Oxford Textbook of
Palliative Medicine

Free personal online access for 12 months

Individual purchasers of this book are also entitled to free personal access to the online edition for 12 months on *Oxford Medicine Online* (www.oxfordmedicine.com). Please refer to the access token card for instructions on token redemption and access.

Online ancillary materials, where available, are noted at the end of the respective chapters in this book. Additionally, *Oxford Medicine Online* allows you to print, save, cite, email, and share content; download high-resolution figures as Microsoft PowerPoint slides; save often-used books, chapters, or searches; annotate; and quickly jump to other chapters or related material on a mobile-optimised platform.

We encourage you to take advantage of these features. If you are interested in ongoing access after the 12-month gift period, please consider an individual subscription or consult with your librarian.

Preface

Facing the challenges of continuity and change

This edition is dedicated to the memory of Professor Geoffrey Hanks, one of the three founding editors of the textbook and co-editor of the first four editions, who died in June 2013. The standing and quality of the textbook as a work of academic excellence reflects Geoffrey's legacy that spanned almost four decades as a clinician, researcher, teacher, and editor. He was a man of great compassion, wisdom, humour, personal charm, humility, and courage. He served as a teacher, friend, and colleague to all of us. While we are greatly saddened by his untimely death, we are inspired by his legacy. Professor Hanks did not participate in the editing of this edition, but he entrusted the development of this fifth edition to an international team including Nathan I. Cherny (Israel), Marie T. Fallon (Scotland), Russell K. Portenoy (United States), Stein Kaasa (Norway), and David Currow (Australia).

In developing the textbook, we are constantly listening to the feedback of the thousands of clinicians and researchers who use this text as a resource and as a benchmark of excellence. The new edition has been substantially revamped. It has many new chapters and new authors, and has new sections devoted to assessment tools, issues in patients with cancer, issues of the very young and very old, and research in palliative care. We also have improved the readability and utility of the textbook by producing a smaller and less cumbersome print version and an online version with expanded references, and in some cases, expanded text versions of the chapters. There is extraordinary talent and thoughtfulness in the world of palliative medicine and we invite the readers of this book to contribute to its continued evolution by providing feedback to the editors about the book, as a whole or its individual chapters. The information you provide will be used to develop subsequent editions. Comments can be sent to us at editors@OTPM5.org

The two decades since the first edition of this textbook was published have witnessed truly remarkable growth in palliative care—as a specialty practice for many disciplines, as diverse types of health-care delivery systems, and as an intellectual framework for the development of an evidence base, clinical guidelines, and professional education. Growth of their scale is challenging to master, and brings both uncertainties and optimism about the future. In this process we see the challenge in complex issues of continuity, development, and change.

Continuity: cardinal concepts underlying the philosophy of palliative medicine

Palliative medicine asserts, boldly and optimistically, that even in the face of overwhelming illness, suffering can and must be relieved. This assertion is derived from a rights ethos. There may be individual barriers that patients or families bring to the clinical setting, or larger pragmatic, economic, geopolitical, or social reasons that make it difficult to provide palliative care, but none of these concerns undermine the duty to prioritize the relief of suffering for people with incurable illnesses and the families that support them.

The factors that motivate palliative medicine practitioners to do what they do in the face of great challenges are the underlying axioms of our professional endeavours. These axioms should be clearly articulated because they underlie the personal, professional, and societal investments that address intense human suffering in the context of inexorably progressive illnesses and impending death.

Care, compassion, empathy, and justice

Care is the recognition that the well-being of others is a matter of consequence. As an integral part of the human experience, it is a motivating force that influences the nature and dynamic of interpersonal behaviours. Compassion is that aspect of care that recognizes the emotional dimension of the human experience and encompasses sympathy for another's loss.

Empathy, the ability to perceive and to understand the emotional experience of others and to relate to it in a meaningful and appropriate manner, predicates care and compassion. In the clinical context, an empathic connection occurs when the clinician understands what his or her patient is experiencing, and communicates it (verbally or non-verbally) such that the patient feels that he or she is understood. The empathic connection is often therapeutic in itself. Beyond that, it contributes to a bond which, in turn, facilitates the trust necessary to forge an effective and sustained therapeutic relationship.

Care and empathy interface with the perception of justice. The claim that access to the means to relieve suffering is a human right derives from the empathic experience; that is, that unnecessary suffering is a profound matter of consequence and that it demands a constructive response. Care, compassion, and empathy motivate

sensitivity, respect, concern, charity, generosity, altruism, and, sometimes, self-sacrifice. The absence of care implies that the well-being of the other is inconsequential and, in its absence, human interaction is often characterized by insensitivity, neglect or negligence.

Resilience in professional caregiving

In taking on the task of palliative care, a professional caregiver willingly accepts the role as first-hand witness to physical, emotional, and existential distress. Caring for people at the end of life and their families in this context day after day (and, in many cases, for years on end), challenges us as professionals and as individuals. Each member of an interdisciplinary team brings personal needs and resources to the clinical experience, and the different stressors born by members of the team can strain even the best of collaborative relationships.

Resilience is the quality that enables professional caregivers to cope, adapt, and continue giving and growing, despite the tidal surge of suffering that we dare to confront. Resilience is buffered by the skills acquired through years of training, and by dedication and good intentions. As teams, resilience is the flexible, binding matrix that keeps us working constructively together despite stress, conflict, interpersonal frictions, and grievances that would potentially fragment or undermine our ability to deliver care.

Common experience suggests that resilience characterizes most clinicians who choose palliative care as a career. These clinicians are self-motivated and driven to develop the skills and relationships that support their ongoing ability to contextualize and manage the suffering they encounter. Not all who work in palliative care do so by choice, however. Interns, resident staff, nursing students, junior members of the allied health team, administrative and support staffs may find themselves addressing the problems of patients with advanced illness by consignment rather than by choice. For those without the resilience of the clinicians who seek to specialize in palliative care, and without good support systems, this can be a high-stress challenge that can only be endured in an understanding and supportive environment that helps foster coping and resilience.

The patients and families we seek to help have not chosen their fate. How they cope, or are helped to cope, hinges on both the provision of meticulous care and the fostering of resilience in the patient, individual family members, and the family unit as a whole. Some patients come with rich sources of personal and family resilience. Others are overwhelmed. Competent palliative care will always seek to support adaptive coping, and psychological and spiritual healing of both patients and families.

Courage

For the incurably ill, fear may be a part of life. There is just so much to fear: death, physical distress and debilitation, dependency, and so many losses: personal control over biological functioning, mental faculties, potency, beauty, future hopes, separation, and loss of life itself.

Courage takes many forms in the lives of our patients and the families who care for them. They need courage to seek meaning in a life that is now demonstrably finite and to savour the remaining life while grieving for the hopes and dreams that cannot and will not be fulfilled. They need courage to confront difficult decisions about treatment options that have both the potential to either improve quality of life or possibly undermine it. No one wants to live with a gastrostomy, to wear a diaper, to have an intercostal catheter, to have a limb amputated, or to undergo endoscopic stent insertion. For many patients, consenting to even simple interventions requires great courage, and the need to believe that the recommendation is born of both knowledge and compassion.

We often try to support our patients in a process that changes focus from 'everything to live longer' to 'everything to live better. We must acknowledge that there is great courage in making decisions to desist from, to forgo, or to withdraw treatments or interventions, and sometimes even greater courage than the decision to undergo another gruelling intervention to try live a short time more.

Humility and audacity

The many issues our patients confront pose challenges to the limits of the art and science of palliative medicine. Understanding the limits of what can be reasonably expected from our care underscores the need to present treatment plans with both hope and humility. Often, there is more than one option that is, potentially, of equal benefit for a patient, and, in presenting therapeutic options, we need to explain not only what we know, but also the manifest uncertainties involved.

An excess of optimism or overconfidence about anticipated treatment outcomes poses the risk of undermining one's credibility. At some point, it becomes hubris. Experienced clinicians desist from saying a treatment 'will help', and rather invoke the contingency 'may help.' We must always commit to vigilant monitoring of outcomes and be ready to readdress the treatment with honesty and a commitment to care that encourages and fosters trust.

Honest and humble evaluation of what we can reasonably expect as outcomes of our care makes us aware of the limitations in treatment options, resources, and clinician knowledge that undermine our ability to provide optimal outcomes for all. It is this critical element of humility that provides the impetus for programme development, political activism to improve resource allocation, and research to improve the knowledge base for the delivery of the best patient-centred care that is possible.

Humility should not prevent us from audacious thought, however. The Serenity Prayer implores us to 'Accept the things we cannot change, to change the things we can and to have the wisdom to know the difference'. The issues that we confront in palliative medicine compel us to seek ways to shift the boundaries between the 'things that cannot be changed' and those that are amenable to intervention and change. This is the dimension of audacity and the imperative of research.

Sensitivity to differences

There is no one best way to deal with life-threatening illness and cultural, religious, and interpersonal factors strongly affect individual approaches. Individualized care is grounded in the recognition that human responses to the same event vary dramatically and that only part of this variation is predictable.

Cultural sensitivity also must recognize the heterogeneity of different cultural and religious communities. Indeed reductionist anthropological approaches that foster cultural stereotyping are best avoided in favour of an individualized approach that explores

the values and goals of the individual patient and his or her family within his or her environment.

Trust

Through empathy, compassion, honesty, humility, sensitivity, and diligence we aim to develop a bond of trust. We aim to build a trust that is sufficiently robust such that patients and their families feel secure in effective care planning, and develop courage and resilience despite the profound difficulties of their circumstances.

Development: education, service delivery, availability, and therapeutics

Education

The maturing of palliative medicine as a profession has been accompanied by the ongoing development of palliative medicine education and educational resources all over the world.

Globally, the principles and precepts of palliative care are finding a new home in medical education. Palliative care is an excellent framework for teaching the biopsychosocial model of illness and the inter-professional approach to complex health-care problems. Curricula have been developed and published in many countries, universities, and individual faculties; moreover, there is a plethora of teaching models and aids that have been published and disseminated.

Undergraduate training raises consciousness and plants a seed that could germinate and grow during postgraduate education. Clinicians who do not choose to specialize in palliative medicine may or may not encounter a systematic effort to promote competency in generalist-level palliative care during the next phase of training. Much more needs to be done to introduce palliative care into the curriculum of training in every specialty that provides care to populations with serious or life-threatening illness. This is especially true for specialists in oncology, intensive care, geriatrics, neurology, nephrology, cardiology, and pulmonology. In all of these specialties, there have been important developments, such as changes in curriculum, training initiatives, publications, and research. Still, change around the world is inconsistent at best, and at worst, disappointing. Despite evidence of progress, the development of a high level of skill and understanding of palliative medicine remains a goal that has yet to be achieved.

Advanced training in palliative medicine has developed substantially but is still very limited around the world. Palliative medicine is now a recognized medical specialty or subspecialty in over 20 countries, and in others application for specialty or subspecialty accreditation are underway or pending.

There is no consensus as to how to best train palliative medicine specialists. The content and duration of advanced training programmes vary greatly around the globe; it is 1 year in the United States, 4 years in the United Kingdom, and 3 years in Australia. Some programmes insist on a research component and others make no such demand. Given that the level of training not only affects competence and service delivery, but also influences the role and well-being of specialist clinicians working in the field, the issue of adequate training is salient. How best to adequately equip specialist palliative care clinicians remains an open question worthy of further evaluation and research.

Research in palliative care

Preclinical, translational, and clinical research are all badly needed to expand the boundaries of knowledge and provide an evidence base for patient care. This truism is valid for the medical endeavour in general, and is particularly relevant to palliative medicine, in which evidence-based practice is still relatively underdeveloped. The proliferation of research relevant to the care of the incurably ill has been a critical part of the maturation of palliative medicine. Research findings have sharpened our understanding of the mechanisms of symptoms we seek to relieve, helped define the limits of old approaches, and have uncovered new approaches to the challenging problems that have hitherto been refractory to older treatments. Indeed, this edition of the textbook is replete with many new insights and evidence-based therapeutic approaches that have been derived from these research endeavours.

By its nature, research in palliative medicine is very broad in its scope. Palliative care needs research in communication, service delivery, quality, and ethics as much as it needs biomedical and psychological research. Rigorous observational studies and well-crafted clinical trials are both essential at this point. The care of the incurably ill and their families is a 'complex system' challenge requiring multiple inputs, resource allocation, pharmacotherapeutic and psychological skills, and social understanding. All of these factors are increasingly represented in the evolving research culture that we encourage and cultivate.

Some believe that palliative care is unlike other disciplines in that it is not possible to inform practice with rigorous trials. We do not believe this. We must learn from our colleagues in other disciplines and ensure that, whenever possible, we run multisite studies.

Given that access to palliative care around the world largely relies on the referral of people with life-limiting illnesses to specialist services, any research done will help to inform the clinical care of those who are *not* referred. Our colleagues in medicine and other specialties will value high-quality data to inform their care of people with life-limiting illnesses.

The research imperative in palliative medicine faces many challenges. Funding is problematic, despite the new funding initiatives discussed in Chapter 19.1. There are few experienced investigators and the populations under study are vulnerable and may be reluctant or unable to participate. These challenges must be met if the field is to progress.

Service delivery

The past two decades have seen a flourishing of palliative medicine services in different settings worldwide. This has been well documented and monitored by the International Observatory of End of Life Care Project. There is not a region in the world that has not observed growth in palliative medicine services in the past 20 years. While there are areas where penetration and integration are tremendous, there are others in which programme development is still evolving and, unfortunately, many in which services are scarce and rudimentary.

There are now a great many models of palliative medicine service delivery: inpatient and home-based hospices, hospital consultation services, acute palliative care wards and day hospitals, ambulatory clinics, and mobile clinics. Although the underlying

principles and philosophy are consistent, the spectrum of observed problems may be profoundly different depending on the care settings.

This is particularly true with the increasing movement towards 'upstream palliative medicine' in which palliative medicine is being delivered at an earlier stage of the trajectory of illness. The issues confronted by clinicians working in early stage palliative medicine units, such as those in acute palliative medicine units, are often quite different from those confronted by clinicians who are providing immediate end-of-life care. The goals of care are different with a greater emphasis on optimizing function and, often, life prolongation (even in the face of progressive incurable disease). In such cases, the duration of care will be prolonged and the fluctuating status of illness (with treatment-induced remissions and relapses) may involve rapidly changing care needs, problem lists, and priorities.

The quality of care that is offered through these services must be measured and responses to variations in the quality of care or its outcomes actively addressed. As in all areas of clinical care, we must each be striving to improve the care offered. In palliative medicine, as in any area of clinical practice, we can and do cause morbidity and, at times, premature mortality. To ensure the ongoing development of the specialty, such outcomes must be acknowledged and critically addressed.

Journals

There are now more than 14 peer-reviewed journals dedicated to issues of palliative care. Additionally, the major journals of many other subspecialties have increasingly embraced palliative care issues. Dedicated palliative care sections in general journals, such as have appeared in *The BMJ, JAMA: The Journal of the American Medical Association*, and the *Journal of Clinical Oncology*, bring palliative care to a wider audience.

Evolution: change and challenges in palliative medicine

One of the early axioms of palliative care is that it sought to provide an alternative to 'aggressive' or 'highly technical' medical care. Indeed palliative care was often presented as 'strong' on care and 'low' on technology. In the 1960s and early 1970s, when these concepts were initially articulated, low technology options were often indeed the very best that could be offered to help relieve patient distress. At that time, there were very few truly effective palliative anti-tumour options beyond radiotherapy, and endoscopy and interventional radiology were in their absolute infancy.

The extraordinary development of non-curative, but potentially beneficial, interventions to address so many of the conditions, symptoms, and complications confronted by patients has created new opportunities, tensions, and dilemmas for palliative medicine clinicians.

New therapeutic opportunities

The last 20 years have seen dramatic changes in the non-curative treatment options for many of the conditions we encounter, particularly in cancer, HIV, and cardiology. These interventions have shifted the natural history of advanced illness. While these interventions cannot cure, they have created new opportunities to prolong life while better controlling the ravages of disease. Some interventions may add months, others, possibly years to survival.

Whereas previously it was often the role of the palliative medicine clinician to present a counterpoint to the high morbidity and low likely benefit of chemotherapy, these developments have necessitated a change. Palliative medicine clinicians now must possess a more sophisticated understanding of disease-modifying palliative approaches for a broad array of common diseases. They often must contribute to a discussion of the risks and burdens versus the potential benefits of these therapies, even as they encourage a broader understanding of the options for care.

New palliative interventions exist not only for specific disease states but also for specific disease complications and symptoms. For example, endoscopic interventions and interventional radiology have radically broadened the range of options in the cases of obstruction of luminal structures (gastrointestinal, genitourinary, vascular, and respiratory). These approaches have altered the management of intestinal, biliary, ureteric, and bronchial obstruction, venous compression syndromes, and, in select cases, pain management. Surgical approaches have made major contributions to the management of complications of cancer such as spinal cord compression, brain metastases, and impending fractures (see Section 12)

Development of a palliative plan of care, and education of the patient and family, requires an understanding of these interventions. Palliative medicine clinicians should be taking an increasing role in the development, evaluation, and advancement of these innovations and developments.

New tensions

Concern is often expressed that the increased availability of technical interventions to relieve distress somehow diminishes from the ability to care, or from the heart of palliative care. The worry is that palliative care is being excessively 'medicalized' or 'professionalized'.

However, just as there is a romantic image of the nineteenth-century physician at the bedside of his patient dying of tuberculosis, who offers perhaps a tincture of opium but primarily provides comfort through his mere presence, there is also a tendency to romanticize the early days of palliative care, which focused on simple symptomatic treatments.

Today, we and the patients we serve have more and better therapeutic options to promote the pursuit of our common goals. Increasingly, palliative care services are integrated with oncology, respiratory medicine, cardiology, and other medical specialties so that appropriate sophisticated treatments may be used with the intent of either palliation or life prolongation (provided that this is a legitimate and compassionate option). This integrated approach needs careful discussion with the patient and their family. This discussion must include clear information about the likelihood of benefits, risks, and alternative approaches.

Many dying patients are not in a rush to die and their desire for life-prolonging treatments is understandable, and often within the bounds of potentially appropriate medical care. Although the World Health Organization's definition of palliative care includes the statement that palliative care 'intends neither to hasten nor postpone death', one must recognize that there is a difference between prolonging dying and prolonging a life in the face of incurable illness. Unfortunately, this distinction is often confused,

leading people to believe that non-curative disease-modifying drugs or other high-tech palliative interventions are not part of palliative care. The consequence of this confusion is substantial. Indeed, some patients are denied palliative care services because they are interested in these interventions or treatments, and others are denied access to treatments that would otherwise serve their goals of care because they are in a palliative care clinical pathway.

New challenges

In some countries, the service delivery models for palliative care were developed with the aim of offering a more cost-effective way of managing patients with incurable illness. Many programmes are budgeted based on assumptions of great savings for the health-care funders.

Cost savings is not a primary objective of palliative care, but it may be an unintended consequence of a focus on medically appropriate care guided in shared decision-making by an informed patient and family. It is essential that policymakers understand this principle and also accept that cost savings is an aggregate concept. For some patients, palliative care is not inexpensive. Specialist palliative care always requires intensive skilled human resources, with adequate staff to allow for the provision of individualized care, and it may require costly technology or pharmaceuticals.

When a system of palliative care is supported in a capitated model, financial sustainability requires careful management of the care and a large enough group to benefit from a risk pool. In the United States, many hospices are small and are forced to limit access or deny treatment with accepted palliative interventions because reimbursements are too low. Even large hospices with access to a substantial risk pool cannot accept patients receiving modern chemotherapy and targeted therapy for cancer, even if the treatment is clearly palliative and minimally life-prolonging. How systems like this one, and many others around the world predicated on payment models that have not yet adapted to the evolving nature of palliative care, will cope with an ever-increasing need for services, is unknown. The developed world has resources but re-distribution of funds to underwrite the development and dissemination of specialist palliative care is needed; the developing world lacks resources. Identifying the means to pay for this necessary care is among the greatest challenges we face.

