment of bone pain in children, due to the low quality of evidence. Although used frequently for the management of neuropathic pain in children, it was not possible to make evidence-based recommendations for or against the use of tricyclic antidepressants (TCAs), selective serotonin reuptake inhibitors (SSRIs), or anticonvulsants as adjuvant medicines. In addition, recommendations regarding the risks or benefits of ketamine or systemic local anaesthetics as adjuvants to opioids for the treatment of neuropathic pain in children, or for the use of benzodiazepines and/or baclofen as adjuvants in the management of pain associated with muscle spasm and spasticity, could not be made based on the current literature. The quality of current evidence, and risks

and benefits of different treatments are summarized in the WHO document. The need for further analgesic research in children is urgent and essential to establish the role of these medicines in paediatric pain treatment.

In reality, however, when faced with the symptoms of very sick and dying children, many of these adjuvant medications are trialled with anecdotal benefit to patients reported. Small case reports and series have been published but robust data are unavailable due to the scientific, ethical, and practical challenges in paediatric palliative medicine practice (Collins et al., 1995; Behm and Kearns, 2001; Tsui et al., 2004; Finkel et al., 2007; Dayioğlu et al., 2008). A recent expert working group has proposed more feasible analgesic study designs for children, including cross over trials and N of 1 trials in the chronic pain and palliative groups (Berde et al., 2012).

Challenging pain syndromes in paediatric palliative care

Pain aetiology in children requiring palliative care is frequently varied and dependent on underlying diagnosis and ongoing complications. A recent multisite prospective study found that the two most common principal diagnoses in 550 children referred to palliative care teams in a 3-month period were congenital disorders (49.7%) and neuromuscular disorders (39.2%) (Feudtner et al., 2011). Other large Western paediatric palliative care centres report that approximately two-thirds of their caseload has non-malignant conditions (McCulloch and Collins, 2006). However, this will depend on geography as AIDs-related illness, cancer, and infection predominate in Africa (Amery et al., 2009; Campbell, 2011; Amery, 2012).

Muscle spasm

Sporadic, episodic pain seen related to muscle spasm is common. A significant source of discomfort in children with neuromuscular conditions and severe neurological impairment, management is often multimodal and requires use of antispasmodic agents, such as dantrolene and baclofen, and non-pharmacological strategies (Tilton et al., 2010). Triggers for muscle spasm might include constipation, seizures, gastro-oesophageal reflux, and discomfort from orthotic supports (Hauer, 2010). Targeted therapies such as botulinum toxin, surgical intervention, and intrathecal drug delivery are becoming more common and may alleviate the child from the systemic side effects of medication (Hoving et al., 2007; Bonouvrié et al., 2008; Esquenazi et al., 2010).

Opioids may be considered for some children with severe chronic pain secondary to muscle spasm. However, regard must be given to the potential for children with non-malignant, life-limiting conditions to survive for many years and there should be regular review of the effectiveness of any opioid prescribed. Although anecdotal practice supports the use of opioid prescribing in children with non-malignant disorders, trial withdrawal of long-term opioids should be considered on a regular basis as the cause of the spasm may dissipate with time.

Bone pain

Bone pain is a common problem in children receiving palliative care. Its association with malignant conditions is well known, but what is often overlooked is that it is also an important problem for many children with non-malignant conditions.

In children with chronic neurological conditions such as cerebral palsy or neuromuscular conditions, bone pain associated with secondary distortion of the normal skeletal structures may occur, especially during periods of growth. It is also documented that non-ambulatory children with chronic neurological conditions have low bone density and an increased propensity to non-traumatic fracture, or fracture with minimal trauma, such as that caused by moving and handling (Khoury and Szalay, 2007). Contributing factors in children with chronic neurological features include immobility, feeding difficulties, use of anticonvulsants, and lack of exposure to sunlight (Henderson et al., 2004).

Bone pain may also be a prominent feature of inherited metabolic disorders of childhood with pathological involvement of bone from systemic disease, mucopolysaccharhidosis (Rossi et al., 2011), or primary defects of structural bone proteins, osteogenesis imperfecta. Osteopenia from secondary distortion of the normal skeletal structures may occur as an effect of systemic treatments such as prolonged steroid use in cancer (Anghelescu et al., 2012).

Bone pain in a child with HIV/AIDS can be due to multiple causes including osteopenia as a result of bone loss and altered bone metabolism, cancer, and infections such as osteomyelitis or septic arthritis. Decreased bone mineral density is seen in children with HIV/AIDS (Fortuny et al., 2008), the pathogenesis of which is likely to be multifactorial, including malnutrition and mineral and vitamin deficiency.

Cancer-induced bone pain (CIBP) has been reported to be the most frequent single symptom of malignant disease (Fanurik et al., 1999). It is associated with primary bone tumours, metastatic tumour, and infiltrative bone marrow disease in haematological malignancy. In children with acute lymphoblastic leukaemia, bone pain has been reported in almost 50% of patients (Anand and the International Evidence-Based Group for Neonatal Pain, 2001).

The effective management of bone pain relies upon an individualized treatment to the identified cause and the clinical condition. This may include an appropriate orthopaedic intervention and the effective use of medication according to the two-step WHO strategy as already discussed. Although there is little evidence for the use of bisphosphonates as an adjuvant, there is increasing experience with use in children with congenital and acquired forms of osteopenia, in terms of analgesic efficacy and safety with long-term use (Stevens et al., 2006; Breau and Camfield, 2011).

Treatment of CIBP may require a multidisciplinary approach such as palliative radiotherapy alongside systemic disease-modifying treatment (chemotherapy) and supportive care (analgesic and integrative therapies). Novel approaches, such as the use of radiopharmaceuticals and interventional techniques (radioablation, magnetic resonance-guided ultrasound), have shown promising results in relieving pain in focal metastatic disease in adults and if accessible, should be considered if other treatments fail (Treede et al., 2008; Bailey et al., 2010; Wilkinson et al., 2012; Hexem et al., 2013).

Neuropathic pain

Neuropathic pain arises as a consequence of a lesion or disease affecting the somatosensory system (Treede et al., 2008). Neuropathic pain can be exceptionally severe and disabling. It is a particularly challenging diagnosis in children due to the

heterogeneity of conditions, diagnostic uncertainty, and unknown trajectories (Walco et al., 2010).

If available, the child's own description provides the best indication that the pain may be of neuropathic origin. The child may describe sensory anomalies such as numbness, itching, tingling, or burning sensations. Unusual expressions such as 'shivering', 'fizzing', 'tickling', or 'pricking' should alert the clinician. Although assessment and diagnosis in adult practice is becoming more rigorous, paediatric practice is some way behind. Early work on quantitative sensory testing in children (which examines sensory perception after application of different mechanical and thermal stimuli) is establishing a paediatric reference base that may be helpful in the future to identify responders to certain treatments in accordance to the underlying pain mechanism (Voepel-Lewis et al., 2008).

The newly proposed grading system to diagnose this condition requires a history suggestive of a relevant lesion, the presence of pain with a distinct sensory distribution in a corresponding body part, indication of negative or positive sensory signs within the area, and confirmation of the lesion by a diagnostic test (Treede et al., 2008). Unfortunately, many children and infants with a possible diagnosis are not able to communicate, making it very difficult to elicit sensory changes. However, if sensory disturbances like allodynia or dysaesthesia are present consistently then these are a strong indicator that neuropathic pain is present.

Any damage to the somatosensory system presents a potential risk of the development of neuropathic pain. Damage can range from single nerve involvement to complex genetic disorders that compromise axonal transport. The clinician may need to think laterally when considering a neuropathic pain diagnosis in children, for example, the child with unstable kyphoscoliosis and vertebral instability compromising the spinal cord and nerve roots, or the population of infants and children with neurometabolic conditions and white matter anomalies that may cause lesions or disordered processes within the nervous system. Neuropathic pain has been reported following orthopaedic surgery in children with cerebral palsy (Lauder and White, 2005) and is a well-known complication of cancer and its treatment.

Peripheral neuropathy is reported to occur in about 13–34% of children with HIV/AIDS (Araújo et al., 2000). Approximately 34% of children in early or later stages of HIV advancement report symptoms and signs of peripheral neuropathy in the absence of potential neurotoxic antiretroviral drugs (Van Dyke et al., 2008). However, there is a higher prevalence of peripheral neuropathy in children with encephalopathy and symptomatic AIDS (Mherekumombe and Collins, 2014).

Cerebral irritability

Cerebral irritability is a term used to describe the clinical presentation of persistent, unremitting agitation and distress. In the paediatric palliative care setting it is most often associated with the non-verbal child with severe neurological impairment but is also seen in infants presenting with an acute illness, children with progressive, often neurodegenerative disorders (adrenoleucodystrophy, AIDS encephalopathy) and, occasionally, towards the end of life in children with malignancy. Cerebral irritability may also be confused with an agitated delirium at the end of life, although clinical management at this stage is very similar.

At present there is very little published information on this phenomenon. It describes a constellation of features, which are the end point of a variety of different processes manifesting as similar clinical symptoms and signs. These processes may be pathological or, as in many children with severe neurological conditions, of unknown aetiology, although there are various hypotheses as to potential causes in this particular group of patients, such as central neuropathic pain and visceral hypersensitivity referred to later in this chapter.

Presentation involves a variety of manifestations depending on the clinical situation; however, agitation and distress are key. Classical symptoms in an infant or non-verbal child with severe neurological impairment include an unrelenting high pitched scream and other pain related behaviours, such as an increase in tone (spasticity) and/or seizures, sleep–wake cycle disruption, autonomic dysfunction (sweating, paradoxical bradycardia), increase in secretions, vomiting, retching, and 'feed intolerance'. If these symptoms present as an acute change in behaviour, a hospital review may be required with appropriate investigations to identify the aetiology and exclude a reversible cause. However, in the neurologically impaired child, this behaviour often evolves over time with the condition and becomes a chronic pattern with a significant burden on often exhausted, parents and carers (Fig. 9.13.4).

It is a commonly held belief that cerebral irritability in a neurologically impaired child in the absence of pathology is due to an abnormal brain, and abnormal neurological processing (Klick and Hauer, 2010). In this situation it is difficult to know whether the child with severe neurological impairment and cerebral irritability is also experiencing pain. Morally and ethically the assumption has to be that pain is a feature of this condition until proven otherwise. This is endorsed by the fact that most of these children will be known to have alternative baseline behaviours when they are not distressed, or cerebral irritability mimics previous pain behaviours that have had a bona fide cause (Breau et al., 2001; Stallard et al., 2002).

Several papers have acknowledged that pain of unknown cause is often the most severe pain in children with impaired cognition (Breau et al., 2003; Hauer et al., 2007; Hauer, 2010).

Children with cerebral irritability present with their own individual narrative, symptomatology, and signs. The most important step in the management of this condition is recording a detailed history and evaluation of the child. In the case of chronic cerebral irritability, it may be necessary to request a symptom diary to establish temporal factors and understand the impact upon the child and family. Exclusion of all other causes of pain and irritability, with relevant investigations, must be undertaken. If the aetiology of acute cerebral irritation is known and reversible, then treatment will obviously be directed towards the cause.

Central pain

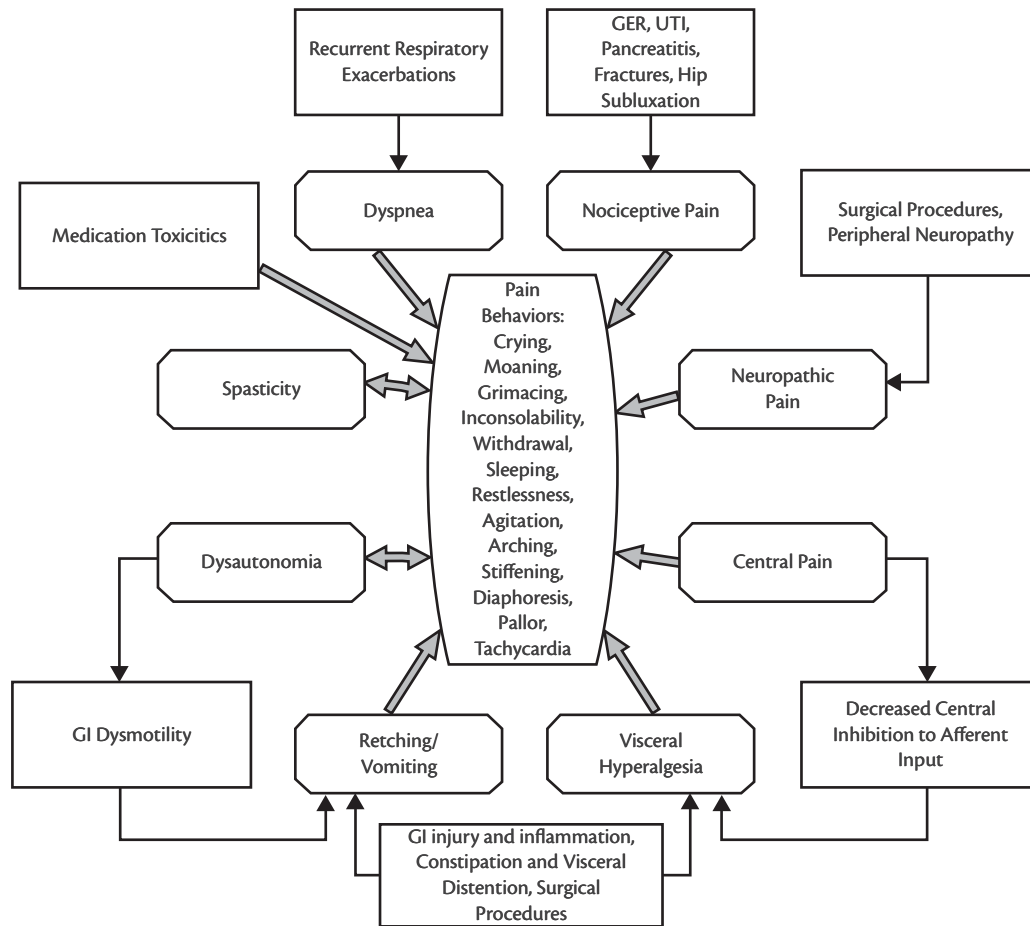
Central pain arises from damage to any part of the central somatosensory system, that is, those parts of the CNS that are specialized for pain perception. Conditions known to cause central neuropathic pain in adults, for example, multiple sclerosis and stroke, are rare in children. However, many other life-limiting conditions in childhood could potentially be the cause of central pain (Hain and Douglas, 2010). Neurodegenerative conditions and the consequences of hypoxic or traumatic brain injury cause a range of different types of damage to the CNS, including


Fig. 9.13.4 Sources of pain behaviours in children with severe neurological injury.

disordered structure, abnormal neuronal migration and myelination, and/or abnormalities of normal neurological systems at the molecular level. A familiar clinical picture in paediatric palliative care is one of persistent screaming and distress, and alongside cerebral irritability (discussed earlier) and visceral hyperalgesia (see following sections), central pain is an important differential diagnosis when considering causes of idiopathic distress in the non-verbal child (Klick and Hauer, 2010).

Visceral hyperalgesia

Visceral hypersensitivity has been hypothesized to be a possible cause of cerebral irritability in children with severe neurological impairment (Hauer, 2010; Klick and Hauer, 2010). Gastrointestinal pain is reported commonly in children with severe cognitive impairment (Houlihan et al., 2004; Hauer, 2010). Chronic cerebral irritability in children with neurological impairment is often related temporally to gastrointestinal symptoms and signs including pain, feed intolerance, flatus, retching, and vomiting. Pain seems to be localized to bowels, gastrointestinal tract, and digestion, despite adequate treatment of constipation and gastro-oesophageal reflux.

Visceral hypersensitivity or hyperalgesia is an altered response to visceral stimulation resulting in activation of pain sensation (Delgado-Aros and Camilleri, 2005). In contrast to other chronic pain states, visceral pain is often associated with gut motor abnormality and exaggerated intraluminal pressures and pain sensation. The presence of nociceptors in the gut wall that can be activated by a variety of modulators at lower, normally ineffective intraluminal pressures seems to be an important factor in generating pain (Buéno et al., 2000). Visceral hypersensitivity caused by abnormal gastrointestinal sensory input may also explain some of these issues in this population of children.

Zangen and colleagues have hypothesized that sensory and motor abnormalities, despite adequate management of motility and gastro-oesophageal reflux, suggest visceral hypersensitivity in the gut (Zangen et al., 2003). They studied 14 children with a lifelong history of retching and vomiting persisting after fundoplication and gastrostomy insertion, 12 of whom were impaired neurologically. Sensory anomaly and/or motility disorders were found in all 14 patients. Twelve patients had a low gastric-volume threshold for retching and seven patients had both reduced gastric volume and a motility disorder. Interventions included pain management with the intention of reducing afferent signals and/or central sensitization including amitriptyline, gabapentin, and imipramine.

Another recent report of a feeding programme for medically ill, non-verbal toddlers described the successful use of an outpatient

programme based on a multidisciplinary pain rehabilitation model. The report hypothesized that pain from gastric distension and retching against a fundoplication maintained or further sensitized the peripheral nociceptive system. Pain management involved either amitriptyline or gabapentin, amongst other interventions such as jejunal feeding to reduce gastric distension. By the end of a 14-week programme all nine patients showed significant improvement in oral feeding and irritability symptoms (Davis et al., 2009).

Hauer et al. have also suggested that visceral hyperalgesia may manifest as feeding intolerance presenting with symptoms of neuro irritability (Hauer et al., 2007). The authors identified retrospectively nine children with severe global developmental impairment who experienced 'recurrent irritability that was disruptive to daily life'. All children had daily crying episodes that lasted at least an hour. Signs reported by parents included arching, crying, feed intolerance, and disrupted sleep and descriptors included irritability, pain, and agitation. Treatment with gabapentin resulted in marked improvement in all individuals. Final doses ranged from 15 to 35 mg/kg per day (Hauer et al., 2007).

Based on information from animal models which reveal gastrointestinal tract inflammation resulting in hyperexcitability of nociceptive neurons, colonic distension producing chronic visceral hypersensitivity and allodynia and hyperalgesia in newborn rats, and altered gastric motility and visceral hyperalgesia in rats with localized gastric ulceration, there are suggestions in the literature that visceral hyperalgesia in this group of patients is likely to be the result of repeated painful gastrointestinal experiences in infancy. These painful gastrointestinal experiences result in recruitment of previously silent nociceptors and sensitization of peripheral visceral afferent fibres causing pain (Zangen et al., 2003). These 'experiences' might include a history of prolonged neonatal care, gastro-oesophageal reflux, constipation, gastrostomy feeding, and fundoplication. This interesting hypothesis, that visceral hyperalgesia is a result of sensitization not of the underlying neurological impairment itself, is a plausible explanation.

Zenger has also proposed that visceral sensory processing occurs as a perinatal event or during infancy as there is evidence to suggest that newborns have neural pathways for detection, transmission and reaction to noxious stimuli but a mature descending inhibitory pathway is lacking (Fitzgerald and McIntosh, 1989; Fitzgerald, 1991; Zangen et al., 2003). One must also consider the potential effects of CNS plasticity in the abnormal but developing brain that may have aberrant neuromodulation and hence contribute significantly to the development of pathological pain pathway. There remain many unknowns within this field and it is an important area for continued investigation. Visceral hypersensitivity may, therefore, be considered as a differential diagnosis for cerebral irritability.

Pharmacological management directed at central neuropathic pain and visceral hypersensitivity has been studied poorly and, in adults, central neuropathic pain classically has been difficult to treat (Klit et al., 2009). Approaches with medication would involve usually a trial of adjuvant agents including TCAs, anticonvulsants, and *N*-methyl-D-aspartate receptor (NMDA) receptor antagonists (Zangen et al., 2003; Hauer et al., 2007; Davis et al., 2009).

The paucity of paediatric data on this topic is striking considering the regular prescribing of anticonvulsants in paediatric practice. A single case report of a 3-month-old infant with neurological impairment and cerebral irritability detailed improvement in tone and disposition after the infant was treated with 5 mg/kg gabapentin at night, following the failure of regular lorazepam and intermittent morphine to provide relief. Gabapentin was tolerated well and dose increases lead to further improvement (Behm and Kearns, 2001).

Benzodiazepines are used commonly for the treatment of irritability and agitation in children both at the end of life and in the context of chronic cerebral irritability. Midazolam is used often in the treatment of cerebral irritability as it is short acting and can be given easily through the buccal route. This short-term efficacy can facilitate 'breaking the cycle' of distress in cerebral agitation, particularly in children with severe neurological conditions. If multiple dosing of midazolam is required on a daily basis, then consideration should be given to a longer-acting benzodiazepine, such as clonazepam. Clonazepam has the added benefit of more anticonvulsant activity relatively, which may be helpful if seizures are a feature of increasing cerebral irritability. Due to the emergence of tolerance with prolonged use of any benzodiazepine, they are best used for a short duration of up to 4 weeks if required regularly or as a 'rescue' treatment when symptoms are particularly difficult on an intermittent basis only. Abrupt withdrawal of benzodiazepines following prolonged use will precipitate an unpleasant withdrawal syndrome and treatment should be tapered slowly as a rule.

Opioids are not a first-line medication in this situation although they have been shown to improve pain in some central neuropathic pain conditions (Dworkin et al., 2007; Attal et al., 2010). They may be appropriate as a short-term control measure for acute neuropathic pain until other agents have been introduced and titrated to effect (Rowbotham et al., 2003; O'Connor et al., 2009; Barrera-Chacon et al., 2011). However, as the use of any analgesic medication for children with cerebral irritability may be necessary for a prolonged period of time, the potential for long-term effects of using the medication must be given due consideration. In the case of a long-term opioid administration, the development of tolerance or opioid-induced hyperalgesia is a concern. Despite these measures, some children will have intractable symptoms and may require additional medications such as benzodiazepines, phenobarbitone, or agents such as levomepromazine and haloperidol.

Neural stimulation therapies including motor cortex stimulation (Fontaine et al., 2009), deep brain stimulation (Owen et al., 2006), and transcranial magnetic stimulation (Leung et al., 2009) have been reported to be successful in adults with treatment-resistant central pain; however, there are no reports of any of these methods being used in children.

Cancer pain

Progressive cancer usually results in increasing illness burden and a myriad of complex and challenging symptoms with the evidence showing pain to be a distressing and prevalent symptom towards the end of life in children with this disease (Heath et al., 2010; Pritchard et al., 2010). In a recent study of 141 parents of children who died of cancer, more than 10% considered hastening their child's death; this was more likely if their child was in pain (Dussel et al., 2010). Anticipation and continuous planning of analgesic need is crucial to effective management, particularly with the drive in many countries to provide as much care as possible outside of the hospital environment.

As disease progresses, the goals of care alter to maximize quality of life and minimize invasive treatments and procedures. Diagnoses regarding pain aetiology are based upon knowledge of disease pathology and clinical signs, with minimal imaging and, frequently, the anticipation of pain or the assumption that pain must be present, particularly in the non-verbal child.

Not infrequently, palliative chemotherapy may be offered in the hope of slowing disease progression and improving symptoms (Farah et al., 2011; Pui et al., 2011) but there is little evidence to show that it improves analgesia. There are data, however, that palliative radiotherapy with locally advanced disease can reduce analgesic requirements, particularly when it is offered in combination with other treatment modalities (Robinson, 2011; Simeoni, 2012).

There is increasing experience with anaesthetic or neurosurgical analgesic options, for example, epidural/intrathecal infusions or neurolytic blocks, when systemic analgesia has failed (Whyte and Lauder, 2012). Epidural and peripheral nerve catheters can be used successfully despite typical contraindications (thrombocytopenia, fever, spinal metastasis, vertebral fracture) and does not preclude patients from being cared for in their preferred setting (Anghelescu et al., 2010).

Polypharmacy and continual addition or increment of medication, without consideration for withdrawal or efficacy of drugs, should be avoided. Of particular concern can be the phenomenon of opioid-induced hypersensitivity (OIH). This may well go unrecognized and is significantly under-reported in children in the literature (Heger et al., 2009; Hallett and Chalkiadis, 2012).

OIH is most broadly defined as a state of nociceptive sensitization caused by exposure to opioids (Mitra, 2008). The state is characterized by a paradoxical response whereby a person receiving opioids for the treatment of pain may become more sensitive to pain and this is thought to be due to neuroplastic changes in the central and peripheral nervous system (Chu et al., 2008). It is important to note that OIH and analgesic tolerance are two distinct pharmacological phenomena that can result in similar net effects on opioid requirements. However, increasing the dose of opioid in OIH will paradoxically aggravate the problem and worsen the patient's pain. Considerable diagnostic confidence is required to reduce the opioid consumption in a child with end-stage cancer. It is therefore advisable to rotate the opioid, potentially in combination with an NMDA receptor antagonist, and methadone has been reported to have efficacy in reducing high-dose OIH (Sjøgren et al., 1994; Laulin et al., 2002; Mercadante and Arcuri, 2005).

Intractable pain

Palliative sedation in end-of-life care is an accepted but controversial means of providing relief from otherwise refractory and intolerable symptoms and distress (Chater et al., 1998; Manzini, 2011). The European Association for Palliative Care defines palliative sedation as the monitored use of medications intended to induce a state of decreased or absent awareness in order to relieve the burden of otherwise intractable suffering in an ethically acceptable manner (Cherny et al., 2009). The use of sedation in the setting of refractory pain assumes that all possible analgesic therapies have been employed and that there is no acceptable means of providing analgesia without compromising consciousness (Collins, 2010).

There is little information regarding palliative sedation in paediatrics, there are no international guidelines for children and little is known about the clinical effectiveness of sedation practice. A recent review of the paediatric literature offers some insight into practice by stating that sedation in children remains controversial and is influenced by educational, cultural, legal, moral, and health policy issues. Importantly, it highlighted that physical symptoms are described as an indication for practice but existential suffering must also be considered in the evaluation of refractoriness of symptoms (Kiman et al., 2011). Existential suffering of parents must also be acknowledged, as their distress behaviour may impact upon patient management, as explored in the study by Dussell et al. (2010)

Reports of pain and suffering at the end of life are described mainly for children with end-stage cancer, but also recognized in HIV/AIDS (Collins, 2005; Bennett and Givens, 2011). Recent studies have shown that incidence may be higher than perhaps expected in some regions. A retrospective case series of children with end-stage cancer showed that 25 of 37 patients received 'palliative sedation' for unrelieved suffering, with pain being the most common symptom cited (Postovsky et al., 2007). Also, a survey of Belgian physicians signing death certificates of all children between the ages of 1 and 17 years found that continuous, deep, and persistent sedation was used in 21.8% of all deaths; 46.8% of all none-sudden deaths (Pousset et al., 2011). Physicians had the explicit or concurrent intention of hastening death in one-quarter of cases. The incidence of continuous sedation in this study was higher than the 14.5% found in a comparable study of adults (Chambaere et al., 2010).

For the specific cohort which requires sedation for intractable pain, recommended therapeutic modalities include opioids, benzodiazepines, neuroleptic, and anaesthetic agents such as propofol (Anghelescu et al., 2012).

Conclusion

In the twenty-first century, dying children should not suffer undue pain. Although managing pain is only one of the aspects of providing palliative care for children, in reality it is a core task, as pain is the one of the most common symptoms experienced and necessitates effective action. Children's pain in palliative care has to be recognized within the wider context of progressive illness, emotional distress, and family influences. Therapy must mitigate both causative and contributing factors, use a multidisciplinary approach to address pharmacological and non-pharmacological treatments, and continually be appraised and evaluated.

Common symptoms and disorders: gastrointestinal symptoms

Dysphagia, dyspepsia, and hiccup

Katherine Clark

Dysphagia

Definition of dysphagia

Dysphagia is defined as difficult swallowing which is different to odynophagia which is painful swallowing. There are two main types of dysphagia: oropharyngeal which reflects difficulty initiating swallow and oesophageal where the food bolus fails to easily traverse the oesophagus.

Dysphagia may occur as a complication of many diseases both malignant and non-malignant. It is highly likely that some people will already be dysphagic at the time of presentation to palliative care. However, there is a second cohort of people who will become dysphagic after referral to palliative care either as a complication of their life-limiting illness or because of increasing frailty. It is a reasonably prevalent condition in this population (Langmore et al., 2009).

Pathophysiology of dysphagia

Normal swallowing is a complex process. The initial phase, known as the *oral phase*, is under voluntary control. The next stage is the *transfer phase* where the solid or fluid bolus is pushed back into the pharynx by the tongue. The involuntary swallow response is evoked when the bolus enters the hypopharnyx. As a result, the larynx is elevated and pushed anteriorly, opening the upper oesophageal sphincter and allowing the tongue to push the bolus into the oesophagus, which in turn relaxes the lower oesophageal sphincter. The bolus entering the oesophagus provokes a primary peristaltic contraction which serves to both clear any residual bolus in the pharynx and propels the bolus through the oesophagus and into the stomach. The movement of the bolus along the oesophagus is assisted by secondary peristaltic actions which occur as a result of oesophageal distension. The oesophagus is divided into two sections: cervical and thoracic. The cervical oesophagus, like the oropharynx, is composed of striated muscle, unlike the thoracic oesophagus which is composed of smooth muscle.

Oropharyngeal dysphagia occurs as a result of difficulty transferring either food or fluid from either the mouth to the pharynx or from the pharynx to the oesophagus (Box 10.1.1). Problems with the oral or pharyngeal phase can result in regurgitation, coughing, or a sense of choking. Oropharyngeal dysphagia carries a high risk of aspiration and respiratory complications, malnourishment, dehydration and, as a result, poorer survival than people without dysphagia.

Aspiration refers to the complication of the passage of either food or fluids through the vocal cords leading to pneumonia.

The severity of the complications depends upon the amount and type of aspirate and the capacity of the individual to subsequently clear the pulmonary tree. Aspiration of solids may lead to fatal airway obstruction. Depending upon the material aspirated, a chemical pneumonia may result if the aspirate is very acidic. The normal flora of the mouth and pharynx may result in bacterial pneumonia.

Oesophageal dysphagia occurs due to narrowing of the lumen of the oesophagus, impaired motor function, or altered oesophageal sensation. This may result in the retention of the food or fluid bolus in the oesophagus (Cook, 2009).

Causes of dysphagia

There are numerous causes of dysphagia which may be subcategorized into either oropharyngeal or oesophageal as summarized in Box 10.1.1.

Prevalence of dysphagia

Oropharyngeal dysphagia is a common problem in older populations and is expected to affect between 40% and 50% of people living in residential care. Although it is prevalent, it should not be considered part of healthy ageing and people presenting with new-onset dysphagia require careful evaluation. High-risk groups include people who have suffered a cardiovascular accident (CVA), where 25–40% of people suffering an acute unilateral stoke will have dysphagia. Up to 60% of CVA patients with dysphagia are likely to die due to nutritional and respiratory complications of their impaired swallow. Other groups at high risk of dysphagia include those with Alzheimer's disease where up to 80% of people are likely to have dysphagia and Parkinson's disease where between 50% and 80% of people are likely to be affected (Kumar, 2010).

Oesophageal dysphagia may be due to oesophageal cancer, the incidence of which is rising. Sadly, more than 50% of people who are diagnosed with oesophageal cancer will have advanced and incurable disease. At the time of diagnosis, more than 70% of these patients are likely to experience oesophageal dysphagia. More than 100 different medications have been linked to oesophageal dysphagia. This suggests such problems may well complicate the lives of people at the end of life (Pace et al., 2009).

The overall prevalence of either type of dysphagia in people at the time of referral to palliative care is not well documented. Whilst under care of the palliative care service, up to 12% of people have been identified as suffering dysphagia, some of which reflects increasing frailty. This rate may be an underestimate.

Box 10.1.1 Causes of dysphagia

Oropharyngeal

- Structural: malignancy, enlarged thyroid, Zencker's diverticulum

- Neurological: CVA, amyotrophic lateral sclerosis, brainstem tumours, bulbar poliomyelitis, multiple sclerosis, Parkinsonism, neuropathy (diabetes, alcohol, cachexia), dementias

- Myopathic: dermatophytosis, muscular dystrophy, polymyositis, myasthenia gravis, thyroid disease

- Iatrogenic: medications that must result in a myopathy (botulin toxin, procainamide, amiodarone, statins, vincristine), medications that inhibit saliva (opioids, tricyclic antidepressants, phenothiazines, atropine, hyoscine), radiotherapy to the head and neck, surgical procedures of the head and neck

- Poor dentition

- Anxiety.

Oesophageal

- Neuromuscular: achalasia, oesophageal spasm, scleroderma, systemic lupus erythematosus, rheumatoid arthritis, inflammatory bowel diseases

- Vascular: ischaemic oesophagus

- Structural: stricture secondary to reflux, diverticula, malignancy (oesophageal, gastric), benign tumours, external vascular compression, mediastinal masses, foreign body, mucosal injury secondary to infections (candidiasis, cytomegalovirus, HIV), mucosal injury secondary to medications (non-steroidal anti-inflammatories, alendronate, ascorbic acid, ferrous sulphate, antibiotics, theophylline), allergic disorders (eosinophilic oesophagitis), mucosal injury secondary to skin disorders (pemphigus vulgaris, pemphigoid, epidermolysis bullosa dystrophica).

Presenting problems of dysphagia

Clinical problems that people with oropharyngeal dysphagia may describe include difficulty initiating swallow and then having to swallow repeatedly to effect pharyngeal clearance. People may experience a hoarse voice, nasopharyngeal regurgitation, or coughing on swallowing. Typically, these people tend to have greater problems when attempting to swallow thin fluids rather than solids. Cough on swallowing is typically due to aspiration. People may describe a sense of food being 'stuck' in both oesophageal and oropharyngeal dysphagia. When such problems occur acutely, the most likely cause is cerebrovascular. Where the onset is more gradual, the presenting problems may include weight loss, malnutrition, recurrent respiratory tract infections, and pneumonia.