Conclusion

Noting that we may be professional carers now and will be patients later, Professor Balfour Mount has said that 'We are all in the same boat'—we all need the care and the services that form the mission of palliative care. In our professional roles too, we are all in the same boat: despite our varying settings and circumstances, we struggle with a similar spectrum of problems, challenges, and questions.

In this text you will find some of the answers to many of the questions. Humility demands that we recognize that, with what we know, not all of the questions can yet be answered. Indeed, often the best that can be offered is a range of suboptimal options to be considered and possibly tried on a sequential basis. This underlies the imperative to work together to push forward the boundaries of what we know, and improve the way in which we apply it to the care of the incurably ill.

We hope that this fifth edition of the *Oxford Textbook of Palliative Medicine* will help in this endeavour.

Contents

List of Abbreviations

5-FU	5-fluorouracil
5-HIAA	5-hydroxyindoleacetic acid
5-HT	5-hydroxytryptamine (serotonin)
5-HTP	5-hydroxytryptophan
AAC	augmentative or alternative communication
AAHPM	American Academy of Hospice and Palliative Medicine
ACD	Anaemia of chronic disease
ACEI	angiotensin-converting enzyme inhibitor
ACGME	Accreditation Council for Graduate Medical Education
ACP	advance care planning
ACPOPC	Association of Physiotherapists in Oncology and Palliative Care
ACTH	adrenocorticotropic hormone
AD	adjustment disorder
ADLs	activities of daily living
ADT	androgen deprivation therapy
AECOPD	acute exacerbation of chronic obstructive pulmonary disease
AED	antiepileptic drug
AFO	ankle–foot orthosis
AIDS	acquired immunodeficiency syndrome
ALP	alkaline phosphatase
ALS	amyotrophic lateral sclerosis
AMPA	α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid
ANC	absolute neutrophil count
ANH	artificial nutrition and hydration
ANZSPM	Australian and New Zealand Society of Palliative Medicine
APC	argon plasma coagulation
APM	Association for Palliative Medicine for the United Kingdom and Ireland
APN	advanced practice nurse
ARB	angiotensin receptor blocker
ASA	acetylsalicylic acid
ASCO	American Society of Clinical Oncology
ASHA	American Speech-Language-Hearing Association
ASIC	acid sensing ion channel;
ATF-3	activating transcription factor
ATP	adenosine triphosphate
AVP	arginine vasopressin
BE	bronchial arterial embolization
BMI	body mass index
BNP	brain natriuretic peptide
BPH	benign prostatic hyperplasia
BPI	Brief Pain Inventory
BTP	breakthrough pain
BTX	botulinum toxin
CAM	complementary and alternative medicine
CAUTI	catheter-associated urinary tract infection
CBC	complete blood cell
CBO	carotid blow-out
CBT	cognitive behavioural therapy
CBT-I	cognitive behaviour therapy for insomnia
CDS	continuous deep sedation
CEE	Central and Eastern Europe
CESCR	Committee on Economic, Social and Cultural Rights
CES-D	Center for Epidemiologic Studies of Depression Scale
CF	cystic fibrosis
CGRP	calcitonin gene-related peptide
CHF	congestive heart failure
CHPCA	Canadian Hospice Palliative Care Association
CI	confidence interval
CIBP	cancer-induced bone pain
CIC	clean intermittent catheterization
CID	clinically important difference
CINV	chemotherapy-induced nausea and vomiting
CIS	Commonwealth of Independent States
CKD	chronic kidney disease
CMV	cytomegalovirus
CNS	central nervous system *or* clinical nurse specialist
COPD	chronic obstructive pulmonary disease
COX	cyclooxygenase
CPE	clinical pastoral education
CPR	cardiopulmonary resuscitation
CPS	clinical prediction of survival
CRP	C-reactive protein
CRS-R	Coma Recovery Scale-Revised
CRQ	Chronic Respiratory Disease Questionnaire
CRT	cardiac resynchronization therapy
CSF	cerebrospinal fluid
CSP	Chartered Society of Physiotherapy

CSPCP	Canadian Society of Palliative Care Physicians	GDP	gross domestic product
CT	computed tomography	GGT	gamma-glutamyl transferase
CTCAE	Common Terminology Criteria for Adverse Events	GI	gastrointestinal
CTZ	chemoreceptor trigger zone	GnRH	gonadotropin-releasing hormone
CYP	cytochrome P450	GORD	gastro-oesophageal reflux disease
DBS	deep brain stimulation	GP	general practitioner
ddC	dideoxycytidine	GPCR	G protein-coupled receptor
DIC	disseminated intravascular coagulopathy	GRK	G protein coupled receptor kinase
DLB	dementia with Lewy bodies	GVHD	graft-versus-host disease
DM	dermatomyositis	HAART	highly active antiretroviral therapy
DME	durable medical equipment	HADS	Hospital Anxiety and Depression Scale
DNI	do not intubate	HCC	hepatocellular carcinoma
DNR	do not resuscitate	HCV	hepatitis C virus
DSM	*Diagnostic and Statistical Manual of Mental Disorders*	HF	heart failure
		HFPEF	heart failure with preserved ejection fraction
DVIU	direct vision internal urethrotomy	HFREF	heart failure with reduced ejection fraction
DVT	deep vein thrombosis	HIPEC	hyperthermic intraperitoneal chemotherapy
EACA	epsilon aminocaproic acid	HIT	health information technology
EAPC	European Association for Palliative Care	HIV	human immunodeficiency virus
EAS	euthanasia or physician-assisted suicide	HNC	head and neck cancer
EBM	evidence-based medicine	HPA	hypothalamic–pituitary–adrenal

NHS	National Health Service	PRN	*pro re nata* (as needed)
NICE	National Institute for Health and Care Excellence	PRO	patient-reported outcome
NIH	National Institutes of Health	PROM	patient-reported outcome measure
NK1	neurokinin 1	PROMIS®	Patient-Reported Outcome Measurement Information System®
NIPPV	non-invasive positive pressure ventilation		
NIV	non-invasive ventilation	PSP	progressive supranuclear palsy
NLSB	neurolytic lumbar sympathetic block	PSQI	Pittsburgh Sleep Quality Index
NMDA	*N*-methyl-D-aspartate receptor	PT	physiotherapist *or* physical therapy
NMT	neurologic music therapy	PTC	percutaneous transhepatic cholangiography
NNH	number needed to harm	PTHrP	parathyroid hormone-related peptide
NNRTI	non-nucleoside reverse transcriptase inhibitor	PTSD	post-traumatic stress disorder
NNT	number needed to treat	PVS	persistent vegetative state
NRTI	nucleoside reverse transcriptase inhibitor	QI	quality improvement
NP	nurse practitioner	QOL	quality of life
NPV	negative predictive value	RANK	receptor activator of nuclear factor kappa B
NRS	numerical rating scale	RANKL	ligand for the receptor activator of nuclear factor kappa B
NRTI	nucleoside reverse transcriptase inhibitor		

RAVE	receptor activation versus endocytosis		TACO	transfusion-associated circulatory overload
RBF	renal blood flow		TAE	transcatheter arterial embolization
RBD	REM sleep behaviour disorder		TBI	traumatic brain injury
RCP	Royal College of Physicians		TCA	tricyclic antidepressant
RCSLT	Royal College of Speech and Language Therapists		tDCS	transcranial direct current stimulation
RCT	randomized controlled trial		TENS	transcutaneous electrical nerve stimulation
REM	rapid eye movement		THC	delta (9)-tetrahydrocannabinol
RF	radiofrequency		TMS	transcranial magnetic stimulation
RFA	radiofrequency ablation		TNF-α	tumour necrosis factor-alpha
RGS	regulators of G-protein signalling		TRP	transient receptor potential
RLS	restless legs syndrome		TRPM8	transient receptor potential menthol receptor
R/S	religious/spiritual		TRVP1	transient receptor potential cation channel
RSCL	Rotterdam Symptom Checklist			subfamily V member 1 (capsaicin receptor/
rTMS	repetitive transcranial magnetic stimulation			vanilloid receptor 1)
RVM	rostroventral medial medulla		TSH	thyroid stimulating hormone
SC	subcutaneous		TURP	transurethral resection of prostate
SCC	spinal cord compression		UACS	upper airway cough syndrome
SCI	problem solving		UFH	unfractionated heparin
SD	standard deviation		UN	United Nations
SDH	superficial dorsal horn		UV	ultraviolet
SDS	Symptom Distress Scale		USAID	United States Agency for International Development
SEMS	self-expandable metal stent			
SGD	salivary gland dysfunction		USRDS	United States Renal Data System
SIAD	syndrome of inappropriate diuresis		VAD	ventricular assist device
SLT	speech and language therapy/therapist		VAS	visual analogue scale
SNRI	serotonin-norepinephrine reuptake inhibitor		VC	vomiting centre
SPARC-45	Sheffield Profile for Assessment and Referral to Care		VDS	visual descriptive scale
			VEGF	vascular endothelial growth factor
SPEED	Screen for Palliative and End-of-life care needs in the Emergency Department		VGCC	voltage-gated calcium channels
			VIP	vasoactive intestinal peptide
SRH	self-rated health		VTE	venous thromboembolism
SSRI	selective serotonin reuptake inhibitor		WBP	wound bed preparation
SUPPORT	Study to Understand Prognosis and Preferences for the Outcomes and Risks of Treatment		WDR	wide dynamic range
			WHO	World Health Organization
SWS	slow-wave sleep		WHOQOL	World Health Organization Quality of Life
TA	tranexamic acid		WPCA	Worldwide Palliative Care Alliance

SECTION 1

The worldwide status of palliative care

International progress in creating palliative medicine as a specialized discipline and the development of palliative care

Sheila Payne and Tom Lynch

Introduction to international progress in creating palliative medicine

Throughout the world approximately 56 million people die each year, with the majority dying with or from non-communicable diseases, often in older age. The populations of Europe, North America, Australasia, and parts of Asia are ageing; increasingly, older people live with chronic and advanced conditions before they die. In other parts of the world, such as sub-Saharan Africa, communicable diseases, including HIV/AIDS, tuberculosis, and malaria, place major demands on palliative care. Palliative medicine offers opportunities for clinicians and other disciplines to work in partnership, to forge innovative alliances to shape the compassionate care of persons facing the final stages of life. Palliative care refers to enhancing the physical, psychological, emotional, social, spiritual, and existential well-being of patients and their families (Sepulveda et al., 2002).

The main objective of this chapter is to review the development of palliative medicine as a specialized discipline, and to trace the development of international initiatives, highlighting achievements and limitations in current comparative methodologies. We offer evidence on the progress of educational initiatives, both within medicine and for other members of the multidisciplinary team, at undergraduate and post-qualification level. It is beyond the scope of this chapter to review the training needs of volunteers or family carers. Finally, we consider what areas of palliative medicine require further development.

The chapter will focus upon developments in palliative medicine that relate to the care of adults, rather than children. The expansion of palliative care into specialist areas, such as cardiology, stroke medicine, or neurology, may increase demands for dual qualifications. Likewise, there are new developments in oncology practice which call for a more explicit integration of palliative care throughout the trajectory of illness and into protracted periods of survivorship with advanced disease (Kaasa et al., 2011).

Progress in international development in palliative care

History of key developments

Prior to the beginning of the twenty-first century, there had only been sporadic progress in the development of palliative care internationally. The first hospices were opened over a century ago in Dublin (Our Lady's Hospice) and in the East End of London (St Joseph's Hospice, Hackney) by Catholic nuns as a charitable and religious mission caring for those dying of tuberculosis and living in poverty (Humphreys, 2001; Winslow and Clark, 2005). Considerably later, St Christopher's Hospice opened in South London in 1967, following the pioneering work of Dame Cicely Saunders, and this was soon followed by hospice and palliative care initiatives in Western European countries (Table 1.1.1).

The first hospital palliative care team was established in the Royal Victoria Hospital, Montreal, by Balfour Mount in 1976, followed by the St Thomas' Hospital, London, team in 1977.

In the United States, hospice programmes began in the 1970s and Medicare funding was secured in 1982 (providing reimbursement of costs through insurance but requiring relinquishment of curative treatments). In 1988, the European Association for Palliative Care (EAPC) was formed (Blumhuber et al., 2002), and in the mid 1990s the International Association of Hospice and Palliative Care (IAHPC) was established in the United States. In South America, the 1994 Declaration of Florianopolis raised awareness of barriers to the accessibility and availability of opioids in the region (Stjernswärd et al., 1995), and in 2000, the Latin American Association of Palliative Care was formed.

During communist rule in the countries of Central and Eastern Europe and Commonwealth of Independent States (CEE/CIS), there had been few significant palliative care developments. Following the political changes of the 1990s, there was a steady development of palliative care services in this region (Table 1.1.2). This was due in part to initiatives such as the Poznan Declaration ('The Poznan Declaration 1998', 1999) and the Eastern and Central Europe Palliative Task Force (ECEPT) which commenced

in 1999 (ECEPT, n.d.). Financial support to the palliative care programmes within CEE and CIS came from the Open Society Foundations (OSF) Public Health Program (OSF, 2014), one of very few donors at the start of the new millennium supporting palliative care in this geographical area.

The early part of the twenty-first century witnessed a number of significant international developments: the Asia Pacific Hospice Palliative Care Network was formed in 2001 (Goh, 2002); in 2002, the Hospice Information Service recommenced in the United Kingdom; the first conference focusing on international development of palliative care was held at the Hague in 2003, and in the same year the European Society for Medical Oncology officially recognized the discipline (Cherny et al., 2003). Also in 2003, palliative care development in the CEE/CIS region was stimulated by the Council of Europe (2003) report on palliative care which provided specific guidelines provision. In 2004, the African Palliative Care Association was formed and two World Health Organization (WHO) publications aimed to improve the quality of care provided at the end of life (Davies and Higginson, 2004a, 2000b). Also in 2004, the United States Agency for International Development (USAID) launched the President's Emergency Plan for AIDS Relief (PEPFAR), which allocated funds to the development of hospice and palliative care. The second conference on international palliative care development was held in Seoul in 2005, and the first World Hospice and Palliative Care Day was celebrated in the same year.

Regular congresses organized by the EAPC provided excellent platforms for increased collaboration in international development of palliative care and by 2012 these had become designated as world congresses. In 2006, a Declaration was compiled that stressed the need for increased palliative care research in resource-poor countries, leading to a pledge to improve palliative care across Europe in 2007 (Radbruch et al., 2007). In the same year, the IAHPC and WHO led in producing a list of 34 essential medicines for palliative care. The Worldwide Palliative Care Alliance (WPCA) was formally constituted in 2009.

Achievements in the mapping and measuring of global palliative care development

Relatively recently, studies which generate comparative analyses of palliative care development and attempt to map the development of palliative care across countries, regions, and continents have begun to occur. The first study focused on seven countries in Western Europe (Clark et al., 2000) and was followed by mapping of 28 countries in Eastern Europe and Central Asia (Clark and Wright 2003). As a result of the latter project, the International Observatory on End of Life Care (IOELC) was established in 2003. The IOELC used comparative methods based on a common template to present its research-based country reports. This resulted in reviews of palliative care development in Africa (26 countries) (Wright et al., 2008), the Middle East (six countries), and South East Asia (three countries) (Wright et al., 2010), as well as India (McDermott et al., 2008).

Two further comparative studies of European palliative care development were undertaken. The first study focused on 11 European countries (Jaspers and Schindler, 2004). The second study focused on 16 European countries (Project on Hospice and Palliative Care in Europe n.d.), including the Czech Republic, Estonia, Hungary, Latvia, Lithuania, Poland, Slovakia, and Ukraine.

The EAPC Task Force on the Development of Palliative Care in Europe was founded in 2003, and has contributed substantially to documenting the progress of palliative care, producing, for the first time, comparative data on the status of services across the whole of the WHO European Region (a geographic area of 53

countries and a population of 879 million people) (Centeno et al., 2004). The Task Force works closely with a number of international hospice and palliative care organizations; in particular, IOELC, IAHPC, and Help the Hospices (HTH). In 2006, the initial findings of the Task Force were presented in the form of a map of specific resources of palliative care in Europe. In 2007, the Task Force produced a set of country reports that documented the existence of palliative care services using a common template to facilitate cross-national and regional comparison, published as a European Atlas of Palliative Care (Centeno et al., 2007a), and disseminated via the web pages of the EAPC (EAPC, 2013). They function as benchmarks, to enable countries to ascertain their level of palliative care development compared with others in their region and to track developments over time.

The *EAPC Review of Palliative Care in Europe* (Rocafort and Centeno, 2008), and associated articles were published in peer-reviewed journals. One article examined data on palliative medicine as an area of certified specialization in 52 European countries (Centeno, et al., 2007b). Another compiled facts and indicators on the development of palliative care in those countries (Centeno et al., 2007c). Two further articles examined barriers to the development of palliative care in both CEE/CIS (Lynch et al., 2009) and Western Europe (Lynch et al., 2010).

Emerging from this series of studies was an ambitious attempt in 2006 to measure and classify global palliative care development. The IOELC built on a basic description that had been produced by the Hospice Information Service but attempted to build more depth into the analysis, by developing a four-part typology, depicting levels of hospice-palliative care development across the globe: no known hospice-palliative care activity (group 1 countries); capacity building activity (group 2 countries); localized hospice-palliative care provision (group 3 countries); and countries where hospice-palliative care services were reaching a measure of integration with the mainstream health-care system (group 4 countries). By presenting a 'world map', the study sought to contribute to debate about the growth and recognition of palliative care services and, in particular, whether or not the four-part typology reflected sequential levels of development (Wright et al., 2008).

Since 2006, there have been further comparative studies of palliative care development. For example, in 2008, the work of the EAPC Task Force was extended in a collaborative study which specifically focused on the 27 member states of the European Union (EU) (Martin-Moreno et al., 2008). This study moved beyond a descriptive comparison of the data, to sketch out the beginnings of a more detailed method for ranking the 27 countries by the level of their palliative care development. A study commissioned by the Lien Foundation in Singapore and carried out by the Economist Intelligence Unit was published in 2010. This produced a ranking of palliative care development; this time in 40 countries of the world, and with a more complex set of indicators (Economist Intelligence Unit 2010). In 2011, a report from Human Rights Watch also documented the state of pain and palliative care services in 40 countries (Human Rights Watch 2011).

Methods for measuring progress and mapping: challenges and limitations

There are a number of practical and methodological challenges inherent in the mapping and measuring of global palliative care development. In 2011, the EAPC Task Force embarked upon a new programme of work to refine its original methods and to produce updated information on the status of palliative care in each European country. The work culminated in the production of a second edition of the *EAPC Atlas of Palliative Care in Europe* that was launched at the EAPC Congress in Prague, June 2013. The Atlas addresses limitations and difficulties associated with standardization of terminology relating to hospice and palliative care services. It also addresses some of the unintended negative effects that may occur when benchmarking studies are undertaken, such as the role of 'human emotions' within the process of collecting the data—the fact that data provided by 'key persons' and national associations could have been inflated by 'competitive tendencies'.

The 2006 study that mapped the global development of palliative care was revised by the Worldwide Palliative Care Alliance in 2011, to update the original findings and facilitate cross-national comparative analysis and stimulate advocacy, policymaking, and service development. The results of the mapping study are shown in Fig. 1.1.1 (Lynch et al 2011).