In contrast, people with oesophageal dysphagia are more likely to have symptoms localized to the chest and are more likely to experience problems with solids compared to liquids. Chest pain

may accompany swallowing particularity when the underlying problem relates to reflux, narrowing of the lumen due to a structural abnormality, or a disorder of peristalsis.

Bedside examination for dysphagia

The bedside examination includes an assessment of the person's current nutritional and hydration, the possible aetiologies of the dysphagia, and the site of the pathology of the dysphagia. A comprehensive medical history can help discern whether this is an acute swallowing problem or associated with more gradual onset. Physical examination requires an examination of the neuromuscular structures that facilitate swallowing.

Bedside examination should include an assessment of whether or not the person is drowsy or confused as such changes in mentation may impair concentration necessary to safely swallow. Ask the person to identify themselves, paying attention to voice quality as dysphonia and dysarthria are signs of motor dysfunction of the structures involved in oral and pharyngeal phases of swallowing.

The oral cavity should be inspected for local problems and the state of the teeth recorded. Poor dentition increases the likelihood of aspiration pneumonia. Cranial nerves V and VII to XII should be systematically assessed. The face should be inspected for symmetry and the strength and sensation of the lips should be assessed (trigeminal and facial cranial nerves). The motor, sensory, and autonomic functions of the glossopharyngeal, vagus, and hypoglossal cranial nerves should be assessed. This includes an inspection of the uvula to ensure it is midline. The motor and sensory aspects of the gag reflex require testing. This reflex is elicited by stroking the pharyngeal mucosa with a tongue depressor. It must be noted that the absence of a gag reflex does not necessarily indicate that a patient is unable to swallow safely. Unilateral retraction of the palate during testing of the gag reflex indicates weakness of the muscles of the contralateral palate and suggests unilateral bulbar pathology. The tongue is inspected particularly in the floor of the mouth for wasting or fasciculations at rest. The person should be asked to move the tongue which should be inspected to ensure that this does not deviate to one side. The person should be asked to cough.

The bedside physical examination should include an observed swallowing test if this is deemed safe. This includes observing how well the person is able to open their mouth, how well they are able to close their mouth when taking fluid or solids, and whether or not they are able to clear the oropharynx or if food residue remains. People need to be observed to see whether or not the swallow changes with fatigue. Drooling, delayed swallow initiation, coughing, or a wet or hoarse voice quality may indicate a problem. After the swallow, observe the patient for 1 minute or more to see if a delayed cough response is present (Bours et al., 2009).

The physical examination must include a respiratory examination to identify if there are any changes to suggest respiratory complications. The physical examination when oesophageal dysphagia is the likely diagnosis is often unremarkable. In this situation, the examination should be directed to an assessment of the person's nutritional and hydration status. The oral cavity should be inspected particularly to consider infections such as candidiasis which may extend to involve the oesophagus and more distally to the stomach.

Investigations of dysphagia

If untreated, the initial investigations include biochemical and haematological parameters of hydration and nutrition (albumin, lymphocyte count, haemoglobin, and haematocrit). A cerebral computed tomography scan or magnetic resonance image may be warranted if the onset was sudden. A plain radiograph of the chest may also be indicated to exclude pneumonia. When indicated, the most useful investigations to explore oropharyngeal dysphagia include video-fluoroscopy, endoscopy, and manometry.

Barium video-fluoroscopy is a commonly used method to localize the site of pathology underlying swallowing difficulties, allowing clinicians to review oral, pharyngeal, and oesophageal structure and function. This investigation is usually organized as a collaboration between a speech pathologist and radiographer and requires the person to be able to sit upright for the duration of the study. Not surprisingly, the main complication is aspiration. However, even with this risk, this investigation has the advantage of visualizing all phases of swallowing. Together with providing important diagnostic information, the results of the study can be utilized as the basis to recommend the most tolerable diet for the patient. In people with adequate life expectancy, this investigation may help clinicians decide which people may even require parenteral feeding.

Flexible endoscopic evaluation of swallowing allows the pharynx and larynx to be directly visualized by the operator. This investigation is not considered to provide as comprehensive information as the barium swallow outlined above but does have the advantage of not exposing the patient to radiation and is not associated with the risk of aspiration. Furthermore, this can be conducted at the bedside, avoiding exposure to radiographs. One of the main disadvantages is that the oral phase of swallowing cannot be assessed.

Intraluminal manometry is used to quantify pharyngeal swallowing strength and to explore whether the upper oesophageal sphincter relaxes appropriately. Manometry is most useful when combined with the investigations listed earlier.

Oesophageal dysphagia

Gastro-oesophageal endoscopy allows visualization of the oesophageal mucosa and allows biopsies to be taken and, if needed, oesophageal dilatation and insertion of a stent. This is usually a well-tolerated investigation that can be performed under sedation. There is the potential risk of oesophageal perforation as a complication of biopsies or stent insertion.

Oesophageal pH monitoring is considered the optimal diagnostic tool to diagnose reflux disease. This is undertaken by inserting a naso-oesophageal probe which allows recording of pH levels.

Management of oesophageal dysphagia

Palliative management of dysphagia aims to maximize swallowing function, maintain adequate nutrition within the context of the stage of life, and allow people to participate in the social activities of eating and drinking. Management strategies differ depending upon whether the problem is localized to the oropharynx or the oesophagus, the chronicity of the underlying disease, and the overall prognosis.

For those with longer prognoses, the aim of management is to maximize the safe intake of an adequate diet to maintain nutrition and hydration, as malnutrition is associated with increased morbidity and mortality.

When considering the management of oropharyngeal dysphagia, for those able to participate in structured programmes, swallowing may be improved through modification of a number of factors. For example, with diet, a pureed diet is most appropriate for people who are experiencing difficulties with the oral phase of swallowing, who pocket food in the buccal recesses, or who have significant pharyngeal retention of chewed solid foods. Other recommendations include increasing the number of times food is chewed and the numbers of swallows per bolus. As well as pureeing food, increasing the thickness of fluids is recommended.

An important component of feeding is to consider how diet may best contribute to maintaining nutrition and hydration. People at risk of aspiration are much more likely to develop complications of aspiration when they are malnourished. This is because resistance to infections is compromised and defence mechanisms such as cough are impaired. Malnutrition may result in deteriorating performance status, anaemia, increased risk of pressure sores, impaired wound healing, and accelerated osteoporosis. Inadequate hydration also places people at risk of metabolic complications and aspiration, increasing the risk of pneumonia. This is because the salivary flow may be reduced therefore altering the normal flora of the oropharynx.

Ensuring good oral hygiene is important to help avoid complications of aspiration. People with impaired clearance of the oropharynx are at risk of altered colonization due to retained secretions and poor nutrition and hydration. Simple measures such as regular mouth washes and artificial salvia may be useful. When possible, medications without anticholinergic adverse effects should be prescribed.

The support of speech pathologists should be sought to consider whether a routine of exercises might be useful. Two distinct types of exercises can be considered. There are exercises aimed at improving the strength of muscles that facilitate swallowing and techniques that improve the safety of swallowing when a person is actually eating.

When trying to improve the strength of muscles involved in swallowing, the exercises are targeted to the site of the pathology. For example, lip exercises may improve a person's ability to prevent drooling when attempting to swallow. Tongue exercises may improve a person's capacity to push a food bolus towards the upper oesophageal sphincter, jaw exercises may improve mastication, and vocal cord adduction exercises can promote strengthening of weak vocal cords thereby limiting aspiration. In some situations, these exercises may be supplemented by low-current electrical stimulation that is administered by electrodes placed on the skin of the neck.

Techniques aimed at improving the safety of swallowing include advice on how to position the person during eating with the intent of improving oropharyngeal clearance and reducing the risk of aspiration. People who have delayed supraglottal closure can be taught how to voluntarily close the glottis before and during swallow thereby preventing aspiration. Other techniques include advising people to tilt their head away from the side of

unilateral weakness of the tongue to force the bolus of food to the strong side.

In some situations, surgery for dysphagia may be considered. This is only in chronic situations where life expectancy is longer. Such procedures might include laryngeal closure or laryngotracheal separation-diversion. Laryngeal closure involves permanent closure of the glottis thereby avoiding aspiration. Separating the larynx from the trachea may be performed acutely by creating a tracheostomy.

For some people, such interventions are either not adequate or appropriate, resulting in a situation where the person is not able to maintain nutrition or hydration safely. Enteral or parenteral feeding might then be considered. However, initiation of parental or enteral feeding must be considered in the context of the individual with factors such as the potential reversibility of the swallowing problem, the degree to which the underlying physical disease can be modified, the wishes of the person with the swallowing problem, and the potential risks involved.

Most feeding tubes are inserted for progressive debilitating conditions such as dementia, motor neurone disease, and cancers. However, despite the fact that feeding is initiated with the aim of maintaining nutrition and avoiding malnutrition, significant complications may accompany enteral feeding.

There are different types of feeding tubes available and when considering insertion of such tubes it is important to understand the risks and benefits of each type. The simplest approach to tube enteral feeding is by inserting a nasogastric tube. This is the least invasive as people do not require sedation or surgery. It is recommended in situations when the need for enteral feeding is short or as a temporary measure until a more definitive approach can be organized. At the time of insertion, problems can include bleeding, trauma, and misplacement of the tube and oesophageal perforation. When used for longer periods, problems include discomfort, nasal ulceration, chronic sinusitis, gastro-oesophageal reflux, and aspiration pneumonia. A variation on the nasogastric tube is the oro-oesophageal tube. This refers to the temporary placement of a narrow-bore tube that remains *in situ* only for the duration of the feed. This may be a useful approach when people do not have a gag reflex and decline other approaches to feeding. However, this requires the person to be compliant and requires a significant time commitment.

More commonly in the longer term is the placement of a percutaneous gastrostomy tube. There are two different ways that such tubes may be inserted. The first is a surgical gastrostomy which requires a general anaesthetic and the second is a percutaneous endoscopic gastrostomy. This latter approach has the benefit that it may be performed under sedation. Both approaches require the insertion of a tube through the anterior abdominal wall. Insertion complications include bleeding, infections, peritonitis, or perforation of other abdominal organs. Observational studies identify that 10% of people are still likely to suffer an aspiration with other complications including infections, tube leakage, tube removal, displacement or migration, bleeding, gastric mucosal overgrowth or ulceration, metabolic and biochemical complications such as re-feeding syndrome, gastrointestinal side effects, and microbial contamination of the feeds. Approximately 50–60% of people are unlikely to survive 12 months after enteral feeding is commenced. Given these problems, an absolute contraindication to commencing supplemental feeding should be a short life expectancy. In these situations, sensitive and knowledgeable communication with the person and their formal and informal carers is required.

More than with oropharyngeal dysphagia, approaches to the management of oesophageal dysphagia are tailored according to the process that underlies the dysphagia. Particular local interventions that require discussion include management of benign and malignant structures, with or without insertions of oesophageal stents and medical management tailored to the underlying problem.

Oesophageal strictures narrow the lumen from processes that affect the structures, function, or problems external to the oesophagus. The most common cause of oesophageal strictures is reflux disease. Whilst treatment of the cause of the stricture is recommended, local interventions including dilatation and stent placement provide palliation for both benign and malignant strictures.

The best results from dilatation alone for benign strictures are achieved when the stricture is simple (i.e. < 2 cm long), straight and an endoscope can easily be passed through it. In this scenario, most people do not require multiple dilatations. Complex strictures are typically longer, tortuous and it is difficult to pass the endoscope. It is not uncommon for people to require a minimum of three dilatations. If more than seven attempts have been made, that stricture is considered 'resistant'. Although usually well tolerated, there are complications associated with dilatation which include perforation, bleeding, and bacteraemia though such complications are expected in less than 1% of people. The more tortuous the stricture or strictures that have occurred as the result of a caustic injury are considered to place people at higher risk of complications.

Complex benign strictures are sometimes managed with oesophageal stenting. Recent observations suggest that biodegradable stents or the short-term use of stents may be useful palliation in the management of benign strictures though the evidence is less robust than the evidence for stents in malignant disease. The main complications include stent migration, difficulty in removing stents, pain, and tissue overgrowth. Although the numbers of observations available to report the benefit or otherwise of stenting in this situation are few, the risk of perforation in this group seems to be less than that experienced by people with malignant strictures (Siersema, 2008; Vlavianos and Zabron, 2012).

Malignant strictures are palliated with a combination of dilatation, stent placement, and adjuvant radiotherapy or brachytherapy. The choice depends upon the person's prognosis. Dilatation without stenting may be used when life expectancy is very short. Stenting alone is typically offered when prognosis is less than 3 months. People expected to live longer than 3 months with inoperable disease are typically offered ether brachytherapy or stenting plus radiotherapy. When a stricture is located in the mid to distal portion of the oesophagus, the main complications with stent insertion include stent migration, stent obstruction (secondary to benign or malignant overgrowth or food), and reflux that may be complicated by aspiration pneumonia. Up to 40% of people are likely to develop problems within the first 2 months of the stent insertion. However, re-stenting is likely to be successful in 90% of these people. Proximal strictures are considered more challenging to stent with a greater risk of food obstruction, fistula formation, and aspiration. It is not considered possible to stent a stricture that crosses the upper oesophageal sphincter. However, more distal to the sphincter, stenting is considered possible. A more flexible

stent which exerts less force on the oesophageal wall has improved outcomes

Single-dose brachytherapy is delivered by passing an applicator into the oesophagus. The main complications are fistula formation, stricture formation, and esophagitis. Comparing patient outcomes from stenting versus brachytherapy have identified that immediate palliation is better with stents but longer-term outcomes are better with brachytherapy, including quality of life assessments (Schembre, 2010; de Wijkerslooth et al., 2011).

Problems such as infections or inflammatory conditions causing oesophageal dysphagia require targeted treatments to manage the specific problem. For example, eosinophilic esophagitis which occurs as the result of inhaled allergens requires identification of the allergen, a trial of inhaled corticosteroids, or systemic corticosteroids depending upon the severity of the presentation (Moawad et al., 2009). Other problems such as oesophageal spasm may also be managed medically. Agents that have been trialled for this include smooth muscle relaxants and calcium channel blockers. More recently sildenafil, a phosphodiesterase-5 inhibitor, has been trialled with success. However, its use is limited by the adverse effects of headache and vertigo. Botulinum toxin injections have been used to manage oesophageal spasm (Roman and Kahrilas, 2012).

Acid reflux is the main contributing factor to oesophageal dysphagia and it is likely that reflux will overlap with other causes of dysphagia. The medications most likely to be of benefit are the proton pump inhibitors (PPIs) with lesser benefit expected from histamine type 2 receptor antagonists (H_2 blockers) (van Pinxteren et al., 2005; Rosemurgy et al., 2011). Despite the use of PPIs, some people continue to suffer distressing symptoms. Although the evidence to support additional agents is less than robust, clinical guidelines recommend supplementing PPIs with a number of other agents. These include suggestions such as avoiding foods that are likely to impair gastric emptying, the use of antacids for intermittent exacerbations, and intermittent prokinetic therapy to promote gastric emptying with either metoclopramide or domperidone, barrier therapy with sucralfate or inhibiting reflux with baclofen (Armstrong and Sifrim, 2010) (see Boxes 10.1.2 and 10.1.3).

Dyspepsia

Definition of dyspepsia

Dyspepsia is a specific term that requires people to have one or more of the four specific symptoms of epigastric pain, epigastric burning, postprandial fullness, or early satiety. Dyspepsia is separate from heartburn which is defined as a sensation of retrosternal burning distinct from epigastric burning. Heartburn may accompany dyspepsia but it is considered a separate entity. Heartburn is considered pivotal for the diagnosis of reflux disease (Oustamanolakis and Tack, 2012).

Dyspepsia may be either a functional disorder where no cause for the problem may be identified or may occur as a secondary problem. The diagnosis of functional dyspepsia is typically made when other causes have been excluded: gastro-oesophageal reflux disease, peptic ulcer disease (PUD), gastric inflammatory conditions, and upper gastrointestinal tract cancers. Although clinically difficult to differentiate, people may also develop dyspeptic symptoms secondary to gastroparesis. Dyspepsia has been identified as

Box 10.1.2 A summary of management strategies to palliate oropharyngeal dysphagia

Managing oropharyngeal dysphagia when life is measured in months to years

- Diet changes:
- avoid thin fluids, avoid very hard or chewy foods
- pureed diet
- thickened fluids
- Nutritional support
- Adequate fluid intake to maintain hydration
- Modification of swallowing behaviours: sitting upright, swallowing three times, taking fluids from a spoon, turning the head to one side to swallow, ensuring residual food is removed from the oral cavity
- Oral hygiene
- Avoid medications likely to contribute to a dry mouth
- Targeted exercises
- Electrical stimulation
- Compensatory techniques
- Surgery
- Parenteral or enteral feeding.

Managing oropharyngeal dysphagia when life is measured in weeks

- Diet
- Positioning
- Avoidance of medications likely to contribute to sedation
- Oral care to improve dry mouth this may contribute to difficulty swallowing
- Meticulous oral hygiene after meals to reduce the risk of aspiration.

Managing oropharyngeal dysphagia in the final stages of life

- Oral hygiene
- Diet as tolerated.

---

a problem that may have a significant detrimental effect on quality of life (Aro et al., 2011).

Pathophysiology of dyspepsia

The major function of the stomach is to facilitate breakdown of solid food, and to empty this as chime into the small bowel along with indigestible foods. The proximal stomach relaxes as a vagally mediated reflex secondary to swallowing. The proximal stomach increasingly relaxes to accommodate increasing volumes whilst

Box 10.1.3 A summary of management strategies to palliate oesophageal dysphagia

Managing oesophageal dysphagia when life is measured in months to years

- Diet
- Surgery
- Stenting
- Brachytherapy
- Radiotherapy
- Medication: PPIs, H$_2$ antagonists, baclofen, metoclopramide, domperidone, sucralfate
- Botulin toxin
- Enteral feeding.

Managing oesophageal dysphagia when life is measured in weeks

- Diet
- Medication
- Dilatation
- Stenting.

Managing oesophageal dysphagia in the very final stages of life

- Diet
- Medication: parenteral PPI, or H$_2$ antagonists, parenteral metoclopramide.

Source: Data from Armstrong, D. and Sifrim, D., New pharmacologic approaches in gastroesophageal reflux disease, *Gastroenterology Clinics of North America,* Volume 39, Issue 3 pp. 393–418, Copyright © 2010 Elsevier Inc. All rights reserved.

concurrently contracting more distally to allow the food to be broken down into smaller and smaller particles. Emptying of liquid into the duodenum requires coordinated contraction of the whole stomach, though the speed at which this occurs is mediated by the pylorus.

Dyspepsia is considered a disorder of gastric motility. Dysmotility may have no identified reason with the changes in gastric emptying that accompany dyspepsia being varied. It is estimated that 25–50% of people with dyspepsia will have delayed gastric emptying but it is not clear how this affects symptoms. The underlying theory is that larger gastric volumes lead to more marked distension and therefore early satiety.

Other changes have been noted in people with functional dyspepsia including impaired accommodation of the proximal stomach in 40% of people, but the mechanism whereby this may lead to symptoms is not well categorized. Likewise, hypomotility of the gastric antrum is commonly observed but again it is unclear how this may lead to symptoms (Aro et al., 2011; Tack et al., 2011; Miwa et al., 2011). As well as functional and secondary causes of dyspepsia, there are a number of problems that can

result in dyspepsia-like symptoms as the result of disordered gastric emptying.

Causes of dyspepsia

There are numerous causes of dyspepsia which include functional and secondary. Functional dyspepsia is defined as a problem that occurs when people present with complex symptoms of pain, burning, early satiety, and postprandial fullness but no clearly identifiable cause. In contrast, secondary dyspepsia may be as the result of numerous causes as summarized in Box 10.1.4.

Box 10.1.4 Causes of dyspepsia

Functional

Secondary

- Gastro-oesophageal reflux
- Oesophagitis secondary to medications:
  - Iron supplements, opioid analgesia, theophylline, digoxin, antibiotics, calcium channel blockers, nitrates, bisphosphonates, non-steroidal anti-inflammatory agents, corticosteroids
- Peptic ulcer disease (PUD):
  - *H. pylori*, NSAIDS
- Malignancy:
  - oesophageal cancer, gastric cancer
  - Coeliac disease

Dyspepsia-like symptoms

- Infections:
  - *Giardia lamblia, Strongyloides stercoralis*, tuberculosis
- Inflammatory:
  - Coeliac sprue, Crohn's disease, sarcoidosis, lymphocytic gastritis, eosinophilic gastroenteritis
- Infiltrative:
  - lymphoma, amyloid, Ménétrier disease
  - recurrent gastric volvulus
  - chronic mesenteric or gastric ischaemia
  - ideopathic gastroparesis
- Drug-induced gastroparesis:
  - Opioids, medications with anticholinergic effects
- Secondary gastroparesis:
  - Metabolic (diabetes, hypercalcaemia, renal failure, hypothyroidism)
  - Neurological (autonomic neuropathy
  - Infiltrative (malignant, systemic sclerosis)
- Other (idiopathic, post-surgical, paraneoplastic).

Prevalence of dyspepsia

Within the whole population, dyspeptic symptoms are estimated to affect between 10% and 45% of the population. There are suggestions that this higher figure may overestimate the problem of dyspepsia by the inclusion of heartburn symptoms which are not considered part of the syndrome. The prevalence of dyspepsia is not clear in palliative care patients.

Presenting problems of dyspepsia

The four cardinal symptoms diagnostic to dyspepsia are post-prandial fullness, early satiation, epigastric pain, and epigastric burning. Other symptoms may accompany these four symptoms including bloating, fullness, belching, nausea, and vomiting.

Other questions may be useful to try and understand the aetiology of the dyspepsia. Functional dyspepsia is not uncommonly accompanied by irritable bowel disease. This may present with recurrent abdominal pain or discomfort often improved by a bowel action. However, in palliative care patients, constipation is a frequently occurring co-morbidity and it is not clear how the regular use of laxatives may contribute to symptoms that mimic irritable bowel syndrome. Other questions to consider include whether or not pain is improved by eating (e.g. PUD), if there post-prandial heartburn (e.g. reflux oesophagitis), what medications the person is currently taking that might contribute to symptoms, how much weight the person has lost, and if there are other changes to appetite. Alternatively, when the dyspeptic symptoms are secondary to gastroparesis, people may also describe vomiting, often of undigested food following meals (Hasler, 2011).

Investigations of dyspepsia

The aim of investigations is help discern whether the underlying problem is functional, organic, or secondary to gastroparesis. The main reason to understand the difference is to allow the most appropriate management to be implemented. The initial steps when people present with dyspeptic symptoms include a comprehensive and focused clinical history and physical examination. Excluding functional dyspepsia requires, at a minimum, people to have an upper gastrointestinal endoscopy, 24-hour oesophageal pH monitoring, and *Helicobacter pylori* assessment.

Management of dyspepsia

Most people with functional dyspepsia do not require medications. Rather, this group are most likely to benefit from reassurance, education about the condition, and recommendations regarding dietary and lifestyle changes. Patients are generally advised to eat smaller and more frequent meals, and to avoid food with high fat content and food that aggravates their symptoms. When symptoms are severe, a trial of a PPI is warranted. Those people who are bothered by postprandial fullness and early satiety may benefit from a prokinetic agent such as domperidone or metoclopramide. More recently, acotiamide, a muscarinic receptor antagonist and cholinesterase inhibitor has been identified as an efficacious agent in the management of functional dyspepsia. In patients with bothersome symptoms that persist despite these initial therapies, a trial of a low-dose tricyclic antidepressant may be considered (Tack and Janssen, 2011).

Box 10.1.5 A summary of approaches to palliate dyspepsia

Palliation of dyspepsia when life is managed in months to years

- Identify and treat underlying cause
- Oral PPIs or H$_2$ antagonists for pain or burning
- Dietary advice
- Positioning
- Prokinetics when early satiety is a feature
- Antidepressants or supportive counselling.

Management of dyspepsia when life is managed in weeks

- Oral PPI or H$_2$ antagonists for pain or burning
- Dietary advice
- Positioning
- Prokinetics.

Management of dyspepsia in final stages of life

- Parenteral PPI, H$_2$ antagonists
- Parenteral metoclopramide.

Source: Data from Loyd, R. A. and McClellan, D. A., Update on the evaluation and management of functional dyspepsia, *American Family Physician*, Volume 83, Number 5, pp. 547–52, Copyright © 2011 American Academy of Family Physicians.

For people with a longer prognosis who present with dyspepsia for which an organic cause is identified, the management strategies require firstly, eradication of the underlying cause and secondly, palliation of symptoms. When people have epigastric pain or burning, the first medications of choice are any of the PPIs or alternatively, H$_2$ receptor blockers (Loyd and McClellan, 2011) (Box 10.1.5).

Hiccup

Definition of hiccups

Hiccup, or more correctly singultus, refers to the situation where people experience a sharp and involuntary contraction of the muscles of inspiration which causes a sudden sharp inspiration and closure of the glottis. This results in the characteristic sound which occurs when the column of air inhaled due to involuntary muscle contraction strikes the closed glottis. Even now, there is no identified physiological purpose for this phenomenon.

Prevalence of hiccups

The prevalence of hiccups has not been well articulated in palliative care. However, clinical experience suggests that this patient population is at greater risk of protracted hiccups compared to the general population. This observation is based on the fact that at any point, palliative care patients are likely to simultaneously have more than one risk factor. Hiccups are more likely to affect men compared to women with usually only one hemi-diaphragm affected.

Pathophysiology of hiccups

Despite no identified purpose, the hiccup reflex arc is a complex series of connections between an afferent limb, efferent limb, and central component. The afferent limb travels between the phrenic nerve, vagus nerve, and the sympathetic chain. The vagus nerve may be irritated anywhere along its path suggesting that hiccups may occur as the abnormalities in the head and neck structures, or thoracic or intra-abdominal structures. In addition, the afferent limb may also be stimulated by chin thrust. This is believed to be as the result of stimulation of the trigeminal nerve to the reticular formation.

The central component of hiccups remains poorly localized but probably involves connections to the fourth cerebral ventricle, the respiratory centre in the brain stem, medial reticular formation, the hypothalamus, and the phrenic nerve nuclei. Whilst there are likely to be numerous neurotransmitters, the most implicated remain dopamine and gamma-aminobutyric acid (GABA).

The efferent limb is mediated through the phrenic nerve to the diaphragm. Additionally, the external intercostal and scalenus anticus nerves cause contraction of the intercostal and scalene muscles. Lastly, the recurrent laryngeal nerve causes the glottis to close. As noted earlier, it is the column of air evoked by diaphragmatic contraction hitting the closed glottis which results in the noise form which the term hiccup is derived.

Causes of hiccups

There are multiple causes of hiccups reported in the literature with data extrapolated from case reports or case series (Woelk, 2011) (Box 10.1.6).

Presenting problems of hiccups

Hiccups have a frequency of four to 60 hiccups per minute and for each individual, there is a relatively constant rate. Higher arterial carbon dioxide levels tend to slow the frequency of hiccups.

Hiccups persisting for less than a few minutes are termed a 'bout' with hiccups persisting more than 48 hours labelled 'protracted'. Hiccups persisting for more than 1 month are considered 'intractable'. Whilst short bouts of hiccups are considered no more than a nuisance with interventions not indicated, more prolonged bouts can lead to serious complications. This is particularly so in people with serious illness already complicated by problems such as fatigue, anorexia, and weight loss. Protracted hiccups may cause sleep disturbances (Kvale and Shuster, 2006). Protracted hiccups may result in daytime drowsiness, mood disturbances such as anxiety and depression, and cognitive dysfunction. Protracted hiccups may also worsen fatigue, through a number of different mechanisms. Protracted hiccups may lead to skeletal muscle fatigue whilst concurrently interfering with people's capacity to eat and drink. In the worst case, hiccups may result in vomiting. Lastly, hiccups have been associated with aspiration and pneumonia. Protracted hiccups in a patient with a tracheostomy may lead to the life-threatening complication of respiratory alkalosis secondary to hyperventilation.

Aside from the physical implications, anecdotal reports suggest that hiccups may cause significant distress and anxiety to the person who has hiccups and to family and informal caregivers.

Investigations of hiccups

The diagnosis of hiccup is a clinical diagnosis only. Short bouts of hiccups are, by definition, self-limiting and therefore do not require investigation.

Box 10.1.6 Causes of hiccup

Central

- Vascular: cerebral aneurysm, ischaemic stroke, haemorrhagic stoke
- Space-occupying lesion: cerebral tumours, cerebral abscess
- Head trauma
- Encephalitis
- Neurodegenerative: multiple sclerosis, Parkinson's disease.

Peripheral

- Oesophageal: oesophageal dilatation, achalasia, food impaction, tumours
- Gastrointestinal: gastric distension, gastritis, reflux, peritoneal traction, small bowel obstruction, ascites
- Hepatic: liver metastases, primary liver cancers, hepatic abscess, cholecystitis
- Iatrogenic: benzodiazepines, opioids, corticosteroids, chemotherapy (e.g. cisplatinum)
- Respiratory: diaphragmatic irritation (pneumonia, pleural effusion, malignancy), subphrenic abscess
- Toxic/metabolic: renal failure, alcohol intoxication, electrolyte disturbances, hypoadrenalism
- Infectious: herpes zoster, gastrointestinal candidiasis
- Cardiovascular: myocardial ischaemia
- Perioperative: intubation, general anaesthesia, mechanical ventilation
- Psychological: anxiety, distress.

More protracted episodes of hiccups may require investigations.

Prior to initiation of investigations, regardless of the stage, a comprehensive history of the factors precipitating hiccups and physical examination is indicated. The physical examination should be directed to ensuring that structures of hiccup arc are considered. Basic investigations should include screening for renal failure, uraemia, and electrolytes disturbances particularly hyponatremia, hypokalaemia, and hypocalcaemia. Imaging studies should be tailored to the results of history and examination.

Management of hiccups

The main problem complicating the management of hiccups is the lack of robust studies. As a result, there are numerous medications and interventions suggested as effective for hiccups with most recommendations based on case reports.

Interventions may be pharmacological and non-pharmacological if reversible causes cannot be found (Jatoi et al., 2009) (Tables 10.1.1 and Table 10.1.2).

Table 10.1.1 A summary of non-pharmacological approaches to palliating hiccups

Intervention	Rationale for intervention
Vagal nerve stimulation using nerve stimulator	Vagus nerve stimulation
Acupuncture	Acupuncture points for hiccups are located near dermatomes related to afferent/efferent pathways, secondary synapses, or nuclei involved in the hiccup reflex arc suggesting that acupuncture may modulate the hiccup reflex
Stimulation of the palate or pharynx with a cotton applicator or catheter	Glottic stimulation
Traction on the tongue	Vagus nerve stimulation
Lifting the uvula with a spoon	Vagus nerve stimulation
Performing a Valsalva manoeuvre	Vagal nerve stimulation
Gargling or drinking ice water	Vagal nerve stimulation
Sudden fright	Sympathetic response
Breath holding	Increase $PaCO_2$
Breathing into a paper bag	Increase $PaCO_2$
Digital rectal massage	Vagus nerve stimulation

Table 10.1.2 Suggested interventions to palliate hiccups

Intervention	Rationale
Dopamine antagonists: Chlorpromazine, Haloperidol, Metoclopramide	Dopamine antagonist
Anticonvulsants: Gabapentin	The proposed mechanism whereby gabapentin is believed to modify hiccups is by inhibiting the $[alpha]_2[delta]$ subunit of voltage-dependent calcium channel and increasing GABA release, which modulates diaphragmatic excitability
Phenytoin, Sodium valproate, Carbamazepine	Blockade of sodium channels
Antispasmodics: Baclofen	Smooth muscle relaxant
Anti-arrhythmia: Nifedipine	Calcium channel blockade
Intravenous lignocaine	Sodium channel blockade
Benzodiazepines: Midazolam	Muscle relaxant, anxiolytic
Nebulized lignocaine	Blockade of sensory afferents
Corticosteroid: Dexamethasone	Anti-inflammatory
Neurostimulant: Methylphenidate	Inhibition of dopamine and noradrenaline (norepinephrine) uptake

Palliation of nausea and vomiting

Janet R. Hardy, Paul Glare, Patsy Yates, and
Kathryn A. Mannix

Introduction to palliation of nausea and vomiting

Nausea and vomiting (NV) are unpleasant symptoms that are reported as highly distressing by sufferers (Bliss et al., 1992; Bruera et al., 2000; Meuser et al., 2001). The symptoms are separate, but related, and arise in many life-limiting conditions such as cancer, AIDS, and hepatic or renal failure. A systematic review of symptom prevalence in various advanced diseases identified nausea prevalence rates ranging from 6–68% for people with advanced cancer, 43–49% for people with AIDS, 17–48% for people with heart disease, and 30–43% for people with renal disease (Solano et al., 2006). Less is known about the prevalence of vomiting, although when it occurs it is often in association with nausea. One study of patients with advanced cancer reported 62% had NV, 34% had isolated nausea and 4% had isolated vomiting (Stephenson and Davies, 2006). Importantly, when these symptoms are present they may significantly impact on well-being. A curvilinear relationship between nausea in cancer patients and Karnofsky performance status (PS) has been reported, with nausea at its worst when PS is rated as 40 (on a scale of 0–100) and decreasing as PS declines (Mercadante et al., 2000). A similar decrease in the prevalence and intensity of nausea at the end of life has also been documented in ambulatory cancer patients. The distress caused by the experience of nausea and, to a lesser extent, vomiting, is now better understood (Seow et al., 2011). NV has a significant impact on activities of daily living. In one study of patients with NV, over 40% rated the impact of NV on general activity and emotional well-being as higher than 5 on a 0–10-point scale (Yates et al., 2005).