Although the 2006 study had been heavily cited and adopted as a tool for international palliative care advocacy, it became clear that the rankings might benefit from refinement and the method of categorization could also be made more robust. Consequently, within the revised typology, changes were made to the criteria for the levels of palliative care development in groups 3 and 4 and these were subdivided to produce two additional levels of categorization: 3a/3b (isolated palliative care provision/generalized palliative care provision) and 4a/4b (countries where hospice-palliative care services are at a stage of preliminary integration into mainstream service provision/countries where hospice-palliative care services are at a stage of advanced integration into mainstream service provision). In addition, the EAPC undertook an extensive, consultative, and consensus-building exercise to agree norms and standards for palliative care within Europe (Radbruch and Payne 2009, 2010).

It was acknowledged that the global mapping study had other limitations. As with the 2006 study, there remained an absence of data for some countries, and respondents often experienced difficulty in choosing between the newly divided categories. Some respondents suggested that their country 'did not fit into any category', that their country was 'somewhere on the border' between two categories, or that 'strengths and limitations' existed within each subcategory. Achieving comparability between settings and the way in which services are counted also proved problematic. Two systems operate in tandem. Services in five of the six continents tend to be counted by provider, irrespective of the number of services. In Europe, they are usually counted by type (e.g. home care, day care, inpatient units, or hospital teams). Although this allows a degree of comparability for services in the countries of Europe and within and across the other five continents, it also inhibits any comparable worldwide analysis. In addition, listing services by provider could be a source of bias as a country with fewer but larger-scale provider organizations would show a lower ratio of services per capita compared with a country having several small providers. Differences in the way in which services are counted may be an artefact of the procedures for 'counting' organizations. The authors attempted to address these issues by listing the number of providers and services in the same category of data under the heading 'services/providers', and attempting to glean clarification from 'key persons' and local palliative care experts.

Reproduced with permission from Lynch, T., Clark, D., and Connor, S.R., *Mapping levels of palliative care development: A global update*, Worldwide Palliative Care Alliance, Copyright © 2011.

A major problem faced in this and other studies was that of standardization and definition in how services are characterized. Terms such as 'hospice', 'inpatient unit', or 'mobile team' do not have a universal currency and globally there were difficulties in comparing them. The authors also note the diversity of provision and the different 'histories' of palliative care in specific jurisdictions and acknowledge the absence of agreed standards and quality measures globally. In addition, the vast majority of data relating to palliative care development originated from palliative care activists and this was acknowledged as a potential source of bias or inaccuracy, with the inherent risk of data that either under-reported or over-reported the number of services.

From mapping, to research, to advocacy
The Access to Opioid Medication in Europe project

The 5-year Access to Opioid Medication in Europe (ATOME) project commenced in December 2009, funded by the European Commission's 7th Framework Programme. The aim of the project is to improve access to opioids in 12 European countries where there is statistical evidence of very low morphine per capita consumption: Estonia, Latvia, Lithuania, Poland, Slovakia, Hungary, Slovenia, Serbia, Bulgaria, Greece, Turkey, and Cyprus. The ten partners of the ATOME project work with country teams, including government officials and public health and medicine experts, to carry out legislative and policy reviews, leading to

recommendations that will facilitate access for all patients requiring treatment with medicines controlled under the international drug conventions. The integration of palliative care and harm reduction is a key aim of the project.

The project is undertaking a national situational analysis in each country with regard to the accessibility and availability of controlled medicines, including their use and causes for underuse. It is conducting an external review of relevant national legislation in each country and recommending appropriate amendments to governments. It is anticipated that the project will improve access to essential controlled medicines, including opioid analgesics and opioids used in substitution therapy for the treatment of opioid dependence, in the majority of the 12 European countries. Improved access will also contribute to the effective prevention of HIV/AIDS transmission among and from injecting drug user populations.

There are a number of research initiatives being undertaken within the ATOME project. For example, the principle of 'balance' in opioid control policy requires governments not only to prevent drug abuse, but also to ensure the availability of opioid analgesics for medical purposes. Efforts to prevent drug abuse and diversion must not interfere with the adequate availability of medication for patients' pain relief and drug substitution therapy. Within this context, the ATOME project has revised the WHO guidelines *Ensuring Balance in National Policies on Controlled Substances* (WHO 2011).

Two ATOME workshops (involving six countries each) drew together relevant stakeholders who formed a country team that

analysed their country situation using a checklist developed by the WHO and the WHO Collaborating Centre for Communication and Policy in Cancer Care (University of Wisconsin, United States). The checklist was used by each country team to identify existing barriers for access to controlled medications at all levels of their respective health-care and legislative systems. As a follow-up to these workshops, 1-day national conferences are being organized in each of the 12 target countries (in collaboration with the country teams) in order to evaluate the implementation of the revised guidelines and to disseminate the project's findings and recommendations to relevant ministries, health-care professionals, and the general public, including patients and their families. Promoting the acceptance of rational use of opioids as medicines, both for pain management and substitution therapy, is also a priority of each conference.

In addition, a workshop was held to discuss the training of lawyers and national counterparts on how to review national controlled substance legislation from the perspective of balancing availability and prevention of abuse; lawyers from each country and 12 national counterparts identified from within the Ministry of Health were in attendance. Recommendations have been drafted to lift these barriers in such a way that prevention of drug abuse is warranted.

It is anticipated that collaboration between government officials and national health professionals in the project's 12 country teams will contribute to research in the area of pain management policy. A strong focus on the recommendations for policy and legislative change and their dissemination to key decision-makers at national and European level will help to ensure that causes of inappropriate prescribing and poor compliance will be identified and policy recommendations for safe, effective, and cost-effective use of medicines in Europe developed. The ATOME project draws on the successful lessons learned in Romania.

Open Society Foundations' International Palliative Care Initiative: the Romanian experience

The International Palliative Care Initiative (IPCI) was established in 2000 with an overall goal of integrating palliative care into national health-care systems. The IPCI promotes the WHO public health model, adopting a multi-pronged strategy that includes legal and policy reform, including drug availability and standards development, as well as education, training, and financing. The economic costs and benefits of palliative care are considered as key themes, as support for health budget monitoring activities may enable access to funding for palliative care treatment. In several countries, the IPCI, in collaboration with the OSF Public Health Program Health Budget Monitoring Advocacy project (HBMA), have managed to get members of the Ministry of Health and other key players (e.g. pharmaceutical and insurance companies) aligned to their way of thinking. This has been achieved through their support for policy analysis debate and for national and regional workshops.

Initially, Romania had a very restrictive controlled drugs legislation, dating back to 1963, which did not allow for adequate pain management or adequate treatment of opioid dependence. Terminally ill cancer patients could qualify for pain medication, but still had to overcome several serious barriers to access it. All other moderate and severe pain patients were excluded from adequate pain relief with opioid analgesics.

In 2002, the IPCI and the Pain and Policy Studies Group (PPSG) WHO Centre for Policy and Communications in Cancer Care, organized a regional workshop with representatives from Ministries of Health, narcotics control, and national HIV and cancer control programmes from six countries: Bulgaria, Croatia, Hungary, Lithuania, Poland, and Romania. Action plans were developed and technical assistance was provided by the Centre, leading to a significant change in legislation in Romania in 2005. This proved to be a watershed event for palliative care development not only in Romania, but more broadly both in the CEE/CIS region and throughout the world. Another activity developed in cooperation with the Romanian Ministry of Health was a workshop on controlled drugs legislation, held in Bucharest under the EU PHARE Programme in December 2003.

Following these initiatives, the Romanian government developed a new controlled drugs act, which was enforced in June 2006. To ensure proper implementation, the WHO Department of Medicines Policy and Standards, PPSG, Hospice Casa Sperantei, and the Romanian Ministry of Health, co-organized a workshop in 2006 where the implementation of the recent legislation was discussed. Policy was also developed for the training of physicians in prescribing opioid analgesics. Furthermore, the government established treatment facilities for opioid dependence in each province and in three prisons. Romania had laid the foundations for adequate access to essential controlled medicines.

Thanks to the IPCI and HBMA's support for budget monitoring activities, in April 2010 the Romanian Ministry of Health decided to finance palliative care and also to contribute to paying the costs of home-based care. Prior to this project, there was no government coverage of palliative care treatment. This project not only enabled access to funding for palliative care treatment, but also, unexpectedly, helped sharpen the national definition of palliative care.

Key initiatives in strengthening education and development of specialized disciplines

Future increases in the need for palliative care will place demands upon knowledge transfer across the whole workforce of those people who are involved. This section will review definitions of education and scholarship, and consider the extent to which early calls for integration between palliative care practice and education have been achieved (Sheldon and Smith, 1996). We draw upon the work of a number of task forces (time-limited expert working groups) convened by the EAPC, who, over the last decade, have made proposals for core educational curricula in medicine, nursing, and psychology. This leads on to discussion of the international growth of specialist palliative medicine as a discipline, highlighting potential advantages and disadvantages of this growth. Finally, we review the opportunities that innovations in communication and information technologies offer in terms of education and knowledge transfer.

Separating education and training as distinct elements of learning might be helpful at the outset. According to Wee and Hughes (2007, p. 2), 'Education is the process through which learning occurs. Training, on the other hand, is about the acquisition of knowledge or skills to deal with particular types of event'. Arguably education is a life-long endeavour, in which new knowledge is gained, embedded in the context of appropriate attitudes and

values, which are used to inform high-quality practice. Palliative care draws upon pedagogical theories that are common to other health and social disciplines, which may be influenced by fashions, trends, and new developments. It is important to recognize that the content of education programmes—the curriculum—has three aspects: the formal curriculum as defined by educators, and often directed by statutory or disciplinary requirements; the informal curriculum which arises out of the interaction between learners and teachers; and the hidden curriculum which refers to the cultural learning environment (Wee and Hughes, 2007). Congruence between all three elements enhances the educational experience.

Multidisciplinary palliative care educational developments have progressed greatly in the United States (Weissman et al., 2007), including those in specific clinical contexts such as cancer care (Coyne et al., 2007) and intensive care (Ferrell et al., 2007). In Europe, the EAPC has coordinated a number of task forces focused on core professional disciplines within palliative care including nurse education (De Vlieger et al., 2004), undergraduate medical education within medicine (EAPC, 2007), postgraduate education for physicians (EAPC, 2009), and postgraduate education for psychologists (Junger and Payne, 2011). Further work is currently underway to identify a core educational curriculum for social workers and in the specialist area of paediatric palliative care. Ten core competences in interdisciplinary palliative care have been drawn together following a rigorous review and consensus process, to provide a framework for practitioners who work within the field (Gamondi et al., 2013a, 2013b). These core competences in palliative care, for all disciplines, provide a benchmark against which educational programme content and assessment can be matched, across institutions and internationally.

There is anecdotal evidence of considerable growth in the provision of post-qualification education in palliative care, but in the absence of collective databases of provision or any assessment of their level and quality, it is remarkably difficult to make accurate estimates of the number of programmes, the level of provision, and the quality of education offered. Moreover, programmes are currently offered by many organizations including hospices, hospitals, higher education and universities, with course lengths varying from a few hours to years. To address this gap in knowledge, a project undertaken by the IOELC has mapped educational provision at post-qualification level. We are aware of increasing numbers of certificated higher education awards being offered by universities; for example, in Asia, Masters in Palliative Care are available in Japan, and doctorate programmes are available for physicians, nurses, and allied health professionals in Singapore, Japan, and Korea (Payne et al., 2012). In Europe, there are exciting innovations with blended-learning programmes leading to a PhD in Palliative Care now being offered in the United Kingdom and Norway, and a large European Commission funded project designed to offer training to 12 PhD students and four post-doctoral fellows (End-of-Life Care 2011). The European Palliative Care Academy, funded by the Bosch Foundation, launched an international programme to enhance palliative care education and leadership training for clinicians across Europe in 2013.

An important drive to improve palliative care for all patients is the implementation of basic education in undergraduate curricula throughout all medical, nursing, and health professional courses globally, with an introduction to the principles of palliative care practice, including symptom control and communication skills.

This should be supplemented by supervised clinical placements in palliative care so that students can engage in experiential learning. This is likely to raise awareness of what palliative care services can offer and means more appropriate and timely referrals of those with complex problems, and empowers professionals to manage better those with less need for specialist input.

Palliative medicine has been recognized as a specialty within the United Kingdom since 1987 and doctors wishing to achieve specialist registration must undergo post-registration specialist clinical training (Centeno et al., 2007b). The number of countries with specialist physician status for palliative medicine continues to grow including Ireland, Israel, and Germany. There remains some debate as to whether subspecialty status, for example, with registration in internal medicine or oncology, offers a better way to encourage high-quality physicians to enter this field and to prevent palliative medicine from becoming marginalized. Within nursing, similar development of specialist training and practice are evident, particularly in resource-rich regions, where clinical nurse specialists in palliative care have been shown to be effective (Larkin, 2008).

Conclusion

To sum up, given that this chapter has covered both a rapid overview of the development of palliative care and has highlighted key developments in palliative care education, it seems safe to conclude that, in some parts of the world, palliative care can be regarded as a success. There is evidence of increasing integration, with mainstream health-care provision, the inclusion of palliative care into national health-care planning process, and in a few places specific Palliative Care Strategic Plans have been adopted. This bodes well, even in times of financial constraint and uncertainty. However, countries with this level of development are very few, and even within these countries there may be inequity for particular patients, such as the very old, those with dementia, and who do not fit comfortably into mainstream society (Oliviere et al., 2011). In our view, one of the major challenges for the future is to improve equity of access to good quality care during the final phase of life, however long that may last. It is likely that advances in medicine and health technologies will mean that greater numbers of people will survive for longer with complex health and social care needs. This will mean a different type of workforce is required to provide basic palliative care wherever the patient and family are located and opportunities for advice, support, and referral to specialist palliative care providers. This will challenge specialist professionals to facilitate and coordinate care, rather than provide 'hands-on' care, which means that developing knowledge and skills in consultancy, advocacy, education, and leadership will form essential components alongside well-recognized knowledge in pain and symptom management, and psychosocial and existential support. A key component of specialist palliative care, however, must be the continued provision of care, otherwise the workforce deskills itself and loses credibility. In economically disadvantaged countries, it is essential that appropriate, sustainable models are developed.

1.2

Providing palliative care in economically disadvantaged countries

M.R. Rajagopal and Reena George

Introduction

A mother in Colombia advertises in a newspaper with a desperate plea to the government to make morphine available to her dying daughter. A man with cancer in India wants to end his life because his doctors would not relieve his pain (Human Rights Watch, 2010). Stories like this are commonplace all over the developing world. Eighty-three per cent of people who live in low- and middle-income countries get only 7% of the world's medical morphine (Pain and Policy Studies Group, 2009).

These inadequacies raise difficult questions for the worldwide palliative care community. How does one provide palliative care when there are so many other disparities in health and economic indices between the rich and poor nations of the world? Table 1.2.1 shows some figures from the reports of the World Health Organization (WHO). The life expectancy in the African Region of the WHO is 20 years less than in Europe. HIV mortality was 40-fold higher. Cardiovascular diseases, the leading cause of death worldwide, are three times as likely to be fatal in resource poor regions (WHO, 2012a).

Eighty per cent of the 17.3 million annual deaths due to cardiovascular diseases and 70% of the 7.6 million annual cancer deaths occurred in low- and middle-income countries. Twenty-five million people have died of HIV in the last three decades, the vast majority in economically disadvantaged countries (WHO, 2012b).

Given the fact that the total annual number of deaths in developing countries will soon reach 50 million, and that about two-thirds of dying patients would probably benefit from palliative care, the only way for universal access to be achieved in resource-poor countries will be by adopting a public health approach (Stjernswärd et al., 2007a, 2007b). The patterns which have evolved, for example, in the United Kingdom and the United States are just far too expensive and, if transplanted into low-income countries, would not reach more than a small percentage of those in need. Any initiatives will have to take into consideration the available resources and ground realities, economic and otherwise, within the developing world.

Important factors influencing the delivery of palliative care in low- and middle-income countries

Poverty and the economic impact of illness

In Africa and India, each with a population of over a billion, about 40% of people live on less than US$1 a day. Government spending on health is disproportionately low (WHO, 2012a). Out-of-pocket expenses for health care, combined with the lack of social security, can have a domino effect on poor families. Treatment-related debt and the loss of a livelihood push families below the poverty line, and children out of schools (Emanuel et al., 2010). Seventy per cent of HIV patients in Africa reported hunger as a symptom (Harding et al., 2012). Palliative care programmes have to find resources to provide free medicines, to support the education of children, and find an alternative source of livelihood for needy families. In Africa, the needs of hundreds of thousands of children orphaned by AIDS have severely stretched the timeline and boundaries of palliative care provision. Many programmes collaborate with other agencies to provide nutritional assistance, safe housing, and income-generation projects (Harding et al., 2003). Currently, only six of 54 African countries have anything approaching a country-wide network of palliative care services, namely South Africa, Kenya, Uganda, Zimbabwe, Zambia, and Malawi (Lynch et al., 2011).

The role of families

In traditional societies, it is rare to find a patient dying alone in a hospital or nursing home. Family members are actively involved in providing physical care and companionship. This is an invaluable resource to build on. Willing hands can be trained in wound management, subcutaneous drug administration, and other tasks. For this to work, palliative care services should develop simple drug and nursing protocols, and respond thoughtfully and sensitively to the caregivers' emotional and financial struggles and their concerns about contagion, addiction, and truth telling.

Table 1.2.1 Disparities in health and economic indices

	Global	High-income countries	Low-income countries	Africa	Europe
Non-communicable diseases age-standardized mortality	573	380	757	779	532
Cardiovascular diseases age-standardized mortality per 100,000, 30–70 years	245	105	375	382	238
Cancer age standardized mortality per 100,000, 30–70 years	150	141	154	147	166
HIV mortality per 100,000	27	2.6	85	160	9.6
HIV prevalence per 100,000	502	207	1445	2740	257
Per capita government expenditure on health in US$	549	2946	10	41	1677
Percentage of population living on less than US$1 per day	22.7	0	48.8	42.6	0
Life expectancy at birth (years)	64	76	52	51	71

Family involvement has its negative aspect too. In societies where the family can override the autonomy of the patient, relatives may demand the continuation of futile treatments, regardless of the wishes of the patient. On the other hand, a fatalistic attitude towards suffering and death may limit care. The health-care team may have to negotiate with numerous relatives before they are allowed to discuss prognosis and options with the patient. Unsolicited advice from the extended family, differences of opinion with accusations about 'not doing enough', and a lack of respect for privacy can also create problems for the patient.

The disease spectrum and dichotomies in existing services

In developing countries, there is often confusion about which diseases fall within the remit of palliative care. In some African countries, more than 20% of the adult population is HIV positive. Twenty-five million people have died of HIV in the last three decades, the vast majority in economically disadvantaged countries. In countries, however, where antiretroviral therapy is provided, HIV is no longer the 'killer' it was (WHO, 2012a).

Financial support from the international donor community is often conditional, for example, limited to people who are HIV positive and with the stipulation that specialized palliative care units take on stable HIV patients just for support care. This impacts adversely on available time and resources and therefore disadvantages many dying patients. People with severe chronic obstructive pulmonary disease may not be eligible for care, even though the suffering may be no less. Cancer in Africa has doubled in incidence with the advent of HIV. Where oncology services and palliative radiotherapy are non-existent, there can be protracted suffering from pain and fungating wounds (Currow et al., 2011).

On the other hand, affluent people in the Middle East, India, and China can easily access state-of-the-art technology for anti-cancer treatment, but not facilities for palliative care. Many centres with the latest machines and anti-cancer treatments do not stock oral morphine for home-based care. The intensive care unit becomes the 'respectable' place to admit the dying patient.

The original WHO description of palliative care as applicable when 'the disease is no longer amenable to curative treatment' may have inadvertently caused suffering by sometimes denying symptom relief and psychosocial support when anti-cancer treatment was still in progress. Those trained in palliative care must be equipped to care for patients with life-limiting illness, whether or not they are at the end of life.

Foundation measures for a public health approach

Palliative care should be integrated with, and not separated from, the mainstream of health care. A public health approach means that the methods adopted must be valid scientifically as well as acceptable, sustainable, and affordable at the community level. The four components of the WHO Public Health Model are:

◆ appropriate policies

◆ adequate drug availability

◆ education of health-care workers and the public

◆ the implementation of palliative care services at all levels in society (Stjernswärd et al., 2007a).

Mongolia is a good example of a successful top-down implementation of the public health strategy. Initial collaboration between the government, local pioneers, and WHO experts led, within just a few years, to modified narcotic prescribing laws, availability of generic morphine, translation of clinical guidelines into the local language, training programmes, and budgetary support for palliative care. Within the first decade, beds were earmarked in government hospitals for patients needing palliative care, palliative care was included within undergraduate medical and nursing curricula, and courses for specialist training were started (Davaasuren et al., 2007).

In larger populations or where consistent government support is lacking, the process may be slower and more fragmented. Nevertheless it is possible to make a start.

Planting palliative care: international collaboration as a fulcrum

The WHO, through its collaborating centres, recognizes that policymaking bodies need individuals and beacon services as fulcra to initiate implementation. Local pioneers can be empowered with advocacy tools, teaching curricula, clinical guidelines, and policy documents developed by international organizations, associations, and academic centres without having to reinvent the wheel. International funding is vital at this stage (Callaway et al., 2007; Praill and Pahl, 2007; Stjernswärd et al., 2007b; Pantilat et al., 2012).

Propagating palliative care: adapting to the local context and multiplying

Pioneers who start with an existing palliative care 'recipe' should review it carefully to discriminate between the essentials to be retained and elements that need to be adapted to local ingredients (resources), cooking methods (health and family systems), and tastes (cultural appropriateness). The adapted recipe becomes a palatable and doable way to propagate palliative care; progressively reducing reliance on external resources and models, but striving to maintain essential standards (Ferris et al., 2007; Pallium India, 2010).

For example, the British inpatient hospice system cannot be replicated widely in developing countries. It is unjust to give superlative care at great cost to 250 inpatients per annum if 2500 others (or more) are denied any help. Furthermore, experience in Uganda and India has shown that care at home, supported by an outpatient clinic and occasional home visits, is cost-effective in terms of achieving population-wide coverage, with a 'back-up' inpatient facility for those with overwhelming problems, or no family and home.

It is likely that a palliative care service in a resource-poor country will, sooner or later, become swamped with patients, and that the service will have to expand indefinitely and/or reduce the quality of the care. So, given the likelihood of an increasing demand for care, it is essential for new services to have a policy which deals with this eventuality. If possible, such a policy should be based on a properly conducted needs assessment. In all this, it is important to keep the following points in mind:

◆ The palliative care delivery system should be realistic and sustainable.

◆ Patients' needs should come first. This is not automatically the case; the success of the organization or department may effectively become the team's main concern.

◆ A partnership in care needs to be established with the patient. Doctors have no right to force decisions on the patient. Formal education and wisdom are not synonymous.

◆ A partnership in care needs to be established with the family. Enough trained nurses will not be available to care for literally millions of patients. However, success is still possible by empowering the relatives to care for the patient.

◆ The family's finances need to be considered before advising on treatment.

◆ Existing resources should be utilized optimally. Constructing new palliative care centres is likely to exhaust available resources. Wherever possible, use should be made of existing facilities, that is, hospitals and primary health centres.

◆ Deficiencies in existing facilities need to be supplemented by non-governmental organizations (NGOs). Ways must be found to complement existing services, thereby 'plugging gaps' and evolving a seamless integrated service. Experience has shown that, with determination and diplomacy, it is generally possible for NGOs to work successfully alongside government health services.

◆ Volunteers can be the backbone of the palliative care service. There are numerous individuals who are kind-hearted and willing to help. However, this potential work force needs to be trained.

◆ Advocacy is essential. A strategy is necessary to influence policy and to improve funding and drug availability. There is a need both to approach health department decision-makers directly and to influence them indirectly through the public.

Prioritizing palliative care: integration into national health policies

Services may begin as a result of the efforts of local and national 'champions' but in order to achieve population-wide coverage, palliative care needs to be integrated into mainstream health care. This requires government policy for palliative care to be an essential or core element of the national health services. Ideally, there should be a comprehensive generic plan for the development of a palliative care programme for non-communicable diseases including cancer and other end-stage diseases, for HIV/AIDS, and for the care of older people with advanced chronic illnesses which can be implemented worldwide (Stjernswärd et al., 2007b). Inevitably, there will be some disease-specific measures; for example, antiretroviral drugs for those infected with HIV. Policies will not work without action plans, time lines, resources, and accountability for implementation. To achieve this amid all the other claims on very limited health budgets, there needs to be strong, well-reasoned advocacy from community groups, the health professions, and the wider public, such as has been the case in relation to AIDS.

Preserving the soul of palliative care: the need to keep the patient at the centre

A public health strategy is not incompatible with remembering the centrality of the patient, and the deep needs for meaning, connection, and peace at the end of life—concepts fundamental to palliative care, whatever the setting (Selman et al., 2011):

> A patient said 'Thank you. And not just for your pills but for your heart . . . '. (Saunders, 2003, p. 40)
>
> Here again comes a key phrase I have often quoted 'I look for someone to look as if they are trying to understand me.' These patients are not looking for pity and indulgence but that we should look at them with respect and an expectation of courage. (Saunders, 2003, p. 3)

Indeed, the remarkable courage and grace with which many desperately poor people face life and death, can evoke not just respect, but awe, in those privileged to be present with them (George, 2010).

Education

The caregivers, whether professional, volunteer, or family, all need training to enable them to acquire the necessary knowledge, attitude, and skills. Education about palliative care must also be extended to the public at large, policy-makers, and health service administrators.

Advocacy and public awareness

Experience has shown repeatedly that the general public is often more open to new ideas than health-care professionals or administrators. Some doctors may see palliative care as an admission of failure, or as a threat to their earnings. Others may assume they already have the necessary skills. Even when a specialist is reluctant to refer patients to a palliative care service, repeated demands by patients eventually can force a change in attitude.

Public understanding is also necessary to overcome the current problem of over-medicalization of death. It is a disturbing paradox that, in cities in economically backward countries, the dying are often subjected to inappropriate high-tech interventions. People with irreversible end-stage disease frequently die while still on ventilators, the family ruined by the high cost of treatment. Those who choose to withdraw life supports in a futile situation have to assume the guilt and the responsibility of being 'discharged against medical advice'. There is often public discussion about euthanasia but rarely about the possibilities of palliative care as an alternative to suffering or to inappropriate high-tech care.

Public demand can also lead to administrative reforms. Advocacy programmes have an important role to play, as shown by tobacco control programmes. It is up to the palliative care fraternity to bring these issues to public attention through a range of activities that could include:

◆ articles and real-life stories in newspapers, on television, and the Internet

◆ inviting key decision-makers and celebrities to Palliative Care Day celebrations

◆ public awareness programmes as part of community activities

◆ involving public figures who have encountered palliative care as 'mascots' for palliative care

◆ involving corporate organizations, clubs, and professional associations in supporting palliative care as a 'worthy cause'

◆ teaching palliative care and related matters in school and college education.

Training palliative care workers

Palliative care training must address not only knowledge acquisition (*head*) but also attitudes (*heart*) and skills (*hands*). Although it is effective in conveying book knowledge, didactic training seldom changes practice because it seldom changes attitudes and does not improve skills. The best way to learn any aspect of medicine is by the bedside, including 'hands-on' training. Unfortunately, this cannot always be arranged. When a short didactic course is all that can be offered, it helps if:

◆ one to two sessions include a clinical presentation with the patient in the classroom

◆ course participants can spend 1–2 hours observing a palliative clinic in action

◆ course participants can join in for a home visit.

Professional and volunteer education is essential at all levels of health care. The following examples from the grass-roots and the tertiary levels illustrate the range of possibilities in the developing world.

Educational initiatives from the grass roots

The Palliative Care Toolkit (Lavy et al., 2008) is a good example of an open-access, easy-to-use curriculum, developed within low-income countries and based on local case studies and available clinical resources.

The Toolkit was written to empower health workers to integrate symptom control and holistic support into the care they are already giving. It takes a 'can-do' approach, encouraging health workers at all levels that, with some basic training, they can make a difference to the lives of patients for whom cure is not possible (Coombes, 2008).

Advice on non-drug treatment runs alongside the medical guide to symptom control, equipping non-prescribers and lay volunteers to give good nursing care even where drugs are not available. Communication skills and psychological and spiritual support are addressed, with attention paid to the special needs of children. A set of tools to be used in the field includes forms for patient records and data collection, advocacy material, teaching aids, and a basic drug list.

The Toolkit training manual (Lavy, 2009) contains ready-made teaching material based on the Toolkit. It has been written for health workers doing palliative care who want to train others but have minimal experience in teaching and little time for preparation. Separate modules can be used as single sessions, or put together to create courses for different audiences and settings. Teaching materials, such as case studies, discussion topics, questions, and answers, are provided.

The Toolkit has been translated and is available at no cost on the Worldwide Palliative Care Alliance website in eight languages (Worldwide Palliative Care Alliance, 2009). Training grants have been awarded to organizations across India, sub-Saharan Africa, and Latin America (Help the Hospices, 2009).

Educational initiatives from national authorities

The notification of a higher speciality training programme, MD (Palliative Medicine), by the Medical Council of India and the Indian government is a significant milestone within the developing world towards developing a cadre of leaders and trainers for the future and integrating palliative medicine in medical education (Medical Council of India, 2010).

Drug availability

It is generally agreed that opioid analgesics are the mainstay of cancer pain management (WHO, 1986). Policies and recommendations for rational public health implementation are available (Joranson and Ryan, 2007), and essential drug policies have been established (De Lima, 2006)

Despite this, limited drug availability, specifically of morphine, continues to be a major obstacle to the development of palliative care. David Joranson, former Director of the Pain and Policy Studies Group, University of Wisconsin Comprehensive Cancer Center, and the team at the WHO Collaborating Center for Policy and Communications in Cancer Care, have helped local palliative care activists in many countries over the last 15 years (Mosoiu et al., 2006). However, it seems that one has to be Houdini to escape from the ensnarement of bureaucratic (and indifferent) red tape.

Widespread poverty in low- and middle-income countries means that, unless drugs are inexpensive, overcoming regulatory barriers alone does not translate into pain relief. Uganda has developed a simple protocol for local pharmacies to prepare inexpensive oral morphine solution from powder (Merriman and Harding, 2010). Through advocacy from Hospice Africa Uganda, with continued funding through Hospice Africa (UK), affordable oral morphine has been introduced to Tanzania, Malawi, Sierra Leone, Nigeria, Cameroon, and Ethiopia. A survey in 12 African countries identified an interplay of factors—regulatory barriers, fear of addiction and punitive regulations, a shortage of drug stocks, prescribers, and dispensers—affecting the availability of analgesics and other essential drugs (Harding et al., 2010).

Paradoxically, expensive drugs are frequently available in many countries. The power of drug companies to buy influence over every key group in health care—doctors, NGOs, charities, patient groups, journalists, politicians—is deeply disturbing (Ferner, 2005). In the absence of close monitoring, questionable practices go undocumented in developing countries.

Put at its simplest, the pharmaceutical industry tends to promote expensive new analgesics. As this is not balanced by medical education in the use of less expensive drugs, this leads to the unnecessary prescription of expensive drugs. It is shameful that many institutions have expensive sustained-release morphine, but not inexpensive ordinary morphine preparations. Many centres use transdermal fentanyl as the first-line strong opioid. Limited resources are thus spent unnecessarily, and thousands of other people are denied pain relief as a consequence. Pharmaco-economics are an important aspect of the implementation of palliative care services. The Morphine Manifesto, which was endorsed by 64 international organizations in 2012, warns governments and medical institutions against this danger (Pallium India et al., 2012).

Implementation

Possibilities and challenges at the national level: two examples of palliative care development in economically disadvantaged settings

Example 1: Uganda

Currently Uganda is the only low-income country in the world with a fully integrated palliative care service (Lynch et al., 2011). This development illustrates the steps of planting, propagation, and prioritization:

Hospice Africa (UK) supported the development of a cost-effective and culturally acceptable model in an African country, which could be adapted to the needs of other African countries. Hospice Africa Uganda started as a pilot project in 1993. A viable home care model was developed, oral morphine was formulated locally, and doctor and nurse training commenced. Sustained advocacy and partnership with the Ministry of Health led to a stakeholders workshop in 1998 supported by the WHO. Palliative care for people with AIDS and cancer was made a priority in the National Health Plan, where it is classed as 'essential clinical care for all Ugandans'. The government committed itself to putting resources and systems in place. Legislation was changed to allow nurses and clinical officers to prescribe oral morphine after they had completed a closely mentored 9-month training programme (Jagwe and Merriman, 2007; Merriman and Harding, 2010).

Uganda has thus established all the foundation measures as recommended by the WHO:

- a clear national policy has been agreed
- education in palliative care is incorporated into the undergraduate curricula of doctors and nurses
- courses and workshops in pain relief and palliative care, are available to health care professionals at all levels
- affordable morphine is produced generically within the country
- the Ministry of Health has published guidelines for handling morphine and other strong opioids
- nurses qualified in palliative care are able to prescribe morphine.

Uganda was a key demonstration country in the WHO's community health approach to palliative care for HIV/AIDS and cancer patients in Africa, a joint project between Botswana, Ethiopia, Tanzania, Uganda, and Zimbabwe (WHO, 2004). It has demonstrated the importance and success of a harmoniously integrated government approach with clear policies and a decentralized, community-based approach, linked to its HIV/AIDS programme.

The African Palliative Care Association was established in 2003. The Association works closely with existing palliative care services throughout Africa to promote advocacy, service development, education, research, and appropriate standards.

Example 2: India

In the early 1980s, there were only a few pain clinics in various parts of India. Modern palliative care was first introduced in 1986 in the form of Shanti Avedna Ashram, an inpatient hospice in Bombay. However, the more widespread development of palliative care was minimal until 1993 when the Indian Association of Palliative Care was launched and the Pain and Palliative Care Society (PPCS) in Kozhikode, Kerala was founded.

The PPCS succeeded in developing an effective, low-cost, home-care system based on an outpatient clinic functioning 6 days a week, supported by home visits when possible, and inpatient facility when essential (Ajithakumari et al., 1997; Rajagopal and Kumar, 1999). In 1995, the PPCS was designated a WHO demonstration project for a community-based approach. The PPCS trained and involved an increasing number of doctors and members of the public in providing palliative care. By working with lay volunteers, a network of 33 palliative care clinics developed in the surrounding part of Kerala over the next 7 years. Typically, these functioned on 1 or 2 days per week (Rajagopal and Venkateswaran, 2003).

Because there are no support systems for the chronically ill, palliative care services were not restricted to people with cancer and AIDS, but extended to:

- stable chronic disorders, such as post-traumatic paraplegia
- fluctuating chronic disorders, such as filarial lymphoedema and sickle-cell disease
- slowly progressive diseases, such as peripheral vascular disease
- all end-stage progressive diseases, such as renal failure and chronic obstructive pulmonary disease with respiratory failure.

Since the turn of the century, Neighbourhood Networks in Palliative Care have been established (Kumar, 2004). These are mainly volunteer driven and community owned. Questions have

been raised about the quality of care that such teams can give (Gupta, 2004). While there is a need for the care system to be evaluated systematically, there is little doubt that these programmes have increased the community's awareness and participation in providing access to palliative care (Downing et al., 2005).

The Indian Association of Palliative Care has been a major force in bringing together palliative care workers in a large country and in sharing ideas. The association has been involved in advocacy, education, and research over 20 years. With support from many funding agencies, Pallium India, an NGO, has catalysed the development of eight palliative care centres in major teaching health-care institutions in North and North-East India and facilitated the initiation of two palliative care training centres in South India.

Although most palliative care delivery in India has been driven by NGOs, government involvement has also been important. For example:

◆ Palliative care centres have been exempted from the need for a 'drug licence', thereby enabling them to dispense morphine without an obligation to employ a qualified pharmacist, something which most centres could not afford (Joranson et al., 2002).

◆ Narcotic regulations have been simplified in 13 of 28 states and there are current efforts to change central legislation to improve access to opioids (Palat and Rajagopal, 2006).

◆ An uninterrupted supply of morphine sulphate powder has been guaranteed from government opium and alkaloid factories (Rajagopal et al., 2001).

◆ Palliative care is now part of the government's national programme for prevention and control of cancer, diabetes, cardiovascular diseases, and stroke (Government of India, 2010).

◆ The Government of Kerala declared a palliative care policy in 2008 integrating palliative care into the government's health-care system (Government of Kerala, 2008).

◆ The Medical Council of India has approved higher speciality training in palliative medicine.

Implementation at the grass roots: small beginnings matter too

Worldwide, only a minority of governments in economically disadvantaged countries have implemented palliative care policies effectively. For much of the world's population, comprehensive top-down approaches providing palliative care may not happen in the near future. The efforts, big and small, of individuals remain invaluable. Those who wish to help, but are uncertain as to how, can use the WHO framework as they plan service development at the grass roots.

'Start low, go slow, but do so' is a good motto when a worthwhile task seems daunting. Many beacon services began as small initiatives when someone was moved by an unmet need, and tried to make a small beginning by using what was available, and supplementing what was not.

But how does one begin? A few questions are helpful:

A. Needs assessment

1. Who needs palliative care where we are working?

2. What are their main problems?

3. What help are they getting at present? What is already available and what is not?

4. What could be added to improve their care and make it holistic (Lavy et al., 2008)?

These questions help think through the complex social and clinical needs to be met, to brainstorm the resources available, and to consider how the gaps could be filled using existing personnel. Allies can be found within and beyond the health-care system- individuals of goodwill in the community, groups involved in areas such as poverty alleviation and literacy, or the care of vulnerable people. As people come together to work for a common goal, new ideas are generated, resources are optimally used, change begins, others join, and the momentum grows.

The service in Kozhikode, India, for example, began with a doctor and a housewife from the community giving a few hours a week to provide pain management and counselling within a government hospital. In less than 5 years the service became a WHO demonstration centre for the developing world. A group of committed people in the United Kingdom provided the support that enabled Anne Merriman to pilot a palliative care programme that later became a model for Africa.

Fig. 1.2.1 from the Palliative Care Toolkit, shows palliative care as a tree. Its roots are the four elements of holistic care: physical, psychological, social and spiritual. Each of these roots can be made up from different components, e.g. existing clinics, faith communities, local NGOs. The branches and leaves which grow from these roots represent holistic palliative care in its different forms—different 'models of care' (Lavy et al., 2008, p. 6).

B. Strategy

What is already available and what is not?

What would be the most appropriate setting to begin in our context, home care? Outpatient clinic? Hospital support team?

Which locally appropriate models can we visit and learn from?

Can any part of the work be undertaken by existing organizations?

C. Education

Do we have a trained doctor and nurse?

Can we develop volunteers to act as the link between the patients and the health-care professionals?

How will we empower families to care for patients?

Are our colleagues sufficiently educated to refer appropriate patients to the new service?

Is the public aware of the benefits of a palliative care service?

D. Drug availability

Do we know how to procure strong opioids, particularly inexpensive preparations of morphine?

How much morphine should we stock?

How much free treatment will we be able to provide?

Do we have enough money for an uninterrupted supply of essential drugs?

E. Implementation

Have we made a practical action plan with short-term, medium-term, and long-term goals?
Fig. 1.2.1 Growing a model of care from available resources.