Despite major advances in antiemetic drug development in the last two decades in the supportive care of patients receiving anti-cancer therapies, the incidence and severity of NV in patients with life-limiting disease remains a significant management problem. The neurophysiology of the vomiting reflex is well established in experimental animals, and is becoming better understood in man (Carpenter, 1990; Yates et al., 1998; Shelke et al., 2004; Sanger and Andrews, 2006). Several multifactorial clinical syndromes can contribute to NV in patients with advanced illness, including conditions associated with gastric stasis, biochemical disturbances, raised intracranial pressure, vestibular disturbances, and bowel dysmotility (Glare et al., 2008). Interventions aimed at reducing NV must therefore take into account the cause of the symptoms and the central emetogenic pathways involved. Treatment requires knowledge of these pathways, careful assessment of the patient, and prescribing tailored to the patient's individual needs. The physiological processes can be partly extrapolated from animal models but the management of a person experiencing nausea also demands empathy, supportive care, and attention to the patient's concerns, in addition to any pharmacological intervention deemed appropriate.

Pathways involved in emesis

Definitions

Nausea is an unpleasant subjective sensation that signals imminent vomiting, that may or may not result in vomiting. Vomiting is an objective patient experience involving the forceful elimination of the contents of the stomach by the sustained action of abdominal muscles and the opening of the gastric cardia (Shelke et al., 2004). It is important to differentiate NV from regurgitation (the passive retrograde flow of oesophageal contents into the mouth), rumination (an eating disorder), and dyspepsia (Glare et al., 2011).

Central pathways involved in emesis

Emesis is mediated centrally by two separate 'centres': the vomiting centre (VC) and chemoreceptor trigger zone (CTZ). Whilst these are anatomically distinct in experimental animals, in man the pathways are more diffuse (see Fig. 10.2.1).

The CTZ is located in the area postrema, in the floor of the fourth ventricle, where there is effectively no blood–brain barrier. Chemosensitive nerve cell projections are bathed by cerebrospinal fluid, which is in chemical equilibrium with blood in the fenestrated local capillaries (Miller and Leslie, 1994). The nature of the chemoreceptors in the CTZ remains obscure. Neural pathways project from the CTZ to the nucleus of the tractus solitarius and the reticular formation in the medulla oblongata, the location of the VC (Carpenter, 1990; Kovac, 2000; Shelke et al., 2004).

There may be a central antiemetic tone sustained by medullary neurons, inhibition of which potentiates the CTZ (Lang, 1999). An encephalinergic pathway has been hypothesized. Displacement of encephalins from their receptors by naloxone (Costello and Borison, 1977) or opioids (Yates et al., 1998) may reduce antiemetic tone, as may inhibition of encephalin synthesis by chemotherapy (Harris, 1982). This interesting hypothesis would help to explain the different emetogenic potentials of chemotherapeutic agents according to the point at which they interrupt cellular protein synthesis. The presence of medullary antiemetic tone and its influence on the CTZ remains speculative.
Fig. 10.2.1 The interrelationship between CTZ, VC, and their afferent inputs. —, established connections; ---, postulated connections; CTZ, chemoreceptor trigger zone; VC, vomiting centre; Enk, enkephalinergic pathways. *Receptors*: D$_2$, dopamine type 2; 5-HT$_{2,3}$, serotonin types 2,3; Ach$_m$, muscarinic cholinergic; H$_1$, histamine type 1.

The VC is a diffuse, interconnecting neural network that integrates emetogenic stimuli with parasympathetic and motor efferent activity to produce the vomiting reflex. It is now thought that the VC is not a distinct anatomical structure, but represents a convergence of a number of different afferent pathways in the lateral reticular formation of the medulla oblongata of the mid brainstem in close proximity to the nucleus of the tractus solitaries and area postrema at the level of the dorsal motor nucleus of the vagus nerve (Carpenter, 1990; Kovac, 2000). The integration of multiple activities mediated by several different centres is necessary for the vomiting reflex (Carpenter, 1990). This is a complex reflex, with respiratory, salivary, vasomotor, and somatic motor components. The VC acts as a central pattern generator. Sequential activation of various components of the VC, with amplification at each step, may be required to trigger vomiting. Nausea in the absence of vomiting may arise from stimuli that excite the VC without sufficient amplification to trigger the vomiting cascade. Thus, nausea usually accompanies the prodromal autonomic effects

that precede vomiting. However, the degree of nausea cannot be predicted by the accompanying autonomic changes; the relative reduction in gastric contraction may not be proportional. Also, nausea is not always relieved by vomiting. This usually indicates continuing excitation of the central emetogenic pathway.

The VC receives afferents from the cerebral cortex and higher brainstem, thalamus, and hypothalamus, the vestibular system, and via the vagus and splanchnic nerves, the pharynx, gastrointestinal (GI) tract, and serosae. There is also input from the CTZ, which can only initiate vomiting via the VC (Fig. 10.2.1) (Willems and Lefebvre, 1986). The close proximity to the VC of areas in the central nervous system associated with balance, vasomotor activity, salivation, and respiration explains why vomiting is often associated with increased salivation, swallowing, sweating, pallor, tachypnoea, tachycardia, and dizziness (Kovac, 2000).

Many potential neurotransmitters and receptors have been identified in the CTZ and nucleus of the tractus solitarius. These include dopamine, serotonin, histamine, opioid, cannabinoid, and

neurokinin receptors. The principal receptors at the CTZ are dopamine type 2 (D_2). At the VC the principal receptors are muscarinic cholinergic (Ach_m) and histamine type 1 (H_1) (Sanger and Andrews, 2006). Both sites exhibit serotonin type 3 (5-HT_3) receptors, and serotonin type 2 (5-HT_2) receptors appear to be important in the VC (Lang, 1999). Neurokinin type 1 (NK_1) receptors are widely distributed in the central nervous system, and particularly in those areas of the brainstem involved in emesis. These emetic neuroreceptor areas serve as sensors and are stimulated by drugs and electrolytes. This initiates a relay of neurotransmitters to the VC and the vomiting reflex (Kovac, 2000; Shelke et al., 2004). The blockade of these receptor sites is the mechanism of action of many antiemetics (Sanger and Andrews, 2006).

Nausea is reported as a highly distressing symptom. The link between nausea and mood may be related to involvement of the inferior frontal gyrus of the human cerebral cortex (Miller et al., 1996). NK_1 receptors, distributed widely in the brain are associated with regulation of mood and are also implicated in emesis. Blockade of NK_1 receptors is associated with both antidepressant (Kramer et al., 1998) and antiemetic (Navari, 2004; Gobbi and Blier, 2005) activity. Thus, the link between nausea and dysphoria may be biochemical or structural.

Afferent pathways involved in emesis

The interrelationship between the CTZ, VC, and their various afferent inputs is summarized in Fig. 10.2.1. The major afferent neural pathway from the body to the central structures is the vagus, with additional input via the splanchnic nerves, sympathetic ganglia, and the glossopharyngeal nerve. The vagus itself is stimulated via mechanoreceptors and chemoreceptors in the GI tract, serosae, and viscera (Willems and Lefebvre, 1986; Andrews et al., 1990; Lichter, 1993; Lang, 1999).

The VC receives descending fibres from higher centres that may stimulate or inhibit activation of the emetic cascade. Most vagal afferents terminate at the VC, but there is some vagal input to the CTZ (Koga and Fukuda, 1992). Projections from the vestibular nuclei, that mediate emesis, are incompletely understood, but are presumed to be similar to those that generate NV after the ingestion of toxins. This would involve the CTZ, but D_2 antagonists are not particularly effective in motion sickness. H_1 and Ach_m antagonists are more effective; they are thought to act on first-order vestibular neurons (Yates et al., 1998).

Choosing an antiemetic

The paucity of evidence to support decisions about antiemetic therapy for patients with advanced disease is well recognized (Glare et al., 2004; Ang et al., 2010). Before prescribing drugs, care should be taken to reduce the stimulus to nausea from the patient's environment. This includes avoidance of cooking smells, attention to unpleasant odours (e.g. from an infected, necrotic tumours), and presentation of small, attractive meals. Cool, fizzy drinks are often more palatable than still or hot drinks. Many patients experience a taste change so that previously innocuous foods taste nauseating.

Nausea can be relieved if it is possible to treat the underlying cause. Nausea associated with hypercalcaemia will improve following treatment with bisphosphonates, drug-related nausea with discontinuation of the drug, raised intracranial pressure with steroids or cranial irradiation, and constipation with laxatives (Ang et al., 2010). Treating the underlying cause is much more likely to relieve the symptom than antiemetics.

Two strategies have been proposed for the management of NV; mechanistic and empirical approaches. The mechanistic approach is detailed in Box 10.2.1 and is currently recommended as the ideal approach to management (Lichter, 1993; Glare et al., 2004). It involves identifying the most likely cause of the nausea and hence the pathways and receptors involved, preferably within the context of a clinical guideline (Peroutka and Snyder, 1982; Ison and Peroutka, 1986; Glare et al., 2004). Drugs known to inhibit those particular receptors are then chosen. Several uncontrolled studies have reported very high response rates when this strategy is utilized (Lichter, 1993; Bentley and Boyd, 2001; Stephenson and Davies, 2006). The difficulty with this approach is that the cause of nausea in advanced disease is often multifactorial, unclear, or of unknown origin (Kennett et al., 2005; Hardy et al., 2010). Moreover, there is no evidence to date that this approach is any more effective than using various antiemetics that cover a range of postulated pathways and receptors or in fact any well-tolerated single agent of proven efficacy irrespective of the underlying cause. This is termed the empirical approach and is equally supported by a number studies (Bruera et al., 1994, 1996, 2000; Mystakidou et al., 1998a).

Antiemetic drugs available

A wide variety of agents have antiemetic efficacy. Many are primarily used for other indications. The availability of specific drugs varies from country to country. Those that have potent, receptor-specific action are summarized in Table 10.2.1. The antiemetic efficacy

---

Box 10.2.1 The mechanistic approach to the management of nausea and vomiting

1. Identify the likely cause(s) of nausea and/or vomiting.

2. Identify the pathway by which each cause triggers the vomiting reflex.

3. Identify the neurotransmitter receptor involved in the identified pathway.

4. Choose the most potent antagonist to the receptor identified—the binding affinity of a particular antagonist predicts its antiemetic efficacy.

5. Choose a route of administration that ensures that the drug reaches its site of action—this often excludes the oral route.

6. Titrate the dose carefully, review the patient frequently.

7. *Give the antiemetic regularly.*

8. If symptoms persist, review the likely cause(s): additional treatment may be required for an overlooked cause, or alternative treatment may be suggested by a different cause becoming apparent.

9. If combining antiemetics, potential drug interactions need to be considered. For example, an antihistamine may counteract the effects of a prokinetic agent.

Table 10.2.1 Receptor-specific antiemetics of use in palliative care

Drug	Receptor and site (see text)		Indications	Dosage and routes	Side effects	Notes
Butyrophenones Haloperidol	D_2	-CTZ	Opioid induced N; chemical/metabolic N	1.5–5.0 mg/day; PO, SC	EPS, QTc, somnolence	Side effects unusual at low doses, caution in severe liver impairment
Prokinetic agents Metoclopramide	D_2 D_2 $5\text{-}HT_4$ (potentiation)	-CTZ -GIT -GIT	Gastric stasis; ileus	10–20 mg 4-hrly PO, SC, IV	EPS, restlessness, drowsiness Colic in GI obstruction	Prolonged half-life in renal failure
	$5\text{-}HT_3$ (at high doses)	-CTZ -GIT	Chemotherapy	N/A		Superseded by $5\text{-}HT_3$ antagonists
Domperidone	D_2 D_2	-CTZ -GIT	Gastric stasis, ileus	10–20 mg PO 4–8-hrly 30–90 mg PR 4–8-hrly	Colic if GIT obstructed; oesophageal pain, QTc	Does not cross BBB, extrapyramidal side effects are rare, cannot be given parenterally (cardiac toxicity)
Cisapride	$5\text{-}HT_4$ (potentiation) Ach	-GIT -GIT	Gastric stasis ileus	10 mg PO 6–8-hrly 30 mg PR 6–8-hrly	Abdominal cramps; diarrhoea; cardiac arrhythmias particularly with systemic azole antifungals, QTc	Prokinetic throughout GIT, withdrawn in many countries because of cardiac toxicity
Phenothiazines (including prochlorperazine chlorpromazine, thiethylperazine)	D_2 D_2 H_1 Ach α_1 Ad	-CTZ -GIT -VC -CNS -GIT -CVS		Prochlorperazine: 5–10 mg PO, 12.5–25 mg IM, 25 mg PR 6–8-hrly Chlorpromazine: 25–50 mg IM 4–6-hrly	Vary according to spectrum of receptor blockade, QTc	
Levomepromazine	$5\text{-}HT_2$ H_1 D_2 α_1 Ad	-VC -VC	Intestinal obstruction: peritoneal irritation; nausea of unknown aetiology; vestibular causes; raised ICP	5–12.5 mg/24-hrly PO, SC	Drowsiness at higher doses, orthostatic hypotension	Long half-life: once daily dosing may suffice
Antihistamines Cyclizine Cinnarizine Diphenylhydramine Promethazine	H_1	-CTZ -GIT -CVS -CNS -VC -vestibular afferents -brain substance -VC		Cyclizine: 25–50 mg 8-hrly PO/SC/PR Promethazine: 12–25 mg 8-hrly PO	Dry mouth, blurred vision, sedation, EPS Skin irritation at SC injection sites QTc	Cyclizine is least sedative but anticholinergic Avoid in the elderly
Diphenylhydramine	Ach_m					

Anticholinergics Hyoscine (scopolamine) Hydrobromide Butylbromide	Ach$_m$	-VC -GIT -GIT	Intestinal obstruction; peritoneal irritation; raised ICP; excess secretions	200–400 mcg 4–8-hrly subling/SC 500–1500 mcg/72-hour transdermal patches 20 mg PO/SC 6-hrly	Dry mouth, sedation, ileus, urinary retention, blurred vision, occasionally agitation	Useful if NV coexist with colic, illogical to give with prokinetics Does not cross BBB, antisecretory; non-sedative Poorly absorbed from the GI tract
5-HT3 antagonists Granisetron Ondansetron Tropisetron Polanesetron Dolasetron	5-HT$_3$	-GIT -CTZ -(VC)	Chemotherapy; abdominal radiotherapy; postoperative NV	Granisetron: 3 mg slowly IV up to 8-hrly; Ondansetron: 8 mg PO or slowly IV 8-hourly; Tropisetron: 5 mg PO or slowly IV daily Palonosetron 250 mcg IV daily	Headache in 30%; constipation; diarrhoea, dizziness, QTc	Effectiveness increased by combination with dexamethasone Indicated for NV related to chemo-, radiotherapy or surgery
NK1 antagonist Aprepitant	NK$_1$	Widespread	Late-onset chemotherapy-related NV	125 mg 1 hour prior to chemotherapy; then 80 mg OD for the next 2 days	Hiccups; asthenia; fatigue; somnolence; anxiety; anorexia; GI upset	Only available PO

CTZ, chemoreceptor trigger zone; VC, vomiting centre; GIT, gastrointestinal tract; ICP, intracranial pressure; mcg, micrograms; NV, nausea and vomiting; PO, by mouth; PR, by rectum; SC, by subcutaneous injection; IV, by intravenous injection; IM, by intramuscular injection; occ, occasionally; OD, once daily, EPS, extrapyramidal symptoms, QTc, prolonged QT interval, EPS, extrapyramidal symptoms.

and side effects of a drug can be predicted by its binding affinity for particular receptors (Peroutka and Snyder, 1982; Ison and Peroutka, 1986).

Drugs with receptor-specification

Dopamine (D$_2$) antagonists

The butyrophenones (haloperidol, droperidol), phenothiazines (promethazine, prochlorperazine) and benzamides (metoclopramide, domperidone) are all D$_2$ antagonists. Of these, haloperidol is said to be the most potent at the CTZ (Peroutka and Snyder, 1982). Although widely used in palliative care, systematic reviews have failed to identify any randomized controlled trials that prove the efficacy of dopamine antagonists (Wallenborn et al., 2006) or droperidol in any setting (Dorman and Perkins, 2010). A prospective uncontrolled clinical trial has suggested that haloperidol provides at least partial relief in around 50% of patients with NV not related to chemotherapy or radiotherapy (Hardy et al., 2010). Metoclopramide and domperidone, whilst having some CTZ anti-dopaminergic activity, act in the gut to antagonize D$_2$ and stimulate 5-HT$_4$ receptors. Metoclopramide is a weak antagonist of peripheral 5-HT$_3$ receptors explaining why high doses are necessary to control chemotherapy induced NV. Local acetylcholine release, mediated by the 5-HT$_4$ receptor, appears to play an important role in reversing gastroparesis and bringing about normal peristalsis in the upper GI tract. At high doses, metoclopramide blocks 5-HT$_3$ receptors in the CTZ and gut. Extrapyramidal symptoms (akathisia, acute dystonia, pseudoparkinsonism, and tardive dyskinesia) are a concern, especially in frail older patients. Prolonged use of metoclopramide (beyond 3 months) is not recommended by the US Food and Drug Administration. A recent study has shown that single doses, even at high doses (50 mg given postoperatively) were associated with surprisingly few side effects (Wallenborn et al., 2006). The development of specific 5-HT$_3$ antagonists has replaced the use of this drug for acute cancer chemotherapy-induced emesis (Basch et al., 2011). Metoclopramide is one of only a few antiemetics with high-grade evidence to support its use in advanced cancer (Glare et al., 2004; Ang et al., 2010).

Any agent that is prokinetic may induce colic in an obstructed intestine. Alternatively, it is postulated that drugs of this class may help to alleviate a partial obstruction by increasing gut motility. The action of prokinetic agents in the lower oesophagus may provoke oesophageal spasm; typically, this is retrosternal and may mimic angina pectoris. Extrapyramidal reactions occur with all of the D$_2$ antagonists, although the incidence with domperidone is extremely low (Ison and Peroutka, 1986). Many of these agents prolong the QT interval. This may be clinically relevant in patients on other drugs with the same effect (e.g. high-dose methadone)

Olanzapine has high affinity for multiple dopaminergic and other receptors (Glare et al., 2008). It is associated with less extrapyramidal side effects at the expense of somnolence and weight gain. There are uncontrolled studies suggesting benefit in NV (Passik et al., 2002; Jackson and Tavernier, 2003; Srivastava et al., 2003).

Phenothiazines

The phenothiazines are less potent D$_2$ antagonists with moderate antihistaminergic and anticholinergic actions. They have varying antagonist activity at other receptors that predicts their side effect profile (e.g. chlorpromazine, an α$_1$ adrenergic receptor may cause hypotension and sedation whereas diphenhydramine, a phenothiazine antihistamine Ach$_m$ receptor, may cause sedation and dry mouth). Chlorpromazine can lower seizure thresholds in patients with chronic seizures or epilepsy.

Levomepromazine blocks a wide spectrum of receptors. At higher doses, it is highly sedative and causes hypotension, but at lower doses (5–12.5 mg per 24 hours by mouth or subcutaneous infusion) it is a useful antiemetic with efficacy in uncontrolled trials similar to that of haloperidol (Eisenchlas et al., 2005; Kennett et al., 2005). Circumstantial evidence suggests that 5-HT$_2$ blockade may mediate levomepromazine antiemetic activity (Twycross et al., 1997). At the VC, its lower affinity for D$_2$ receptors may contribute to its broad-spectrum antiemetic activity. Comparative clinical trials are awaited.

Historically, prochlorperazine has been considered the drug of choice for motion sickness. In many countries, it is not licensed for parenteral use. Chlorpromazine is not effective for the prevention of motion sickness (Yates et al., 1998; Kovac, 2000) and is dose limited by sedation and hypotension (Mystakidou et al., 1998a, 1998b). Phenothiazines, along with most antiemetics are likely to worsen Parkinsonian symptoms.

Antihistamines and anticholinergics

The antihistamines act on H$_1$ receptors in the VC and on vestibular afferents. H$_1$ antagonists alleviate NV induced by vestibular disorders and motion sickness but not that related to chemotherapy (Shelke et al., 2004). Cyclizine is less sedating than the anticholinergic hyoscine (hyoscyamine, scopolamine) hydrobromide, which blocks Ach$_m$ receptors in the VC and peripherally (Ison and Peroutka, 1986). Although very widely used, the evidence to support the efficacy of this drug is very weak (Glare et al., 2004). Hyoscine hydrobromide can be given sublingually, subcutaneously, and transdermally. Its side effects are those of parasympathetic blockade, which may be beneficial (drying of secretions, reduction of colic) or troublesome (dry mouth, ileus, urinary retention, blurred vision). Hyoscine butylbromide (Buscopan®) does not have central antiemetic action as it does not cross the blood–brain barrier. In the gut, its anticholinergic properties reduce peristalsis and inhibit exocrine secretions, thus contributing to the palliation of colic and nausea in intestinal obstruction (De Conno et al., 1991). Promethazine has little anticholinergic activity. It is sedating and can cause skin irritation when delivered subcutaneously. According to Beers criteria (The American Geriatrics Society Beers Criteria Update Expert, 2012), the drug should be avoided in the elderly as clearance is reduced, resulting in increased risk of confusion, dry mouth, and other anticholinergic side effects.

5-HT$_3$ receptor antagonists

The discovery of selective 5-HT$_3$ receptor antagonists has been one of the most significant developments in supportive care in recent times and has revolutionized antiemetic prescribing for chemotherapy-induced nausea and vomiting (CINV). The initial early promise of this class of drugs in the 1980s has proved successful for acute-onset emesis in chemotherapy, although later-onset nausea remained a problem (Lichter, 1993; Gardner et al., 1995; Navari et al., 1999) until the development of the NK$_1$ receptor blockers (see 'NK$_1$ receptor antagonists'). Evidence of

benefit for the 5-HT$_3$ inhibitors has subsequently been shown for both radiotherapy (Feyer et al., 2011) and postoperative emesis (Carlisle and Stevenson, 2006) and these drugs are licensed specifically for these indications in many countries. Although extremely effective for the indications as specified above, no definitive place has been demonstrated for 5-HT$_3$ antagonists in the management of NV from other causes. An increasing body of evidence suggests that they may be as effective as many of the other agents in common use (Mystakidou et al., 1998a; Porcel et al., 1998; Hardy et al., 2002; Weschules et al., 2006).

5-HT$_3$ receptors have been demonstrated in the CTZ and VC centrally, and on terminals of vagal afferents in the gut peripherally. The emetogenic action of serotonin derived from enterochromaffin cells appears to be by direct stimulation of local vagal 5-HT$_3$ receptors. High abdominal vagotomy abolishes emesis induced by abdominal irradiation, and blood serotonin levels are rarely raised during emesis, although raised urinary levels of the serotonin metabolite 5-hydroxindole acetic acid reflect the timing and severity of emesis after chemotherapy (Cubeddu et al., 1995). Antagonists of 5-HT$_3$ block vagal afferent activity. A reflex increase in vagal efferent activity may be caused, and this has been shown to give rise to temporary (and inconsequential) bradyarrhythmias in patients receiving repeated doses of these drugs, although not in healthy volunteers (Upward et al., 1990; Watanabe et al., 1995). Several 5-HT$_3$ antagonists are currently available (see Table 10.2.1). Oral formulations are as effective and safe as intravenous. All are equivalent with respect to antiemetic activity and safety (Basch et al., 2011) and share similar adverse events (headache, constipation, and transient elevations of serum aminotransferases). Palonosetron was developed because of its longer serum half-life and higher binding affinity to the 5-HT$_3$ serotonin receptor. It is preferred in some centres as it can be given as a single dose. Dolasetron and its major metabolite, and granisetron are the most specific 5-HT$_3$ receptor antagonists. Ondansetron and tropisetron show some affinity for other receptors including α-adrenergic, other 5-HT and opioid μ receptors.

In contrast to ondansetron, the metabolism of granisetron is not subject to induction by cytochrome P450 inducers (Upward et al., 1990). All are licensed for use in children, and adverse effects are few. Evidence-based antiemetic guidelines issued by the American Society of Clinical Oncology make no distinction between the different agents available, suggesting that cost should dictate local practice. They also recommend the use of cheaper oral preparations rather than intravenous treatment as first line.

NK$_1$ receptor antagonists
These drugs have proven efficacy in control of late emesis from chemotherapy (Hesketh et al., 2003a; Basch et al., 2011) and are now included in international CINV antiemetic guidelines (Roila et al., 2010; Basch et al., 2011). While it is generally accepted that acute CINV is mainly due to release of serotonin within the GI tract, delayed CINV is thought to be occur following release of substance P in the brainstem (Darmani et al., 2009). An analysis of the timing of the effect demonstrates differential stimulation of 5-HT$_3$ receptors during the first 8 hours following emetogenic chemotherapy, followed by onset of stimulation of NK$_1$ receptors and loss of response to 5-HT$_3$ antagonists (Hesketh et al., 2003b). Aprepitant, the first commercial

NK$_1$ receptor antagonist antiemetic made available, is an oral preparation. Fosaprepitant dimeglumine is now available in a water soluble injectable formulation (Huang and Korlipara, 2010). The role of NK$_1$ receptor antagonists in palliative care settings is yet to be explored.

Other antiemetic drugs
Corticosteroids
Corticosteroids are known to possess intrinsic antiemetic properties and to enhance the effect of other antiemetics (Basch et al., 2011). Their mechanism of action is unclear and may be multiple. Corticosteroids may enhance antiemetic tone in the medulla by: reducing the permeability of the blood–brain barrier to chemicals that antagonize medullary antiemetic tone (such as chemotherapy agents), depleting the inhibitory amine γ-aminobutyric acid (GABA) in medullary antiemetic neurons, and/or reducing leu-encephalin release in the brainstem. Alternatively, the mode of action may relate to their established effects of reducing inflammation and oedema through eicosanoid metabolism (Sanger and Andrews, 2006). They do not ameliorate acute apomorphine or ipecacuanha-induced emesis (Sanger and Andrews, 2006).

The anti-inflammatory effects of corticosteroids in reducing tumour-associated oedema is thought to reduce the stimulus to emesis from peripheral autonomic stretch receptors or from intracranial tumours. Steroids may hasten the resolution of bowel obstruction and therefore the vomiting associated with this condition (Feuer and Broadley, 2000). Dexamethasone has efficacy against postoperative NV equivalent to ondansetron and droperidol (Apfel et al., 2004).

Cannabinoids
Anecdotal reports of a lower incidence of chemotherapy-induced emesis amongst marijuana smokers led to clinical trials of cannabinoids. Subsequently, the antiemetic activity of cannabinoids in both animals and humans has been well documented (Gonzalez-Rosales and Walsh, 1997; Parker et al., 2011). Two oral formulations, dronabinol and nabilone, are approved by the US Food and Drug Administration for use in CINV refractory to conventional antiemetic therapy. These drugs have shown superiority to dopamine antagonists in preventing CINV (Slatkin, 2007). This activity may occur at doses lower than those that lead to psychotropic side effects.

The mechanism of action of the cannabinoids has recently been explored with the discovery of the endocannabinoid system (Parker et al., 2011). Cannabinoid agonists act mainly on peripheral CB$_1$ receptors to decrease intestinal motility but may act centrally to attenuate emesis. Cannabinoid receptors have been detected within the dorsal vagal complex (Devane et al., 1992; Van Sickle et al., 2003). Some antiemetic effects of synthetic cannabinoids are reversed by naloxone, raising the possibility that some of their mechanism of action is on opioid μ receptors.

The use of the currently licensed cannabinoids is limited by psychomimetic side effects, particularly dysphoria in the elderly. This effect is said be reduced by low-dose phenothiazines but the resulting drowsiness may undermine any therapeutic advantage of the cannabinoids (Cunningham et al., 1985). Euphoria is more

common than dysphoria in younger patients, and there are reports of the successful use of nabilone for intractable nausea in AIDS patients, who tend to be younger than adults with cancer, and in children receiving chemotherapy (Dalzell et al., 1986; Green et al., 1989; Flynn and Hanif, 1992).

Benzodiazepines

Benzodiazepines have been used in chemotherapy antiemetic combinations, generally for the treatment and prevention of anticipatory nausea. However, there are no prospective trials to establish their effectiveness in this setting (Basch et al., 2011). Although they have little antiemetic activity per se, in drug combinations they reduce anxiety and the likelihood of anticipatory nausea. They decrease the anxiety and restlessness associated with anaesthesia and surgery thereby may decrease postoperative NV (Diflorio, 1992). These drugs are sedative and sometimes amnesic when used in effective doses, which limits their usefulness for patients with chronic nausea (Potanovich et al., 1993).

Octreotide

Octreotide is a somatostatin analogue that exerts wide-ranging potent inhibition of endocrine and exocrine secretions, promoting reabsorption of electrolytes in the gut (Lamberts et al., 1996) with both inhibition and restoration of normal GI transit (Soudah et al., 1991; Fallon, 1994). It is thus commonly used in an attempt to reduce the vomiting associated with bowel obstruction. Inhibition of exocrine secretion in the gut reduces distension, thus potentially contributing to diminished nausea (Mystakidou et al., 2002; Ripamonti et al., 2000; Laval et al., 2012).

Propofol

Propofol, an intravenous anaesthetic agent, has been noted to protect against postoperative emesis (Barst, 1990; Raftery and Sherry, 1992). Furthermore, subhypnotic doses of propofol have antiemetic action in postanaesthetic and chemotherapy-induced emesis (Scher et al., 1992; Borgeat et al., 1994). The duration of antiemetic action of an intravenous low-dose bolus outlasts the very short duration of hypnosis that would be introduced by a far larger dose, suggesting that hypnosis or anxiolysis are not the mechanisms of antiemetic action. Propofol has a widespread central nervous system depressant effect and it is possible that its antiemetic action is at a subcortical level, in either the CTZ or within the VC complex. The observation that propofol is less successful as an antiemetic following vagal-stimulating abdominal surgery suggests that its site of action may be the CTZ.

Opioids

As opioid receptors are abundant in the CTZ, it is thought that opioids or encephalins may possess antiemetic properties (Shelke et al., 2004). Patients will often complain of nausea when first commenced on opioids, probably through stimulation of receptors in the area postrema. The resolution of NV after a few days may be attributed to the antiemetic activity of opioids once they have crossed the blood–brain barrier (Yates et al., 1998). Opioids can induce or block emesis in experimental models and both actions can be antagonized by naloxone (Costello and Borison, 1977). Experimentally, intravenous fentanyl in subanaesthetic doses abolishes emesis due to morphine, cisplatin, and copper sulphate,

an effect that is reversed by naloxone (Barnes et al., 1991). The release of endogenous opioids during emesis could be part of the physiological mechanism by which the vomiting reflex is terminated (Yates et al., 1998). In clinical practice, the persistent nauseating properties of the opioids are well known and it remains doubtful whether these agents may have any role as antiemetics.

Mirtazapine

Mirtazapine is an antidepressant with some 5-HT$_3$ receptor antagonist activity. There are anecdotal reports of its benefit in the management of NV (Pae, 2006).

Non-drug measures of palliation of nausea and vomiting

Psychological techniques and massage

Most of the authoritative research on psychological techniques for palliation of emesis has been conducted amongst chemotherapy patients, which is not necessarily analogous to the situation of nauseated patients with disease not related to the treatment of cancer. However, these studies have shown that patients can learn techniques such as progressive muscle relaxation and guided mental imagery, and use these during the stress of chemotherapy with good effect (Cotanch, 1991; Burish and Tope, 1992; Fallowfield, 1992). Cognitive therapy has been used to help relieve the psychological morbidity arising from physical symptoms in advanced cancer (Moorey and Greer, 2002). Behavioural therapy with systematic desensitization is recommended for the management of anticipatory nausea (Basch et al., 2011).

One review of mind–body interventions for management of symptoms at the end of life identified 11 studies of massage interventions of which three reported improved outcomes for patients experiencing nausea. The review also identified 16 studies of meditation-based interventions for symptom management, of which six reported benefits for patients experiencing nausea. However, the methods and results were often inconsistent across studies, with many studies including mixed samples of patients who did not have advanced illness (Lafferty et al., 2006). Nevertheless, the possibility of adapting such techniques for the needs of nauseated patients with advanced diseases warrants further exploration (see Chapter 9.11).

Transcutaneous electrical nerve stimulation

Transcutaneous electrical nerve stimulation (TENS) has been shown to enhance the effect of antiemetic drugs. The TENS effect is blocked by naloxone, suggesting that it is mediated by endogenous opioid peptides (Saller et al., 1986). In a more recent study, TENS reduced the incidence of nausea and emesis after laparoscopic cholecystectomy when compared to placebo (Silva et al., 2012) (see Chapter 9.9).

Acupuncture and acupressure

There is some evidence for the benefit of acupuncture and acupressure when used in conjunction with standard antiemetics during chemotherapy (Ezzo et al., 2006; Bao, 2009) and to reduce postoperative NV (Lee and Fan, 2009). The benefit of acupuncture is lost if administered under general anaesthetic (Vickers, 1996). Acupressure prolongs the effect of acupuncture, and the

use of TENS in place of traditional acupuncture needles at the P6 acupuncture point is a practical technique for self-use by patients, being only slightly less effective than the use of traditional needles (Dundee et al., 1991). The P6 (Neiguan) acupuncture point is located in the midline of the palmar aspect of each wrist, approximately 3 cm from the palmar crease (see Chapter 9.12).

Dietary modification, ginger, fish oil, and aromatherapy

There is limited published evidence about dietary modifications to minimize NV for people with advanced illness. However, avoiding sights, sounds, and smells that can trigger NV, and respecting an individual's preferences and food choices are major considerations in advanced illness (Yates, 2012). Ginger has been used to treat nausea in a range of settings. No additional benefit was found over and above modern-day antiemetics (5-HT$_3$ antagonists and aprepitant) in a randomized controlled trial of CINV (Zick et al., 2009). Aromatherapy is less effective than standard antiemetics in postoperative NV (Hines et al., 2012). Fish oil supplements provided no benefit with respect to nausea in patients with advanced cancer (Bruera et al., 1987, 2003).