PHYSICAL	PSYCHOLOGICAL	SPIRITUAL	SOCIAL
Patient care:	Counselling:	Individuals:	NGOs:
Health centre	Social worker	Local religious leaders	FBOs
Local hospital	Trained volunteer	Volunteers from faith communities	Food supply work
Private clinics	HIV counselor	Social workers	OVC groups
Traditional healers	Patient advocates –	Family members	Income generation schemes
NGOs doing healthcare	Others with the same illness		Small loan schemes
ART clinic		Groups:	
	Support groups:	Faith community, e.g. church,	Individual professionals:
Drug supply:	PLHIV group	mosque, temple, synagogue	Social worker
Hospital pharmacy	Women's group	Women's groups	Legal advisor, for making wills
Local pharmacy shops	Youth organizations	Hospital visiting team	
		Children's groups	Involving others:
Advice and support:	Support at home:		Community leaders
Local doctor/nurse/clinician	HBC volunteers		Local schools and colleges
Local physiotherapist	Family members		Community groups
National palliative care association			

FBO: faith-based organization; HBC: home-based care; OVC: orphans and vulnerable care groups; PLHIV: people living with HIV.

Reproduced from Lavy V., Bond, C., and Woolridge, R., (2008) Palliative care toolkit: improving care from the roots up in resource-limited settings, Help the Hospices, London, with kind permission.

Do we have stated deadlines for drug availability and educational activities?

When do we schedule our reviews?

What performance indices should we monitor? Are they important and measurable (Downing et al., 2012)?

Implementation in the longer term

Building up without burning out

It is not easy to be a pioneer in palliative care in the developing world. The numbers unreached, intensity of suffering, and abject poverty create an urgent imperative. Juxtaposed with this, the lack of trained hands, essential drugs, acceptance within mainstream health care, and sustainable funding can be demoralizing. The gaps between needs and resources on the one hand, and idealism and personal limitations on the other, increase the risk of burnout.

Burnout happens in many professions and contexts (Maslach et al., 2001). It is touched upon in this chapter because both the risk of burnout and its impact on the provision of palliative care are likely to be significant, albeit unacknowledged in economically disadvantaged settings. To take an analogy from mountaineering, climbing an uncharted peak is more challenging and risky than when there are maps, systems, and resources in place.

Palliative care pioneers could base preventive measures on the same strategies that mountain climbers use in preparing for the long haul. The acronym '*TEAMS*' summarizes some important components: *training* that is multifaceted, *equipment* and resources that are appropriate, *awareness* of possible dangers, *mentors* to accompany, and *spaces* that are base camps to recuperate and recharge (see Box 1.2.1).

In many resource-poor settings, there may be not be occupational health services or human resource departments to deal with staff stress and burnout. Developing creative and accessible ways to address these issues should be a part of the strategy to provide sustainable palliative care in the developing world.

Charisma versus routinization

It has been said that history alternates between charisma and routinization. In this context, charisma refers to the ability of exceptional individuals to act as a catalyst for social change, and acknowledges the impact of personality in bringing about radical innovation in institutions and established beliefs. In relation to the evolution of palliative care in the United Kingdom, United States, and other English-speaking Western countries, Cicely Saunders was the initial charismatic influence. Now, in countries where palliative care is well established and fully integrated into the National Health Service, a major challenge is to prevent palliative care moving from the creative and disruptive influence of charisma to the cosy ambience of routinization (Twycross, 2002).

Conclusion

It is crucial to the continuing development of palliative care worldwide that palliative care remains *a movement with momentum*, manifesting an ongoing creative tension between charisma and routinization. Fortunately, so far, this often seems to be the case. It is heartening that in many countries palliative care is breaking out of its original cocoon, and is responding imaginatively and compassionately to neglected and unsupported suffering of many kinds in the community.

Box 1.2.1 'TEAMS': Strategies to reduce burnout in palliative care workers

Training: training in areas of management such as strategic planning, writing a business plan, assertiveness, working in teams, fundraising, setting boundaries, and conflict management.

Equipping: human resources and funds, even within resource-limited settings, need to be reasonably proportional to the expectations from the service. Training, empowering, involving the community, and developing a public health approach are long-term strategies for sustainability. However, during lean periods, when staffing and resources are low, it may be necessary to take difficult decisions about what to prioritize, what to cut out, and how to invest in obtaining more resources before the service itself 'burns out' trying to be all things to all people.

Awareness: pioneers need to be aware of the possibility of burnout, to develop the maturity to be self-aware, recognize danger signs, and accept constructive criticism (Maslach et al., 2014). Colleagues, patients, and family members may recognize withdrawal, cynicism, or emotional exhaustion long before the person affected acknowledges it.

Mentorship: mentorship can be provided by local colleagues as well as by advisors who are experienced in palliative care, administration, policymaking, and stress management. Resilient and balanced teams protect against burnout as they understand the strengths, interests, and weaknesses of team members, deploy this diversity in varied team roles (HumanMetrics, n.d.), and are willing to give and receive mutual support.

Safe spaces: pacing oneself, by interspersing activities that provide renewal and rest, is legitimate and not 'selfish' when so much remains to be done. Wisely investing off-duty hours in hobbies, holidays, family pursuits, sleep, physical fitness, and spirituality are good external ways to recharge from the demands of work. Within work itself, an analysis of one's motivations and talents (Assessment.com, 2014), can identify specific activities, for example, teaching, research, or networking that are invigorating. Making space to look back and be grateful for what has already been achieved can guard against a reduced sense of personal accomplishment.

1.3

Essential medicines for palliative care

Liliana De Lima, Lukas Radbruch, and Eduardo Bruera

Introduction to essential medicines for palliative care

The 'essential medicines' concept developed by the World Health Organization (WHO) states that there is a list of minimum medicines for a basic health-care system, including the most efficacious, safe, and cost-effective ones for priority conditions (WHO, 2012). According to the WHO, essential medicines are those that satisfy the primary health-care needs of the population (WHO, 2000). Thus, essential medicines should always be available, affordable, and used adequately.

Access to essential medicines as part of the right to the highest attainable standard of health ('the right to health') is well founded in international law. The right to health first emerged as a social right in the WHO Constitution (International Health Conference, 1946) and in the Universal Declaration of Human Rights (United Nations (UN), 1948). The binding International Covenant on Economic, Social, and Cultural Rights (ICESCR) of 1966 details the progressive realization of the right to health through four concrete steps, including access to health facilities, goods, and services. The General Comment 14 (UN, 2000a) further applies the principles of accessibility, availability, appropriateness, and assured quality to goods and services, which include essential medicines as defined by the WHO. In accordance with this, Target 8E of the eighth Millennium Development Goal (UN, 2000b) relates to access to essential medicines: 'In cooperation with pharmaceutical companies, provide access to affordable essential medicines in developing countries was measured using nine indicators for measuring access to medicines using data collected by WHO and its partners'. In addition, access to medical products and technologies as part of the right to health recognized in countries' constitutions or national legislation is the first country progress indicator for Strategic Objective 11 ('Ensure improved access, quality and use of medical products and technologies') of the WHO *Medium-Term Strategic Plan for 2008–2013* (WHO, 2008). In spite of all these efforts and commitments, the vast majority of the global population still does not have access to essential medicines. A UN report (UN, 2011) found that in the public sector, generic medicines are only available in 38.1% of facilities, and on average cost 250% more than the international reference price. In the private sector, those same medicines are available in 63.3% of facilities, but cost on average about 610% more than the international reference price. High prices limit access to medicines with common treatment regimens, costing a significant portion of the

salary of workers in developing countries. The cost of treatment for chronic diseases is particularly unaffordable because of the need for long-term treatment protocols. Although there are no specific reports on access to essential medicines used in palliative care, many of these global reports include medications used in palliative care, such as potent analgesics, antidepressants, laxatives, and others. Of these, lack of access to opioids is a global problem which has been highlighted in many global and regional reports (African Palliative Care Association, 2006; International Narcotics Control Board, 2011; European School of Medical Oncology, 2012). The WHO estimates that 80% of the world's population, including tens of millions of people worldwide who suffer from moderate to severe pain, does not have adequate access to pain treatment. This includes 5.5 million terminal cancer and 1 million end-stage AIDS patients (WHO 2009). Many organizations, including UN bodies and non-governmental organizations, have called on governments to improve availability of these essential medicines and developed programmes and projects to increase awareness and knowledge. This chapter describes two such projects developed by the International Association for Hospice and Palliative Care (IAHPC), based on the 'essential medications' concept: they are the IAHPC List of Essential Medicines in Palliative Care and the Opioid Essential Prescription Package (OEPP). The main goal of these projects is to improve access to medicines and better patient care throughout the world.

The first section of this chapter describes the development of the IAHPC List of Essential Medicines followed by a description of the development of the OEPP. The final section describes the dissemination strategies and future developments for each.

IAHPC List of Essential Medicines in Palliative Care

In 2004, the WHO requested support from the IAHPC to develop a list of essential medicines for palliative care. At that time, the WHO Model List of Essential Medicines (WHO, 2005) had a section called 'Palliative Care', which did not list any medications, but contained a paragraph suggesting that all drugs mentioned in the WHO publication *Cancer Pain Relief with a Guide to Opioid Availability* (2nd ed.) (WHO, 1996) be considered essential. This publication has since been revised by WHO and replaced by other publications including *WHO Guidelines on the Pharmacological Treatment of Persisting Pain in Children with Medical Illnesses* (WHO, 2012) and two more currently in preparation: *WHO*

Guidelines on the Pharmacological Treatment of Persisting Pain in Adults with Medical Illnesses, and the *WHO Guidelines on the Pharmacological Treatment of Acute Pain*. The List of Essential Medicines in Palliative Care was completed in 2006.

The IAHPC convened a working group of international experts in the field. The Committee developed a plan of action, with the following steps:

Identification of the most prevalent symptoms in palliative care: it was agreed that the list would focus on medications to treat symptoms and not underlying conditions. As an example, disease-modifying treatments for cancers and HIV were excluded. An initial list of the 21 most common symptoms in palliative care was developed by the working group based on a review of the published literature at that time (Box 1.3.1) (Education for Physicians on End-of-Life Care, 1999; Lipman et al., 2000; Carr et al., 2002; Potter et al., 2003; Plan and Arnold, 2005; Solano et al., 2006).

Development of a baseline list: palliative care leaders from around the world were asked to propose appropriate medications for the 21 most frequently encountered symptoms. Of a total of 40 people who responded, 34 were physicians (85%) and 15 were from developing countries. In total, they recommended 147 products. This initial list was decreased to 120 by removing non-medications (e.g. oxygen and vitamins) and duplicates.

Delphi survey: an online survey with rating panels was sent to 112 physicians and pharmacists (77 from developing countries). Using a scale of 1–9, participants were asked to rate the safety and efficacy of each medication. Seventy-one participants (63% RR) responded.

Development of the final list: 28 global, regional, and professional representatives of pain and palliative care organizations were

invited to a face-to-face-meeting in May 2006. Representatives from 26 of these organizations attended. Through a discussion and consensus process, each one of the medications resulting from the modified Delphi process was reviewed, based on the available evidence and the participants' own experience. Thirty-three medications for which there was consensus on efficacy and safety were included in the list. The resulting list was approved by all the participants as the IAHPC Essential Medicines List for Palliative Care (Table 1.3.1).

The group agreed that there was not enough evidence to recommend any medications as both safe and effective for five symptoms—bone pain, dry mouth, sweating, fatigue, and hiccups—and recognized that additional research was needed to identify safe and effective medications to treat these symptoms.

The resulting IAHPC List of Essential Medicines was published in several journals and widely disseminated (De Lima, 2006).

Opioid essential prescription package

The IAHPC List of Essential Medicines in Palliative Care does not specify dosages or combinations of treatment regimens such as those needed for chronic pain treatment, for example, the list does not recommend which opioid, laxative, and antiemetic may be most safe and effective in the treatment of chronic pain in patients who require initiation of strong opioids. In 2011, the IAHPC wanted to recommend an essential package of medications that could ensure that opioids are more available to patients and therefore lead to more sustained improvements in pain control.

Opioid medications are the mainstay of moderate to severe pain treatment (WHO, 2002). However, an estimated 80% of patients in need do not have adequate access to analgesics (WHO, 2007; Deandrea et al., 2008). Regulatory barriers and limited resources are among several causes of poor availability of medications. In addition, inadequate training of health-care professionals and poor communication between physicians and patients often lead to undertreated pain and the presence of adverse effects which are preventable or treatable.

Adverse effects of opioids, such as constipation and nausea, may limit the dosing of opioids and lead to early discontinuation and inadequate analgesia.

Constipation affects up to 87% of people with advanced conditions who are receiving opioids (Sykes, 1998). There are recommendations that laxative prophylaxis for prevention of constipation should be a priority when patients are starting opioid medication (Larkin et al., 2008). Laxatives can be separated into two types: those that act by softening faecal matter and those that act through direct stimulation of peristalsis. The evidence to favour one laxative over another in palliative care is scarce. Only a few trials show that oral lactulose, polyethylene glycol/electrolyte solutions, and senna are effective in people with opioid-induced constipation (Agra et al., 1998; Ramesh et al., 1998).

Nausea and vomiting occur in 15–40% of patients (Campora et al., 1991; Aparasu et al., 1999). Some health-care professionals suggest using antiemetics for the prevention of nausea and vomiting whenever opioids are prescribed, but there is limited evidence to support this recommendation (Nicholson, 2003). Metoclopramide is generally recommended as first-line therapy given that it has central effects as well as aids gastric emptying. Medications with

---

Box 1.3.1 Most common symptoms in palliative care

Anorexia–cachexia
Anxiety
Constipation
Delirium
Depression
Diarrhoea
Dry mouth
Dyspnoea
Fatigue
Hiccups
Insomnia
Nausea
Pain (intensity):
　　mild to moderate
　　moderate to severe
Pain (type):
　　bone
　　neuropathic
　　visceral
Sweating
Terminal respiratory congestion
Terminal restlessness
Vomiting

Table 1.3.1 IAHPC List of Essential Medicines for Palliative Care©

Medication	Formulation	Indication for palliative care
*Amitriptyline**	50–150 mg tablets	Depression Neuropathic pain
Bisacodyl	10 mg tablets 10 mg rectal suppositories	Constipation
Carbamazepine**	100–200 mg tablet	Neuropathic pain
Citalopram (*or any other equivalent generic SSRI except paroxetine and fluvoxamine*)	20 mg tablets 10 mg/5mL oral solution 20–40 mg injectable	Depression
Codeine	30 mg tablets	Diarrhoea Pain—mild to moderate
Dexamethasone	0.5–4 mg tablets 4 mg/mL injectable	Anorexia Nausea Neuropathic pain Vomiting
Diazepam	2.5–10 mg tablets 5 mg/mL injectable 10 mg rectal suppository	Anxiety
Diclofenac	25–50 mg tablets 50 and 75 mg/3 mL injectable	Pain—mild to moderate
Diphenhydramine	25 mg tablets 50 mg/mL injectable	Nausea Vomiting
Fentanyl (*transdermal patch*)	25 micrograms/hour 50 micrograms/hour	Pain—moderate to severe
Gabapentin	300 mg or 400 mg tablets	Neuropathic pain
Haloperidol	0.5–5 mg tablets 0.5–5 mg drops 0.5–5 mg/mL injectable	Delirium Nausea Vomiting Terminal restlessness
Hyoscine butylbromide	20 mg/1 mL oral solution 10 mg tablets 10 mg/mL injectable	Nausea Terminal respiratory congestion Visceral pain Vomiting
Ibuprofen	200 mg tablets 400 mg tablets	Pain—mild to moderate
Levomepromazine	5–50 mg tablets 25 mg/mL injectable	Delirium Terminal restlessness
Loperamide	2 mg tablets	Diarrhoea
Lorazepam***	0.5–2 mg tablets 2 mg/mL liquid/drops 2–4 mg/mL injectable	Anxiety Insomnia
Megestrol acetate	160 mg tablets 40 mg/mL solution	Anorexia
Methadone (*immediate release*)	5 mg tablets 1 mg/mL oral solution	Pain—moderate to severe
Metoclopramide	10 mg tablets 5 mg/mL injectable	Nausea Vomiting

Table 1.3.1 Continued

Medication	Formulation	Indication for palliative care
Midazolam	1–5 mg/mL injectable	Anxiety Terminal restlessness
Mineral oil enema		
Mirtazapine (or any other generic dual action NassA or SNRI)	15–30 mg tablets 7.5–15 mg injectable	Depression
Morphine	Immediate release: 10–60 mg tablets Immediate release: 10 mg/5 mL oral solution Immediate release: 10 mg/mL injectable Sustained release: 10 mg tablets Sustained release: 30 mg tablets	Dyspnoea Pain—moderate to severe
Octreotide	100 micrograms/mL injectable	Diarrhoea Vomiting
Oral rehydration salts		Diarrhoea
Oxycodone	5 mg tablet	Pain—moderate to severe
Paracetamol (Acetaminophen)	100–500 mg tablets 500 mg rectal suppositories	Pain—mild to moderate
Prednisolone (as an alternative to dexamethasone)	5 mg tablet	Anorexia
Senna	8.6 mg tablets	Constipation
Tramadol	50 mg immediate release tablets/capsules 100 mg/1 mL oral solution 50 mg/mL injectable	Pain—mild to moderate
Trazodone	25–75 mg tablets 50 mg injectable	Insomnia
Zolpidem (still patented)	5–10 mg tablets	Insomnia

Complementary: require special training and/or delivery method.
* Side effects limit dose.
** Alternatives to amitriptyline and tricyclic antidepressants (should have at least one drug other than dexamethasone).
*** For short-term use in insomnia.

Notes:
Non-benzodiazepines should be used in the elderly.
Non-steroidal anti-inflammatory medicines (NSAIMs) should be used for brief periods of time
No government should approve modified-release morphine, fentanyl, or oxycodone without also guaranteeing widely available immediate release oral morphine.

central nervous system effects, such as haloperidol (Vella-Brincat and Macleod, 2004), levomepromazine (Twycross et al., 1997), and cyclizine (Walder and Aitkenhead, 1995), have been shown to be effective but may cause sedation and other adverse effects. There are no studies to indicate the effectiveness of one antiemetic over another in the management of opioid-induced nausea.

The IAHPC convened a working group of international experts from academic and research institutions. The working group designed the study using the following steps.

A Delphi technique with two rounds was used to determine consensus. The survey contained medications listed in the IAHPC List of Essential Medicines for Palliative Care for the treatment of severe pain, nausea and vomiting, and constipation plus additional medications for which additional studies have been published since the development of the IAHPC list (Thomas and Cooney, 2008; Cherny et al., 2010; National Cancer Institute, 2010):

◆ *opioids*: morphine, oxycodone, methadone, and fentanyl (transdermal patch)

◆ *laxatives*: bisacodyl, sennosides, lactulose, polyethylene glycol, and magnesium hydroxide (oral liquid—Milk of Magnesia)

◆ *antiemetics:* metoclopramide, haloperidol, and levomepromazine.

Participants were asked to rank a list of medications in order of preference from 'most safe and effective' to 'least safe and

effective' for the treatment of moderate to severe chronic pain due to cancer and other life-threatening conditions in adults initiating strong opioids. They were also given the opportunity to suggest other medications not included in the survey. In addition, participants were asked if their patients had difficulties accessing any of the medications listed in the study and if so, which medications.

Quantitative data were analysed using simple descriptive statistics. Open responses were coded, categorized, and used to inform the final OEPP. The components of the final OEPP were based on whether consensus was reached for drug and administration selection after both Delphi rounds.

Sixty pain and palliative care physicians agreed to participate in the study.

Preferred opioid: in the first round, morphine was selected by 89.4% (n = 51) of the participants, achieving consensus as the opioid of first choice to be included in OEPP. Hydromorphone was suggested as an alternative opioid and therefore included in the second round. In the second round, the vast majority agreed to oral morphine 5 mg every 4 hours as the first line of treatment. No consensus was reached regarding an alternative opioid of choice in case of lack of availability of morphine.

Preferred laxative: after both rounds, there was no clear consensus regarding a laxative of first choice with the combination of sennosides and docusate reaching the highest level of agreement, 59.2% (n = 29), followed by bisacodyl, 24.5% (n = 12). There was consensus that laxatives should always be given when opioid treatment is started, 93% (n = 53).

Preferred antiemetic: after both rounds metoclopramide reached a consensus of 75.5% (n = 37) as the antiemetic of first choice. No consensus was reached regarding frequency of antiemetic administration. After both rounds, 51.0% (n = 25) chose 'as needed' while 49.0% (n = 24) selected 'regularly'.

Availability and access to medications: a substantial proportion of participants had difficulty accessing opioids in their country, ranging from 33% (morphine) to 45% (methadone). Most laxatives are more readily available, although over one-third of participants (38.8%) would have difficulty accessing sennosides and docusate. Of the three antiemetics, the highest frequency in terms of problems with medication access was for levomepromazine (46.9%). Poor access to opioids, except fentanyl, was significantly higher in middle-low- and low-income countries (p < 0.05). No significant differences in accessibility for laxatives were found between high- and low-income countries. Access to levomepromazine was significantly more difficult in middle-low- and low-income countries. The number of participants in each geographical region was too small to determine significant differences among the responses from participants in each region.

OEPP: using the results from both rounds, members of the working group developed the OEPP and identified the appropriate dosage and route of administration for each medication in accordance with the Food and Drug Administration's approved manufacturer's recommendation. Box 1.3.2 shows the resulting OEPP.

The underlying aim of these two projects is to facilitate and improve care provision and effective symptom control.

Box 1.3.2 IAHPC Opioid Essential Prescription Package (OEPP)©

Opioid

Morphine, oral, 5 mg every 4 hours.

Laxative

Combination of senna and docusate, oral, 8.6 mg/50 mg every 12 hours.

OR:

Bisacodyl, oral, 5 mg every 12 hours.

Antiemetic

Metoclopramide, oral, 10 mg every 4 hours OR as needed.

Reproduced from Vignaroli E et al., Strategic Pain Management: The Identification and Development of the IAHPC Opioid Essential Prescription Package, *Journal of Palliative Medicine*, Volume 15, Number 2, Copyright © Mary Ann Liebert, Inc. 2012, with permission from Mary Ann Liebert, Inc.

The selection of the medications for the IAHPC List of Essential Medicines for Palliative Care and in the OEPP is consistent with different clinical guidelines and critical reviews in symptom management (Hanks et al., 2001; Davis et al., 2005).

A significant percentage of participants in both projects reported problems with availability and access of medications, especially opioids. Challenges in the provision of pain treatment in many developing countries are complex and include poverty; illiteracy; language barriers; limited health-care resources; lack of training; and unnecessarily restrictive laws and regulations which limit the distribution, prescription, dispensation, and use of controlled medications (Joranson and Ryan, 2007; Human Rights Watch, 2009). In some countries, more expensive medications and formulations become available before cheaper medications or formulations. In response to this situation, the IAHPC included a footnote in the List of Essential Medicines for Palliative care, stating that no government should approve modified-release morphine, fentanyl, or oxycodone without also guaranteeing the availability of immediate-release oral morphine.

The IAHPC List of Essential Medicines in Palliative Care and the OEPP are not directives, but rather are offered for guidance. In order for these resources to be useful, it is necessary that:

◆ physicians, nurses, pharmacists, and students in these disciplines are taught how to use these medicines in palliative care

◆ the medicines are available and accessible

◆ they are part of a broad palliative care strategy, both at the institutional and national levels.

Limitations of these studies

Both studies have several limitations:

◆ Participants were selected from convenience samples.

◆ The final results were based on consensus expert opinion. Additional research to evaluate the safety and efficacy of these medications needs to be carried out.

◆ These projects did not address cost and affordability issues—this is work that is needed.

◆ The list was developed for adult patients—a list for children with palliative care needs is urgent and should be developed.

Dissemination and future work

As the holder of the copyrights to the IAHPC List of Essential Medicines for Palliative Care and the OEPP, the IAHPC grants permission to all those interested in reproducing and using both resources as educational and advocacy tools to promote access to medicines and palliative care. It especially encourages use of the list and the OEPP as models for countries in which there currently is limited availability of drugs as well as those which are developing national palliative medication lists tailored to local needs and resources.

IAHPC distributed the List of Essential Medicines for Palliative Care and the OEPP to editors in different journals requesting them to announce and disseminate them.

The IAHPC will conduct a review and update of the List of Essential Medicines for Palliative Care in 2015 taking into account new evidence on safety and efficacy of medications, as well as new formulations which have since become available.

Further work is also needed to update the OEPP to establish a recommended type and dose of laxative, as well as a dosing schedule for metoclopramide and to compare the use of these medications on outcomes such as symptom prevalence and intensity, improvements in patient compliance, and reduction of adverse effects.

The IAHPC OEPP is designed for moderate to severe chronic pain in adult patients who require initiation of strong opioids. Further work is needed to examine the effectiveness of the OEPP compared to usual care in reducing adverse effects and improving tolerability of opioid treatment, leading to better pain management.

Recent Developments

Two important developments occurred recently which have global implications: In 2013, a section with medicines for pain and palliative care was included in both WHO Model Lists of Essential Medicines for adults (EML) and for children (EMLc) following an application of the IAHPC. (WHO EML 20013, WHO EMLc 2013). And in 2014 the World Health Assembly adopted a PC resolution which among other things, calls on governments to update national EM lists, in the light of the changes in the WHO EML (WHA 2014).

1.4

Policy in palliative care

David C. Currow and Stein Kaasa

Hospice and palliative care

Hospice and palliative care services have developed in very different ways around the world due to local experts (and their networks of colleagues), differing health and social systems, differing sources of funding, and different perceptions of needs by the communities served by these services. In the 1950s, 1960s, and 1970s much of the developmental stage of hospice and palliative care around the world was as a counterculture, explicitly outside the normal health system policy and planning processes (Clark, 2000). It is doubtful that any country in the world has commenced hospice or palliative care services in response to well-formed national policies with an adequately funded planning and development phase. Instead, most settings have built hospice/palliative care on the momentum of visionary clinicians and funders who have responded to perceived needs from health-care providers, patients, families, and the communities in which they live. This background is important, because it places in context the work that is being done at pan-national, national, and sub-national levels to create effective policies that can further the key work of hospice/palliative care long after services have commenced and, often, after a large number of apparently unconnected local services have been well established.

Policy considerations—general

National policy initiatives reflect the breadth of service provision, the diversity of service delivery models (in response to local funding and broader health service provision models in health and social services), and the basic philosophies about life, death, and care in the communities in which the services have been built. In some specific cases, policy generation (and any accompanying legislation or regulation) may also reflect specific political imperatives at particular time points in a jurisdictional environment.

A fundamental aim of good government is to develop and implement policy that optimizes the well-being of its citizens. Given the universal nature of death, and the increasing prevalence of 'expected' death from chronic, progressive conditions, it should be expected that there are policies and even legislation that ensure good care is given to people at the end of life. Such policy must be informed by the best possible data, and seek to understand explicitly the needs of people at the end of life and their caregivers in order to generate the best possible frameworks for care delivery and support.

Policy in health and social services reflects the complex political processes that underpin priorities and the subsequent responses that may or may not include budgetary allocation and changes to legislation, regulations, or both. In most settings around the world, formulation of health policy is variously shared between politicians, professional organizations (such as medical and nursing societies), patient organizations, public servants, and the general society. In some cases, policy is driven by a political imperative and at other times by public servants or other bodies presenting key issues to their government, with proposals to prioritize a particular issue and on how best to prosecute the issue in public policy. In most settings, this makes for a dynamic process of tacit or overt negotiation between the political and operational arms of government.

Any policy is a series of compromises: there are always competing interests that will help shape the final results. The factors that influence policy are not always explicit and may relate, at times, to policy initiatives that are seemingly unrelated. Tracing such processes is almost impossible. Changes in health-care policy will often take time, and consistent work is often needed to generate and sustain any change in direction.

At times, there may also be differences in the approach between various levels of government and public administration within the same country. This may lead to differences in policies and documents that may be difficult to reconcile. Vested interests abound in bringing together the wide variety of opinions that help to inform any societal policy, given the increasing plurality seen in many communities around the world.

Policy that relates to health service delivery will have significant pressure exerted on it, depending on the funding models that are used to pay for health care. Private practitioners operating on a fee-for-service basis may bring very different pressures to negotiations than a health system where payment is primarily through capitation. Financial gains and losses are powerful factors in influencing policy and hence referral from one clinical service to another.

Health policy—palliative care

There are particular challenges in forming public policy on hospice/palliative care, and especially the end-of-life component. In so many ways, such conversations go to the very heart of existential beliefs and how these beliefs are manifest in the day-to-day lives of individuals and of whole communities. How individuals and groups within communities view death will have influence on the policies that are put in place for hospice/palliative care.

Accommodating widely varying and, at times, diametrically opposed views is a key challenge in the development of any relevant public policy that will actually have meaning in helping to shape the care provided in such communities. The spectrum of beliefs is wide: at one extreme there may be a belief that any life is sacred in and of itself, even in a vegetative state; the other extreme is that life can only be enjoyed if there is little or no compromise

to physical and psychological well-being. The number of variations along this spectrum makes any public policy in this area incredibly difficult to generate in a way that all people are satisfied. First and foremost, good public policy is about ensuring that the well-being of all people, including the weak and voiceless, is respected and protected. This often does not, in itself, deliver policy that will necessarily please every lobby group, but it is a crucial tenet around which to build strong public policy. Depending upon the society, the basic values held by the community, the economic strength of that community, and the health-care system in which hospice/palliative care services are being built are among other intrinsic factors which influence priorities between treatments: cure, life prolongation, or relief of symptoms at the end-of-life care. Such priorities may be challenging for developing good end-of-life care. For example, in many health systems, the drivers to invest in marginal life prolongations seem to be many with economic, marketing, and professional pressures all influencing the ultimate policy decision.

'Patients' voices'

The voice of the community in democratic societies helps to inform health policies including end-of-life care. A key challenge in hospice/palliative care is the lack of an effective patient voice. People at the end of life can rarely find the sustained voice needed to truly influence public policy. Caregivers for people at the end of life are working tirelessly to provide care for the person with the life-limiting illness. After the care recipient dies, many caregivers are unable to devote significant time and energy to advocacy. Often this leaves professional bodies in the role of social advocates, with the inherent concern that there may be an element of self-interest in the requests being made by health professionals, seemingly on behalf of their patients.

The almost absent voice of consumers in service development means that in the public discourse of policy development, it is easy to drown out key views and values that are important to people with life-limiting illnesses and their caregivers. Simply asking the well population what they would like at the end of life is unlikely to be sufficient, and may lead to policy that is not congruent with the wishes of people actually facing an advanced, progressive, life-limiting illness. By definition, such a lack of advocacy is likely to continue to be there, and finding ways of respectfully but adequately consulting people at the end of life about such policy remains an ongoing challenge.

Policy documents

Several key initiatives are underway around the world to improve the quality of care and to provide stronger data to inform policy. Initiatives across the globe are each seeking to have a stronger framework to reflect the feedback of the actual experience of patients and caregivers (Barbera et al., 2010; Bausewein et al., 2010; Eagar et al., 2010; Payne and the EAPC Task Force on Family Carers, 2010a, 2010b; Kamal et al., 2011; Casarett et al., 2012; Centeno et al., 2013).

From evidence-based medicine to evidence-based practice

Evidence-based public policy is as important as evidence-based clinical practice, and where sufficient evidence is not available, it

Table 1.4.1 From evidence-based medicine to evidence-based practice

Step 1	Literature reviews ± Review of best practice
Step II	International/national guidelines
Step III	Clinical care pathway(s)
Step IV	Audit/assessment of outcomes(s)

is imperative that adequate research is done to understand the net effects (benefits and harms) not just with highly motivated clinicians who are willing to participate in such studies, but in 'greenfield' hospice/palliative care sites that are not particularly invested in the process. Further, after implementation, sufficient resources need to be invested in the ongoing evaluation of the training required, the uptake, and the outcomes using prospectively collected data with specific questions about the performance of the programme as well as seeking signals of any untoward or unintended consequences, as part of a learning health-care system (Basch and Abernethy, 2011).

Ideally good public policy is informed by the best available evidence, not simply political expediency (Loman, 2000; Alliance for Health Policy and Systems Research, 2007; Head, 2007; Banks, 2009; Brownson et al., 2009; Gluckman, 2011) A formal structure applied in several areas of medicine may also be applied in palliative care (Table 1.4.1). Step II and step III should ideally be endorsed by national or regional health-care authorities in order to assure the allocation of sufficient resources to implement the pathways and evaluate the pathways' impacts on health outcomes. This assessment must include the effectiveness of introducing these measures, levels of adherence to the pathways, and reasons for non-adherence or poor uptake. Ideally the effect/outcomes on patient care before and after the introduction of a pathway should be prospectively assessed. This assessment can be conducted at patient level but also through pre-defined quality indicators at institutional, regional, and/or national level.

For example, the wide uptake into health policy of the Liverpool Care Pathway (LCP) with all of its strengths and weaknesses deserves careful exploration (Currow and Abernethy, 2014). What was the level of evidence that was available to policymakers as they mandated uptake of the LCP across the health system in the United Kingdom? It could be argued that there was no level II or level I evidence, and the generalizability from the studies which had been reported by the time of the initial decision to mandate widespread uptake were not sufficient to ensure that the net effects of the LCP were known (Costantini et al., 2014). The UK government has subsequently taken the step not to recommend the use of the LCP in the United Kingdom at this time. This decision itself has sparked debate (The Lancet Oncology, 2013).

The World Health Organization and hospice/palliative care policy

Policy documents reveal the wide range of responsibilities and mandates of health and social services around the world. This section presents an overview of a sample of international and national

policy documents that relate to hospice/palliative care. The list is not exhaustive, but serves to illustrate the issues frequently seen in health policy relating to end-of-life care.

The WHO most recently published its 'Knowledge into Action: WHO Guide for Effective Programmes' modules in which palliative care sits under 'Cancer Control' (WHO, 2007). The overarching aim of the document is to 'reduce unnecessary suffering of patients and their families'. In this, palliative care is embedded as one key aspect of cancer control although the palliative care aspects of the document are not limited to people with the diagnosis of cancer. The palliative care module contains three steps for planning strategically to improve hospice/palliative care:

◆ understanding the current context of palliative care

◆ determining where a programme wants to be within the next 5 years

◆ mapping out ways to achieve this outcome.

In policy terms, the WHO document frames hospice/palliative care in the context of the humanitarian needs that must be met. Internationally, this then defines the greatest needs as those of low- and medium-resource level countries where the highest proportion of patients present with advanced disease, and hence where little can be done to modify the course of the life-limiting illness. Emphasis is placed on the integration of hospice/palliative care into the existing health system whether in the public or private sector, rather than creating a parallel system of care, with an understandable focus on community and home-based care. Explicitly, the document outlines the need to adapt these three principles in ways that respect the cultural, social, and economic settings in which the care is being delivered. The document also reflects the need to cover all age groups including children. Interestingly, one key message from the document is that palliation should be linked to other aspects of the continuum of cancer control: prevention, early detection, and treatment services. The WHO document also clearly states that hospice/palliative care services should be able to work alongside therapies that may improve prognosis, such as chemotherapy or radiotherapy in the case of cancer.

Adopting a public health approach to palliative care was the framework deliberately chosen by the WHO as far back as 1996 (Stjernswärd et al., 1996). The three key elements outlined in a public health approach were:

◆ a government policy ensuring integration with other health services

◆ an education policy spanning health-care workers (including volunteers) and the public

◆ a medication policy that ensured the availability of essential medications (see Chapter 2.3).

These key elements are based on work defining the greatest perceived needs of people at the end of life from work done by the WHO: pain relief, accessible and affordable medications, and financial support. The WHO guide also outlines the aspirational goal of having 80% of all people who die from cancer seen by a palliative care service (and 60–80% of people dying from AIDS). Of note, the WHO guide includes an outline of the need for adequate information systems to complement physical, human, and financial resources for a comprehensive programme. The need for protocols, guidelines, and standards are also integral to successful programmes.

Accompanying the principles just outlined, the WHO guide provides a step-by-step process of planning, implementing, and evaluating a hospice/palliative care programme at a national level. This guidance encourages national policies explicitly to take into account the financial, cultural, and ethical context in which the programme is going to exist.

The WHO has in place an important framework that can influence policy at national and sub-national levels but there is no direct effector arm. The care of people at the end of life and the way that care is delivered through policy, associated funding models, and the other resources made available are beyond the jurisdiction of the WHO/United Nations. Although the WHO guide is a seminal document, it has no direct mandate in jurisdictions that choose to ignore it.

Country- state-, and topic-specific examples

The following subsections do not exhaustively outline every national policy document that has been published, but seek instead to reflect on aspects of several national policy documents or legislation in order to highlight key aspects that illustrate the breadth and complexity of public policy in any setting.

Most have themes that fit broadly with the year 2000 Australian *National Palliative Care Strategy: A National Framework for Palliative Care Service Development* which include:

◆ raising awareness and understanding about palliative care

◆ improving the quality and effectiveness services

◆ enhancing partnerships between service providers (Anonymous 2000).

By way of integration of policy, these principles are then reflected in other key national strategy documents: the *National Chronic Disease Strategy*; the *National Service Improvement Framework for Cancer*; and the *National Service Improvement Framework for Heart, Stroke and Vascular Disease* (Dowrick, 2006).

Country-specific example: the United States

Internationally, a watershed moment was in the early 1980s when the United States passed legislation to include an explicit payment provision for hospice care in the 1982 Tax Equity and Fiscal Responsibility Act. This allowed for a per diem payment for people who had limited prognosis and were eligible for Medicare payments. An act by any legislature is the mechanism that enshrines policy in the most overt way. As this Act had a sunset clause of 1986, the Congress replaced it permanently with a Medicare Hospice Benefit that year (Miller and Mike, 1995). This was a world-first legislation in recognizing the needs of people at the end of life and the care they required.

There were arguably two effects from this landmark legislation by the United States: it enshrined hospice/palliative care in law which was a positive outcome; but because it was a legislated per diem payment that was limited to the last 6 months of life, it may have limited referral to hospice services to later in the disease trajectory than intended (Christakis and Iwashyna, 2003). The legislation did not index the payment, thereby also potentially subsequently limiting the care that could be purchased in later years.

Country-specific example: Norway

The development of palliative care in Norway, as in many other countries has an evolutionary pattern. It started from the late

1970s with the establishment of informal palliative care groups in most health regions in the country. The primary goal of these groups was to inform, promote, and teach about palliative care at a local level. The needs were seen from the patients' and health-care pioneers' points of view. This first phase can be categorized as an 'information and policymaking phase'. Key politicians locally and nationally were approached with the aim to build a more formal platform for palliative care.

This process culminated in a national governmental report on care for dying patients in 1984 (Official Norwegian Reports, 1984). This report recommended establishing institutional sites. The governmental report from 1984 was used actively by the health-care providers in the field of palliative care to promote the need for establishing the combined academic and clinical units. It took almost 10 years (1993) to establish the first academic palliative care unit in Trondheim. It was established within the Department of Oncology at the Trondheim University Hospital with a full-time professor. Simultaneously, patient care was established in the Oslo region and in Bergen. In this process a non-governmental organization (NGO)—the Norwegian Cancer Society—was involved and, through a major grant to the Trondheim University Hospital, the professorial chair was funded for 5 years with an agreement that the university (the public health-care system) should continue to pay for this position after this time. The Norwegian Cancer Society also paid for the establishment of an inpatient unit at the Trondheim University Hospital at the same time.