Clinical syndromes associated with nausea and vomiting

Table 10.2.2 summarizes some common or important causes of NV in patients receiving palliative care. They are grouped according to the pathway that mediates emesis, and are similarly grouped in the following discussion. In advanced cancer, there are a number of factors that are predictors of NV. These include: female gender (Walsh et al., 2000); GI symptoms such as local pathology or intestinal obstruction (Mercadante et al., 2000); age under 65 years (Walsh et al., 2000); specific tumour types such as gynaecological, stomach, oesophageal, and breast cancers (Vainio and Auvinen, 1996); the presence of metastases in the lung, pleura, peritoneum (Morita et al., 1999); and opioid medication (Meuser et al., 2001).

It must be emphasized, however, that in advanced disease, NV may have more than one cause, stimulating symptoms by more than one pathway (Hardy et al., 2010; Kennett et al., 2005). Sometimes, apparently appropriate treatment fails to relieve symptoms, necessitating a search for additional and less obvious causes. Sometimes, a cause cannot be identified. Into this category are likely to fall those with cancer-associated autonomic failure. Growth factors and other tumour products may be emetogenic; their actions are still only partly understood, but it is likely that such factors would act via the CTZ. Tumours arising outside the areas described in Table 10.2.2 may generate emesis via the same pathways, for example, head and neck tumours cause pressure effects which trigger autonomic relays to the VC. The key to good management of NV is a high index of suspicion, an understanding of the pathways involved, regular antiemetics, and the setting of realistic goals.

Chemical causes of emesis

Drug-induced nausea may arise by chemical action at the CTZ, by serotonin release in the gut, through GI irritation or gastric stasis, or a combination of these (Table 10.2.3).

Transient nausea mediated by the CTZ accompanies the introduction or increase of morphine in about one-third of patients (Campora et al., 1991) and can lead to chronic nausea in some patients on opioids. A number of clinical characteristics and specific genetic polymorphisms have been shown to be associated with the variability in NV amongst cancer patients receiving opioids (Laugsand et al., 2011). Most patients on opioids experience a degree of opioid-induced gastric stasis and associated constipation.

Multiple neurotransmitters are thought to be involved in the aetiology of CINV. Acute CINV is primarily related to the release of 5-HT within the GI tract while the delayed phase is related to the release of substance P in the brainstem (Darmani et al., 2009). Cytotoxic-induced nausea is mediated by the CTZ and by 5-HT$_3$ receptors on vagal gut afferents. Selective blockade of 5-HT$_3$ receptors in the gut is highly effective for immediate-onset emesis (Gregory and Ettinger, 1998). These drugs may also act at the CTZ. The addition of drugs that target other sites (e.g. corticosteroids and NK$_1$ receptor antagonists) enhances the effectiveness of treatment, particularly for delayed-onset emesis.

Metabolic causes of nausea include organ failure and hypercalcaemia, that may progress insidiously. Nausea in this scenario may be controlled using a central D$_2$ blocker.

Gastrointestinal causes of emesis

Pharyngeal irritation may cause retching, nausea, or cough-induced vomiting. The oropharynx is richly innervated by the glossopharyngeal nerve and vagus, and is highly sensitive to touch. Tenacious sputum or candida overlying the pharyngeal mucosa can stimulate the VC via these afferents. People with AIDS may also have mucosal lesions of cytomegalovirus or herpes simplex. Appropriate antimicrobial therapy is indicated for infections of mouth, pharynx, oesophagus, or respiratory tract. Sticky sputum may be loosened by inhalations, and irritating nocturnal cough causing retching and disturbed sleep may be palliated by the application of local anaesthetic spray to the pharynx (with appropriate caution about eating and drinking for the next few hours).

Delayed gastric emptying may arise from physiological abnormalities or mechanical resistance to emptying. Mechanical resistance includes ascites, hepatomegaly, pre-pyloric inflammation, duodenal ulceration or tumour, and pancreatic cancer. Resistance may be partial or there may be complete obstruction. Physiological abnormalities include anticholinergic effects of drugs (Table 10.2.3), and autonomic failure. The symptoms are listed in Table 10.2.2, they may not all occur and the diagnosis can easily be missed.

Complete gastric outlet obstruction is managed as high intestinal obstruction (see Chapter 14.3). Other causes of delayed emptying are managed by attention to optimizing gastric emptying and reducing stimulus to gastric stretch. The prokinetic agents metoclopramide and domperidone normalize the rate of gastric and upper intestinal peristalsis, increase lower oesophageal tone (thus reducing reflux), and relax the pylorus. Gastric and upper intestinal transit time is thus shortened. The prokinetic agent cisapride increases the rate of peristalsis throughout the GI tract. This drug has been withdrawn in several countries because of concerns about cardiotoxicity. Reduction in volume of meals and drinks and inhibition of gastric secretion using

H_2 blockers, proton pump inhibitors, or octreotide will reduce gastric stretch, thus reducing both the diaphragmatic irritation that gives rise to hiccup and the vagal stimulation that gives rise to nausea and pain.

Stretch and distortion of the GI tract activates mechanoreceptors in the bowel wall. Similar receptors are present in visceral capsules and in parietal serosal surfaces. Their afferent input is to the VC via the vagus and splanchnic nerves. Mechanoreceptors may be triggered by tumour distorting an organ, stretching or directly invading serosa or mesentery, or by increased transmural pressure in a hollow viscus proximal to a site of obstruction, such as the ureter or colon. This is, therefore, a common complication of advanced intra-abdominal, retroperitoneal, or pelvic malignancy. Local inflammation may potentiate afferent nerve receptors in the GI tract, mediating emesis in bowel infections such as cryptosporidiosis in AIDS patients.

If reversal of the cause of emesis is not possible, nausea may be palliated by using antiemetics active at the VC. Control of vomiting may be more difficult to achieve with obstruction in the GI tract. This is discussed in more detail in Chapter 14.3.

Constipation, with resultant colonic stretch, is assumed to be a cause of nausea and anorexia in advanced disease, although there are no studies to prove this. Management is of the constipation, although antiemetics acting at the VC may help to reduce the nausea. Concomitant anticholinergic agents should be avoided or reduced as they will exacerbate the constipation.

Cranial causes of emesis

Raised intracranial pressure may present with NV before headache is apparent. Meningeal irritation can also trigger emesis. Clinical associations are with intracerebral tumours (primary and secondary), bone metastases to skull (base of skull metastases may give rise to cranial nerve symptoms and signs), intracranial bleeding, and cerebral oedema. High-dose corticosteroids are the treatment of choice. An antiemetic acting at the VC may be necessary in addition. Palliative radiotherapy, chemotherapy, or surgery should be considered.

Other causes of emesis

Motion sickness can occur when sensory inputs regarding body position in space are contradictory, or are different from those predicted from experience and is dependent on signals from the vestibular system (Yates et al., 1998). Movement-associated emesis may be triggered by distorted or distended viscera exerting increased traction upon their mesentery during movement. Movement-associated nausea may also occur as a side effect of opioids, related to increased vestibular sensitivity. Centrally mediated emesis must be distinguished from passive regurgitation of gastric contents during movement in a terminally ill patient, which is usually related to gastroparesis. Placement of a nasogastric tube to aspirate the stomach dry of fluid and gas may be necessary to relieve this symptom.

Anxiety-induced emesis is a common experience in healthy people. The patient with advanced disease may be able to identify anxiety as the trigger to nausea, or carers may notice an association between symptoms and stressful situations or conversations. Other causes of emesis must be excluded as far as possible before attributing NV to anxiety. Treatment is by identifying anxiety as a trigger and then working collaboratively with the patient to increase relaxation, identify and manage anxiety-provoking thoughts, and establishing workable coping strategies (Fallowfield, 1992; Moorey and Greer, 2002). A number of behavioural techniques have been found to be effective including progressive relaxation, systematic desensitization, hypnosis, and cognitive and internal distraction (Shelke et al., 2004). Benzodiazepines may be useful as short-term adjuvants. Some patients benefit from tricyclic antidepressants with secondary anxiolytic properties, such as amitriptyline.

Anticipatory emesis is a conditioned response in some patients who have suffered nausea and/or vomiting provoked by a previous experience. Several studies have confirmed that the development of anticipatory NV involves elements of classical conditioning (Shelke et al., 2004). Any reminder of their previous experience may trigger emesis, such as television pictures of hospitals, hospital smells, or visits by hospital personnel. In the case of chemotherapy-induced NV, correlates and determinants of anticipatory nausea include female sex, young age, high levels of anxiety, distress, limited ability to cope, a history of alcoholism, or the experience of strange tastes during chemotherapy (Morrow and Rosenthal, 1996). It can be refractory to treatment and is best managed by ensuring good control of emesis from the first cycle of chemotherapy. Management is as for anxiety-induced emesis.

Intractable nausea

As with pain, the pathways of emesis are incompletely documented. Identification and reversal of the cause and administration of appropriate antiemetics given regularly and prophylactically (rather than only when the patient is reporting nausea) leads to control in most patients. In a minority, NV continues unabated. There are few published data about these patients. In those with cachexia and chronic nausea, one group has identified a subgroup of people with a degree of autonomic failure (Bruera et al., 1987).

Appropriate goal setting is important. It is unwise to expect or to promise total relief of NV, especially in cases of mechanical obstruction (e.g. bowel obstruction). Most patients will be content with some relief of nausea, even if intermittent vomiting continues, provided they have been informed that this is a possible outcome.

When all apparently appropriate measures have failed to relieve symptoms, and combinations of antiemetics directed at different receptors have proved ineffective, empirical use of drugs acting at a range of different receptors such as levomepromazine may offer relief to some patients. Good clinical trials of therapy for patients with refractory nausea are indicated.

Future developments

Progress has been made in the recognition of nausea as an important symptom that must be evaluated separately from vomiting. This has improved the quality of the data emerging from chemotherapy-related emesis and postoperative NV studies.

Patients' perceptions are different from those of nurses observing them, and there is a need for an agreed tool for measurement of NV (Olver et al., 1994). The development of tools for self-evaluation of symptoms by patients, and the identification of biological markers for emesis, would enhance the evaluation of antiemetic strategies. A comprehensive review of available tools for rating NV in palliative care concluded that an ideal measurement tool for the assessment of NV and retching has not yet been developed (Saxby et al.,

Table 10.2.2 Common syndromes involving nausea and vomiting in patients requiring palliative care

Syndrome	Causes	Key features	Pathway and receptors	Treatment possibilities
Chemically induced nausea	◆ Drugs: opioids, digoxin, anticonvulsants, antibiotics, cytotoxics ◆ Toxins: food poisoning, ischaemic bowel, e.g. gut obstruction, ? tumour products ◆ Metabolic: organ failure, hypercalcaemia, ketoacidosis	Of drug toxicity or of underlying disease, plus constant nausea, variable vomiting	Chemical action stimulates D_2 ($\pm$ 5-HT_3) in CTZ Chemotherapy $\rightarrow$ serotonin release in GI tract $\rightarrow$ 5-HT_3 receptors on vagus Chemotherapy $\rightarrow$ NK_1 receptor activation in brain	◆ Stop or reduce the offending drug ◆ Treat the underlying cause ◆ Haloperidol ◆ 5-HT_3 antagonists for chemotherapy or irradiation induced NV ◆ NK_1 antagonist for delayed emesis with chemotherapy

Gastric stasis	◆ Anticholinergic drugs, opioids
	◆ Ascites
	◆ Hepatomegaly
	◆ Peptic ulcer
	◆ Gastritis
	  • Stress
	  • Drugs
	  • Radiotherapy
	◆ Autonomic failure
		Epigastric pain, fullness, nausea, early satiety, flatulence, acid reflux, hiccup, large volume vomits (possibly projectile) gastric regurgitation, other features of autonomic failure	Gastric mecho-receptors
			↓
			Vagal afferents
			↓
			VC
			H1; Achm
				◆ Treat the underlying causes
				◆ Prokinetic agents
				◆ Reduce gastric secretions:
				  • H_2 blocker
				  • proton pump inhibitor
				  • Octreotide
				◆ Aid eructation: dimeticone

Stretch/distortion of GI tract	◆ Constipation ◆ Intestinal obstruction ◆ Mesenteric metastases	Altered bowel habit, nausea, vomiting, may be faeculent, colic	Gut/serosal Mechanoreceptors ↓ Vagal afferents ↓ VC	◆ Treat underlying cause ◆ Active bowel management ◆ Corticosteroids may reduce swelling associated with a tumour mass
Serosal stretch/ irritation	e.g.: ◆ Liver metastases ◆ Ureteric obstruction ◆ Retroperitoneal cancer	Of underlying condition, nausea, occasional vomiting	H_1; Ach_m	◆ Cyclizine ◆ Hyoscine butylbromide if bowel paralysis is acceptable
Irritation of GI tract	◆ e.g. cryptospordiosis	Profuse diarrhoea, nausea, occasional vomiting.		
Raised intracranial pressure/meningism	◆ Cerebral oedema ◆ Intracranial tumour ◆ Intracranial bleeding ◆ Meningeal infiltration by tumour ◆ Skull metastases ◆ Cerebral infections (AIDS)	Headache (diurnal); papilloedema, photophobia may be absent. Nausea may be diurnal; neurological signs may be absent	May be direct stimulation of cerebral H_1 meningeal mechanoreceptors ↓ VC H_1; Ach_m	◆ Treat underlying cause ◆ High-dose corticosteroids may reduce cerebral oedema ◆ Cyclizine ◆ Levomepromazine

(continued)

Table 10.2.2 Continued

Syndrome	Causes	Key features	Pathway and receptors	Treatment possibilities
Movement-associated emesis	◆ Opioids (more common in ambulant patients) ◆ Gut distortion ◆ Gastroparesis → passive regurgitation	Nausea and/or sudden vomits on movement/turning in bed	Opioid-induced sensitivity of vestibular afferents H_1; Ach_m Gut mechanoreceptors ↓ vagal afferents ↓ VC H_1;Ach_m	◆ Treat the underlying cause ◆ Nasogastric aspiration in terminal gastroparesis ◆ Cyclizine ◆ Cinnarizine ◆ Hyoscine hydrobromide ◆ Prochlorperazine
Anxiety-induced emesis	◆ Anxiety: • about self • about others • about disease • about symptoms ◆ Anticipatory emesis with cytotoxics	'Waves' of nausea, ± vomiting, reminders trigger nausea; may be relieved by distraction	Cortex ↓ VC H_1; Ach_m	◆ Address the anxiety ◆ Psychological techniques ◆ Relaxation ◆ Benzodiazepines may be useful

D_2, dopamine type 2 receptor; $5\text{-}HT_3$, serotonin type 3 receptor; H_1, histamine type 1 receptor; Achm—muscarinic cholinergic receptor; CTZ, chemoreceptor trigger zone; VC, vomiting centre; GI, gastrointestinal.

Table 10.2.3 Causes of drug-induced nausea

Mechanism	Drugs	
Activation of chemo-receptor trigger zone	Opioids	Cytotoxics
	Digoxin	Imidazoles
	Anticoagulants	Antibiotics
Gastrointestinal irritation	Non-steroidal anti-inflammatory drugs	Antibiotics
		Cytotoxics
	Iron supplements	
Gastric stasis	Tricyclics	Opioids
	Phenothiazines	Anticholinergics

2007) although numerical rating scales have been used to measure other subjective symptoms and are likely to be just as relevant for nausea (Hjermstad et al., 2011).

Much of the research to date has attempted to identify key neurotransmitter receptors and find ways of interfering with their action. The underlying assumption of this approach is that a particular transmitter or receptor is pivotal and that a stimulus to emesis operates via one predominant pathway (Sanger and Andrews, 2006). This seems unlikely in a palliative care population. Improved outcomes in the management of CINV have followed the use of several drugs in combination (i.e. a 5-HT$_3$ antagonist plus an NK$_1$ inhibitor and dexamethasone) to suppress more than one pathway. Whether this approach may be of benefit for the control of NV not related to chemotherapy and whether a combination of antiemetics is any better than a broad-spectrum single agent remains unknown.

Recent work around symptom clusters (Skerman et al., 2012) has highlighted the need to maximize treatment of those symptoms commonly associated with NV (e.g. anorexia, dyspepsia, and fatigue). It would be of interest to explore whether a more holistic approach to NV would lead to improved outcomes.

10.3

Constipation and diarrhoea

Nigel P. Sykes

Definition of constipation and diarrhoea

A working definition of constipation is 'the passage of small, hard faeces infrequently and with difficulty' (Larkin et al., 2008). The often-referred-to Rome Criteria (Longstreth et al., 2006), designed for gastroenterological research into idiopathic constipation, require that a constipated patient should have had for at least 3 months two or more of the following: straining during at least 25% of defecations, a sensation of anorectal obstruction during at least 25% of defecations, lumpy or hard stools at least 25% of the time, and fewer than three bowel movements per week.

   Patients, however, differ in the weights they give to different aspects of this symptom cluster and the length of time over which they have to persist before they consider themselves constipated. Therefore they may consider themselves constipated when a doctor using the Rome Criteria would not (Probert et al., 1994). The importance of constipation in the context of cancer is as a symptom—or a syndrome—rather than as a disease, and it is therefore appropriate that we should be hearing the patient's complaint of constipation and understanding what they mean by it rather than trying to validate their opinion by comparison with external norms.

Prevalence of constipation and diarrhoea

In the general population, around 10% will report themselves to have constipation (Connell et al., 1965; Everhart et al., 1989), with the highest prevalences tending to be associated with older age and female gender. Physical illness is a risk factor for constipation: 63% of elderly people in hospital have been found to be constipated, compared with 22% of the same age group living at home (Wigzell, 1969). Constipation is more common in people terminally ill with cancer than in those dying of other causes (Cartwright et al., 1973), and about 50% of patients admitted to British hospices complain of it. There is evidence that constipation is inadequately treated in both cancer units (Laugsand et al., 2011) and palliative care (Goodman et al., 2005). As a result, constipation rivals pain in prevalence (Potter et al., 2003) and as a source of distress (Dunlop, 1989) in this patient group.

Normal intestinal physiology

Bowel function is the result not only of the state of intestinal motility but also of its fluid handling.

Intestinal motility

Gut contents spend 2–4 hours in the small bowel, whereas transit time through the colon is usually 24–48 hours and may be considerably longer: nearly half of a hospice population had transit times of between 4 and 12 days (Sykes, 1990).

   Small and large intestines each have their own characteristic motility patterns, but throughout the gut most muscle movements mix the contents rather than propel them. This facilitates enzymatic and bacterial breakdown of food and absorption of the resulting nutrients and of water.

   The colon shows episodes of forward peristalsis, resulting in mass movements of gut contents, about six times per day grouped into two peaks, a larger one associated with wakening and breakfast and a smaller one associated with the midday meal (Bassotti and Gaburri, 1988). The frequency is reduced by inactivity.

   Gut muscle layers form a syncytium through which depolarization spreads from pacemaker areas. The myenteric nerve plexus coordinates motility, which is also under external neuronal influence, particularly via the parasympathetic system. High spinal cord transection mainly abolishes the motility response to food, but low cord or pelvic outflow lesions produce colonic dilation and slowing of transit in the descending and distal transverse colon.

   Autonomic neuropathy can occur as a non-metastatic manifestation of malignancy, particularly in association with small cell carcinoma of the lung and carcinoid tumours. The resulting neural damage most commonly causes gastroparesis, but can also be associated with severe constipation (Walsh and Nelson, 2002).

   The two principal neurotransmitters involved in the control of peristalsis appear to be acetylcholine (ACh) and vasoactive intestinal peptide (VIP). Peristalsis movements have two components, ascending contraction and descending relaxation; ACh mediates the first of these and VIP the second. Both ACh and VIP neurons are modulated by other agents of which endogenous opioids are one group. Both exogenous opioids and drugs with anticholinergic effects will therefore have the capacity to disrupt peristalsis and precipitate constipation.

Intestinal fluid handling

About 7 L of fluid are secreted into the gut each day, to which are added at least 1.5 L of dietary fluid. Most of this is reabsorbed by the small bowel, especially the jejunum, but over 1 L is left to enter the colon. As daily stool water content is around 200 mL and the difference between constipation and diarrhoea in terms of fluid excretion is only about 100 mL per day, the fine tuning of fluid absorption by the colon is very important in maintaining a convenient bowel habit.

   Fluid handling reflects a dynamic state of absorption and secretion in the gut wall. Most secretion occurs from the mucosal crypt cells and absorption takes place in the villous cells. Through the

enteric nervous system mechanical stimulation of mucosal sensory neurons activates secretion as well as stimulating blood flow and smooth muscle contraction. 5-hydroxytryptamine (5-HT), substance P, and neurokinins 1 and 2 are involved in the sensory side of the reflex and VIP is the secretomotor neurotransmitter (Cooke et al., 1997). The presumed physiological importance of this linkage is the enhancement of digestion through greater mixing and dilution of luminal contents and the increased absorption that has been shown to accompany an increase in motility.

Causes of constipation

Constipation in patients with progressive disease is usually multifactorial. Thus, an ill person with poor food intake, impaired mobility, and a requirement for opioid analgesia has three reasons to be constipated. A list of the constipating factors most relevant to palliative medicine is given in Box 10.3.1. Of these, other than in patients undergoing cancer chemotherapy where some regimens commonly have constipation as an adverse effect, the most important are the secondary effects of disease and the use of opioids.

In advanced cancer, the use of morphine and the other opioid analgesia is probably the greatest single constipating factor which can be isolated, but there is a background of widespread constipation arising from debility. In one study, 63% of advanced cancer patients not taking morphine required laxatives, a figure similar to that found in the ill elderly, but 87% of those receiving morphine needed them and used a higher average dose (Sykes, 1998).

The functional effect of opioids is to reduce peristaltic propulsion, but to enhance non-propulsive contractions. Opioids also cause constipation through changes in intestinal fluid handling. In part these changes result simply from the additional time available for water absorption because luminal contents are slowed down but, in addition, opioids cause inhibition of secretomotor neurons so that less fluid enters the gut. The result is drier, harder, and smaller stools that are more difficult to pass (Bannister et al., 1987). Opioids also reduce sensations of gut distension, including rectal distension. This may help to precipitate faecal impaction, especially in older patients in whom rectal sensitivity may already be impaired as a result of ageing.

Most opioids are probably similar in their constipating potency. However, there is evidence that transdermal fentanyl is somewhat less constipating than morphine (Radbruch et al., 2000) or oxycodone (Ackerman et al., 2004), the same probably being also true of other lipophilic opioids such as buprenorphine and alfentanil that require only relatively small doses to be given in order to achieve central nervous system penetration. Methadone analgesia has been associated with lower laxative requirements than the use of either morphine (Daeninck and Bruera, 1999) or hydromorphone (Mancini et al., 2000). This has been attributed to the effects of methadone being only partly mediated through opioid receptors as a result of its *N*-methyl-D-aspartate receptor activity. Tramadol and tapentadol, also opioids whose actions are partly mediated via other receptor types, may also be less constipating than morphine but are also less potent analgesics.

A group of drugs frequently used in palliative care that exacerbate constipation are those with anticholinergic effects, such as tricyclics, antihistamines, and neuroleptics. This effect is unsurprising, given the role of ACh as the chief stimulant neurotransmitter for peristalsis.

Box 10.3.1 Causes of constipation in palliative medicine

Malignancy

Directly due to tumour:

- Intestinal obstruction due to (i) tumour in the bowel wall or(ii) external compression by abdominal or pelvic tumour
- Damage to lumbosacral spinal cord, cauda equina or pelvic plexus
- Hypercalcaemia.

  Due to secondary effects of disease:

- Inadequate food intake
- Low-fibre diet
- Dehydration
- Weakness
- Inactivity
- Confusion
- Depression
- Unfamiliar toilet arrangements.

Drugs

- Opioids
- Drugs with anticholinergic effects:
  - Hyoscine
  - Phenothiazines
  - Tricyclic antidepressants
  - Antiparkinsonian agents
- Antacids (calcium and aluminium compounds)
- Diuretics
- Anticonvulsants
- Iron
- Antihypertensive agents
- Vincristine.

Concurrent disease

- Diabetes
- Hypothyroidism
- Hypokalaemia
- Hernia
- Diverticular disease
- Rectocele
- Anal fissure or stenosis
- Anterior mucosal prolapse
- Haemorrhoids
- Colitis.

Diagnosis

Assessment

It is the frequency and difficulty of defecation that are the basis for the diagnosis of constipation and, given the normal variability of bowel habit, should be compared with the pre-illness pattern. Abdominal examination and, unless there has been a recent full evacuation, rectal examination, will help to avoid the major pitfalls in the diagnosis of constipation in palliative medicine. These are:

Impaction, presenting as diarrhoea, often with incontinence

This occurs characteristically in elderly patients in whom confusion or rectal insensitivity leads to the formation of a large faecal mass that is impossible to pass spontaneously. Semi-liquid faecal material from higher in the colon seeps past the mass, appearing as diarrhoea and, if the closing pressure of the anal sphincters has been exceeded by the mass, faecal leakage or incontinence. Most faecal impactions are low enough to be apparent on rectal examination.

Intestinal obstruction by tumour or adhesions

Known intra-abdominal malignant deposits, previous intestinal surgery, alternating constipation and diarrhoea, gut colic, and nausea and vomiting combine to suggest the presence of intestinal obstruction. A similar picture can, however, occur in severe constipation. The distinction is important, as attempts to clear 'constipation' which is actually obstruction, by use of stimulant laxatives can cause severe pain. A plain abdominal radiograph may help clarify the diagnosis.

Nausea

Some patients rapidly experience nausea, with or without vomiting, in the presence of intestinal hold-up (Twycross and Lack, 1986a). Unexplained nausea or vomiting should prompt enquiry and examination for constipation.

Abdominal pain

The effort of colonic muscle to propel hard faeces commonly causes abdominal pain, frequently colicky in nature. Such pain may be particularly marked—and difficult to diagnose—where abdominal or pelvic tumour exists, presumably as a result either of pressure on the tumour from distended gut or because of partial intestinal obstruction. Abdominal palpation may reveal faecal masses in the line of the descending colon and even that of the more proximal colon and caecum. The distinction between tumour and faecal masses can be hard to make. Faeces will usually indent, if the patient will tolerate sufficiently firm pressure, and may give a crepitus-like sensation because of entrained gas. They also move, given time. Occasionally an abdominal radiograph is needed to distinguish tumour from stool.

The complete absence of stool on rectal examination implies colonic inertia. Rectal examination may also uncover rectal tumour, a rectocele, solitary rectal ulcer, or anal stenosis. A lax anal sphincter may indicate spinal cord damage associated with colonic hypotonia. If a rectocele or compression from pelvic tumour masses is suspected, vaginal examination may be justifiable.

Examination of the stool itself can be useful. Small, hard pellets suggest slow colonic transit, ribbon-like stools suggest stenosis or haemorrhoids, and blood or mucus suggests tumour, haemorrhoids, or coexisting colitis.

Urinary incontinence

Faecal impaction is a well-recognized precipitant of urinary incontinence in the elderly, and the recent onset of incontinence should indicate abdominal and rectal examination as the first investigative steps.

Investigations

Investigations are rarely needed in the assessment of constipation in palliative medicine. Abdominal radiography may distinguish between constipation and obstruction if there is persisting doubt, but is rarely necessary and should certainly not be a standard procedure.

Blood tests are even more rarely needed but, but if the clinical picture is suggestive, corrected calcium levels and thyroid function tests should be performed.

Measurement tools

Patients' perception of their constipation can be formally assessed by use of visual analogue (VAS) or verbal rating scales, or questionnaires. A discrete response modification of the VAS and a verbal rating scale have each been found to have validity and to be easy to use in a palliative care setting (Sykes, 2001). Since the most common cause of diarrhoea in palliative care is the treatment of constipation (Twycross and Lack, 1986b) it is appropriate that any subjective measure of bowel function includes the ability to assess not only constipation but also diarrhoea as well. This is easily applied with VAS and adjectival scales, but is lacking in the questionnaires that have been validated only for the assessment of constipation, such as the well-established Constipation Assessment Scale (McMillan and Williams, 1989), the PAC-SYM (Patient Assessment of Constipation Symptoms) (Frank et al., 1999), or the newer Constipation Severity Instrument (Varma et al., 2008). In contrast, the Victoria Bowel Performance Scale was designed for use in palliative care and assesses both constipation and diarrhoea equally (Downing et al., 2007). It has proved acceptable to staff in this setting and capable of influencing improvement in constipation management (Hawley et al., 2011).

The aspects of bowel function that are objectively measurable by direct assessment are stool frequency and form. Simply counting the number of occasions when some stool has been passed may be misleading in making a diagnosis of the presence or absence of constipation: a frequent loose stool may indicate not diarrhoea but faecal impaction with overflow. What is more helpful is to count only episodes of formed stool leading to a sense of reasonably complete rectal evacuation. The basis of comparison is the individual's previous normal pattern, as the range of normal bowel movement frequency is very wide, ranging from three to 21 stools per week (Connell et al., 1965).

The shape of the stools is a guide to their consistency and has also been shown to be correlated with bowel transit time in both idiopathic constipation and palliative care cancer populations (O'Donnell et al., 1990; Sykes, 1990). With the aid of illustrated charts, of which the Bristol Stool Form Scale (Fig. 10.3.1) is best known, patients can estimate stool form reliably for themselves as an adjunct to recording stool frequency.

Scoring systems for radiological assessment of constipation exist, including in palliative care (Bruera et al., 1994), but have been heavily criticized for their unreliability (Jackson et al., 2009).

THE BRISTOL STOOL FORM SCALE

Type 1		Separate hard lumps, like nuts (hard to pass)
Type 2		Sausage-shaped but lumpy
Type 3		Like a sausage but with cracks on its surface
Type 4		Like a sausage or snake, smooth and soft
Type 5		Soft blobs with clear-cut edges (passed easily)
Type 6		Fluffy pieces with ragged edges, a mushy stool
Type 7		Watery, no solid pieces ENTIRELY LIQUID

Fig. 10.3.1 The Bristol Stool Form Scale.

Treatment

Good overall symptom management sets the best context for relief of constipation. Thus, tackling pain and breathlessness with the aid of both drugs and physiotherapy will maximize mobility; control of nausea and provision of a tailored diet containing as much fibre as tolerable will maximize dietary intake; and encouragement of fluids will minimize dehydration. The sum effect of all these interventions will be to normalize as far as possible the gut's working environment.

Despite these measures most patients with advanced disease will need additional assistance in order to avoid constipation. Some will wish to use non-pharmacological methods initially or on an ongoing basis. Herbal remedies may contain the same types of chemical as proprietary laxatives and so will have a similar effectiveness, albeit less predictable because less standardized. However, there is little or no evidence for other complementary approaches to constipation, whose principal contribution is likely to be to the overall sense of well-being of the patient rather than the specific relief of their constipation. The best support is for abdominal massage, which can equal the effect of a regular laxative regimen but at a significantly greater cost in terms of staff time (Emly et al., 1998).

The predominant action of laxative agents can be characterized as either softening the stool or stimulating peristalsis. Clinical

experience has suggested that, although initially a softening laxative alone may be adequate, more severe constipation tends to respond best to a combination of the two types (Larkin et al., 2008). There is some experimental support for this view from a study conducted on healthy volunteers using a model of opioid-induced constipation. Here the combination of a stimulant and a softening laxative resulted in fewer adverse effects, such as colic, and a lower medication burden than the use of either type of laxative on its own (Sykes, 1997). However, a study in cancer patients failed to show a clear advantage to the addition of a softener (docusate) to a stimulant (senna) (Hawley and Byeon, 2008) and the stimulant sodium picosulfate has been found to be effective and well tolerated when used as a single agent in a palliative care population ((Twycross et al., 2006).

A systematic review of laxative use in the elderly found that any laxative would increase bowel frequency by about 1.4 stools per week compared with placebo (Petticrew et al., 1997). Given the lack of evidence for true differences in efficacy and their generally mediocre palatability (Morrison and Pirrello, 2011), the choice of laxative should be strongly influenced by patient preference and by cost.

Stimulant laxatives

Examples include senna, bisacodyl, dantron, and sodium picosulfate. These drugs differ in the extent to which they require activation by colonic bacteria and are subject to hepatic recirculation. They all act on the myenteric plexus to stimulate intestinal contraction. Concerns about carcinogenicity with continued use appear to be unsupported in practice (Nusko et al., 2000). However, dantron is subject to a limited licence in some countries for this reason and also has the potential to cause perianal skin rashes in incontinent patients.

$5-HT_4$ agonists, of which tegaserod is currently licensed in some countries, may also be considered stimulant laxatives in that they reinforce normal enteric neuronal stimulation of peristalsis (Kamm et al., 2005). Whether they are effective in situations where the enteric nervous system is damaged, as in some cases of cancer-related constipation, has not been demonstrated.

Softening laxatives

All these preparations primarily soften the stool, making it easier to pass, but do so by different mechanisms.

Osmotic agents retain water within the gut lumen. Sugars, such as lactulose, act in their native form in the small bowel before being broken down by colonic flora to organic acids whose pH-lowering effect is speculated to enhance motility and secretion in the proximal colon (Jouet et al., 2008). In practice, lactulose is a relatively weak laxative and gives rise to flatulence in about 20% of patients. Conversely, inorganic osmotic substances such as magnesium hydroxide or sulphate are not absorbed and so maintain their osmotic potency throughout the intestine. They also appear capable of stimulating peristalsis and at higher doses give a pronounced purgative effect.

Surfactants such as docusate or poloxamer increase water penetration of the stools. Docusate also promotes water, sodium, and chloride secretion in the jejunum and colon, but its efficacy has been questioned (Hurdon et al., 2000).

Macrogols, such as polyethylene glycol, render water unabsorbable by the gut. Their effect therefore depends on the volume of water in which they are dissolved. Secondarily this also contributes to stimulation of gut contraction as a reflex response to distension. Macrogols are now one of the best-evidenced groups of laxatives (American College of Gastroenterology, 2005) and have been shown to be an effective oral treatment for faecal impaction (Culbert et al., 1998), but this may require the daily consumption of a litre of the solution, which not all patients can tolerate.

Chloride channel activator: lubiprostone is to date the only example of this mode of action. Acting on type 2 chloride channels on the apical surface of the luminal epithelium, it increases secretions without electrolyte disturbance. A secondary effect on motility is claimed and both small and large bowel transit is accelerated (Camilleri et al., 2006).