This is an example of the use of a government report, involvement by an NGO and consistent policy work by health-care providers succeeding in developing palliative care in the country. Such an investment provided impetus for a second national government report in the form of a national cancer plan (Official Norwegian Reports, 1997) which included recommendations on the future development of palliative care and a report on care for the dying which was released in 1999 (Official Norwegian Reports, 1999).

Public health-care in Norway is fully paid for by the government. The financial system is based upon a basic payment of approximately 50% and a diagnosed-related group (DRG) by the remaining 50%. In order to further develop palliative care, a special DRG was established to make it economically feasible for health-care institutions to establish palliative care teams in hospitals and also community outreach teams. The DRG was followed by national standards on how to organize palliative care in teaching and local hospitals, as well as in community care. This combination of an official national policy on how to organize palliative care matched by DRG-based funding mechanisms had a catalytic effect on the development of clinical palliative care across Norway.

Country-specific example: Germany

In Germany, palliative care has developed rapidly since the establishment of the first palliative care unit in 1983 and the first inpatient hospice in 1986, using a two-pronged approach. Palliative care pioneers worked within the health-care system, while hospice care was established as a community-based citizens' movement, with a major focus on volunteers. Despite some conflicts between these two tiers (e.g. warning against a medicalization of palliative care), both approaches now collaborate and have succeeded in integrating palliative and hospice care in the health-care system. This is evident not only from the large and still increasing number of specialist inpatient and outpatient services (195 inpatient hospices and 231 palliative care units in hospitals in 2011, 1500 home care services with volunteers), but also from the establishment of academic palliative care departments across the country (Aachen, Bonn, Cologne, Erlangen, Freiburg, Göttingen, Mainz, München, and Münster).

Recently, medical education in palliative medicine has been incorporated as an integral part of medical studies at German universities. As part of national policy, starting in 2014, physicians applying for a licence to practise medicine will have to provide a certificate of basic training in palliative medicine—a world first. A challenge in upcoming years will be establishing and enhancing comprehensive, standardized, and quality-controlled education within universities.

Only minimal requirements are legislatively specified for education of nurses in palliative care. However, standardized and quality-controlled advanced training courses are available. This training is more frequently being requested as a prerequisite for nurses working in palliative care.

Changes in the legislation have influenced the situation for home care enormously in the last 5 years, also making it more complex. With the Law for the Consolidation of the Competition in Compulsory Health Insurance (Gesetz zur Stärkung des Wettbewerbs in der gesetzlichen Krankenversicherung), a legal claim for palliative home care has been implemented in the fifth book of the social law in 2007. The ambitious goal of full coverage with comprehensive palliative home care has still not been achieved in most locations. However, after initial negotiation difficulties between palliative care providers and health insurance funds, an increasing number of contracts have been signed. As a consequence, more than 100 palliative care teams have begun work in the field of specialized palliative home care. Legal regulations for the supply of opioids and other medications for the treatment of patients at home have been adapted recently, thus, facilitating faster and more comprehensive medical treatment in emergency situations. Volunteer hospice services receive reimbursements for payment of the coordinators from the sickness funds. Overall, the legislation has been adapted significantly, contributing to improvements for patients requiring palliative care.

Even though hospice and palliative care is gaining increasing acknowledgement from political stakeholders, a national strategy on palliative and hospice care is still lacking. The German Association for Palliative Care in collaboration with the German Hospice Association and the German Medical Association has produced the 'Charter for the Care of Severely Ill and Dying Patients in Germany' as the German contribution to the Budapest Commitments, and is currently using this charter as the basis for the development of a national strategy. A research agenda for palliative care has also been commissioned by the Leopoldina German Academy of Science and will be published in 2014.

Country-specific example: Canada

Canada continues to be a leader in hospice/palliative care, in part because of a strong policy framework that has underpinned the development of services and the environment within which those services operate. Canada has not only set up a national strategy on palliative and end-of-life care, but has also publically evaluated it in a way that allows others to learn from it (Anonymous, 2007). In the life of that strategy, five working groups were established

and each took forward a work programme which was coordinated with the other groups. They were:

- Best practices and quality care working group
- Education for formal caregivers working group
- Public information and awareness working group
- Research working group
- Surveillance working group.

These groups cover the full spectrum of hospice/palliative care public policy. Of particular note, the last group was charged with the role of developing a system for collecting and utilizing information about palliative and end-of-life care. The two key foci were *who used services* and *how the quality of those services could be systematically measured*. A whole-of-government approach utilizing existing organizations charged with understanding the measurement and reporting of the health system were engaged in the process. A key outcome of such far-reaching policy work was an inventory of performance measures in palliative and end-of-life care. The outputs also included a standard dataset to be collected on palliative care patients across participating services, complementing the work done by the *Best practices and quality care working group*.

The importance of a public awareness arm of any policy should not be overlooked. The programme of this working group encompassed the processes of both understanding what Canadians knew and thought about palliative and end-of-life care and, from that, what key messages needed to be more widely understood. This group also took explicit responsibility for the informational needs for family and friends as caregivers.

Country-specific example: New Zealand
New Zealand published a review of its government's policies regarding palliative and end-of-life care (Anonymous, 2010). It highlights many of the fundamental challenges of any policy: how was it implemented and how have outcomes been measured? Although there are no issues that are unique to any one jurisdiction, the challenges faced by New Zealand bring into sharp focus the issues of the social determinants of health and the impact that socioeconomic status still manifests at the end of life (Currow, 2009). In public policy, such recognition is crucial as, reproducibly across the globe, people from rural areas, the socioeconomically disadvantaged, people from first nations, and those whose birth place was not their country of residence, especially if the language is different, have poorer health outcomes, even at the end of life. Principles espoused in the policy include universal access to hospice/palliative care services irrespective of diagnosis and geography. Importantly, documents from New Zealand also do not limit access by prognosis.

The document highlights that, despite substantial investments by governments, measures have not been agreed universally for the evaluation of the impact of hospice/palliative care services. As such, data to evaluate the impact of a national approach are not available and become a key priority for the next iteration of a national approach to improving access and uptake of hospice/palliative care by moving towards 'an outcomes focused monitoring and evaluation framework'. The stated aim of 'a systematic and informed approach to the provision and funding of palliative care services' is challenging to achieve without measures being routinely collected and analysed. Without a specific investment in measuring performance, it will continue to be difficult to understand fully the benefits of the national policy.

The first national strategy was put in place in 2001 in New Zealand (Anonymous, 2001). A long-term commitment by funders and policymakers is required if the benefits of a more systematic approach to the availability and uptake of hospice/palliative care is going to be taken. Such a lead time should ideally see greater uptake into policy documents in areas that interface with hospice/palliative care and, arguably, is a key measure for the evaluation of the success of policy at the level of policymakers.

Country-specific example: Romania
In Romania, hospice/palliative care services are potentially in a position not encountered in some more resource-advantaged countries—the ability to build hospice/palliative care services strategically as an integral part of a rapidly evolving health system. Such services are a mixture of public, charitable, and for-profit services arising where key opinion leaders and communities have sought and developed local solutions. Payment models include per diem payments for inpatients and fee-for-service for community-based care.

The national strategy is refreshingly honest—each service develops relationship with referring services according to the local service's own strategy (Mosoiu, 2009). Although this happens right around the world, few policy documents reflect the status quo with such accuracy. Given resource constraints, the national strategy has limited itself to people 'whose disease is not responsive to curative treatment' (WHO, 1990) thus temporarily rejecting the broader definition adopted by the international agency in 2002 which included a broader timeframe across the disease trajectory. The timeframe for review of this Romania stance is set for 2020.

The principles around which the Romanian National Strategy document has been built have universal application:

- the need for services to meet the 'specific and distinctive needs of the people they are intended for'
- availability (including availability at times convenient to service users not just providers)
- accessibility (financial, geographic, language, and culture-related issues, spanning all tiers of educational ability)
- quality care
- providing true continuity of care
- in an economically sustainable way.

The implementation of such principles in any national or state/provincial setting is likely to lead to significantly improved services.

The document also candidly addresses the challenge of the interface between specialist and generalist services as more health professional devote themselves full time to palliative care practice. This leads to the challenges in continuity of care especially at times of transition between physical locations of care. In any health system this creates difficulties, but at the end of life such fractured service delivery is arguably even more counter-productive. Given the small number of services for a large population, the other challenge is to ensure that additional services are created in geographic areas where currently there is no coverage.

State-specific example: Kerala
Kerala, in India's south west, is a populous state with excellent levels of education and infrastructure. Its palliative care services are

examples of what can be achieved with high levels of commitment to local service delivery that is relevant, affordable, and patient centred. The programme of work, underpinned by a strong policy document, delivers a level of support that few would have thought possible three decades ago (Anonymous, 2008). The programme seeks to embrace both those who are dying and those with chronic conditions that would benefit from a palliative approach. Such population coverage requires the programme to be predominantly delivered by primary care. As such, palliative care was accorded 'priority status in public health and disease control programmes'. This enshrines the need to grow palliative care as an integral part of the health system and, unlike many countries with greater resources where palliative care will only be funded when everything else has been developed, it allows genuine integration of palliative care right across the spectrum of health service provision.

Ultimately the policies in Kerala set out a clear manifesto—good palliative care is everybody's business—from the most junior and least skilled health worker to the most highly trained specialist in any field of clinical endeavour. Care must be based around a person's home with their family and community providing care, supported by health professionals that are also locally based.

The policy also draws strongly on trained volunteers to achieve the immediate, medium-, and long-term aims of improving the well-being of people in the state by systematically decreasing suffering. Volunteers may not be paid, but their training and ongoing supervision requires explicit resources.

In policy, good palliative care delivery in the community also relies heavily on cross-sectoral support and cooperation. This requires governments, health services, professionals and their associated professional bodies, and community organizations to work closely together for a common goal. Each has a role not only in coordinating service delivery but also in building the capacity of the whole community, not just health professionals, to provide such care. This also requires close integration with other key policies in terms of cross-referencing and in prioritizing the available resources.

Topic-specific example: improving access to palliative care medications in Australia

There was a community imperative to improve community-based care in Australia. One key aspect of this was the availability of key symptom control medications in the community. At a policy level, such a process had to be completed within current legislative and regulatory frameworks (Rowett et al., 2009). A true whole-of-government, whole-of-community working party was established in 2002 to address this issue in the context of a national policy commitment to improve end-of-life care systematically.

The work was underpinned by a national survey to define medications essential to good palliation, the level of evidence underpinning such processes, and the current (subsidized) availability of the medication (Good et al., 2006). The survey identified many medications, most of which did not have sufficient evidence to support registration nor subsidy (comparative cost-effectiveness) applications. For those medications that were considered essential and did have sufficient evidence, a new section of the national subsidized formulary was created for palliative care patients. (In policy terms, this was the first patient-defined section of the formulary. Until that time it had always been defined in terms of the medications that different practitioners could prescribe. The

process has since been replicated in paediatrics and Aboriginal and Torres Strait Islander populations, demonstrating that good palliative care policy can positively influence policy in other parts of health.)

A work programme to improve systematically the evidence to inform prescribing has grown out of this work, with studies designed in consultation with regulatory and funding bodies to ensure the quality of the evidence will satisfy them if the studies are positive. Such national policy has collateral benefits around the world, given that phase III data are somewhat limited in their availability in hospice/palliative care. A national policy that community-based medications become more available has led to a number of benefits to patients including better evidence for how to use key medications in helping to relieve suffering in people with life-limiting illnesses.

Policy and hospice/palliative care

Ultimately, successfully developing hospice/palliative care services requires every level of government, funders, and the community to develop and support policies that can ensure the widest reach of services, and the most equitable distribution of limited resources. This requires the development and maintenance of close ties with existing health and social policymakers and funders. Building on international, national, and sub-national initiatives is delivering improved access to hospice/palliative care services around the globe.

SECTION 2

The challenge of palliative medicine

The problem of suffering and the principles of assessment in palliative medicine

Nathan I. Cherny

Introduction to the problem of suffering and the principles of assessment in palliative medicine

Despite the advances of modern medicine, many illnesses continue to evade cure. Chronic, progressive, incurable illness is a major cause of disability, distress, suffering, and, ultimately, death. This is true for many causes of cancer, progressive neurological disorders, AIDS, and other disorders of vital organs. Progressive chronic diseases of this ilk are most common in late adulthood and old age, but they occur in all ages.

When cure is not possible, as often it is not, the relief of suffering is the cardinal goal of medicine. Recognition of this axiom is at the heart of the philosophy, science, and practice of palliative medicine.

Understanding suffering

For the patient with incurable illnesses such as cancer, the goals of care may be stated as the alleviation of suffering, the optimization of quality of life until death ensues, and the provision of comfort in death (Wanzer et al., 1989; Duggleby and Berry, 2005). Persistent suffering that is inadequately relieved (or the anticipation of this situation) undermines, for the sufferer, the value of life. Without hope that this situation will be relieved, patients, their families, and professional health-care providers may see elective death by suicide, euthanasia, or assisted suicide as their only alternatives. The truth of the perception that patients need to be killed or assisted to kill themselves to be adequately relieved of suffering depends upon the adequacy of the available measures to relieve suffering. The essence of the controversy is the problem of suffering.

The alleviation of suffering is universally acknowledged as a cardinal goal of medical care (Angell, 1982; President's Commission for the Study of Ethical Problems in Medical and Biomedical and Behavioral Research, 1983; Wanzer et al., 1989; Roy, 1991, 1993; American Nurses Association Center for Ethics and Human Rights Task Force on the Nurse's Role in End-of-Life Decisions, 1992; American Medical Association, 1996; Rich, 2001; Snyder and Leffler, 2005). The ability to formulate a response to the challenge of suffering requires a clinically relevant understanding of the nature of the problem.

A conceptual framework for suffering

Suffering can be defined as an aversive experience characterized by the perception of personal distress that is generated by adverse factors that undermine quality of life (Cassell, 1982, 1991; Saunders, 1984; Cherny et al., 1994a; Krikorian et al., 2012). The defining characteristics of suffering include (1) the presence of perceptual capacity (sentience), (2) that the factors undermining quality of life are appraised as distressing, and (3) that the experience is aversive. According to this definition, suffering is a phenomenon of conscious human existence, the intensity of which is determined by the number and severity of the factors reducing quality of life, the processes of appraisal, and perception. Each of these variables is amenable to therapeutic interventions.

The encounter with terminal illness is a potential cause of great distress to patients, their families, and the professional caregivers attending them. Among patients with incurable illness, significant pain and numerous other physical symptoms can diminish the patient's quality of life. Furthermore, many patients endure enormous psychological distress, and in some cases, form an existential perspective that, even without pain or other physical symptoms, continued life may be without meaning. For the families and loved ones of patients there is, likewise, great distress in this process: anticipated loss, standing witness to the physical and emotional distress of the patient, and bearing the burdens of care. Finally, professional caregivers may potentially be stressed by the suffering which they witness and which challenges their clinical and emotional resources. According to this model (Cherny et al., 1994a), the suffering of each of these three groups is inextricably interrelated such that the perceived distress of any one of these three groups may amplify the distress of the others (Fig. 2.1.1); this has been called reciprocal suffering (Wittenberg-Lyles et al., 2011).

Suffering, personal growth, and resilience

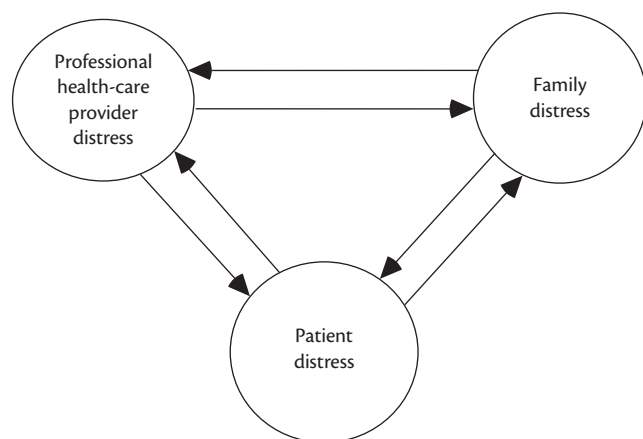
The potential for personal development and net positive gain in overcoming situations of adversity and suffering is widely recognized and it is often referred to as post-traumatic growth (Block,


Fig. 2.1.1 The interrelationship between the distress of the patient, the family, and the health-care providers.

2001; Hefferon et al., 2009). This potential, however, is predicated on the ability to cope with the prevailing problems and challenges. It is the phenomenon of coping that generates the potential for growth and reward (Lazarus, 1985; Folkman et al., 1986; Block, 2001). Coping does not occur if the demands of the situation *are* overwhelming (as distinct from merely being appraised as overwhelming). For example, the patient with inadequately relieved pain, shortness of breath, or vomiting may be absolutely unable to address issues related to his offspring and spouse. The spouse and offspring who are overwhelmed by problems of daily care requirements may be absolutely unable to appreciate time with the patient.

Suffering in chronic debilitating illness cannot be eliminated, but if adequate relief is achieved then coping and growth can occur. By understanding and addressing the factors that may potentially overwhelm the patient, family, and health-care providers, the necessary preconditions for coping and growth are established. Intervention programmes focusing on mindfulness, healing arts, and spiritual care can facilitate post-traumatic growth of this sort (Block, 2001; Garland et al., 2007).

The potential for growth and adaptation are related to the quality and process of resilience (Hefferon et al., 2009). Resilience is the capacity of an individual person or a social system to grow and to develop in the face of very difficult circumstances (Vanistendael, 1996; Woodgate, 1999; Lloyd, 2006). The situational challenges may trigger the development of hitherto hidden or poorly developed resources and strengths in a person, triggering a process of personal development and growth.

Resilience is not limited to victims and patients, but also to their families and friends, and to the staff providing care. Resilience has several important attributes: resilience is not an absolute; rather it is a relative personal attribute which may vary over time. It consists of dimensions of resistance to adversity and the ability to make constructive adaptation. This latter characteristic implies the capacity to transform a negative event into an element of growth. It is important to emphasize that resilience does not ignore the need to deal with problems and negative situations: it involves processes of grieving and negative emotions such as sadness and fear but also involves looking for positive elements to (re) build life. Resilience does not invoke denial, but, rather, a realistic

appraisal that is not exclusively focused on problems and which recognizes and identifies positive opportunities (Woodgate, 1999; Lloyd, 2006).

Relieving suffering: a right

It is widely held that terminally ill patients have a right to adequate relief of uncontrolled suffering (Brennan, 2007; Gwyther et al., 2009). Indeed, the World Health Organization asserts that the relief of pain and other symptoms is a right of the patient with advanced and incurable cancer (World Health Organization, 1996) and the right to the adequate provision of palliative care for the terminally ill has been ratified by a host of medical societies and professional organizations. The right has legal status recognized by the Supreme Court of the United States (Burt, 1997) and an Israeli statute law defining the rights of the dying (Steinberg and Sprung, 2006).

The corollary of this right is the responsibility of caregivers to ensure that adequate provisions are made for relief. The formulation of a therapeutic response to suffering, however, requires an understanding of the phenomenon of suffering and of the factors that contribute to it. Indeed, the failure to appreciate, or to effectively address, the full diversity of contributing factors may confound effective therapeutic strategies (Krikorian et al., 2012).

Patient distress

Physical symptoms

Among patients with advanced incurable illness, physical symptoms are common—they are often multiple and they cause a variable degree of distress (Kirkova et al., 2010b; Seng Beng et al., 2013) (see Section 8).