Bulk-forming agents such as psyllium and methyl cellulose increase the size of stools partly by providing material that resists bacterial breakdown and hence remains in the gut, and partly by providing a substrate for bacterial growth and gas production. Effective in mild constipation, they are less helpful in cancer patients for three main reasons. First, they need to be taken with at least 200–300 mL of water; this and their consistency are unacceptable to many people who feel unwell. Second, if taken with inadequate water, a viscous mass may result, which can complete an incipient malignant obstruction. Third, their effectiveness in severe constipation is doubtful.

The key to using general laxatives such as those mentioned above is to titrate the dose against response. This implies that there is in place some disciplined follow-up of patients' perception of their bowel function, preferably assisted by recording of the frequency and type of bowel actions passed. Common practice has been to initiate laxative therapy with a softening agent. However, there is growing evidence that a stimulant laxative which, although principally having a motor effect will also to some extent soften stool through both reducing the time available for water absorption and a direct secretory action, may be a more effective single-agent choice. Addition of a softener is indicated if colic occurs.

If oral laxatives are inadequate, recourse can be had to rectal interventions: suppositories, enemas, or, at the last resort and with appropriate analgesia and sedation, manual evacuation of the rectum. Anything introduced into the rectum may induce defecation via the ano-colic reflex, but suppositories may additionally have an osmotic softening action (glycerine or sodium phosphate) or may locally stimulate peristalsis (bisacodyl). Enemas may lubricate (olive or arachis oils) or soften via osmotic (sorbitol, sodium phosphate, or sodium citrate) or surfactant (sodium docusate, sodium lauryl, or alkyl sulphoacetate) actions. Attention to laxative dosing can halve the use of enemas and suppositories (Sykes, 1991). This is important not only because of the staff time involved but also because rectal laxatives are widely disliked, with only 17% preferring suppositories or enemas to oral laxatives. Nevertheless, it has been reported that among late-stage cancer patients 72% have received suppositories and 65% an enema, with no less than 40% continuing to receive them on an ongoing basis (Droney et al., 2008).

Newer developments

The limitations of existing general laxatives have led to interest in finding specific agents for opioid-induced constipation. As the constipating action of opioids is predominantly peripheral in man, mediated via opioid receptors in the gut itself, an opioid

antagonist could prevent or relieve this provided it did not reach the opioid receptors in the central nervous system responsible for analgesia. Two opioid antagonists are currently licensed for this indication.

Methylnaltrexone is a quaternary derivative of the mu-opioid antagonist naltrexone whose polarity prevents it from crossing the blood–brain barrier. It is administered by subcutaneous injection and in a series of 134 patients who were taking regular opioids and had advanced disease was significantly (p < 0.0001) more likely than placebo to induce a bowel action. Median time to response was 0.5 hours (Thomas et al., 2008). For patients who had not responded to the first dose the chance of a bowel movement response to a second dose was 35% and to those who had not responded to either of the first two doses there was a 26% response rate to a third dose (Chamberlain et al., 2009). If no response has been obtained after three methylnaltrexone doses it is appropriate to seek other remedies. The overall response rate in this sample was about 50%, probably indicating the important role of other constipating factors even where opioids are involved. The observed adverse effects did not suggest any methylnaltrexone antagonism of central effects of opioids.

Methylnaltrexone appears appropriate to use when constipation is associated with opioid use, has not been satisfactorily controlled with general laxatives by mouth and either an enema or suppositories are being considered (Fig. 10.3.2). For a few people, methylnaltrexone may become their routine therapy for constipation but the excess cost over existing laxatives is considerable, and it seems likely that for most patients the role of methylnaltrexone will be to remove an accumulation of stool and allow a fresh start to be made on laxative therapy in order to establish an effective regimen.

Early work with naloxone administered orally for opioid-induced constipation found an unacceptable occurrence of opioid withdrawal or return of pain, despite the drug having only a 1–3% bioavailability by this route (Sykes, 2005). However, an oral sustained-release combination of oxycodone and naloxone in a fixed 1:2 dose ratio has been licensed as an analgesic with the claimed advantage of reducing the risk of opioid-induced constipation. There is evidence that it reduces the perceived severity of constipation and also increases bowel movement frequency (Vondrackova et al., 2008). The ability to improve constipation while preserving analgesia compared with use of oxycodone alone was confirmed in a group of cancer patients (Ahmedzai et al., 2011). These studies did not show an excess of opioid withdrawal effects, perhaps as a result of the lower peak of naloxone absorption achieved through use of the sustained-release mechanism rather than the immediate-release formulation employed in previous studies. It might be noted that the low oral bioavailability of naloxone depends on rapid metabolism by the liver: in hepatic impairment blood levels can be very much greater. Patients with impaired liver function were excluded from trials of the oxycodone/naloxone combination.

A suggested guide to the management of constipation in palliative care is given in Fig. 10.3.2.

Diarrhoea

Diarrhoea is the passage of frequent loose stools with urgency. Objectively, it has been defined as the passage of more than three unformed stools (Bristol stool forms 5–7 (see Figure 10.3.1)) within a 24-hour period. Patients, however, may describe as 'diarrhoea' a single loose stool, frequent small stools of normal or even hard consistency, or faecal incontinence. As with constipation, a complaint of diarrhoea requires careful clarification.

Prevalence of diarrhoea

Diarrhoea is a complaint of 7–10% of cancer patients on admission to a hospice and 6% of similar patients in hospital. It is, therefore, a far less common problem in palliative medicine than constipation when cancer patients are being considered, but 27% of symptomatic HIV-infected patients have been reported to suffer diarrhoea (Rolston et al., 1989) (for management of HIV-related diarrhoea, see Chapter 15.1.).

Clinical manifestations and diagnostic considerations

Diarrhoea persisting for over 3 weeks is said to be chronic and is often linked to serious organic disease. Most diarrhoea is acute, lasting only a few days, and is generally the result of gastrointestinal infection (Box 10.3.2), possibly including overgrowth by *Candida*.

However, the commonest cause of diarrhoea in palliative medicine is an imbalance of laxative therapy (Twycross and Lack, 1986b). This particularly occurs when laxative doses have been increased to clear a backlog of constipated stool. The diarrhoea normally settles within 24–48 hours if laxatives are temporarily stopped, after which they should be reinstated at a lower dose. Meanwhile the diarrhoea may be distressing, especially if it leads to faecal incontinence.

A variety of other common drugs can also precipitate diarrhoea, either commonly, as in the case of antacids and antibiotics, or idiosyncratically, as in the case of non-steroidal anti-inflammatory agents or iron preparations. Sorbitol, used as a sweetener in some 'sugar-free' elixirs, is easily overlooked as a cause of diarrhoea in sensitive patients. Those receiving enteral feeding appear particularly prone, sorbitol being more than twice as likely to be the cause of diarrhoea as the feed itself (Edes et al., 1990).

Malignant intestinal obstruction and faecal impaction are the next most common causes of diarrhoea in this patient group. Complete intestinal obstruction produces intractable constipation, but partial obstruction may present with either diarrhoea or alternating diarrhoea and constipation. This clinical picture can also result from severe constipation caused by opioid analgesia, where it has been dubbed the 'narcotic bowel syndrome' (Sandgren et al., 1984). Faecal impaction results in fluid stool leaking past the mass, often with anal leakage or incontinence. In elderly patients hospitalized for non-malignant disease, faecal impaction can account for 55% of instances of diarrhoea (Kinnunen et al., 1989), emphasizing the need for careful attention to regular laxative therapy in any ill, relatively immobile population.

Many disease-modifying medication used in the palliative management of advanced cancer can cause diarrhoea. Certain cytotoxic chemotherapy agents most commonly 5-fluorouracil, capecitabine, and irinotecan (CPT-11) can cause severe diarrhoea through epithelial necrosis and inflammation leading to a loss of absorptive surface and an imbalance between absorptive and secretory cells (Kornblau et al., 2000). Interleukin-2 therapy can also cause severe watery diarrhoea. Additionally, almost all of the recently developed small-molecule-targeted therapies cause

Prophylaxis and ongoing assessment of bowel pattern

Ongoing monitoring
- Monitor patient satisfaction with bowel pattern using checklist
- Monitor for improvements or deterioration in bowel pattern
- Monitor risk factors for constipation
- Anticipate constipating effects of pharmacological agents such as opioids
  - Prescribe laxative prophylactically

Patient education
- Encourage lifestyle changes within patient limits:
  - Increase fluid intake
  - Encourage mobility
  - Ensure privacy and comfort to allow a patient to defecate normally

Exclude malignant obstruction

Treatment of causes

Treatment

Patient complains of constipation (or in some cases if defecation <3 times/week)

Assess patient to confirm constipation → Exclude malignant intestinal obstruction

Assessment of causes → **Correctable** → Treatment of causes

Not correctable

Treatment of constipation

First-line treatment with oral laxative:
A softener (e.g. polyethylene glycol and electrolytes or lactulose) and/or a stimulant (e.g. senna or sodium picosulphate) according to patient needs → **Improvement of symptoms** → Continue with regimen

No improvement of symptoms

Second-line treatment:
Rectal suppository and enema
Consider use of a peripherally-specific opioid antagonist, e.g. methylnaltrexone, if patient taking an opioid → **Improvement of symptoms** → Continue with regimen

No improvement of symptoms

Third-line treatment: Manual evacuation
Consider use of a peripherally-specific opioid antagonist, e.g. methylnaltrexone, if patient taking an opioid → **Improvement of symptoms** → Consider next steps

Fig. 10.3.2 An approach to the management of constipation.

diarrhoea as a side effect. Diarrhoea, which can be severe, has been reported in 30–50% of patients receiving bortezomib, erlotinib, gefitinib, sorafenib, sunitinib, and imatinib, and the m-Tor inhibitors temsirolimus and everolimus. The monoclonal therapies targeting the epidermal growth factor receptor, cetuximab and panitumumab, both cause diarrhoea in 10–20% of patients which may be severe in a small subset of patients.

High volume diarrhoea can be a feature of graft-versus-host disease (GVHD) resulting from an allogeneic stem cell or bone marrow transplant into an immuno-compromised recipient, and may be life-threatening. The diarrhoea can persist into chronic GVHD, where rather than the intense mucosal inflammation seen in acute GVHD the cause may be infection, motility disturbance, or malabsorption secondary to pancreatic insufficiency (Lee et al., 2003).

Radiotherapy involving the abdomen or pelvis is liable to cause diarrhoea, with a peak incidence in the second or third week of therapy and continuing for some time after cessation of the course. Damage to intestinal mucosa by radiation results in the release of prostaglandins and the malabsorption of bile salts, both of which increase peristaltic activity. Chronic radiation enteritis rarely presents as diarrhoea.

Uncommonly, another iatrogenic cause of diarrhoea relevant to palliative care is coeliac plexus blockade, which can be associated with the onset of profuse, long-lasting watery diarrhoea. This possibly results from anatomical variations in the innervation of the gut so that in certain individuals interruption of the coeliac plexus has an excessive influence on bowel activity (Dean and Reed, 1991).

Box 10.3.2 Causes of diarrhoea in palliative medicine

- Drugs:
  - Laxatives
  - Antacids
  - Antibiotics
  - Chemotherapy
  - NSAID, especially mefenamic acid, diclofenac, indomethacin
  - Mitomycin
  - Iron preparations
  - Disaccharide-containing elixirs
- Radiation
- Graft-versus-host disease
- Obstruction:
  - Malignant
  - Faecal impaction
  - Narcotic bowel syndrome
- Malabsorption:
  - Pancreatic carcinoma
  - Gastrectomy
  - Ileal resection
  - Colectomy
- Tumour:
  - Colonic or rectal carcinoma
  - Pancreatic islet cell tumours
  - Carcinoid tumours
- Concurrent disease:
  - Diabetes mellitus
  - Hyperthyroidism
  - Inflammatory bowel disease
  - Irritable bowel syndrome
  - Gastrointestinal infection
- Diet:
  - Bran
  - Fruit
  - Hot spices
  - Alcohol.

Malabsorption sufficient to cause diarrhoea may occur in carcinoma of the head of the pancreas or after gastrectomy or ileal resection. Failure of pancreatic secretion leads to reduced fat absorption and consequent steatorrhoea. Gastrectomy can also produce steatorrhoea, presumably as a result of poor mixing of food with pancreatic and biliary secretions. However, the accompanying vagotomy causes increased faecal secretion of bile acids

in some patients, resulting in increased water and electrolyte secretion in the colon and hence a chologenic diarrhoea, compounding the problem.

A different type of malabsorption that can be seen in palliative care patients treated with antibiotics, or as a complication of gut infection such as *Clostridium difficile*, is lactose intolerance secondary to changes in the intestinal flora. This will gradually correct itself but meanwhile a lactose-free diet produces prompt resolution of the diarrhoea (Noble at al., 2002).

Ileal resection reduces the gut's ability to reabsorb bile acids, of which up to 97% are normally recirculated, again producing chologenic diarrhoea, which is characteristically watery and explosive. If less than 100 cm of terminal ileum is removed, fat malabsorption generally does not occur, as the liver can compensate for the increased biliary loss. A resection of over about 100 cm results in relative bile acid deficiency and hence fat malabsorption, exacerbating the diarrhoea. Ileal resection also produces a disaccharidase deficiency proportional to the length of removed and thus an osmotic diarrhoea due to carbohydrate malabsorption.

Partial colectomy produces little, if any, persistent diarrhoea. However, total or almost total colectomy results in a high volume of liquid effluent that rapidly diminishes over 7–10 days but still remains at 400–800 mL/day owing to the small intestine's inability to compensate fully for the loss of the colon's water absorbing capacity. For this reason an ileostomy is normally fashioned. Such patients require an average of an extra litre of water per day and about 7 g of extra salt to compensate, with special care needed in hot weather. Iron and vitamin supplementation is also indicated. Similar symptoms can also result from an enterocolic fistula, caused either by cancer or as a result of operation (Mercadante, 1992). Alteration of gut anatomy by surgery may also promote diarrhoea through bacterial overgrowth.

A colonic or rectal tumour can precipitate diarrhoea through causing partial intestinal obstruction, or loosen stools through increased mucus secretion. Rarely, endocrine tumours cause a secretory diarrhoea. The WDHA syndrome (watery diarrhoea hypokalaemia achlorhydria) is associated with tumours of the pancreatic islet cells and of the sympathetic nervous system, including the adrenal glands, and can occur with bronchogenic carcinomas. VIP is thought to be the causative hormone both here and in the diarrhoea of the Verner–Morrison syndrome encountered in childhood ganglioneuroblastoma. Diarrhoea occurs also in the Zollinger–Ellison syndrome, seen with pancreatic islet cell tumours secreting gastrin, and in carcinoid tumours, where serotonin, prostaglandins, bradykinin, and VIP secretions have all been implicated.

Apart from concurrent gastrointestinal disease, the ability of dietary factors to cause diarrhoea should be remembered. Excessive dietary fibre may produce diarrhoea and fruits may do so both by this means and by their content of specific laxative factors.

Assessment
A complaint of diarrhoea demands a careful history, detailing first of all the frequency of defecation, the nature of the stools, and the time course of the problem. Together, these often indicate the diagnosis. Defecation described as 'diarrhoea', which occurs only once or twice a day, suggests anal incontinence. Profuse watery stools are characteristic of colonic diarrhoea, whereas the pale, fatty, offensive stools of steatorrhoea indicate malabsorption due

to a pancreatic or small intestinal cause. The sudden advent of diarrhoea following a period of constipation, perhaps with little warning of impending defecation, should raise the suspicion of faecal impaction.

Both current and recent medication should be sought. If laxatives are to blame, the error may be of insufficiently regular therapy, resulting in alternating constipation and diarrhoea, or an excessive dose. Too much of a predominantly peristalsis-stimulating laxative tends to produce colic and urgency, and too much of a predominantly stool-softening agent may cause faecal leakage, although at high doses lactulose and docusate have the ability to produce colic and watery diarrhoea in some patients.

The occurrence of pyrexia, blood in the stools, or dehydration as features of diarrhoea should be watched out for, as they signal the presence of potentially life-threatening complications and the need for more intensive support and intervention. In a palliative care context this situation is principally likely to arise as a result of recent cytotoxic chemotherapy. Diarrhoea in the presence of neutropenia should suggest the presence of neutropenic enterocolitis in which mucosal ulceration occurs, allowing bacterial and fungal invasion and consequent septicaemia as well as the possibility of intestinal perforation. Incidence has been reported to be 5% or more in adults receiving chemotherapy for solid malignancies and the condition carries a mortality of 30–50% (Ullery et al., 2009).

Examination and investigations

Examination should exclude the possibilities of faecal impaction and intestinal obstruction, and should therefore include rectal examination and abdominal palpation for faecal masses. If there is doubt, an abdominal radiograph will make the distinction, but this is rarely necessary.

Steatorrhoea is generally clearly suggested in the history and readily confirmed on examination of the stool. Persistent watery diarrhoea, without systemic upset, which would suggest an infective cause, may be more difficult to diagnose. If in doubt, the stool osmolality and sodium and potassium concentrations should be measured. The anion gap, the difference between the stool osmolality and double the sum of the cation concentrations, is over 50 mmol/L in osmotic diarrhoea, because of the presence of an additional non-absorbed solute, for example, a disaccharide from a medicinal elixir. An anion gap of below 50 mmol/L shows secretory diarrhoea, resulting from active secretion of fluid and electrolytes, as in the WDHA syndrome. Ileal resection gives rise to a mixed picture, which will become purely secretory if the patient can be fasted.

In any persistent diarrhoea, haematology and blood chemistry should be checked.

Diarrhoea occurring within 3 days of inpatient admission may be due to community-acquired bacterial enteric pathogens such as *Salmonella, Shigella*, or *Campylobacter*, or to viral infection. After this point the infection is likely to have originated in the inpatient unit and stool culture is usually unrewarding; repeating the culture does not improve the diagnostic yield (Chitkara et al., 1996). *Clostridium difficile* is the most commonly detected cause of nosocomial diarrhoea and is associated with antibiotic treatment, particularly quinolones or cephalosporins. It affects predominantly the over 65 age group, in whom its incidence in the United States more than doubled between 2000 and 2005 (Lessa et al., 2012). This rise has been accompanied by an increase

in multidrug resistance. Although there is evidence that stricter antibiotic and hospital hygiene policies are slowing the rate of rise in incidence, *Clostridium difficile* diarrhoea is still common and may be life-threatening unless diagnosed and treated with appropriate antimicrobials as directed by stool sample analysis.

Management approaches

Supportive treatment

Other than in HIV infection or as a result of chemotherapy, diarrhoea in palliative medicine is rarely severe or prolonged enough to cause significant risk through dehydration. If rehydration *is* needed, the oral route is superior to the intravenous. Proprietary rehydration solutions, containing appropriate electrolyte concentrations and a source of glucose to facilitate active electrolyte transport across the gut wall, are adequate for all but the most severe diarrhoea. Any diarrhoea will benefit from a diet of clear liquids, such as flat lemonade or ginger ale, and simple carbohydrates, as in toast or crackers. Some infective causes of diarrhoea cause transient lactase deficiency and so milk should be avoided in these circumstances (Noble et al., 2002). Protein and, later, fats are reintroduced gradually to the diet as the diarrhoea resolves.

NCI grade 3 or 4 diarrhoea, characterized by pyrexia, neutropenia, dehydration or bloody stools, requires inpatient management with intravenous fluid support, octreotide with or without opioid antidiarrhoeals (see 'General treatment'), assessment of stool for the presence of infection (*Clostridium difficile, Salmonella, Escherischia coli*, and *Campylobacter*) and antibiotic treatment as indicated (Benson et al., 2004). Neutropenic colitis may also involve fungal infection, principally by *Candida* spp., and there is some indication of reduced mortality if antifungal therapy is provided (Cardona Zorrilla et al., 2006). Management may also entail administration of granulocyte colony-stimulating factor or resection of the affected bowel (Ullery et al., 2009) and hence should be carried out in a setting where such options are available.

Specific treatment

Specific treatments exist for several causes of diarrhoea. Pancreatin is a combination of amylase, lipase, and protease, which is available in several forms for pancreatic enzyme replacement. The effective dose varies widely between individuals and it may be more effective if gastric acidity is reduced with an H_2-receptor antagonist, in which case enteric-coated preparations should not be used.

Cholestyramine is a bile acid-binding resin that is effective in controlling chologenic diarrhoea provided ileal resection has not been too extensive. It is often found unpalatable. Sulfasalazine appears in clinical practice guidelines for prophylaxis of radiation-induced diarrhoea (Rubenstein et al., 2004), while both cholestyramine (Condon et al., 1996) and aspirin (Mennie et al., 1975) have been claimed to be effective for its treatment. However, 5-aminosalicylic acid (Baughan et al., 1993) and mesalazine (Resbuet et al., 1997) have been found ineffective for this type of diarrhoea.

Carcinoid syndrome diarrhoea often responds to general antidiarrhoeals, but peripheral serotonin antagonists, such as methysergide or the less toxic cyproheptadine, have been used against more severe diarrhoea and, sometimes, the accompanying malabsorption. 5-HT$_3$ antagonists may also have a role in this type of diarrhoea (Saslow et al., 1998).

Metronidazole remains the first-line antibiotic for *Clostridium difficile* diarrhoea, and can reasonably be tried also in situations where diarrhoea is suspected to be due to bacterial overgrowth, where it may produce a prompt resolution.

General treatment

Non-specific antidiarrhoeal agents are numerous, but are either absorbent, adsorbent, mucosal prostaglandin inhibitors, opioids, or somatostatin derivatives. These agents may make illness due to *Shigella* and *Clostridium difficile* worse and so should be used with caution if these organisms are known to be present, or if there is blood in the stool, or fever.

Absorbent agents absorb water to form a gelatinous or colloidal mass that gives a thicker consistency to loose stools. Examples are pectin and bulk-forming agents such as methyl cellulose. Bulk-forming agents may have a delay of up to 48 hours in onset of antidiarrhoeal action and are poorly tolerated in ill patients. They have proved useful in the management of colostomies but exacerbate electrolyte loss from ileostomies. The use of pectin is time-honoured and there is some evidence of effectiveness in children (de la Motte et al., 1997).

Adsorbent agents non-specifically take up dissolved or suspended substances, such as bacteria, toxins, and water, on to their surfaces. All are naturally occurring minerals, for example, kaolin and attapulgite. Attapulgite has been shown to be better than placebo in acute diarrhoea although significantly less effective than loperamide (DuPont et al., 1990). Kaolin is often combined with morphine as an antidiarrhoeal mixture and there is no evidence for efficacy separate from that of the opioid.

Mucosal prostaglandin inhibitors inhibit intestinal water and electrolyte secretion. Bismuth subsalicylate has a direct antimicrobial effect on enterotoxigenic *Escherichia coli*, but no more than that of wine (Weisse et al., 1995), and is used for treatment of non-specific acute diarrhoea. Aspirin is used as a specific antidiarrhoeal treatment for radiation-induced diarrhoea, and mesalazine for ulcerative colitis.

Opioid agents act via specific gut opioid receptors to reduce peristalsis, and possibly water and electrolyte secretion, in the colon. The opioids are the mainstay of general antidiarrhoeal treatment in palliative medicine and a requirement for morphine analgesia may obviate the need for any additional antidiarrhoeal medication. Loperamide is the opioid antidiarrhoeal of choice, as it does not reach or cross the blood–brain barrier significantly and so causes few adverse effects, at least in adults (Ruppin, 1987). It is significantly more effective than diphenoxylate or codeine, both of which are prone to cause systemic opioid effects. Diphenoxylate is available only in combination with atropine in order to limit its abuse potential. Codeine is cheap.

In man, approximate equivalent antidiarrhoeal doses are 200 mg/day of codeine, 10 mg/day of diphenoxylate, and 4 mg/day of loperamide (Twycross and Lack, 1986b). Despite the research evidence, clinical experience suggests that the individual response to opioids for diarrhoea can be as idiosyncratic as that for pain, and in some patients codeine has superior antidiarrhoeal properties to the other opioids without causing excessive nausea or drowsiness. Opioids increase anal sphincter pressure, and loperamide and codeine have been shown to improve continence in patients with diarrhoea suffering from faecal incontinence (Palmer et al., 1980).

Somatostatin analogues mimic the activity of the natural gut hormone on intestinal epithelial receptors to inhibit secretion and peristalsis. Octreotide has been shown to be effective in cryptosporidial diarrhoea and diarrhoea due to the carcinoid, Zollinger–Ellison, and Verner–Morrison syndromes as well as to ileostomy (Riley and Fallon, 1994) or enterocolic fistula (Mercadante, 1992). Subcutaneous injection of octreotide may be painful, but continuous subcutaneous infusion is generally well tolerated and the drug can be combined with morphine, diamorphine, haloperidol, midazolam, or hyoscine without apparent loss of efficacy (Riley and Fallon, 1994). Mixing with cyclizine may cause precipitation.

Octreotide is established as an effective therapy for severe secretory diarrhoea, particularly that related to HIV infection, where doses up to 1500 micrograms/24 hours have been found necessary (Romeu et al., 1991). Expert consensus has recommended octreotide dose titration as high as 1500 micrograms/24 hours for chemotherapy-induced diarrhoea (Benson et al., 2004). Lanreotide has a far more prolonged duration of action and so requires neither frequent injections nor an infusion device, but is also less flexible for use in the continually changing clinical situations of palliative care.

New developments

Calcium carbonate 3.6 g/day reduced stool frequency by a mean of 49% and faecal wet weight by 50% over 12 weeks in 15 post-gut-resection patients. No change in plasma calcium concentrations was found (Steinbach et al., 1996). Results in healthy subjects have been variable and it was ineffective in nelfinavir-associated diarrhoea in HIV-positive patients (Jensen- Fangel et al., 2003).

There is increasing interest in the use of probiotics, or beneficial microorganisms, for the management of diarrhoea. *Lactobacillus* spp. are the most commonly used. There is some evidence that probiotics can be effective in infective diarrhoea in adults (Hickson, 2011) and in the management of acquired lactose intolerance (Noble et al., 2002).

The pathogenesis of diarrhoea frequently involves neurohumoral mechanisms controlling water secretion. Antagonists to 5-HT and substance P may prove clinically useful in the future, as may peptide YY and neuropeptide Y, both of which reduce intestinal fluid secretion and inhibit gut transit (Tough et al., 2011).

10.4

Jaundice, ascites, and encephalopathy

Jeremy Keen

Introduction to jaundice, ascites, and encephalopathy

For many people, jaundice will occur as part of an episode of acute, self-limiting, viral hepatitis but in the context of chronic hepatic disease or malignancy, the development of jaundice or ascites is usually an ominous indicator of advanced disease.

In two reported studies of individuals admitted to hospital with jaundice, 24% and 42% of patients with malignancy and 23% with cirrhosis died during their first admission (Whitehead et al., 2001; Bjornsson et al., 2003). The necessity of a willingness to adopt a 'palliative approach' to the care of such individuals is obvious.

This chapter will discuss three features of liver impairment that may be encountered in those for whom palliative care is appropriate but the review of ascites will concentrate on causes other than cirrhosis and portal hypertension.

Jaundice

The approach to the investigation and management of jaundice developing during palliative care should follow a logical progression which aids the difficult ethical decision-making which often arises. An indication of the frequency of disorders causing jaundice and a commonly used classification system are shown in Tables 10.4.1 and 10.4.2.

Pre-hepatic jaundice

Pre-hepatic causes of jaundice include Gilbert's syndrome, an inherited disorder characterized by mild chronic unconjugated hyperbilirubinaemia in the absence of liver disease or overt haemolysis. Between 3% and 10% of the general population may be affected by this syndrome and may demonstrate elevated bilirubin levels in response to stresses including fasting and comorbidity (Bosma et al., 1995). Therapeutic interventions for malignancy in individuals with Gilbert's may lead to hyperbilirubinaemia and mild jaundice (Wasserman et al., 1997; Engin et al., 2003; Ruiz-Arguelles et al., 2005) and there has been debate as to whether individuals with Gilbert's are more prone to toxic side effects with certain cytotoxic agents (Mandala et al., 2004). Prolonged parenteral nutrition has also been associated with hyperbilirubinaemia in individuals with Gilbert's syndrome (Au et al., 2004).

Hepatic jaundice

Hepatic causes of jaundice include any process which interferes with the excretion of conjugated bilirubin into the biliary system.

Table 10.4.1 Causes of jaundice in a series of 121 patients in Wales (Whitehead et al., 2001) and 171 patients in Sweden (Bjornsson et al., 2003)

Cause of jaundice	Wales (%)	Sweden (%)
Malignancy	35	33
Septicaemia	22	2.5
Cirrhosis	21	11
Gall stones	13	16
Drugs	6	1
Autoimmune hepatitis	1.5	2.5
Viral hepatitis	1.5	3.5

Such processes have either resulted in widespread necrosis of hepatocytes (hepatocellular jaundice) or impairment of bile excretory mechanisms (cholestatic jaundice). Worldwide, chronic viral and alcohol-related hepatitis are the major causes of hepatic jaundice. According to the most recent data, over 200 000 individuals

	Budd–Chiari syndrome	

in the United Kingdom are living with chronic hepatitis C infection. The number of hospital admissions and deaths with hepatitis C-related end-stage liver disease and hepatocellular carcinoma more than tripled between 1998 and 2010 (Health Protection Agency, 2012) and it is now one of the most common indications for liver transplant.

It is important to be aware of the existence and characteristics of chronic hepatitic viral infection in any individual for whom immunosuppressive therapy is being considered. Fulminant liver failure is a well-recognized complication of chemotherapy and other immunosuppressive therapy (allowing viral reactivation and proliferation) or, more frequently, its discontinuation (allowing a rebound immune and inflammatory response) (Xunrong et al., 2001; Esteve et al., 2004). Importantly, given their widespread use in palliative care, reactivation of hepatitis B infection has been related to the use of corticosteroids for comorbid conditions (Koga et al., 1992; Hammond et al., 1999) and the inclusion of steroids in cytotoxic regimens (Cheng et al., 2003; Yeo et al., 2004).

Hepatic failure after chronic infection with hepatitis B and/or C viruses is now a major cause of death for individuals infected with HIV (Williams, 2006). The Data Collection on Adverse Events of Anti-HIV Drugs study, which followed over 23 000 HIV-infected persons from three continents reported that 14.5% of deaths were from liver-related causes (Echejoh et al., 2006). Two post-mortem series from Nigeria and India noted the presence of tuberculous granulomata within the liver of individuals with AIDS as the most frequent abnormal histological finding (Amarapurkar and Sangle, 2005; Echejoh et al., 2006) and cholestatic, non-obstructive, jaundice has been described as a consequence of hepatic involvement in tuberculosis (Ghoda, 2005).

Drug-induced liver disease

Of hospital admissions for non-obstructive jaundice 2–7% have been reported to be drug induced (Ryder and Beckingham, 2001). Although most drug effects simply lead to an increase in serum liver enzymes, there is a significant mortality associated with the development of jaundice. Drug-induced liver disease accounts for over 50% of cases of acute liver failure in the United States of which approximately 70% relate to paracetamol overdose and the remainder a result of idiosyncratic reaction to one of over 600 medicinal compounds that have been reported to cause hepatotoxicity of one form or another (Bissell et al., 2001). A recent Swedish audit reported that 77 of 1164 new referrals to a hepatology clinic were deemed to have drug-induced liver disease with 29 having clinical jaundice (De Valle et al., 2006). Flucloxacillin, diclofenac, and ciprofloxacin were the most frequently associated drugs with mean lengths of exposure of 10, 23, and 6 days respectively.

Jaundice in drug-induced liver disease can be both hepatocellular and cholestatic such that histological findings include acute hepatocyte necrosis, chronic hepatitis, vascular injury, and bile ductular injury. Raised serum hepatic enzyme levels will usually rapidly return to normal after withdrawal of the offending drug (a reduction of 50% after 2 weeks and to baseline by 4 weeks is a general rule), but induced immune-mediated cholestatic reactions do have the potential for chronicity despite drug withdrawal (Table 10.4.3).

Complementary medications may be responsible for up to 5% of drug-induced liver disease and include preparations such as

Table 10.4.3 Drugs associated with immune-mediated liver disease

Hepatocellular reactions	Cholestatic/mixed reactions
Allopurinol	Amoxicillin/clavulanic acid
Germander (& other herbal medications)	Chlorpromazine/levomepromazine Erythromycin
Halothane	Tricyclic antidepressants
Minocycline	Fluoxetine
Phenytoin	Acetylcholinesterase inhibitors

germander and mistletoe (Harvey and Colin-Jones, 1981; Laliberte and Villeneuve, 1996).

There appears to be little evidence that there is an increased risk of drug-related hepatotoxicity in individuals with pre-existing liver disease although they are at increased risk of systemic drug toxicity secondary to slowed metabolism. For example, individuals with cirrhosis tolerate therapeutic doses of paracetamol without deterioration in liver function (Dart et al., 2000; Ford-Dunn, 2005). Exceptions include an increased rate of hepatotoxicity with the anti-androgens flutamide and cyproterone in those with chronic hepatitis B or C infection (Pu et al., 1999).

Sepsis

Cholestatic, non-obstructive jaundice is a feature of chronic liver disorders such as primary biliary cirrhosis and sclerosing cholangitis but can also occur as a result of sepsis and/or shock (21% of cases of jaundice in one study in the United Kingdom (Moseley et al., 2001)). Cholestasis may result from hypotension and low hepatic blood flow but also from direct inhibition of bile secretion by endotoxin and inflammatory cytokines (interleukin-1, interleukin-6, and tumour necrosis factor alpha (TNF-α)) (Moseley, 2004).

Cardiac failure and the liver

Eight patients out of 661 presenting with jaundice in a recent series were found to have cardiac failure as their main diagnosis (van Lingen et al., 2005). Although jaundice is clearly a rare presentation of heart failure, altered liver function is common in severe heart failure. It is thought to be mainly a result of sinusoidal congestion although significant hypotension (usually secondary to infarction or valvular disease) can lead to an ischaemic hepatitis signalled by a massive rise in aminotransferases and prolonged prothrombin time. Hepatic congestion produces a cholestatic derangement of liver enzymes thought to represent secondary damage to the bile canaliculae as a result of sinusoidal disruption (Cogger et al., 2003). Sinusoidal congestion is most marked in tricuspid valve regurgitation and a clear correlation between severity of regurgitation and serum levels of alkaline phosphatase (ALP) and gamma-glutamyl transferase (GGT) has been demonstrated (Lau et al., 2002).

Venous occlusion

A rapid onset of jaundice can occur in the venous occlusion of the Budd–Chiari syndrome although a chronic form of the syndrome resulting in the usual symptoms of chronic liver disease is more

usual (Zimmerman et al., 2006). Venous obstruction can occur at any point from the hepatic venules to the right atrium and is particularly associated with disorders which produce a hypercoagulable state such as the myeloproliferative disorders, polycythaemia rubra vera and essential thrombocytosis. Malignancy is clearly associated with Budd–Chiari syndrome both through increased thrombogenicity and local obstruction of the venous system by solid tumours. Untreated acute Budd–Chiari syndrome requires an urgent and aggressive approach to management, if appropriate in the context of the individual's disease status. Inferior vena caval stenting and transjugular intrahepatic portosystemic shunt formation are relatively uninvasive procedures that can be of significant benefit in selected individuals. In those unsuitable for interventional procedures, a decision regarding anticoagulant therapy is required but the outlook with medical therapy alone is bleak with a mortality of over 80% in one series (McCarthy et al., 1985).

Obstructive jaundice

Obstruction of the biliary tract can occur at any point from within the liver to the ampulla of Vater. To give rise to jaundice this usually occurs at the confluence of the major ducts at the porta hepatis or more distally.

In two population studies of the causes of obstructive jaundice, gall stones were found to be responsible in 13% and 16% of individuals but carcinoma of the head of the pancreas, cholangiocarcinoma, and metastatic disease were most commonly identified (Luman et al., 2001; Bjornsson et al., 2003). Hepatocellular carcinoma is being increasingly diagnosed as a cause of jaundice given the prevalence of chronic viral hepatitis and cirrhosis.

Symptoms related to jaundice

Studies involving patients who have undergone procedures to relieve biliary obstruction give some indication of the symptoms related to hyperbilirubinaemia. In addition to the expected clearing of jaundice and relief of pruritus, significant improvements were noted in anorexia, indigestion, sleep pattern, and global health scores (Ballinger et al., 1994; Luman et al., 1997). A Canadian study demonstrated a significant association between the degree of reduction in bilirubin levels after stenting and an improvement in social function and mental health as assessed by the SF-36 Health Survey Questionnaire (Abraham et al., 2002).

Malignant obstructive jaundice is classically thought to be 'painless' and therefore distinguished from benign causes such as gallstones. However, a study of elderly patients with biliary duct obstruction reported that 32% of those with a malignant cause alone presented with abdominal pain (Ashton et al., 1998).

Investigation of jaundice

It has been estimated that a thorough history, physical examination, and biochemical liver function tests are sufficient for making an accurate diagnosis of the type of liver disease in at least 80% of patients Table 10.4.4, (Kamath, 1996). During palliative care, the history should elucidate the primary disease process and set the onset of

Table 10.4.4 Clinical characteristics of jaundice of differing aetiologies

Clinical factors	Haemolytic	Hepatocellular	Intrahepatic Cholestatic	Post-hepatic Cholestatic ('obstructive')
Symptoms	Asymptomatic or backache, arthralgia	Nausea, vomiting, anorexia, pyrexia	Deep jaundice, Dark urine, light stools Pruritus	Deep jaundice, Dark urine, light stools Pruritus, cholangitis Biliary colic
Physical	Splenomegaly	Tender hepatomegaly	Tender hepatomegaly	Hepatomegaly Palpable gallbladder
Liver function tests				
Bilirubin	< 100µmol/L	Variable	Variable may be >500 µmol/L	<500 µmol/L
ALT	Normal	> 5-fold increase	2-to 5-fold increase	< 2-to 3-fold increase but 3- to 5-fold increase with cholangitis
ALP	Normal	<2- to 3-fold increase	>3- to 5-fold increase	>3- to 5-fold increase
Prothrombin time	Normal	Prolonged	Prolonged	Prolonged
Corrected by Vitamin K?	—	No	Variable	Yes
Dilated bile ducts on ultrasound?	No	No	No	Yes

ALT, alanine aminotransferase; ALP, alkaline phosphatase.

jaundice in the context of other markers of disease status. A drug history from the patient including non-prescription items is clearly vital.

Physical examination may confirm signs of chronic liver disease, portal hypertension, and/or intra-abdominal malignancy and may give clues as to current liver function. It is important to assess cognitive function for signs of associated encephalopathy. In all cases, signs of infection must be looked for within the biliary tree or peritoneum (if ascites is present) particularly if the patient is immunosuppressed by chronic infection, including HIV, or drugs (including corticosteroids). Infective cholangitis is associated with a significant mortality rate.

Blood tests

A clinical diagnosis of jaundice is confirmed by elevated serum levels of bilirubin. Should there be no derangement of liver enzymes to suggest cholestasis or hepatocellular injury then relative levels of unconjugated and conjugated bilirubin can be measured to distinguish between pre-hepatic and hepatic causes of jaundice. A review of over 1000 patients presenting with obstructive jaundice found serum bilirubin levels of higher than 100 µmol/l had sensitivity and specificity for a malignant aetiology of 71.9% and 86.9% respectively (Garcea et al., 2011). The performance of serum bilirubin levels in terms of distinguishing benign from malignant causes of obstructive jaundice in comparison with a variety of imaging techniques is shown in Table 10.4.5. Elevated levels of ALP and GGT with relatively normal, or only moderately increased, levels of aspartate transaminase and alanine transaminase would be a typical finding in cholestatic jaundice (Table 10.4.4). Isolated elevation of ALP is unusual in cholestasis and if present may reflect bone disease. Isolated raised GGT may indicate a drug effect. Serum albumin levels and prothrombin time reflect, in part, the synthetic functioning of the liver and evidence of coagulopathy is vital information prior to performing invasive investigations and therapeutic procedures.

Table 10.4.5 Distinguishing a benign from malignant cause of obstructive jaundice: serum bilirubin levels compared with other assessment modalities

Modality	Patients, *N*	Sensitivity, %	Specificity, %
Bilirubin, µmol/L	1026		
> 100		71.9	88.0
> 250		31.9	98.0
CA19-9	776	68.4	72.5
MRCP[a]	4711	95.0	97.0
ERCP	220	74.0	94.0
EUS	3532	78.0	84.0
PET-CT	46	89.0	74.0

[a] Includes patients with jaundice secondary to stone disease.

CT, computed tomography; ERCP, endoscopic retrograde cholangiopancreatography; EUS, endoscopic ultrasonography; MRCP, magnetic resonance cholangiopancreatography; PET-CT, positron emission tomography

Imaging

Imaging the individual with jaundice aims to visualize the liver and biliary tree as an aid to confirming or identifying the underlying diagnosis as well as determining the location and extent of disease and the potential for treatment.

Ultrasound

Ultrasound scanning remains the first imaging investigation of choice in the patient with jaundice. It can be used at the bedside, does not involve radiation, and is relatively cheap. In a patient with obstructive jaundice, ultrasound will detect bile duct dilatation with a sensitivity and specificity of between 95% and 99% (Stott et al., 1991; Stroszczynski and Hunerbein, 2005). However, ultrasound is highly operator dependent and is problematic in obese patients and in situations where bowel gas overlies the region studied. Indeed, a review of reports of the use of standard transcutaneous ultrasound imaging to determine the level and the aetiology of biliary obstruction reported a range of respective accuracies of 27–95% and 23–88% (Blackbourne et al., 1994). The diagnosis of carcinoma of the ampulla is particularly difficult with transabdominal ultrasound with sensitivities of as low as 5% reported. However, endoscopic ultrasonography is proving more sensitive for detecting pancreatic cancers than computed tomography (CT), magnetic resonance imaging, or endoscopic retrograde cholangiopancreatography (ERCP).

Computed tomography

Given the advantages of ultrasound, the principal role of CT in the investigation of obstructive jaundice is to determine the extent and stage of disease to inform treatment options. However, CT with intravenous contrast allows better imaging of the liver parenchyma in hepatocellular causes of jaundice. The introduction of spiral CT and, more recently, multidetector CT, has resulted in improved resolution for the detection and characterization of small obstructing lesions to levels approaching magnetic resonance and direct cholangiography.

Magnetic resonance cholangiopancreatography

Magnetic resonance cholangiopancreatography (MRCP) is non-invasive, does not involve exposure to radiation, and does not require intravenous injection of contrast medium (Fig. 10.4.1). A large systematic review of the diagnostic ability of MRCP in biliary obstruction reported a pooled sensitivity of 95% for the demonstration of the level of obstruction and an 88% sensitivity in distinguishing between benign and malignant lesions (Romagnuolo et al., 2003). MRCP can, therefore, demonstrate the level of obstruction as accurately as direct cholangiography but avoids the risks associated with cannulation of the biliary tract. MRCP also allows simultaneous imaging of the abdomen to determine the extent of disease and has therefore been proposed as the complete diagnostic study (Pavone et al., 1999).

Many centres will use MRCP, if available, after initial ultrasound assessment leaving ERCP or percutaneous transhepatic cholangiography (PTC) to be used only when therapeutic interventions are required. Developments in CT techniques will continue to challenge magnetic resonance and relative cost-effectiveness will need regular review.
Fig. 10.4.1 A volume-rendered image from MRCP in a 49-year-old man with jaundice showing dilatation of the pancreatic duct (thin arrow) and common bile duct (thick arrow). The features are suggestive of a periampullary mass.

Fig. 10.4.2 Percutaneous transhepatic cholangiogram showing a long stricture of the common bile duct (arrow) caused by a cholangiocarcinoma. Endoscopic cholangiography and bile duct stenting had proved impossible but a stent was successfully deployed via the percutaneous route.

Cholangiography

Both ERCP and PTC allow imaging, cytological sampling, and palliative drainage of the biliary system via dilatation and stent insertion. Access to the biliary tree via the percutaneous route is usually only attempted when the level of biliary obstruction is proximal to the common hepatic duct or when distorted anatomy, often due to previous surgery or the presence of local tumour, precludes ERCP (Fig. 10.4.2).

Both procedures are associated with potentially fatal complications including bacterial cholangitis, bleeding, and bile leakage with acute pancreatitis being a particular complication of ERCP. However, the incidence of adverse events in both approaches is low, being reported in 0.5–5% of patients and is, to an extent, operator dependent (Bilbao et al., 1976; Harbin et al., 1980).

Management of jaundice

Antitumour therapy for sensitive malignancies may allow at least temporary relief of jaundice in those thought fit enough to receive a likely net benefit. Treatment can be considered even in the presence of incipient hepatic failure resulting from widespread tumour infiltration. Careful drug selection and dose titration is required but significant improvements in symptoms and survival can be achieved (Gurevich and Akerley, 2001; Schull et al., 2003).

Uncontrolled studies of biliary drainage procedures for obstructive jaundice suggest the potential for significant and rapid improvement in symptoms, particularly pruritus, pain, nausea, anorexia, and in overall quality of life (Larssen et al., 2002; Larssen et al., 2011; Barkay et al., 2013). However, a recent case report illustrates the need for careful individual assessment in advanced disease (Dy et al., 2012). In certain individuals, if biliary drainage is combined with post-procedural antitumour therapy, rapid predictable improvement in symptom control can be combined with potential prolonged survival and stent patency (Qian et al., 2006).

Jaundice resulting from superinfection or malignancy in individuals with AIDS may well respond to specific treatment if adequate doses of antibacterial, antiviral, antifungal, or cytotoxic chemotherapy can be tolerated.

Biliary drainage procedures

Obstructive jaundice is present at the time of presentation in 70–80% of individuals with pancreatic carcinoma and 85% are deemed unsuitable for curative resection (Andtbacka et al., 2004). In one review of over 8000 patients with unresectable carcinoma of the pancreas, those who underwent a surgical bypass procedure allowing biliary drainage had a significant improvement in quality and length of survival (Sarr and Cameron, 1982). Patients deemed unfit for surgery should be considered for biliary stenting via endoscopic or percutaneous routes. One study of quality of life related to endoscopic biliary drainage demonstrated increased quality of life post drainage but only in those individuals with pre-procedure serum bilirubin levels below 222 μmol/L (Ballinger et al., 1994). The authors proposed, therefore, that careful assessment is carried out prior to stent insertion in those with very high serum bilirubin levels.

Individuals with high bile duct obstruction or distorted duodenal anatomy may require a percutaneous approach either for stent placement or to allow external drainage of bile for symptomatic relief and to widen the choice, if appropriate, of systemic cytotoxic agents that maybe administered (Covey and Brown, 2006a). Chronic loss of bile through the drain can lead to nutritional deficiencies and if stents cannot be deployed then an attempt to pass an internal-external catheter via guidewire manipulation may be made. This catheter has side holes positioned proximal to the obstruction and the tip lies within the bowel to allow drainage of bile either externally or internally (Covey and Brown, 2006b).

Nutrition

Chronic cholestasis can lead to malabsorption of fat-soluble vitamins. Vitamin K deficiency contributes to the prolonged clotting time that may be associated with jaundice (O'Brienet al., 1994). The international normalized ratio should be regularly checked in jaundiced patients and vitamin K given either parenterally or orally (both routes, interestingly, seem as effective (Green et al., 2000)). Even in patients with end stage disease this intervention may reduce the likelihood of distressing haemorrhage.

Pruritus

Pruritus is one of the most distressing symptoms experienced by individuals with jaundice. Successful management is rare and the symptom so impacting on quality of life that severe pruritus is an indication for liver transplant in chronic liver disease.

The self-rated severity of itching or observed scratching behaviour does not correlate with serum bilirubin levels or the stage of chronic liver disease. Itch may be mild or severe, localized or generalized, but a pattern in which itch typically starts on the palms of the hands and soles of the feet before becoming more generalized has been described (Twycross et al., 2003). Itching in cholestasis appears to follow a circadian rhythm being at its worst between 1200 and 1800 hours (Bergasa et al., 1995) and one small pilot study suggested a benefit of bright-light therapy directed towards the eyes to disrupt this rhythm (Bergasa et al., 2001).

The pathogenesis of pruritus in jaundice is thought to involve either the stimulation of peripheral itch receptors within the skin, by an increased level of circulating bile acids and other pruritogens, or via central neural mechanisms resulting from alterations in neurotransmitters such as endogenous opioids, serotonin, and gamma-aminobutyric acid (GABA).

Opioid systems

Pruritus, although a rare side effect of systemically administered opioids, has been reported to occur in between 30% and 100% of individuals after epidural or intrathecal infusion (Szarvas et al., 2003). Increased plasma levels of opioid peptides have been recorded in individuals with primary biliary cirrhosis (Thornton and Losowsky, 1988) and animal models suggest increased hepatic synthesis of encephalins in cholestatic states. Furthermore, animals display naloxone-reversible scratching behaviour when given plasma extracts from humans with cholestasis and pruritus (but not from those without pruritus) (Jones and Zylicz, 1993).

Published reports describe a significant improvement in cholestatic pruritus, by both subjective and objective assessment, after the intravenous infusion of naloxone (Bergasa et al., 1992, 1995) and with the oral opioid antagonists naltrexone and nalmefene (Carson et al., 1996; Wolfhagen et al., 1997; Bergasa et al., 1998; Terg et al., 2002). Various protocols have been suggested to lessen the withdrawal-like reactions that can occur with antagonist therapy even in individuals not receiving exogenous opioids (Jones and Zylicz, 2001; Jones et al., 2002). Many individuals receiving palliative care will, however, require exogenous opioids for pain control. Trials in postoperative anaesthesia have demonstrated a reduction in opioid-induced side effects, including pruritus, without loss of pain control or increased opioid requirements, by the addition of low-dose naloxone to morphine for intravenous infusion (Cepeda et al., 2004; Maxwell et al., 2005). Interestingly, one small trial reports a significant decrease in pruritus associated with perioperative intrathecal analgesia with morphine if low-dose, intravenous buprenorphine was co-administered (Beltrutti et al., 2002). A small case series found significant relief from cholestatic pruritus in two out of five patients treated with buprenorphine but intolerable side effects in three patients (Juby et al., 1994).

Recent attention has switched to the potential role of central and peripheral kappa opioid receptors in the regulation of pruritus. It is thought, in very general terms, that activation of kappa receptors inhibits mu receptor activity. The serum and hypothalamic levels of the endogenous kappa agonist, dynorphin A, have been shown to be reduced after bile duct ligation in animal models (Inan and Cowan, 2005) and cessation of scratching behaviour has been demonstrated in animals given the kappa agonist, nalfurafane (Inan and Cowan, 2006). Nalfurafane has been clinically trialled for the relief of uraemic pruritus and there are case reports of the use of butorphanol, a partial kappa agonist, in cholestatic and paraneoplastic itch (Phan et al., 2012).

Serotoninergic systems

There are close links between the central opioidergic and serotonergic transmission systems. Although early reports suggested substantial beneficial effects of serotonin type 3 (5-HT$_3$) receptor antagonists, such as ondansetron, in cholestatic pruritus (Raderer et al., 1994; Schworer et al., 1995) more recent controlled trials have suggested only modest or no benefit (Muller et al., 1998; O'Donohue et al., 2005). Case series have attested to the potential benefit of the serotonin re-uptake inhibitor sertraline in cholestatic pruritus (Browning et al., 2003). Sertraline at doses of 75–100 mg per day is now recommended by the guidelines of the American Association for the Study of Liver Diseases as fourth-line treatment (after cholestyramine, rifampicin and naltrexone) of cholestatic pruritus associated with primary biliary cirrhosis (Lindor et al., 2009).

GABAergic systems

Opioids antagonize the central inhibitory effects of GABA and several groups have shown recent interest in the use of propofol, a GABA agonist to reduce spinal opioid-induced pruritus. An early, small randomized trial showed benefit of subhypnotic doses of propofol in cholestatic pruritus (Borgeat et al., 1993). Phenobarbitone has been shown in two case series to improve itch in cholestasis associated with pregnancy and chronic liver disease (Bloomer and Boyer, 1975; Heikkinen et al., 1982). This effect may be related to enzyme induction effects on the liver but phenobarbitone is also a central GABA agonist. Another GABA enhancer, midazolam, gave prolonged relief of cholestatic pruritus when given by continuous infusion, without undue sedation, in one case report (Prieto, 2004).

Lysophosphatidic acid and autotaxin

Perhaps the most significant recent contribution to the advancement of an understanding of the pathogenesis of cholestatic pruritus has come from the identification of high levels of lysophosphatidic acid (LPA) in the serum of individuals with cholestatic itch (Kremer et al., 2010) A correlation has been shown between the serum levels of LPA and the severity of itch and intradermal injection of the compound induces scratching behaviour in animal models. The same group have also identified markedly elevated activity of autotaxin, a lysophospholipase enzyme that

converts lysophosphatidylcholine to active LPA, in the serum of pruritic individuals when compared to serum from those without pruritus (Kremer et al., 2012). Furthermore, the group demonstrated that a response to conventional approaches to pruritic management (bile acid chelators, rifampicin, biliary drainage) correlated directly with a lowering of serum autotaxin activity. Interestingly, rifampicin has been shown to reduce levels of autotaxin *in vivo* by down-regulating gene transcription via agonism of the pregnane X receptor (Jones, 2012). However, other disease states demonstrate high levels of autotaxin activity but without associated pruritus. Therefore, there is likely to be a co-factor, possibly either bile acids or endogenous opioids, working with LPA at the level of the pruritogenic peripheral neurons.

Drawing on these observations, Jones has proposed a model to describe the possible pathogenesis of cholestatic pruritus and to highlight points at which therapeutic agents may be targeted (Fig. 10.4.3).

TGR5

The close relationship between pain and itch sensory transmission in the peripheral and central nervous systems has been very recently described by a large international research group (Alemi et al., 2013). In animal models they report that bile acids can induce both itch and analgesia through the activation of G-protein-coupled plasma membrane bile acid receptors (TGR5) expressed on peripheral sensory neurons and in the spinal cord. Scratching behaviour did not occur in *Tgr5*-knockout mice given

intradermal injections of bile acids and an exaggerated response was noted in mice that over-expressed the gene.

The research group acknowledged both the evidence of a role for autotaxin and LPA in cholestatic pruritus and the lack of evidence of a direct correlation between levels of circulating bile acids and the severity of pruritus. It is likely, therefore, that pruritogens in addition to bile acids, such as LPA, are involved in the generation of pruritus in a pathway still to be fully elucidated.

Removal of pruritogens

Early studies of the management of cholestatic pruritus focussed on lowering plasma levels of bile acids by reducing intestinal reabsorption with chelating agents such as cholestyramine (Datta and Sherlock, 1963; Di Padova, 1984). Such agents are unlikely to be helpful in complete biliary duct obstruction. Cholestyramine is not very palatable, can lead to bloating and constipation and can bind and interfere with the absorption of numerous drugs. A relatively new chelating agent, colesevelam, seemed to be well tolerated and to relieve cholestatic pruritus in one small study (Berg, 2001) but a recent larger randomized control trial found no benefit over placebo (Kuiper et al., 2010).

Cholestyramine and other similar agents may bind other pruritogens that are more influential in the generation of pruritus than bile acids. A study of extracorporeal plasma separation and anion adsorption demonstrated a significant reduction in cholestatic pruritus but which did not correlate to reduction in plasma levels of bile acids (Pusl et al., 2006). Other extracorporeal techniques
Fig. 10.4.3 A possible model for the pathogenesis of pruritus in cholestasis. A putative Factor X, found in increased levels in cholestasis (1) can, in turn, increase circulating levels of autotaxin (ATX) by either upregulating transcription or by decreasing breakdown (2) The resulting increased cleavage of lysophosphatidylcholine (LPC), generates increased levels of lysophosphatidic acid (LPA) (3). LPA has a direct action on puritoceptive nerve fibres (4). However, high levels of ATX are present in conditions other than cholestasis without associated pruritus. Jones therefore suggests the need for a co-factor, 'Factor Y' (5, possibly endogenous opioids) to act with LPA to stimulate pruritic signalling.

Reproduced from Jones DE, Pathogenesis of cholestatic itch: old questions, new answers, and future opportunities, *Hepatology*, Volume 56, Issue 4, pp.1194–1196, Copyright © 2012 American Association for the Study of Liver Diseases, with permission from John Wiley & Sons, Inc.

for removing pruritogens have been suggested including haemodialysis (Hoek et al., 1982), charcoal haemoperfusion (Lauterburg et al., 1980), plasmapheresis (Warren et al., 2005) and albumin dialysis (Parés et al., 2010).

Enzyme induction

Hepatic enzyme inducers such as flumecinol, rifampicin and phenobarbitone have been advocated in the management of cholestatic pruritus although their mechanism of action is unknown (Bloomer and Boyer, 1975; Ghent and Carruthers, 1988). Rifampicin is the only member of this group that is used regularly in the management of cholestatic itch. However, it has potential activity at multiple points on the pruritic pathway including the alteration of bowel flora, inhibition of bile acid uptake by hepatocytes (Bachs et al., 1989), central opioid antagonism (Bergasa et al., 2004), and most recently described, the reduction in circulating levels of autotaxin (Jones, 2012).

Antihistamines

Histological evidence of mast cell activity within the skin of jaundiced individuals is limited and conflicting. However, clinical observation suggests that antihistamines are generally ineffective in relieving the itch associated with jaundice, with any benefit reported most likely to reflect an improvement in sleep through their sedative action.

Non-pharmacological measures

In pruritus of cholestasis the value of topical emollients and environmental measures to cool and lessen sweating is unclear. Most benefit may be obtained from keeping finger nails cut short and wearing cotton gloves at night to lessen damage to the skin through scratching.

Ascites

The development of ascites as a complication of either chronic liver disease or malignancy not only heralds a poor prognosis in terms of survival but also can be associated with multiple distressing symptoms resulting from increased intra-abdominal pressure.

Cirrhosis is the precursor to ascites in approximately 75% of individuals, malignancy is the main cause in 10%, and cardiac failure and tuberculosis in 3% and 2% of individuals respectively (Rosenberg, 2006). There are several excellent published reviews of the pathogenesis of ascites and its management in individuals with cirrhosis to which the reader is directed (Gines et al., 2004; Moore and Aithal, 2006). The literature concerning malignant ascites is not as extensive or consensual and this form of ascites will become the focus for the ensuing section of the chapter.

Malignant ascites

A survey of Canadian physicians and their management of malignant ascites produced comments such as 'generally impossible to manage', 'it is a frustrating clinical situation', and 'a practical and effective solution is needed' (Lee et al., 1998).

The main frustrations in the management of ascites relate to questions such as the role of diuretic therapy, imaging and the method of paracentesis, each of which remain poorly tested in formal trials. However, recent interest in the pathophysiology of ascites formation may lead to more individualized and novel methods of management.

Incidence/prevalence

Problems related to the presence of malignant ascites are present in 3.6–6% of patients admitted to palliative care units (Preston, 1995; Keen and Fallon, 2002). Malignant ascites is most frequently associated with a primary diagnosis of ovarian carcinoma and less frequently with endometrial, breast, colonic, gastric, pancreatic, or unknown primary carcinoma (Ringenberg et al., 1989; Malik et al., 1991; Parsons et al., 1996). The presence of ascites is usually an indicator of advanced disease and, unfortunately, is detectable at the time of initial diagnosis in over half of the patients in whom it develops (Garrison et al., 1986). Patients with ovarian cancer, however, do have a longer mean survival from the time of development of ascites when compared to those with other malignancies (Parsons et al., 1996). This may relate to ascites being a complication of relatively early stage ovarian cancer and its relative sensitivity to cytotoxic chemotherapy.

Control of ascites often requires repeated inpatient episodes that, in one series of patients with ovarian cancer, showed a rapid increase in frequency over the last year of life to a median of seven admissions in the last 3 months (von Gruenigen et al., 2003).

Symptoms related to ascites

Symptoms requiring palliation relate to increased intra-abdominal pressure; discomfort of the abdominal wall, dyspnoea, anorexia, early satiety, nausea and vomiting, oesophageal reflux, poor mobility, insomnia related to general discomfort, pain in the groins and subcostal regions, and lower limb oedema. Abdominal compartment syndrome with resultant multisystem failure has also been reported (Etzion et al., 2004). Easily overlooked can be the significant negative effect of abdominal distension on body image.

Pathophysiology of ascites

Ascites formation in cirrhosis occurs predominantly as a result of a cascade of events including portal hypertension and consequent splanchnic vasodilatation that results in both sodium and fluid retention and an increase in intestinal capillary pressure and permeability (Gines et al., 2004). In contrast, it is tumour invasion of the visceral or parietal peritoneum that is the major cause of ascites in individuals with malignancy (Rosenberg, 2006).

Ascites accumulates as a result of an imbalance in the normal state of influx and efflux of fluid from the peritoneal cavity. A decreased rate of fluid efflux may occur as a result of blockage of open ended diaphragmatic lymphatics by tumour and this has been shown histologically in association with malignant ascites in animal models (Feldman et al., 1972).

It is unlikely that a reduced rate of fluid efflux alone is sufficient to cause the accumulation of massive amounts of ascitic fluid. Indeed, the rate of efflux has been shown to increase to rates approaching 80 mL/hour as ascites accumulates and intra-abdominal pressure increases (Hirabayashi and Graham, 1970).

The rate of fluid influx into the peritoneal space may be increased in malignancy as a result of two distinct mechanisms. Each mechanism will result in ascitic fluid of different biochemical properties and may respond to different modes of treatment.

1. Increased hepatic venous pressure, as an anatomical consequence of multiple hepatic metastases, or single large (sometimes benign) tumours causing a Budd–Chiari syndrome (Sebastian et al., 2004). An increase in venous pressure results in both fluid leakage into the peritoneum from the sinusoids and, via an

increase in plasma renin concentration, to the retention of salt and water by the kidneys. The ascitic fluid resulting from this mechanism is similar to that seen as a result of cirrhosis and has the properties of a *transudate*.

2. An *exudate*, of relatively high protein concentration, may be produced as a result of increased vascular permeability. Peritoneal tumour neovasculature is thought to be intrinsically leaky allowing extravasation of fluid. Additionally, neovascularization of the otherwise normal parietal peritoneum has been observed in patients with malignant ascites and ovarian carcinoma (Beecham et al., 1983).

The permeability of normal microvessels, such as those which line the peritoneal cavity, can be increased by a variety of tumour or inflammatory cell derived cytokines including transforming growth factors alpha and beta, epidermal growth factor, and vascular endothelial growth factor (VEGF) (De Simone, 1999). VEGF also stimulates angiogenesis, facilitating tumour growth and, potentially, the observed neovascularization of normal peritoneum. Animal experiments have demonstrated a significant relationship between the degree of tumour cell expression of VEGF and observed levels of angiogenesis and ascites production (Yoneda et al., 1998; Huang et al., 2000). VEGF has been detected in high concentrations in malignant as opposed to non-malignant ascites and associated with metastases from a variety of primary sites (Verheul et al., 1999; Zebrowski et al., 1999; Verheul et al., 2000).

In an individual patient, the relative contribution of these two principal mechanisms of ascitic fluid production can be estimated from the calculation of the serum–ascites albumin gradient. The serum–ascites gradient is calculated by subtracting the albumin concentration of the ascitic fluid from that within a serum specimen obtained on the same day. The gradient correlates with the portal venous pressure with a value of 11g/L or higher being indicative of a transudate and the presence of portal hypertension (Runyon, 1994). This may be of importance in assessing the likelihood of response to diuretic therapy with an aldosterone antagonist.

The formation of chylous ascites is a complication of retroperitoneal tumour spread or its treatment and arises either from damage to lymphatic vessels or through obstruction of lymphatic flow through lymph nodes or the pancreas.

Diagnosis of ascites

The diagnosis of the presence of ascites relies on a relevant clinical history and examination (Williams and Simel, 1992). Where there is doubt, usually with typical symptoms present in a patient with an obese abdomen or with potential bowel obstruction, ultrasound scanning can detect as little as 100 mL of free fluid in the peritoneum (Regnard and Mannix et al., 1970). The presence of ascites in a patient with known malignancy cannot always be assumed to be secondary to the presence of intra-abdominal tumour and other causes, such as cirrhosis, congestive heart failure, nephrotic syndrome, tuberculosis and pancreatitis must be excluded

Management of ascites

Guidelines and treatment algorithms for management of problems such as ascites have been developed and are helpful (Regnard and Mannix, 1989; Stephenson and Gilbert, 2002) but the temptation is to manipulate every patient into particular protocols and lose sight

of individual risk:benefit analyses. Furthermore, the evidence underpinning common approaches is weak at best. A recent systematic review of the management of malignant ascites detected 32 studies, of which none were randomized trials and 26 were non-analytical studies such as case series (Becker et al., 2006).

Antitumour therapy

Specific antitumour therapy should always be considered, particularly for individuals developing ascites with known ovarian or breast carcinoma. Malik et al. (1991) demonstrated complete clearance or significant reduction of ascites in 46% of patients with ovarian cancer treated with systemic cytotoxic chemotherapy. Significant response in ovarian cancer can be observed with second- and even third-line chemotherapy, so should always be considered.

Cytotoxic agents have been given intraperitoneally from as early as the 1950s (Weisberger et al., 1955). A resurgence of interest has accompanied the development of hyperthermic intraperitoneal chemotherapy (HIPEC) that appears to allow greater tissue penetration and lowers levels of drug resistance (Witkamp et al., 2001). A multi-institutional analysis of the outcome of 52 individuals treated with laparoscopic HIPEC demonstrated complete resolution of ascites in 94% with a mean hospital stay of 2.3 days and complicated by only two minor wound infections and a deep venous thrombosis (Valle et al., 2009).

Chylous ascites, when associated with retroperitoneal lymphoma and a consequent disruption of normal lymphatic drainage pathways, may be expected to show some response to chemotherapy if it be first- or second-line treatment.

The success of the intracavitary instillation of a variety of agents in the control of malignant pleural effusions has encouraged a similar approach to the treatment of malignant ascites. There have been numerous small trials and case series reporting the use of radioisotopes, cytotoxics, and more recently, biological agents and response modifiers to reduce ascitic fluid formation (Box 10.4.1). One phase II study found that intraperitoneal instillation of the corticosteroid, triamcinolone hexacetonide, resulted in a significant slowing of ascites accumulation (Mackey et al., 2000). The effect was noted particularly in patients with an albumin serum–ascites gradient of less than 11 g/L. The authors postulated the effect to have been mediated through a steroid-induced reduction of the secretion of VEGF.

Other approaches

Initial pre-clinical trials with anti-VEGF antibodies, anti-VEGF receptor antibodies, and an inhibitor of VEGF receptor tyrosine kinase activity (Xu et al., 2000) have been reported to show a reduction in ascites formation in animal models. Transfection of a mutated gene controlling production of VEGF has decreased ascites production in mice (Huang et al., 2000). Clinical trials of the humanized VEGF antibody, bevacizumab, given both systemically and intra-peritoneally have been promising (Numnum et al., 2006; Kobold et al., 2009). More recently, aflibercept, a decoy VEGF receptor that binds and neutralizes VEGF, has shown good inhibitory effects on ascites production but parenteral therapy in phase II trials was associated with a relatively high level of side effects, principally intestinal perforation (Colombo et al., 2012; Gotlieb et al., 2012).

TNF has been found to block re-accumulation of ascites in an animal model by inhibiting the expression of VEGF mRNA

Box 10.4.1 Agents reported to have been employed for intraperitoneal instillation in the management of peritoneal malignancy and ascites

◆ Thiotepa	◆ ^{198}Au
◆ Fluorouracil	◆ ^{32}CrPO$_4$
◆ Mustine	◆ Interferon alpha
◆ Bleomycin	◆ Interferon beta
◆ Cisplatinum	◆ Tumour necrosis factor
◆ Catumaxomab	◆ Interleukin-2
◆ Carboplatin	◆ Radiolabelled monoclonal antibodies
◆ Etoposide	◆ Metalloproteinase inhibitors
◆ Mitomycin C	◆ Corticosteroids
◆ Adriamycin	◆ *Corynebacterium parvum*
◆ Docetaxel	◆ OK-432 (extract from *Streptococcus pyogenes*).
◆ Mitoxantrone	

(Gotlieb et al., 2000) and an early clinical study suggested benefit from the administration of recombinant TNF-α (Rath et al., 1991). VEGF expression and associated angiogenesis has also been shown to be reduced by ketoprofen (Sakayama et al., 2004), green tea (Kojima-Yuasa et al., 2003) and angiotensin-converting enzyme inhibitors (Yoshiji et al., 2004).

The use of octreotide, the somatostatin analogue, to reduce the volume of ascites has been proposed but the results of small case series have been variable (Cairns and Malone, 1999; Cairns and Malone et al., 2012). The physiological mechanism remains unclear although there is some evidence that octreotide may be an inhibitor of VEGF (Cascinu et al., 2009). A small case series did report the successful control of chylous ascites with the combination of octreotide and a fat-free diet (Mincher et al., 2005).

Diuretic therapy

Diuretic therapy remains the mainstay of control of ascites of non-malignant origin where 90% of patients would be expected to respond to treatment (Runyon, 1994). The role of diuretics in the management of malignant ascites remains controversial. A very small study of the use of diuretics in patients with ascites and either massive hepatic metastases, 'peritoneal carcinomatosis', or chylous ascites only demonstrated a reduction in estimated ascitic volume in the group with hepatic metastases (Pockros et al., 1992). Each patient with hepatic metastases had raised plasma renin levels, a high serum–ascites albumin gradient, and responded to the aldosterone antagonist, spironolactone.

It seems appropriate to consider a trial of diuretics in individuals with malignant ascites and a high serum–ascites albumin gradient. Amiloride has a faster onset of action than spironolactone and although not a classical mineralocorticoid receptor antagonist appears to interfere with aldosterone activity and to have a similar effect to spironolactone on endothelial cells (Oberleithner et al., 2004). If spironolactone is used, the initial addition of a loop diuretic may speed the clinical response during the accumulation period (Amiel et al., 1984).

In addition to the usual potential side effects of diuretic therapy in a frail population, hepatic encephalopathy may be triggered in patients with limited residual hepatic function.

Paracentesis

Abdominal paracentesis affords quick symptomatic relief in a population that often has a relatively short prognosis and for whom diuretic therapy, if effective, may include a lag period and be associated with significant side effects.

The reported techniques and equipment used for the procedure are numerous and allows palliative care physicians full expression of their creativity. A Cochrane Review published in 2010 could find no evidence to support particular methods of paracentesis with no answers to questions relating to the length of time that a drain should remain in place, the use of intravenous replacement of fluid, the clamping of drains, and the recording of vital observations during drainage (Keen et al., 2010).

Stephenson and Gilbert reported the successful introduction of guidelines for paracentesis into an oncology unit that resulted in reductions in the use of ultrasound to mark sites for drainage, the mean duration of drainage, and the length of inpatient stay (Stephenson and Gilbert, 2002). Catheters were left in for no more than 6 hours with up to 5 L being drained and intravenous fluids only considered if patients were hypotensive, dehydrated, or known to have severe renal impairment.

The debate over the use of replacement parenteral fluid stems from the large experience of the potential problems associated with paracentesis in patients with hepatic cirrhosis. In the absence of a serum–ascites gradient of 11g/L or greater, complications of paracentesis are rare in patients with malignant ascites and fluid maybe drained off relatively rapidly with no need to routinely administer intravenous colloid or albumin. Indeed, the use of vacuum bottles allowing several litres to be removed in a matter of minutes, with apparently few complications, has been reported to be particularly useful in the outpatient clinic or even the patient's home (Moorsom, 2001). Patients without peripheral oedema or with a high serum–ascitic albumin gradient who do not respond to diuretics may be particularly prone to hypovolaemia. Intravascular volume can be replenished by intravenous infusion of either colloid or plasma protein solution should hypotension develop.

A study of 35 patients with ascites and ovarian cancer demonstrated a direct correlation between the measured value of intraperitoneal pressure and the severity of symptoms reported (Gotleib et al., 1998). The most significant drop in intra-abdominal pressure occurs with the removal of the first few litres of fluid. One study confirmed that in a group of patients from whom a mean of 5.3 L were drained over 24 hours no further improvement in symptom scores occurred after the first 2 hours of drainage (McNamara, 2000). It would have been of interest if perception of body image had been factored into these studies.

Since symptoms can often be relieved by the removal of relatively small volumes of ascites over a short time period this is to be recommended, particularly in the very frail with a limited prognosis. One to 2 L of fluid can be removed simply over 30 minutes via a plastic intravenous cannula. The insertion of the cannula into the peritoneal cavity is simple and if used in conjunction with infiltration of local anaesthetic is a relatively comfortable procedure. The removal of such a modest volume is unlikely to cause symptomatic hypovolaemia and the use of a small cannula for a short time is highly unlikely to cause local complications.

Clearly without antitumour therapy ascites is likely to re-accumulate and should the prognosis be more than a few days then regular moderate volume paracenteses through a temporary

catheter will be required to allow the individual a reasonable time period between admissions with acceptable symptom control.

There has been increasing evidence of the effectiveness, safety, tolerability, and potential financial savings afforded by the use of implanted 'permanent' peritoneal catheters allowing regular ascitic drainage at home (Fig. 10.4.4). Indeed in England and Wales, the National Institute for Health and Care Excellence (NICE) issued a report in 2012 recommending the use of this system in the NHS for individuals with malignant ascites likely to require repeated large volume paracenteses for palliation of symptoms (NICE, 2012). The system results in financial savings if regular large volume paracenteses involve an overnight stay in hospital but not if usually performed on a day-case or outpatient basis.

The most likely complications of the drainage of malignant ascites include bowel perforation, peritonitis, and localized cellulitis surrounding the drain site. One study reported two deaths from peritonitis in a series of 127 paracenteses in 100 patients (Parsons et al., 1996). Infection was a particular problem in an early case series of patients with permanent implanted drains (Belfort et al., 1990). However, a more recent series of ten patients treated with tunnelled PleurX® (Denver Biomedical, Denver, Colorado) catheters recorded no catheter-related infections with a mean catheter survival of 70 days (Richard et al., 2001). Two case reports of the prolonged use implanted catheters for 17 and 18 months, with twice weekly and daily drainage respectively, each described only one episode of infection treated with antibiotics and not necessitating catheter removal (Bui et al., 1999; Brooks and Herzog, 2006).

Anecdotal experience would suggest that many patients feel extremely tired for several days following paracentesis and both hyponatraemia and a progressive fall in plasma albumin concentration with repeated paracenteses have been recorded in some series, although not all.

Fig. 10.4.4 PleurX® catheter and vacuum flask for repeated, rapid, drainage of ascites. Once the catheter has been inserted individuals with ascites, or their carers, can continue to perform intermittent drainage at home.

Patients with severely compromised hepatic function are at particular risk of hepatic failure and encephalopathy over the first 24 hours after ascitic drainage.

Peritoneovenous shunting

Potential problems of repeated paracentesis such as intravascular hypovolaemia, hypoalbuminaemia, infection, and visceral damage, and the expense, discomfort, and inconvenience of repeated hospital admissions have prompted the development of alternative drainage procedures. Peritoneovenous shunting was established in the mid 1970s (Le Veen et al., 1974) and remains the most common procedure performed.

Two forms of shunt have been commonly used, the original Le Veen (production now discontinued) and the Denver shunt. The shunts are designed to allow drainage of ascites into the central venous system, usually via the internal jugular or femoral veins. They may be placed surgically, laparoscopically, or percutaneously with one study reporting no difference in performance or complication rate on direct comparison of these methods (Clara et al., 2004).

A review of published case series that described the placement of a total of 353 Denver shunts reported that they provided 'effective palliation' in approximately 75% of cases (White et al., 2011). Complications occurred in 38% of patients including shunt occlusion (24%) and disseminated intravascular coagulation (9%). Shunt patency averaged 87 ± 57 days and 74% of patients died with functioning shunts. Shunt lumen occlusion appears to occur more frequently during drainage of malignant ascites than cirrhotic ascites and usually occurs as a result of thrombosis of the venous terminal or from debris in the peritoneal end of the shunt.

Other complications include postoperative fluid overload with pulmonary oedema, thromboembolism, vena caval thrombosis, hepatic encephalopathy, peritonitis, and tumour seeding to the subcutaneous tissues of the anterior abdominal wall.

The potential effects of the introduction of tumour cells from the peritoneal cavity into the circulation via the shunt have been examined in a small series of post-mortem examinations (Markey et al., 1984). The study reported a variety of observations but concluded that metastases, although occurring in some patients as a direct result of shunt placement, are not clinically significant and do not alter prognosis.

Peritoneovenous shunts are clearly unsuitable for patients with loculated ascites and are not advised if the ascites is haemorrhagic or chylous, or the patient has poor cardiac or renal function, or a tendency to hepatic encephalopathy. Portal hypertension, massive pleural effusion, and coagulation disorders are relative contraindications (Markey et al., 1979; Qazi and Savlov, 1982).

A reported series of patients with ascites and non-gynaecological primary tumours showed the best outcomes of peritoneovenous shunts to occur in patients with normal renal function and tumours of non-gastrointestinal primary origin (Bieligk et al., 2001). One study measured 'quality of life' by a single question and visual analogue scale and found a non-significant trend to an improvement with either paracenteses or shunts but no difference between the two methods of drainage, despite a progressive reduction in serum albumin in the group treated by serial paracenteses (Gough and Balderson, 1993).

The relatively long survival of patients with ascites and gynaecological malignancies and the potential savings in terms of

repeated hospitalizations for paracenteses should make peritoneovenous shunting an option to be considered in all cases.

Summary

Despite numerous small studies of the intraperitoneal administration of various cytotoxic agents, radioisotopes, and immune/biological response modifiers, management of malignant ascites continues to rely upon the use of diuretics, abdominal paracentesis, and peritoneovenous shunts. There is increasing interest in the use of 'long-term' indwelling drainage catheters to alleviate the need for repeated hospital attendance.

However, it is from recent studies into the pathophysiology of ascites production in intra-abdominal malignancy that new and specific ways to slow or halt ascitic fluid production are likely to emerge. In particular, the present interest in the role of vascular endothelial growth factor in tumour angiogenesis, peritoneal neovascularization, and resultant ascites production has highlighted a possible new target for therapy.

Hepatic encephalopathy

Hepatic encephalopathy manifests as a complex neuropsychiatric disturbance often developing as a consequence of progressive liver disease with cirrhosis. It may occur as a complication of acute liver failure associated with acute cerebral oedema or may also result from portosystemic bypass with no intrinsic hepatocellular disease. Abnormal cognitive and motor function and psychiatric disorders are characteristic with severity varying from mild abnormalities, detected only by formal psychometric testing, to deep coma. Signs of neuromotor impairment include hyper-reflexia, rigidity, myoclonus, and asterixis.

An international working party has proposed a nomenclature that defines hepatic encephalopathy with respect to both the underlying hepatic abnormality and the associated duration and characteristics of neurological signs and symptoms (Mullen, 2007).

Whilst encephalopathy is most often associated with chronic liver disease it can complicate a diagnosis of malignancy. Rarely, hepatic failure and encephalopathy can result from massive infiltration by primary or metastatic tumour but the prognosis in such cases is usually measured in days (Alexopoulou et al., 2006). Individuals with hepatocellular carcinoma, as reported by a study from Hong Kong, had a median survival of 1 month following the first presentation with encephalopathy (Cheung et al., 2006).

Encephalopathy is a sign of decompensation in cirrhosis and is related to the development of significant portosystemic venous shunting. The first episode of encephalopathy is associated with a subsequent estimated 1-year survival of 42% and a 3-year survival of 23% (Bustamante et al., 1999). Individuals with raised serum bilirubin, ALP, potassium, and urea along with reduced albumin and prothrombin activity have a significantly worse prognosis. The survival of all individuals with chronic liver disease after their first episode of acute encephalopathy is less than that associated with liver transplantation which should therefore always be considered at this stage in the disease process.

Pathogenesis of hepatic encephalopathy

A raised blood ammonia level can be found in over 90% of individuals with clinical signs of hepatic encephalopathy. Although two studies have demonstrated a correlation between blood levels of ammonia and severity of encephalopathy (Ong et al., 2003; Odeh et al., 2005), other studies have failed to demonstrate such a relationship and it is likely that there are other variable factors involved, in addition to hyperammonaemia, in the pathogenesis of encephalopathy.

Ammonia is generated in the small intestine by the action of glutaminase on glutamine and in the colon by the activity of bacterial urease. Individuals with normal liver function will metabolize over 90% of the ammonia entering the portal system (Mas, 2006). Raised levels of ammonia in the systemic circulation come principally from either portosystemic shunting or from a reduction in the processing capacity of the liver. In individuals with hepatic failure an intestinal protein load either from the diet or from, for example, oesophageal variceal haemorrhage, will significantly increase ammonia levels and can produce overt encephalopathy.

The mechanism by which increased circulating blood ammonia leads to encephalopathy remains unclear. Recent evidence suggests that the observed oedema of glial cells that accompanies hyperammonaemia, and which can be exacerbated by other factors known to predispose to hepatic encephalopathy, is likely to be important (Haussinger and Schliess, 2008). Ammonia readily passes through the blood–brain barrier and can be detoxified, in astrocytes, by scavenging processes producing glutamine from glutamate. Increased cerebral metabolism of ammonia has been demonstrated by positron emission tomography in individuals with hepatic encephalopathy (Lockwood, 2002). Increased intracellular levels of osmotically active glutamine cause intra-astrocytic oedema. This oedematous change has been found to occur primarily within the frontal and occipital white matter, the globus pallidus, the putamen, and the anterior limb of the internal capsule (Haussinger and Schliess, 2008). It is thought that astrocytic oedema may cause alterations in cell function and gene expression in part through oxidative stress-dependent modifications of proteins and RNA. Alteration of GABAergic and glutamatergic neurotransmission systems may be examples of such effects on cell function. Enhanced GABA$_A$ receptor activity that is only partially reversed by a benzodiazepine antagonist such as flumazenil, is one of several possible pathways involved in the generation of hepatic encephalopathy.

In addition to ammonia, intestinal bacteria produce other potential central neurotoxins such as benzodiazepine-like compounds, mercaptans, phenols, and short- and medium-chain fatty acids, all of which have been found in relatively high levels in individuals with chronic liver disease (Williams, 2007).

Elevated serum levels of manganese have also been detected in individuals with cirrhosis and encephalopathy and autopsy specimens have demonstrated increased deposition of manganese within the basal ganglia (Rose et al., 1999). It has been postulated that the deposition of manganese, a known neurotoxin, may cause, either directly or via effects on dopamine receptors, the extrapyramidal signs and symptoms noted in some individuals with encephalopathy. Manganese may also act synergistically with ammonia to increase the activity of GABAergic neurotransmission (Jones and Basile, 1998).

Episodes of acute hepatic encephalopathy in chronic liver disease can be precipitated by a variety of factors, most frequently infection, alcohol, or other sedative drugs, gastrointestinal haemorrhage, electrolyte disturbance, dehydration, and constipation (Box 10.4.2). Infection can precipitate delirium in any individual

Box 10.4.2   Common precipitating factors of hepatic encephalopathy

- Infection
- Drugs (benzodiazepines, opioids, alcohol and other sedatives)
- Gastrointestinal bleeding
- Excessive dietary protein
- Constipation
- Dehydration
- Uraemia
- Hypokalaemia
- Hypoglycaemia
- Anaemia
- Hypoxia.

ut those with chronic liver disease seem particularly susceptible. It has been postulated that inflammatory cytokines produced in response to infection may affect the central nervous system at several different levels and, in synergism with hyperammonae-mia, precipitate frank encephalopathy. Interleukins 1 and 6 and TNF-α have been particularly implicated (Blei, 2004). Another theory suggests that the reduced cerebral blood flow associated with bacteraemia may augment the existing reduced cerebral flow associated with chronic liver disease (Blei, 2004).

Diagnosis of hepatic encephalopathy

The diagnosis of hepatic encephalopathy could be thought of as one of exclusion given the many possible causes of delirium associated with abnormal neurological signs. Other metabolic disorders, infection, cerebrovascular events, and intracranial space-occupying lesions may all present in a similar fashion. However, in individuals with known liver disease, the existence of a precipitating factor and/or a prior history of hepatic encephalopathy the diagnosis can usually be safely made. The presence of asterixis ('liver flap'), fetor hepaticus, and extrapyramidal signs help strengthen the diagnosis but are not always present. Elevated blood ammonia levels may confirm the degree of underlying liver disease and susceptibility to encephalopathy.

Other objective diagnostic methods have been described including the measurement of visual and auditory evoked potentials (Sandford and Saul, 1988), electroencephalography, and, more recently, actigraphy (Hourmand-Ollivier et al., 2006).

An International Working Party has recommended the use of the West Haven criteria (Table 10.4.6) and Glasgow Coma scales for grading and monitoring established encephalopathy (Mullen, 2007).

Covert encephalopathy

An estimated 50–80% of individuals with cirrhosis will have subclinical encephalopathy, without classic clinical signs and demonstrated only by altered formal psychometric testing. These individuals are not only at increased risk of acute episodes of frank encephalopathy (Mullen, 2007) but also have associated impaired daily functioning,

disturbed sleep patterns, and a predisposition to other dangers such as road traffic accidents (Kappus and Bajaj, 2011). The potential to reverse such 'covert encephalopathy', or to at least delay progression to overt encephalopathy, means recognition of the condition is important (Cordoba et al., 1998; Groeneweg et al., 1998).

Psychometric testing has been recommended by an International Working Party as a reliable method of detecting and monitoring covert encephalopathy. The group recommended the use of at least two instruments including either the number connection tests-A and/or B, the block design test or the digit symbol test (Quero et al., 1996).

Management of encephalopathy

The care of individuals with encephalopathy will be similar to that given to those with delirium. The environment and approach taken by care staff is particularly important for individuals likely to be disorientated and at risk of falls. The family and other lay carers are likely to need particular support and should be included in care procedures wherever possible.

Precipitating factors of encephalopathy in chronic liver disease have been well described (Table 10.4.6) and investigation and treatment should firstly be directed at such factors. A careful history is required with particular note taken of symptoms suggestive of an infection or upper gastrointestinal haemorrhage and a review made of recent psychotropic drug use, prescribed and otherwise.

Table 10.4.6   West Haven criteria of altered mental state in hepatic encephalopathy

Stage 0	Lack of detectable changes in personality or behaviour
	Impairment noted only on formal psychomotor testing
	Asterixis absent
Stage 1	Mild lack of awareness
	Shortened attention span
	Altered sleep pattern
	Mild asterixis or tremor
Stage 2	Lethargy
	Disorientation
	Inappropriate behaviour
	Slurred speech
	Obvious asterixis
Stage 3	Somnolent but rousable
	Gross disorientation
	Bizarre behaviour
	Asterixis generally absent
	Increased muscle tone and hyper-reflexia
Stage 4	Coma
	Decerebrate posturing

Reproduced from Ferenci P et al., Hepatic encephalopathy—definition, nomenclature, diagnosis, and quantification: final report of the working party at the 11th World Congresses of Gastroenterology, Vienna, 1998, *Hepatology*, Volume 37, Issue 3, pp. 716-21, Copyright © 2002 American Association for the Study of Liver Diseases, with permission from John Wiley & Sons, Inc.

It is generally agreed that the production of ammonia and possibly other, as yet undefined, neurotoxins by intestinal bacteria is key to the pathogenesis of hepatic encephalopathy. Most proposed therapeutic options are therefore directed towards a reduction in ammonia production or increased clearance through dietary manipulation, non-absorbable disaccharides, and broad-spectrum antibiotics.

Diet

A high-protein diet can increase ammonia production and precipitate encephalopathy and in the acute stages restriction of dietary protein intake is usually suggested. However, in the longer term, protein restriction can aggravate encephalopathy, and in the setting of the increased catabolic rate that is often present in chronic liver disease, can lead to a reduced skeletal muscle mass with a consequent reduced ability to detoxify ammonia (Blei and Cordoba, 2001). A recent International Working Group has suggested an optimal diet comprises 1.2–1.5 g/kg/day of mainly vegetable protein along with a late-night snack of complex carbohydrates to minimize protein metabolism (Amodio et al., 2013).

Disaccharides

The cornerstone of the medical management of encephalopathy has for many years been the use of non-absorbable disaccharides, such as lactulose. Lactulose is not broken down by intestinal enzymes so reaches the colon where it is metabolized by bacteria to acetic and lactic acid. Intestinal bacteria will preferentially take up carbohydrate over protein so that lactulose or any other carbohydrate in the diet will potentially reduce bacterial ammonia production. Additionally, as result of bacterial metabolism, acidification of the intestinal contents converts ammonia to non-diffusible ammonium, helps catharsis and excretion of potential toxins and may aid a change in microbial population from urease producing bacteria to acidophilic non-urease producing organisms (Bass, 2007). The use of additional probiotic and synbiotic preparations to further aid the change in intestinal flora has also been proposed, but whilst trials suggest benefit they have been of generally poor quality (McGee et al., 2011; Shukla et al., 2011). Protocols for the use of lactulose usually suggest titration of dosing to produce two or three soft stools per day. Lactulose can produce nausea, bloating, abdominal cramps, and, in cases of excessive diarrhoea, dehydration and hypernatraemia which can exacerbate encephalopathy. Despite the regular use of disaccharides such as lactulose in the management of hepatic encephalopathy for many years, a recent Cochrane systematic review found only modest benefit overall and no significant benefit when only high quality trials were included in the analysis (Als-Nielsen et al., 2004c). The authors concluded there was insufficient evidence to support or refute the use of disaccharides in encephalopathy and, additionally, in head-to-head trials antibiotics were superior to disaccharides in terms of improved symptoms and lowered ammonia levels.

Antibiotics

Antibiotics to reduce the numbers of urease-producing bacteria in the intestine have been employed in the management of encephalopathy for many years. The use of neomycin, metronidazole, ampicillin and, more recently, rifaximin have been described (Festi et al., 2006). The evidence for the use of neomycin and metronidazole is modest and there is concern over the prolonged use of these agents because of the risk of toxicity. Rifaximin is a broad-spectrum, poorly-absorbed, antibiotic with a tolerability comparable to placebo (Huang and DuPont, 2005). Several trials have demonstrated its efficacy in relieving symptoms of encephalopathy, reducing blood ammonia levels and improving electroencephalographic abnormalities (Festi et al., 2006). One recent study demonstrated lower serum levels of ammonia, benzodiazepine-like substances, and endotoxin in individuals treated with rifaximin (Lighthouse et al., 2004). Interestingly this same study demonstrated that clinical improvement could be maintained by sequential administration of rifaximin followed by a probiotic mixture of lactobacilli and bifidobacter.

Neurotransmitters

Although endogenous or bacterial-derived benzodiazepine-like substances are thought to be involved in the pathogenesis of encephalopathy, studies of the use of the antagonist, flumazenil, have shown a short-lived effect at best (Als-Nielsen et al., 2004a). The use of this approach is probably limited to managing encephalopathy precipitated by the intake of benzodiazepine medications.

The presence of extrapyramidal signs in some individuals with hepatic encephalopathy has generated a small number of studies into the use of the dopaminergic agonists such as L-dopa and bromocriptine. A recent Cochrane systematic review concluded that there was insufficient evidence to recommend their use (Als-Nielsen et al., 2004b).

Miscellaneous

The maintenance of circulating blood volume by correction of dehydration (often caused by overuse of diuretics) is important to maintain adequate renal excretion of ammonia (Shawcross and Jalan, 2005).

Skeletal muscle reduces circulating ammonia through the synthesis of glutamine and L-ornithine L-aspartate can provide intermediates that increase glutamate availability. Several studies suggest that administration of L-ornithine L-aspartate can improve the symptoms of encephalopathy (Shawcross and Jalan, 2005).

The administration of phenylbutyrate provides an alternate pathway of nitrogen excretion whereby glutamine is conjugated and excreted by the kidney with no production of ammonia. Early studies have been promising (Rockey et al., 2014).

The role of external detoxification devices akin to dialysis in renal failure has been proposed for individuals with hepatic encephalopathy. Artificial support systems such as MARS (molecular adsorbents recirculating system) and bioartificial systems have been shown in a systematic review of a small number of trials to significantly improve symptoms of encephalopathy and are under continued investigation (Liu et al., 2004). Interestingly one trial showed significant improvement in encephalopathy with MARS without changes in blood levels of ammonia (Sen et al., 2004).

Liver transplantation should always be considered when hepatic encephalopathy develops in chronic liver disease. Unfortunately signs and symptoms do not always resolve indicating that permanent organic cerebral changes can occur (Mas, 206).

There is a recent awakening of interest in the management of hepatic encephalopathy prompted by advances in molecular biology and imaging techniques. The role of anti-inflammatory

agents, *N*-methyl-D-aspartate receptor antagonists, L-carnitine, sodium benzoate and phenylacetate, manganese chelators, and zinc supplementation are all under investigation.

Summary

At present, given the relative lack of evidence for any of the medical interventions described, it is imperative that any individual presenting with hepatic encephalopathy is, if appropriate given the context of the associated disease process, intensively investigated for precipitating factors. Close attention paid to treating infections, dehydration, acid–base and electrolyte disturbances, and constipation is likely to have the most significant impact on the clinical situation. If no precipitating factors are identified or symptoms are persistent, then antibiotics such as neomycin or particularly rifaximin, if available, should receive a trial of therapy. The care of individuals with covert hepatic encephalopathy continues to be a worthy subject of debate.

Aetiology, classification, assessment, and treatment of the anorexia-cachexia syndrome

Vickie E. Baracos, Sharon M. Watanabe, and Kenneth C. H. Fearon

Introduction to aetiology, classification, assessment and treatment of the anorexia-cachexia syndrome

The anorexia-cachexia syndrome is a complex multidimensional problem and, until recently (Evans et al., 2008; Fearon et al., 2011), there has been no generally agreed classification system or treatment algorithm. This had led clinicians to feel that perhaps it was not worth trying to grapple with the difficult problem of assessment and treatment of patients with cachexia. Recent progress in our understanding of the underlying biology and the development of new biological therapeutic targets has led to a new era of hopeful optimism. The aim of this chapter is to resolve some of these issues and provide (a) the reader with some background principles to classification, (b) a simple approach to patient assessment and a robust algorithm for basic multimodal treatment, and (c) an overview of the evidence base for different pharmacological interventions.

Cachexia affects a wide spectrum of patients with a variety of chronic diseases including cancer, chronic heart failure, end-stage renal failure, rheumatoid arthritis, and HIV. The common feature of cachexia is that it is not possible to completely reverse the syndrome with conventional nutritional support. Whilst undoubtedly there are common mechanisms of wasting in each of these conditions, there are many unique aspects which are too complex to explore in a single chapter. The present chapter focuses primarily on the patient with cancer. It is hoped that the principles outlined will provide a platform on which to build an approach for other groups of patients. To this end, comment is added in 'Pharmacological treatment' section on specific pharmacological interventions where the latter have been tested in large groups of cachectic patients with chronic diseases other than cancer.

Before approaching classification and therapeutics, it is useful to have some understanding of the pathophysiology of cachexia as these principles should underpin the logic behind the clinical management of patients. Cachexia is characterized by a negative energy and protein balance driven by a variable combination of reduced food intake and abnormal metabolism. Thus it is important to assess and manage actively both food intake and abnormal metabolism in all patients. Cancer cachexia may be considered initially an adaptive response to access body stores of energy and protein. Mobilization of skeletal muscle and adipose tissue is a highly organized response. Inflammation is widely agreed to be a unifying mechanism for the entire cluster of sickness behaviours (asthenia, increased slow wave sleep, mood alteration, lethargy, depression, anorexia, fever, anhedonia, cognitive impairment, hyperalgesia, and decreased social interaction), including loss of fat and muscle. Inflammation is generated in the brain, by the tumour, by tissues in the locale of the tumour and by a diversity of host cells including skeletal muscle, adipose tissue, and cells of the immune system and liver. The specific identity of the inflammatory and neuro-endocrine mediators participating in cancer cachexia is emerging (Fearon et al., 2012).

It is also important to recognize that cachexia in general, and muscle wasting in particular, does not occur in isolation. Other factors that can exacerbate muscle wasting include co-morbid conditions (e.g. cardiac failure, chronic obstructive pulmonary disease (COPD), and chronic renal failure), old age (age-related sarcopenia), physical deconditioning, hypogonadism, insulin resistance, nutritional deficiency, drugs, and medical interventions (including all major cancer therapies: surgery, radiotherapy and chemotherapy). Given such clinical complexity, there has been a drive to establish specific clinics to deal with cachexia and this is something that may develop further in the future.

Classification

A conceptual framework for classification

Cachexia is a syndrome of involuntary weight loss, which may progress through various phases (pre-cachexia, cachexia syndrome, refractory cachexia (Fearon, K., Strasser, F., Anker, S., et al. (2011). Definition and classification of cancer cachexia: an international consensus. The Lancet Oncology, 12, 489–495)) and culminate in a grossly emaciated state (severe cachexia). The depletion pertains to body weight and its major elements which constitute the physiological stores of energy and protein in the body (i.e. adipose tissue and skeletal muscle). Varying degrees of depletion are associated with quantifiable risks. The health risks that have been considered range from functional loss (e.g. physical function, immune function), morbidity (e.g. injuries from falls, infections), increased
Fig. 10.5.1 The timing and magnitude of the clinical risks associated with cachexia are determined, in part, by the size of the initial body stores and the rate at which they are lost.

health service utilization and associated costs (e.g. hospital stay, emergency room visit) to mortality (Fig. 10.5.1). The timing of the emergence of and the magnitude of the clinical risks associated with body weight loss are affected by the patients' initial body weight (constituting the stores that may be mobilized) and the dynamic rate of loss of these constituents.

Weight and weight loss classification

The designation of clinically underweight is consistent with the notion of depletion of body reserves below a functionally important threshold. The simplest and most widely understood classification scheme is the World Health Organization (WHO) (WHO, 2000) categories of body mass adjusted for stature (body mass index (BMI): weight (kg)/height (m²)) are widely used to classify clinically important deviations of body weight (Table 10.5.1). In addition to the risks from a variety of morbidities and mortality from secondary causes, depletion to a BMI in the vicinity of 10–11 kg/m² is, of itself, fatal (Rigaud et al., 2000). It should be noted that in patients over 65 years of age, a somewhat higher limit for underweight (20 kg/m²) is generally accepted. During weight loss, individuals may pass through a zone conventionally referred to as 'normal', 'healthy', or 'ideal' body weight. However, depending on the intensity of weight loss, severe depletion will occur sooner or later; this situation is neither healthy nor ideal.

Healthy adults are highly resistant to weight reduction and the appearance of involuntary weight loss is both a fundamental abnormality of physiological regulation and a cardinal diagnostic criterion of cancer cachexia. Various classification schemes for weight loss have been developed with different intent. The National Cancer Institute's Common Toxicity Criteria (Cancer Therapy Evaluation Program, 2006) are used widely to define cancer- and cancer therapy-associated toxicity and these define the total degree of loss relative to stable body weight as follows: grade 0, up to 4.9% loss; grade 1, 5–9.9%; grade 2, 10–19.9%; and grade 3, 20% or higher. Grade 4 (life-threatening) weight loss is not defined. The scored Patient-Generated Subjective Global Assessment (PG-SGA) (Ottery 1996), a tool designed to screen for malnutrition, includes a grading system incorporating four weight loss grades that can be based on a 1-month or 6-month weight history, whichever is available (Table 10.5.2). These different grading systems provide one possible explanation for the considerable confusion amongst oncologists as to what constitutes a clinically significant degree of weight loss (Spiro et al., 2006). A recent analysis of an international sample of over 11,000 patients with advanced stages of cancer (Martin et al., in press) provides a

Table 10.5.1 WHO classification of body mass adjusted for stature: body mass index (BMI)

	BMI (kg/m²)
Severely underweight	<16
Moderately underweight	16–17
Mildly underweight	17–18.5[a]
Normal	18.5–25
Overweight	25–30
Class I obesity	30–35
Class II obesity	35–40
Morbid obesity	>40

[a] Range extended 17–20 in elderly.

grading system based on BMI and percentage weight loss, allowing both the degree of depletion of BMI and the rate of their loss to be simultaneously incorporated. BMI and weight loss were entered into a multivariate analysis controlling for age, sex, cancer site, stage, and performance status and their relationships to overall survival were examined to develop a grading system based on their prognostic weight. Five categories of BMI (< 20.0, 20.0–21.9,

Grade	0	1	2	3	4	P
Colon	28.3	22.8	21.6	17.3	7.3	0.002
Esophagus	18.4	12.8	10.3	7.6	4.4	0.003
Palliative care	5.8	5.0	3.9	3.7	3.2	0.002
Lung	11.3	9.9	8.2	5.6	4.2	0.001
Fig. 10.5.2 (BMI-adjusted) Weight loss grade. Grading scheme is based on groupings showing distinct median survival. Different colours denote distinct survival (P < 0.001; adjusted for age, sex, disease site, stage and performance status).

22.0–24.9, 25.0–27.9, ≥ 28.0 kg/m^2) differed in overall survival (P < 0.001). Five categories of weight behavior also differed in survival (P < 0.001): (weight stable (+2.4 to –2.4%) and weight loss –2.5 to –5.9%, –6.0 to –10.9%, –11.0 to –14.9%, ≥ –15.0%). Grade (0–4) was assigned according to the combined prognostic weight of BMI and weight loss (Fig. 10.5.2).

Measurement of tissue wasting

It is clear that the main constituents of body weight, adipose and lean tissues, merit separate consideration. This adds new orders of complexity to our understanding of wasting syndromes. Both muscle protein and adipose tissues can be considered as independent physiologic stores. The presence of a large adipose tissue reserve, at least up to a certain point, is a favourable prognostic factor in patients embarking on different types of wasting syndromes. By itself, depletion of muscle mass is associated with health risks, including frailty, functional problems in gait and balance, risk of falls, inability to complete tasks of daily living, extended hospital stay and infectious and non-infectious complications in hospital, as well as overall mortality (Baumgartner et al., 1998; Morley et al., 2001; Roubenoff, 2003; Kyle et al., 2005; Cosqueric et al., 2006). These health risks are seen to be independent of adiposity and are present in normal body weight ranges, as well as in obese persons. Skeletal muscle wasting may be under-recognized in the context of epidemic obesity. Overweight and obese patients may already have substantial ongoing muscle depletion (sarcopenic obesity) at the time of presentation.

The independent significance of muscle wasting requires some clinical capacity to determine muscle mass. Individuals within a population present with different degrees of muscularity, and this feature is variously expressed in the literature depending on the methods used for its determination. Whole-body muscle mass may be evaluated using image-based approaches, and is often expressed in the same units as BMI (kg skeletal muscle/m^2). Methods such as whole-body computed tomography (CT) or magnetic resonance image analysis are required to determine this value. Dual energy X-ray absorptiometry may be used to quantify muscle in the arms and legs only, expressed as total appendicular skeletal muscle (kg/m^2). Anthropometrics constitute a simple tool to estimate skeletal muscle stores, as mid-arm muscle circumference. It should be noted that there are important methodological considerations. Ease of determination is often counterbalanced by low precision. Upper arm measurements are prone to inter-observer variation. Scoring fatness and muscularity on physical examination has utility in the hands of a highly trained observer, but is otherwise difficult to standardize. Mid-arm muscle circumference is based on the assumption that the upper arm is perfectly cylindrical, which it is evidently not. The image-based methods enjoying high precision and the ability to discriminate muscle and adipose tissues require instrumentation, money, and time. Cut-off points have been proposed for clinically important depletion of skeletal muscle (sarcopenia) (i.e. below the 5th percentile for healthy adults). Sex-specific cut points for severe muscle depletion have been suggested, according to the available methods of assessment: mid upper-arm muscle area by anthropometry (men < 32 cm^2, women < 18 cm^2); appendicular skeletal muscle index determined by dual-energy X-ray absorptiometry (men < 7.26 kg/m^2; women < 5.45 kg/m^2); lumbar skeletal muscle index determined from oncology CT imaging (men < 55 cm^2/m^2; women < 39 cm^2/m^2); whole-body fat-free mass index without bone determined by bioelectrical impedance (men < 14.6 kg/m^2; women < 11.4 kg/m^2). This series of options includes methods with clinical utility as well as options for specialized or research-related investigations.

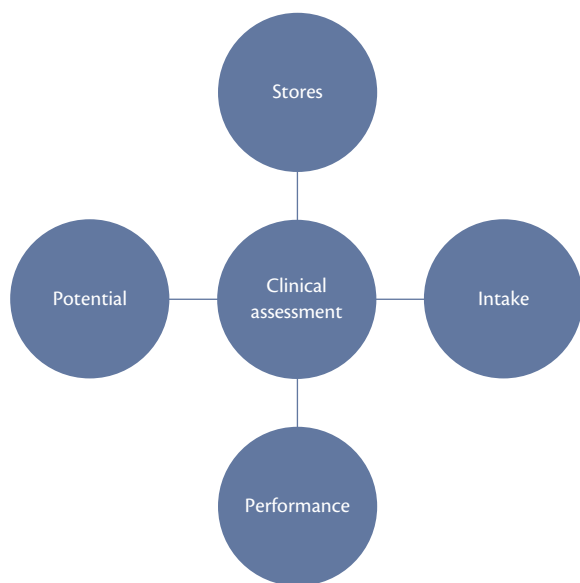
Multiple-factor classification systems

The definition of cachexia is a multifactorial syndrome characterized by an ongoing loss of skeletal muscle mass (with or without loss of fat mass) that cannot be fully reversed by conventional nutritional support and which leads to progressive functional impairment (Fearon et al., 2011). Reduced food intake is caused by primary anorexia (i.e. central nervous system level) and may be compounded by secondary impairments to oral intake. Concurrent hypermetabolism, hypercatabolism and hypoanabolism aggravate the associated weight loss and are provoked by systemic inflammation and catabolic factors that may act peripherally and via the central nervous system. Cachexia is thus a multidimensional problem and therefore it may not be possible to reflect the physiological change and clinical risks the patient sustains by a single measurement (e.g. loss of weight or skeletal muscle mass). On the basis that risk derives from several key elements in the cachexia syndrome, a classification system based on weight loss (> 10%), reduced food intake (< 1500 kcal/day) and systemic inflammation (serum C-reactive protein concentration > 10 mg/L) has been proposed (Fearon et al., 2006). Patients with all three features have increased physiological impairment and reduced survival. Of key clinical importance is that patients with

early stage of disease who demonstrate these features are at high risk of early demise and are therefore a key group to target for early and effective intervention. The current international consensus classification system (Fearon et al., 2011) includes these three essential features but has extended the assessment domains to include anorexia/intake, reserves (including muscle mass), catabolic drivers (e.g. systemic inflammation) and functional and psychosocial impairment.

Clinical assessment and treatment strategy

When medical or nursing professionals who have not received specific training are confronted with a patient who requires nutritional assessment the prospect can seem daunting. Moreover, the purpose of such assessment is often muddled since no clear link between assessment and treatment has been provided. The purpose of this section is to provide a clear, logical framework for patient assessment and to link this with a simple treatment algorithm.

Patients lose weight as a result of reduced food intake, abnormal metabolic activity, or, most commonly, a combination of the two. Weight loss reflects that the patient has a negative energy balance (resulting in loss of fat mass: the main energy reserve) and a negative protein balance (resulting in loss of skeletal muscle: the main protein reserve). The purpose of nutritional assessment (Fig. 10.5.3) is to determine to what extent *stores* have been depleted, what contribution to this loss has been due to reduced food *intake*, what impact such changes are having on the patient's *performance*, and what *potential* there is for reversal of the situation. In turn, the potential for reversal is partly dependent on the nature of catabolic drivers including such factors as systemic inflammation and tumour progression. Each of these domains can be considered in relation to the patient's clinical journey (i.e. past, present, and future). The Scored PG-SGA (Ottery 1996) is a validated screening tool designed specifically for patients with cancer


and is recommended by the Oncology Nutrition Dietetic Practice Group of the American Dietetic Association, and Oncology Nursing Society. Several elements of this instrument have practical utility for patient assessment, including the weight loss history (Table 10.5.2), the dietary intake component, checklist of 13 'nutrition impact' symptoms, and functional capacity component.

Stores (including muscle mass): the primary variables that are assessed readily are weight and weight loss history. Key questions include: height and current weight (kg), previous stable weight, duration of weight loss, and calculation of percentage weight loss. Weight loss grade 3 or 4 (Table 10.5.2) and/or a BMI less than 18.5 kg/m^2 are indicators of depletion of energy and/or protein reserves. As indicated previously, in the relatively near future it may be possible in routine practice to derive a direct measure of muscle wasting from diagnostic cross sectional imaging.

Intake: routine clinical assessment with the PG-SGA includes basic questions concerning type and amount of intake, loss of appetite, presence of early satiety, and other symptoms impeding dietary intake. This level of assessment is intended for non-specialists, and is useful for deciding when to refer patients to a nutrition health-care professional (dietitian or specialist in clinical nutrition). A detailed diet history or diet diary is a specialized assessment which usually undertaken by a dietician. The information from such assessments can be used to estimate total energy and macronutrient intakes.

Performance/psychosocial impact: every clinical, medical, or surgical oncologist is used to assessing the performance status of patients. The functional capacity component of the PG-SGA, is a version of the Eastern Cooperative Oncology Group (ECOG) performance status score; alternatively either the WHO or Karnofsky scales may be used. Knowledge whether the patient is active and mobile is vital in determining not only how depletion of stores/intake is affecting quality of life but also what the nature of therapy should be. Bed-bound patients suffer from anabolic resistance and in these circumstances it is very difficult to improve muscle mass/function. *It is also important to consider the psychosocial impact of cachexia both on the patient and their family* (Oberholzer et al., 2013). Physical activity may be impaired by the loss of muscle tissue, concentration, and alertness diminished by fatigue, and mood dominated by lethargy and increasing indifference. Patients may become isolated due to shrinking physical, mental, and emotional activity. Some families exhaust themselves by trying to fight the patient's visible loss of weight and power; urging him or her to eat despite the absence of appetite and finally experiencing frustration, helplessness, and fear.

Catabolic drivers (potential for reversal): knowledge of the patient's tumour type, stage of disease, and purpose of current cancer therapy can give a ready impression of prognosis and the purpose of nutritional intervention. The presence or absence of systemic inflammation (serum C-reactive protein > 10mg/L) may also identify the patient who requires early nutritional/metabolic support (Fearon et al., 2006). For the patient with relatively stable disease and with more than 2 months to live it is reasonable to plan nutritional intervention. For the patient whose disease is progressing rapidly and has less than 2–3 months to live, symptomatic management (e.g. steroids) is perhaps more appropriate (refractory cachexia). It is also important to consider carefully the patients' expectations concerning the future benefits of any intervention. The burden of intervention (e.g. daily intake of oral

Fig. 10.5.3 Patients should be assessed briefly, if found to be at risk more detailed assessment is warranted and overall management should be guided by performance status

nutritional supplements) has to match what the patient is willing to consider in the light of possible gains.

Intervention strategy

A simple treatment algorithm is outlined in Fig. 10.5.4. For those not at nutritional risk (e.g. weight stable, adequate macronutrient stores, normal appetite/intake, good performance status, and stable disease) it would be reasonable simply to review or ask the patients to seek further advice if they lose weight. For patients at nutritional risk (grade 3 or 4 weight loss, BMI <18.5, evidence of depletion of lean body mass, reduced appetite/intake), it is vital to undertake a screen for reversible causes of anorexia/reduced food intake and to ensure that their underlying primary disease and co-morbidities are being managed optimally. Key variables to consider in relation to secondary causes of reduced intake include oral ulceration, intestinal obstruction, constipation, diarrhoea, nausea, vomiting, uncontrolled pain, and side effects of drugs. Metabolism-related variables include the development of diabetes or malabsorption (e.g. both common associations with advanced pancreatic cancer) and which if not managed with insulin/pancreatic enzyme supplements will result in continuing weight loss independent of any nutritional intervention.

The next stage in assessment involves consideration of the patient's performance status, prognosis, and expectations. For patients reaching an end-of-life phase and whose main complaint is anorexia, it would be reasonable to consider the prescription of oral steroids or megestrol acetate. For patients with a better prognosis (including those undergoing palliative chemotherapy/radiotherapy) and who are not bed-bound consideration should be given to the following four specific domains:

Oral intake

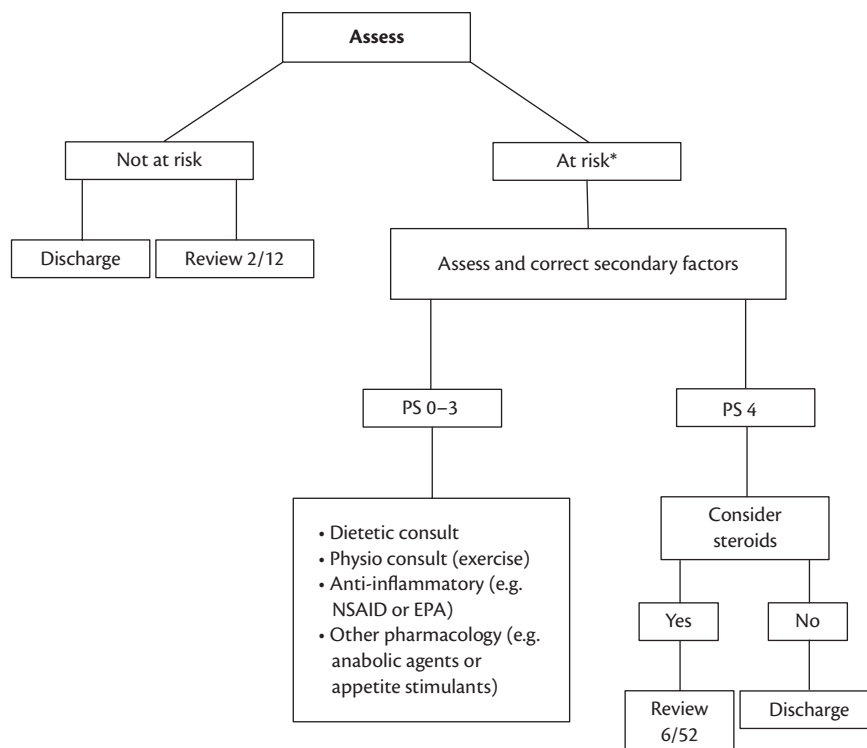
Cancer patients are often anxious about whether their diet has contributed to the development of cancer or whether it may modify the course of established illness. In general it is important to emphasize the need for a broad balanced diet and to explain the importance of maintaining a normal food intake in order to undergo cancer therapy or to optimize quality of life. It is vital to explore what patients consider to be a normal diet and to identify the principal daily source of protein in the diet. Two key basics in dietary advice are (a) that the average daily calorie deficit in a weight-losing cancer patient is of the order of 250–400 kcal/day and (b) that it is vital to maintain protein intake at a high level in order to either stabilize or replete diminished skeletal muscle mass. Protein intake should generally be maintained between 1–1.5g/kg/day (Wolfe, 2006). In order to achieve this intake, patients will generally need to consume red or white meat or fish on a daily basis and supplement this with dairy products (e.g. milk or cheese). An alternative approach is to take an energy- and protein-dense oral nutritional supplement. A 250 mL carton with 1.5 kcal/mL should contain sufficient calories and protein to make up the average daily deficit. However, significant repletion of a patient with depleted stores will probably require consumption of two such supplements per day. Patients will often benefit from specialist dietary assessment and advice from a


Fig. 10.5.4 Cachexia intervention algorithm.
* At risk defined by the presence of persistent weight loss, reduced dietary intake,

dietician especially if they continue to lose weight after initial management.

Exercise

The average physical activity levels of advanced cancer patients still attending the outpatient clinic is reduced by about 40–50% (Dahele et al., 2007). Many patients with advanced cancer are elderly and may have significant co-morbidity. Thus, the idea of resistance exercise training to optimize muscle mass is beyond their capacity. However, it is vital to explain to patients the value of daily exercise to counteract muscle wasting. Simply maintaining mobility and going out for a regular daily walk are reasonable goals to set. Motivated patients may benefit from the advice of a physiotherapist.

Anti-inflammatory

There is growing evidence concerning the role of systemic inflammation in most forms of cachexia. Inflammatory mediators contribute to both reduced food intake and metabolic change. There is no ideal anti-inflammatory strategy that has been proven to be of benefit in cachexia. However, two common approaches are either non-steroidal anti-inflammatory drugs (NSAIDs) (Preston et al., 1995) or fish oil (eicosapentaenoic acid (EPA), docosahexaenoic acid). NSAIDs with a low incidence of gastrointestinal side effects such as ibuprofen (400mg three times daily) can be taken long term with or without gastric mucosal protection. Fish oil represents a 'natural' alternative and may appeal more to some patients. A total dose of 1.5–2.0 g/day EPA is recommended and can be taken either as fish oil capsules (Wigmore et al., 1996) or as a fish oil enriched oral nutritional supplement (Fearon et al., 2003; Moses et al., 2004).

Other specific pharmacological agents

See following section on 'Pharmacological treatment'.

Pharmacological treatment

Pharmacological approaches to wasting syndromes have a number of specific treatment targets and have been evaluated in a variety of diseases, including cancer, AIDS, and COPD. Such pharmacological treatments have been assessed in randomized clinical trials, and there are a number of high-quality systematic reviews (i.e. Cochrane Database) available summarizing the evidence. The reader is referred to these reviews for full details. The results of the systematic reviews are summarized in the following paragraphs, with information from subsequently published trials added. The section on cancer is the most extensive and an attempt to group the agents according to evidence/benefit has been made. With the introduction of effective antiretroviral therapy for HIV, the clinical problem of progressive wasting in this condition has mostly resolved in Western society. An abbreviated summary of the evidence for the management of HIV-related anorexia-cachexia is therefore presented.

Cancer

In 2005, Yavuzsen and colleagues published a systematic review of pharmacological therapies for cancer-associated anorexia and weight loss in adult patients with non-haematological malignancies. Fifty-five randomized controlled trials were included. Only two classes of drugs (progestins and corticosteroids) were found to have sufficient evidence to support their use in cancer patients. Studies with other agents had mixed outcomes, positive results in only a single trial, or were not adequately controlled. Note was made of heterogeneity amongst trials with respect to outcome measures, assessment tools, treatment duration, and timing of assessment (Yavuzsen et al., 2005).

Approaches well supported by evidence
Progestins

In the Yavuzsen review, the largest number of studies involved progestins (29 trials conducted in a total of 4139 patients). Twenty-three trials in 3436 patients involved megestrol acetate (MA) at doses of 160–1600 mg per day for 2 weeks to 2 years. Results for appetite and weight gain favoured MA over placebo. Five trials comparing different doses suggested that the optimal dose is between 480 and 800 mg per day. The influence of MA on quality of life was minimal.

Five trials compared MA with other drugs. MA was equivalent to corticosteroids and significantly better than dronabinol and fluoxymesterone for appetite stimulation. Compared with cisapride, MA was associated with significantly less weight loss and better appetite. Ibuprofen plus MA was significantly better than MA plus placebo at maintaining weight. A study comparing MA with EPA will be discussed later.

Six trials in 703 patients involved medroxyprogesterone acetate (MPA) at doses of 300 mg to 1200 mg per day for 6–12 weeks. Significant advantages were demonstrated for MPA versus placebo in terms of appetite improvement, increased caloric intake, and weight gain or attenuation of weight loss. Effects on quality of life were inconsistent (Yavuzsen et al., 2005).

In 2005, Berenstein and Ortiz published a systematic review of MA for the treatment of anorexia-cachexia syndrome in patients with cancer, AIDS or other underlying pathologies. Thirty-four randomized controlled trials involving 4826 patients were identified. Twenty-six were performed in cancer patients, while the remainder were in patients with AIDS, chronic obstructive lung disease, and cystic fibrosis, as well as in the elderly. Compared with placebo, relative risks for appetite improvement and weight gain in cancer patients were 3.03 (95% confidence interval (CI) 1.83–5.01) and 2.14 (95% CI 1.41–3.24), respectively. Oedema of the lower limbs was the only side effect that occurred at a significantly greater frequency with MA compared with placebo (relative risk 1.74, 95% CI 1.29–2.35) (Berenstein and Ortiz, 2005).

Corticosteroids

Corticosteroids were the subject of six studies conducted in a total of 637 patients, in the Yavuzsen review. Three trials in 402 patients used methylprednisolone orally or intravenously at doses of 32–125 mg per day for 1–8 weeks. Versus placebo, significant improvements were seen in appetite and quality of life, but not weight.

One trial in 61 patients involved prednisolone 10 mg per day for 6 weeks. Compared with placebo, appetite and well-being were significantly improved. Two trials in 184 patients used dexamethasone 3–8 mg per day for 4 days or until time of death. A transient improvement in appetite compared to placebo was seen.

Due to their well-known adverse effects, particularly with longer duration of use, corticosteroids may be more suitable for patients with a short life expectancy, especially if they have other symptoms that may be alleviated by this drug such as pain or nausea.

New approaches with limited supportive evidence
Androgenic steroids

Two trials examining the effects of androgenic steroids in a total of 512 patients were included in the review by Yavuzsen. The first compared chemotherapy plus nandrolone 200 mg intramuscularly weekly for 4 weeks versus chemotherapy alone. The nandrolone-treated patients demonstrated a trend towards less weight loss. The second trial, mentioned previously, compared fluoxymesterone with megestrol acetate or dexamethasone. Fluoxymesterone was inferior in terms of appetite and weight gain.

Eicosapentaenoic acid

In 2007, Dewey and colleagues published a systematic review that included five trials in a total of 587 patients, examining the effects of EPA given at doses of 1–6 g per day for 1 week to 3 months. Three studies compared EPA to placebo. Improvements were not shown for weight, lean body mass, quality of life, appetite, or total energy intake in patients treated with EPA. Two studies compared EPA to active treatment controls. One compared an EPA-containing nutritional supplement to a nutritional supplement without EPA; differences were not seen between arms for lean body mass and nutritional intake. The other compared EPA plus placebo, MA plus placebo, and EPA plus MA; appetite was not improved with EPA. Combined data from these two studies showed no benefit of EPA for weight gain or quality of life. The review concluded that there were insufficient data to establish whether oral EPA is better than placebo (Dewey et al., 2007).

Subsequently, a trial was published in which 518 patients were randomized to receive EPA 2 g per day, EPA 4 g per day, or placebo for 8 weeks; trends to improvement in weight and lean body mass were seen in patients treated with EPA 2 g per day (Fearon et al., 2006). In a double-blind randomized trial ($N = 40$), administration of EPA during chemotherapy for lung cancer was associated with better quality of life, performance status, and physical activity (van der Meij et al., 2012).

Ghrelin

A single-centre randomized double-blind placebo-controlled double-crossover trial was performed in 20 patients. They received ghrelin 2 micrograms per kg or 8 micrograms per kg intravenously prior to lunch on days 1 and 8, placebo on days 4 and 11, or vice versa. Patient preference scores tended to favour ghrelin. No differences between treatments were seen for nutritional intake, symptoms, adverse effects, or tolerability (Strasser et al., 2008).

In another study, 31 patients with metastatic gastrointestinal cancer were randomized in a double-blind manner to ghrelin 10 micrograms per kg or 0.5 micrograms per kg subcutaneously daily for 8 weeks. In the high-dose group, versus the low-dose group, appetite scores were significantly better, and there was a trend to less fat-free mass loss and improved energy balance. There were no differences in food intake, quality of life or physical activity (Lundholm et al., 2010).

Anamorelin

A pilot study was published, examining the short-term effects of anamorelin, a novel oral mimetic of ghrelin. Sixteen patients with incurable cancer and involuntary weight loss participated in this multicentre, randomized, double-blind, placebo-controlled, crossover trial. Treatment consisted of anamorelin 50 mg or placebo daily for 3 days, followed by a washout period of 3–7 days, then the alternative treatment for 3 days. Compared to placebo

treatment, anamorelin treatment was associated with significant advantages in terms of weight gain, and improvement in appetite and total symptom and quality of life scores. The drug was well-tolerated (Garcia et al., 2013). Results of a series of phase III trials are awaited.

Insulin

A single-centre, randomized, open-label trial was conducted to evaluate the effect of adding long-acting insulin to 'best available support', which consisted of indomethacin if erythrocyte sedimentation rate and C-reactive protein were elevated, erythropoietin if haemoglobin was below normal, and oral or parenteral nutritional supplementation if oral intake was reduced. One hundred and thirty-eight patients with advanced gastrointestinal malignancies were entered and followed until death or withdrawal from the study. Insulin treatment was associated with significantly higher carbohydrate but not overall caloric intake. Body weight and lean tissue mass did not differ, but trunk and leg fat was significantly higher with insulin treatment. Metabolic efficiency during exercise was significantly better with insulin treatment, but not maximum exercise capacity, maximum work load or physical activity. Quality of life was not different between groups. Survival was significantly longer in insulin-treated patients, suggesting that tumour growth was not stimulated (Lundholm et al., 2007).

Adenosine 5'-triphosphate

In a single-centre trial, 58 stage IIIB or IV non-small cell lung cancer patients were randomized in an unblinded manner to receive adenosine 5'-triphophate (ATP) and supportive care, or supportive care alone. ATP was administered by 30-hour intravenous infusion every 2 weeks for seven doses, and then every 4 weeks for three doses. Treatment was given on an inpatient basis. Compared with placebo, ATP was associated with significantly less weight loss, improved upper and lower extremity strength, better quality of life, increased energy intake and greater appetite (Agteresch et al., 2000, 2002).

Combined therapy

A single-centre, randomized, open-label phase III clinical trial of five different arms of treatment was conducted in 332 patients, who received one of (1) MPA 500 mg or MA 320 mg per day, (2) EPA 2.2 g per day in a nutritional supplement, (3) L-carnitine 4 g per day, (4) thalidomide 200 mg per day, or (5) the combination of the four treatments. All patients also received polyphenols, lipoic acid, carbocysteine, vitamin E, vitamin A, and vitamin C. The MPA/MA and EPA arms were stopped early at interim analysis due to inferiority. The combination arm was found to be significantly superior for increase in lean body, decrease in resting energy expenditure, decrease in fatigue, and increase in appetite. Toxicity was negligible and comparable (Mantovani et al., 2010).

The same group published a single-centre, randomized, open-label phase III clinical trial of combined treatment for cachexia in patients with gynaecological cancers. One hundred and forty-four gynaecological cancer patients with progressive or recurrent disease after one of more lines of chemotherapy and weight loss received either a combined treatment of the antioxidant agents alpha lipoic acid 600 mg and carbocysteine 2.7 g per day, L-carnitine 4 g per day, and MA 320 mg per day, or MA 320 mg per day alone. Significant differences were seen in favour

of combined treatment for increase in lean body mass, decrease in resting energy expenditure, decrease in fatigue, and improvement in quality of life. Toxicity was negligible and comparable (Maccio et al., 2012).

The same group also published a single-centre, randomized, open-label phase III non-inferiority study, the aim of which was to simplify combined treatment. Sixty patients with advanced cancer, weight loss, and abnormal proinflammatory cytokine and/or C-reactive protein levels received L-carnitine 4 g per day plus celecoxib, or L-carnitine plus celecoxib plus MA 320 mg per day for 4 months. All patients also received polyphenols, lipoic acid, carbocysteine, vitamin E, vitamin A, and vitamin C. Both groups demonstrated a significant gain in lean body mass, without a difference between arms. Neither arm showed a change in total daily physical activity. Significant improvement in the 6-minute walk test was seen in both arms, without a difference between arms. Grip strength did not change in either arm. Resting energy expenditure, fatigue, performance status, and Glasgow Prognostic Score decreased in both arms. Body weight tended to increase in the arm with MA. Appetite improved in both arms. Adverse effects were negligible and comparable (Madeddu et al., 2012).

Enobosarm

Enobosarm is a selective androgen modulator, which is a new class of non-steroidal, tissue-specific, anabolic agents. In a multicentre, randomized, double-blind phase 2 trial, 159 weight-losing patients with stages II–IV cancer of various types received enobosarm 1 mg, enobosarm 3 mg, or placebo for up to 113 days. One hundred patients were evaluable for efficacy. Patients in both enobosarm groups demonstrated significant improvements in total lean body mass and physical function (i.e. stair climb time and stair climb power) compared to baseline, whereas patients in the placebo group did not. The drug appeared to be well tolerated (Dobs et al., 2013).

Approaches shown to have little or no benefit
Melatonin

The review by Yavuzsen included two trials examining the effects of melatonin in a total of 186 patients, using doses of 20 mg per day for 1 to 16 weeks. Patients on melatonin lost significantly less weight than control patients. No improvement was seen in nutritional intake and appetite (Yavuzsen et al., 2005).

In a subsequent single-centre study, patients with advanced lung or gastrointestinal cancer were randomized in a double-blind manner to melatonin 20 mg daily or placebo for 28 days. The study was closed after an interim analysis of 48 patients revealed no significant differences between groups for appetite, weight, lean body mass, symptoms, or quality of life (Del Fabbro et al., 2013).

Tumour necrosis factor alpha inhibitors

In a multicentre proof-of-concept study, 63 patients were randomized in a double-blind manner to etanercept 25 mg or placebo subcutaneously twice weekly for up to 24 weeks. The study was terminated early when none of the patients in either arm achieved the primary endpoint of weight gain of 10% or more of baseline. No differences were seen in weight gain, appetite, quality of life, or overall survival (Jatoi et al., 2007).

In a multicentre phase II study, 89 patients with locally advanced or metastatic adenocarcinoma of the pancreas were randomized in a double-blind fashion to infliximab plus gemcitabine. There were no differences in the primary endpoint of change in lean body mass

at 8 weeks, nor in overall survival, progression-free survival, performance status, or 6-minute walk test (Wiedenmann et al., 2008).

Another multicentre, randomized, double-blind, placebo-controlled trial was conducted in elderly or poor performance status patients with metastatic non-small cell lung cancer. All patients received docetaxel and were randomized to infliximab. The trial was stopped after 61 patients had been entered due to slow accrual; in addition, no patient in either arm achieved the primary endpoint of 10% or higher weight gain. Moreover, infliximab-treated patients had worse fatigue, and functional and physical well-being. There were no differences in tumour response, survival, or toxicity (Jatoi et al., 2010).

Thalidomide

In 2012, Reid and colleagues published a systematic review that identified three randomized controlled trials of thalidomide for cancer cachexia, conducted in a total of 406 patients. Due to the small number of studies and high heterogeneity among them, meta-analysis was not possible. Overall, the review concluded that there is insufficient evidence to refute or support the use of thalidomide for the management of cachexia in advanced cancer patients (Reid et al., 2012).

Subsequently, a single-centre study was published in which 31 patients were randomized in a double-blind manner to thalidomide 100 mg or placebo for 14 days. The trial was hampered by poor accrual and high attrition. No differences between groups were seen in symptoms, body composition, resting metabolic rate or cytokines (Yennurajalingam et al., 2012).

Amino acids

A multicentre study was published in which 49 patients were randomized in a double-blind manner to beta-hydroxy-beta-methylbutyrate 3 g, L-arginine 14 g, and L-glutamine 14 g, or a nitrogen content-matched non-essential amino acid mixture orally daily for 24 weeks. At 4 weeks, the active treatment group demonstrated an increase in fat-free mass that was significantly different from control patients; there was also a trend to greater weight gain. Only nine patients completed 24 weeks; a trend to greater weight and fat-free mass gain in the active treatment group was apparent. No differences were seen in quality of life (May et al., 2002).

In another multicentre, randomized, double-blind trial, 472 patients received β-hydroxyl β-methyl butyrate, glutamine, and arginine mixture or placebo orally twice a day for 8 weeks. The non-compliance rate was high, resulting in only 197 analysable patients. No differences were seen in percentage change in lean body mass, fatigue, or quality of life. In the area under the curve analysis, patients on the active arm demonstrated a strong trend towards higher lean body mass throughout the study (Berk et al., 2008).

Cannabinoids

The review by Yavuzsen included one trial in 469 patients comparing dronabinol 5 mg per day versus MA 800 mg per day versus the combination. Improvement in appetite was significantly greater with MA than with dronabinol alone. There was no additional benefit to combining the drugs.

In a subsequent multicentre trial, 243 patients were randomized in a double-blind manner to receive cannabis extract, dronabinol 2.5 mg, or placebo twice a day for 6 weeks. The study was terminated after the first interim analysis because of insufficient differences in

the primary endpoint of appetite change between active treatment and placebo arms (Strasser et al., 2006).

In a two-centre proof-of-principle trial, 46 advanced cancer patients with chemosensory alteration and decreased food intake were randomized in a double-blind manner to dronabinol or placebo for 18 days. The drug could be titrated to a maximum of 20 mg per day. Compared to the placebo group, dronabinol-treated patients demonstrated significant improvements in chemosensory enhancement, appetite, and protein intake (Brisbois et al., 2011).

HIV

Anabolic steroids

In 2005, Johns and colleagues published a systematic review of randomized controlled trials of anabolic steroids for the treatment of weight loss in HIV-infected individuals. Thirteen randomized controlled trials were included. Drugs studied were testosterone, nandrolone, oxandrolone, and oxymetholone. The trials involved different routes of delivery, doses, duration of therapy, and methodology of reporting adverse events. Meta-analysis of change from baseline in lean body mass in 532 analysable patients revealed a weighted mean difference of 1.3 kg (95% CI 0.6–2.0) in favour of anabolic steroid therapy. Meta-analysis of change from baseline in body weight in 629 analysable patients showed a weighted mean difference of 1.1 kg (95% CI 0.3–2.0) in favour of anabolic steroid therapy. Adverse events were usually reported as mild and reversible (Johns et al., 2005).

Subsequent to the systematic review, additional trials have been published. In a multicentre trial, 262 men were randomized in a double-blind manner to oxandrolone 20, 40, or 80 mg or placebo orally daily for 12 weeks. All patients then received oxandrolone 20 mg daily in an open-label fashion. At 12 weeks or the last measurement, weight gain was greater in the oxandrolone 40 mg per day group than the placebo group. Increase in body cell mass was greater in the oxandrolone 40 mg and 80 mg per day groups than the placebo group. There were no differences in quality of life and total work output. By 24 weeks, weight gain was not different between groups. Oxandrolone treatment was accompanied by significant increases in transaminases and low-density lipoprotein and decreases in high-density lipoprotein (Grunfeld et al., 2006).

Two randomized, double-blind trials have compared nandrolone 150 mg, testosterone 250 mg, or placebo intramuscularly every 2 weeks for 12 weeks. A multicentre trial conducted in 303 men revealed that lean body mass increased significantly more with nandrolone versus placebo. Also, weight gain and patient perception of benefit were significantly better with nandrolone versus testosterone and placebo (Gold et al., 2006). A single-centre trial conducted in 104 men showed that weight gain was significantly greater with nandrolone and testosterone versus placebo. There was no difference between arms in adverse events (Sardar et al., 2010).

Recombinant human growth hormone (rhGH)

In a review article, it was noted that gains in weight and lean body mass with rhGH in randomized controlled trials were in the order of 3 kg, and the most common adverse events were blood glucose elevation, arthralgia, myalgia, and peripheral oedema (Gelato et al., 2007).

Dronabinol