Among patients with advanced cancer, 70–90% will have significant pain that requires the use of opioid drugs (van den Beuken-van Everdingen et al., 2007). Persistent pain interferes with the ability to eat (Feuz and Rapin, 1994), sleep (Hugel et al., 2004), think, interact with others (Ferrell, 1995), and is correlated with fatigue (Burrows et al., 1998), depression, and anxiety (Mystakidou et al., 2006). The prevalence of symptoms other than pain in the advanced cancer patient has been well documented in the hospice and palliative care literature (Teunissen et al., 2007). Symptoms often appear to cluster and indeed several common patterns of symptom clusters have been recognized including one cluster of nausea–vomiting, anxiety–depression, fatigue–drowsiness, and pain–constipation, and another of nausea–vomiting, anxiety–depression, and dyspnoea–cough (Kirkova et al., 2010a, 2011). Multiple, concurrent physical symptoms are common during the last weeks of life with a particularly high prevalence of fatigue and generalized weakness (Chang et al., 2000), and in the last few days of life dyspnoea, delirium, nausea and vomiting are most common (Reuben et al., 1988; Coyle, 1990; Lichter and Hunt, 1990; Ventafridda et al., 1990; Fainsinger et al., 1991; Henteleff, 1991; Johanson, 1991).

The data on the prevalence of physical symptoms among children with advanced and incurable cancer are similarly dramatic. In a Swedish survey of the parents of dying children, the symptoms which had a moderate or high impact on the child's well-being were physical fatigue (86%), reduced mobility (76%), pain (73%), and decreased appetite (71%) (Jalmsell et al., 2006). Findings from

an English survey were similar: pain was observed in 71–92% of children and the other major symptoms were anorexia, weight loss, and weakness (Goldman et al., 2006).

The symptoms at the end of life in disease other than cancer are remarkably similar to those experienced by cancer patients (Janssen et al., 2008a, 2008b). In a study that evaluated the relative prevalence of 11 common symptoms (pain, depression, anxiety, confusion, fatigue, dyspnoea, insomnia, nausea, constipation, diarrhoea, and anorexia) among end-stage patients suffering from five common, chronic, and progressive diseases (cancer, AIDS, heart disease, chronic obstructive pulmonary disease (COPD), and renal disease), three symptoms—pain, breathlessness, and fatigue—were found among more than 50% of patients, for all five diseases. The great similarity in the spectrum of symptoms seen across all illness groups suggests that there are a number of common symptoms found as patients approach death in in both malignant and non-malignant chronic illnesses (Solano et al., 2006).

Psychological symptoms

Anxiety, depression, confusion, and insomnia are all common problems in cancer and non-cancer-related chronic terminal diseases including COPD, renal failure, and heart failure (Solano et al., 2006) (see Section 17).

Among cancer patients, the prevalence of psychiatric distress is variably estimated from 12% (Kadan-Lottick et al., 2005), 40% (Grabsch et al., 2006), to upwards of 60% of patients with far advanced cancer (Breitbart et al., 1995; Breitbart and Jacobsen, 1996). Whatever the prevalence, there is agreement that the most common problems are adjustment disorders, depression, anxiety, and delirium (Portenoy et al., 1994; Breitbart and Jacobsen, 1996; Grabsch et al., 2006; Strong et al., 2007; Annunziata et al., 2012). All four of these symptoms may contribute to the development of suicidal thoughts, and indeed, psychiatric disorders are present in the vast majority of cancer patients who are suicidal (Breitbart, 1988; Breitbart et al., 2010).

Factors that adversely influence the prevalence and severity of psychological distress are the presence of advanced disease; distressing physical symptoms (especially pain) (Derogatis et al., 1983; Mystakidou et al., 2006); disability; unresolved previous experiences of loss or separation (Nordin et al., 2001); feelings of frustration and hopelessness (Nordin et al., 2001); a lack of perceived support from at least one loved person (Stedeford, 1984); strained interpersonal relationships (Stedeford, 1984); controlling personality trait (Watson et al., 1990); difficulties in adapting to the illness and its implications (Farberow et al., 1963); economic concerns (Hanratty et al., 2007; Sharp et al., 2012); impaired cognitive abilities (Nordin et al., 2001); and unsatisfactory communication regarding illness or treatment (particularly where there has been the precipitous disclosure of poor prognosis without allowance for a process of adjustment and assimilation of information) (Mager and Andrykowski, 2002). Uncontrolled pain is an important precipitant of psychological distress and is a suicide risk factor (Laird et al., 2009; Breitbart et al., 2010). In a large prospective study of psychological symptoms in cancer patients (Derogatis et al., 1983), the prevalence of cancer-related pain was 39% in those who had a psychiatric diagnosis and only 19% in those without such a diagnosis. Indeed, it has been observed that psychiatric symptoms commonly resolve with adequate pain relief (Mystakidou et al., 2006).

Spiritual and existential distress

The importance of spirituality in care of the dying is increasingly acknowledged by clinicians, researchers, and educators in end-of-life care. The Institute of Medicine (Field and Cassel, 1997) lists spiritual well-being as one of six domains of quality supportive care of the dying. Consequentially, exploring this dimension of well-being is an important part of routine physician inquiry, especially among patients with advanced and incurable illness (Ambuel, 2003; Pearce et al., 2012; Seng Beng et al., 2013) (see Chapter 17.1).

Defining existential issues such as spirituality is challenging and definitions abound. One comprehensive review of the health literature documented 92 definitions of the term 'spirituality' (Unruh et al., 2002). This review identified seven definitional themes: relationship to God, a spiritual being, a higher power, or a reality greater than the self; not of the self; transcendence or connectedness to a bigger picture but unrelated to a belief in a higher being; a conviction that there is more to life than what we can observe materially; meaning and purpose in life; life force of the person, integrating aspects of the person; and summative definitions that combined multiple themes. In another interesting study that evaluated Buddhist and Christian terminally ill patients in Taiwan (Chao et al., 2002), ten themes in four broad categories emerged: communion with self (self-identity, wholeness, inner peace); communion with others (love, reconciliation); communion with nature (inspiration creativity); and communion with a higher being (faithfulness, hope, gratitude).

Positive connections to life around us inspire a conscious or unconscious perception that life has significance, purpose, and meaning. This is of practical consequence, particularly in the context of discovering or building connections. These connections may be with God, relations, projects, responsibilities, special objects, rituals, non-sectarian religion or philosophy, or even the shared appreciation of beauty, poetry, or music (Vanistendael, 2007). While the source of inspiration for such significance will vary from person to person, what they hold in common is their ability to imbue life with an overarching sense of purpose and meaning, including a sustained investment in life itself.

Within the religious world view, spirituality is usually associated with a sense of connectedness to a God, whereas within the secular realm, it often invokes a search for significance and meaning. According to Viktor Frankl, having a sense that one's life has meaning involves the conviction that one is fulfilling a unique role and purpose in life. He suggests that life is a gift that comes with a responsibility to live to one's full potential as a human being, and that through this process one can achieve a sense of peace, contentment, or even transcendence through connectedness with something greater than oneself. He describes central paths to fulfil one's potential as a human being through (1) involvement in creative or productive actions, (2) life experience, and (3) connectedness and love. Of these three paths he ascribes greatest importance to connectedness and love (Frankl, 1992).

Among patients with advanced cancer, unmet spiritual needs are common (Moadel et al., 1999; Pearce et al., 2012). One study of 248 cancer outpatients found that spiritual or existential needs were commonly unmet; common among them were overcoming fears (51%), finding hope (42%) and meaning in life (40%), finding spiritual resources (39%), and having someone to talk with about the meaning of life and death (25%) (Moadel et al., 1999).

The common existential issues for patients with advanced cancer include hopelessness, futility, meaninglessness, disappointment, remorse, death anxiety, and disruption of personal identity. Existential distresses may be related to past, present, or future concerns. Current personal integrity, the sense of who one is as a person, can be disrupted by changes in body image; somatic, intellectual, social and professional function; and in perceived attractiveness as a person and as a sexual partner (Cassell, 1982; Bolmsjo, 2000). For some patients retrospection can trigger profound disappointment (from unfulfilled aspirations or a depreciation of the value of previous achievements), or remorse from unresolved guilt (Yalom, 1980; Cassell, 1982; Bolmsjo, 2000).

If life is perceived to offer, at best, comfort in the setting of fading potency or, at worst, ongoing physical and emotional distress as days pass slowly until death, anticipation of the future may be associated with feelings of hopelessness, futility, or meaninglessness such that the patient sees no value in continuing to live. Death anxiety is common among cancer patients; surveys have shown that 50–80% of terminally ill patients have concerns or troubling thoughts about death, and that only a minority achieve an untroubled acceptance of death (Bolmsjo, 2000). Together, these symptoms have been labelled a 'demoralization syndrome' (Kissane et al., 2001).

More recent studies indicate that the same spectrum of spiritual distress is observed in patients suffering from chronic life-threatening diseases other than cancer (Selman et al., 2007; Haynes and Watt, 2008; Bekelman et al., 2009; Steinhauser et al., 2011). Although these existential issues are sometimes referred to as 'spiritual', they appear to be universal, and independent of religion and religious practice (Yalom, 1980; Kissane, 2000).

Family/social distress

The perception by the patient of the distress of family, friends, and health-care providers can further amplify the patient's distress, and thus contribute to the nihilistic conclusion that ongoing existence only constitutes a perpetuation of the burden to self and to others.

Family distress

The development of a chronic life-limiting illness in a family member impacts upon the entire family (King and Quill, 2006; Janssen et al., 2011; Seng Beng et al., 2013). The challenges confronting the family—to acknowledge the ending of life as they have known it, and to define a new way of constructively living out their final days together as best possible—engender great stresses (Davies et al., 1990; King and Quill, 2006). Among the contributing factors to the ensuing distress are empathic suffering with the distress of the patient; grief and bereavement; role changes; and the physical, financial, and psychological sequelae of the burdens of care (Wittenberg-Lyles et al., 2011; Seng Beng et al., 2013) (see Chapter 17.6).

Furthermore, the family carers of adults with advanced chronic illness have been shown to constitute a vulnerable population (Janssen et al., 2011). In one study, almost a quarter of the family caregivers for the terminally ill had chronic health problems themselves (West et al., 1986), and others have highlighted the further detriment to health incurred by family carers (Schachter, 1992). A very high prevalence of anxiety and adjustment difficulties have also been identified among family members, the severity of which is often as great as that of the patients themselves (Grov et al., 2005, 2006).

Family needs

The needs of the families of patients with advanced cancer (Kristjanson, 1989; Ferrell et al., 1991a, 1991b; Kristjanson et al., 1995, 1997a; Milberg and Strang, 2000; Steinhauser et al., 2000; Soothill et al., 2001; Scott et al., 2001; Funk et al., 2010; Stajduhar et al., 2010, 2011) and other chronic illnesses (Scott et al., 2001; Goy et al., 2008; Ben Natan et al., 2010) have been surveyed by several researchers. The prompt and effective relief of patient symptoms is a major priority for family members, as are the needs for education in the comfort care of the patient, and for physician and nursing availability (Kristjanson et al., 1997a; Steinhauser et al., 2000; Fridriksdottir et al., 2006; Funk et al., 2010; Stajduhar et al., 2010, 2011;). Families often express the need for communication from health-care providers that is honest, direct, and compassionate, in which family concerns and opinions are heard and valued, and that conveys information that can help in patient care (Steinhauser et al., 2000; Scott et al., 2001; Goy et al., 2008; Adams et al., 2009; Funk et al., 2010; Stajduhar et al., 2010, 2011). Material supports such as a hospital bed, and professional supports in the framework of family meetings are similarly valued (Funk et al., 2010; Stajduhar et al., 2010, 2011). Besides lack of professional, financial, and home management supports which are endemic, other commonly unmet needs include the need to receive assurance of the patient's comfort; to be informed of the patient's condition; to ventilate emotions; to receive comfort and support from family members; and to receive acceptance, support, and comfort from health-care professionals (Sharpe et al., 2005).

Psychosocial distress among family members

Psychological distress among family caregivers is very common, occurring in 40–60% of family caregivers who care for a loved one during the end-of-life experience, especially as the patient's level of autonomy diminishes.

A review of the data on the impact of cancer on family members identified 11 major issues for family members: emotional strain, physical demands, uncertainty, fear that the patient will die, alteration in roles and lifestyles, financial concerns, ways to comfort the patient, perceived inadequacy of care services, existential concerns, sexuality, and non-convergent needs among family members (Lewis, 1986). These issues can be profoundly influenced by the trajectory of the illness. For example, a long illness characterized by a remitting and relapsing course may produce persistent anxiety and uncertainty which can produce severe emotional fatigue (Blood et al., 1994; Steele, 2000). To resolve those feelings, family members may, in some circumstances, hope for the patient's rapid demise. In contrast, when the time from diagnosis to impending death has been short, there may be little opportunity for family members to come to terms with the presence of life-threatening illness let alone impending death (Coolican, 1994; Casarett et al., 2001).

Psychological problems of anxiety, depression, and adjustment disorder are common among family members of patients with advanced cancer (Dumont et al., 2006; Gaudio et al., 2012; Seng Beng et al., 2013). Studies of family cohesiveness indicate that these problems are more prevalent in families with low levels of

cohesiveness and high levels of conflict (Ozono et al., 2005). Good communication within the family mitigates against psychological distress in general (Ozono et al., 2005) and anxiety in particular (Edwards and Clarke, 2004).

Grief

In most cases, the pre-terminal phase of the chronic fatal illness experience is associated with a period of anticipatory grieving (Kissane et al., 1997; Simon, 2008; Johansson and Grimby, 2012, Johansson et al., 2012) in which the family undergoes a transition associated with the patient's 'fading away' (Davies et al., 1990). In one study (Davies et al., 1990), the onset of this transition was generally heralded by a deterioration in the patient's condition that challenged ongoing denial. The most heralding events were unrecoverable weakness, loss of independence in ambulation and personal care, and loss of mental clarity. These events are distressing in that they constitute losses, diminish hope for recovery, and focus attention on the inevitability of the patient's demise.

Caregiver burden

Although most patients die in the hospital setting, most of the care prior to dying is carried out at home by the family members with the support of health-care professionals. The care of a terminally ill family member greatly strains the physical, emotional, and psychological resources of the family unit and its individual members (Bialon and Coke, 2012; Seng Beng et al., 2013).

Home care often involves participation in personal hygiene needs, administration of medication by non-invasive or invasive routes, attention to nutritional needs, psychological support, and emergency management of such problems as pain, dyspnoea, or bleeding. The heavy physical work of transferring a weak or immobile patient, and attending to other needs (such as laundering or cleaning), is often further compounded by exhaustion as a result of sleep deprivation due to anxious thoughts or patient care needs (Aoun et al., 2010). For many this is a new experience and the uncertainties about the dying process, and the ability to cope with the problems that lie ahead, may become a focus for anxiety or ruminative thoughts. Family caregivers may be ill prepared to assume these tasks, requiring information on the disease and treatment, as well as instruction in technical and care skills. Moreover, caregiving must be balanced against already established roles and role responsibilities.

Financial distress

Financial distress has been underappreciated and is often neglected in routine care (Rabow et al., 2004; Longo et al., 2006; Hanratty et al., 2007). Studies comparing the relative costs of home- and hospital-based terminal care (Ventafridda et al., 1989; Beck-Friis et al., 1991) have generally neglected the financial and social costs to the family. In the National Hospice Study, 26% of primary care takers either left their work or lost their jobs, and 60% reported a significant reduction in income due to either absenteeism or a change in work arrangements (Muurinen, 1986). Permanent loss of employment occurred most frequently among those who could least afford it: older women and low-income families (Muurinen, 1986). The costs of caring for a family member can leave the surviving family with severely compromised resources (Grunfeld et al., 2004a). This distress is often exacerbated by inadequate insurance coverage.

Caregiver conflicts

The caregiver may experience profound conflict in this situation: conflict between the desire to provide adequate relief of distressing symptoms while, at the same time, wanting to preserve their loved one's alertness, and to avoid hastening death; and conflict between the duty to care for a loved one and to care for oneself, and one's other responsibilities. Additionally, there is often conflict between caregiving family members regarding goals of care, limits of care, and aggressiveness of care (Kramer et al., 2006; Kramer et al., 2010). Guilt, anger, denial, and other emotional influences sometimes compel family members into conflicted opinions whether to treat a devastating illness aggressively or discontinue life-sustaining measures (Bloche, 2005). These conflicts may reflect low levels of pre-existing cohesiveness, or they may threaten family closeness and collaboration in previously cohesive families.

Identifying families at risk

The endurability of the burdens of care is an important consideration in long-term care planning; the family members' current and future welfare is an important consideration when care demands are great and supportive resources for home care are limited (Callahan, 1988; Given et al., 2001, 2004). The ability and willingness of family members to participate in care is very variable (Abernethy et al., 2009) and in one retrospective survey, 22% of families of terminally ill patients were unable or unwilling to provide personal or medical care (Wellisch et al., 1989).

The identification of populations at particularly high risk for early intervention is facilitated by an assessment of stressors, particular family needs, and the resources available to the family. A survey of bereavement councillors highlighted several different risk factors: perceived lack of caregiver social support (70%), caregiver history of drug/alcohol abuse (68%), poor caregiver coping skills (68%), caregiver history of mental illness (67%), and patient is a child (63%) (Ellifritt et al., 2003).

Another approach has been to look at global family functioning as a predictor of coping. In a large longitudinal study, Kissane and colleagues identified characteristics of families with high prevalence of distress and poor coping (Kissane et al., 2003). Families classified as 'hostile' were characterized by low cohesiveness, low expressiveness, and high conflict. Family members typically described family life as fraught with frequent arguing, little teamwork or felt closeness among members, and minimal communication. Families classified as 'sullen' were also characterized by reduced cohesiveness and expressiveness, but only mild to moderate conflict. Reports of overt hostility were low in this group, suggesting that anger is muted, with depression gaining more prominence as the anger is directed inwards.

In contrast, the attributes identified to facilitate effective function include the ability to work cohesively, prior successful experience in handling stress, a substantial and flexible repertoire of coping strategies, family stability, financial security, the availability of outside supports to which the family is receptive, and a readiness to view this difficult period as potentially growth-producing (Quinn and Herndon, 1986). Kissane et al. identified two positive patterns of family function predictive of good coping. 'Supportive families' described family life as intimate and mutually supportive, with open and honest communication among its members,

tolerance of emotional expression, and little to no escalation in conflict. Similarly 'conflict-resolving' families which had cohesiveness and above-average expressiveness, but also the presence of conflict but with good conflict management (characterized by the ability to both voice and resolve differences between family members) (Kissane et al., 2003).

Health-care professional distress

Stressors

Health-care professionals may experience distress due to the constant exposure to suffering, loss, and grief that they are expected to be able to ease or relieve. Among the stressors experienced by professionals working in this field are patients who experience high morbidity and mortality; high work pressure; frequent life and death decisions (which sometimes occur in ambiguous circumstances); high consumer expectations; interstaff conflict; severe patient dependency, debilitation, or disfigurement; severe emotional distress among patients and their families; and issues relating to suffering and distress caused by the treatments themselves (Kash et al., 2000). It is not unusual for clinicians to bond strongly with patients who remind them of someone special in their lives or identify with patients who are similar to themselves in age, appearance, or background (Meier et al., 2001; Ekedahl and Wengstrom, 2007). Identification with patients can revive personal pain and heighten feelings of guilt or a lack of control, resulting in burnout (Escot et al., 2001; Keidel, 2002; Ekedahl and Wengstrom, 2007) (see Chapter 4.16).

Physician distress

There is a paucity of data on physician burnout among palliative medicine specialists and much of the understanding regarding burnout is derived from studies of oncologists who deal with patients with advanced cancer (Martins Pereira et al., 2011). Stress and burnout are common phenomenon among clinicians managing patients with incurable cancer. Among oncologists, various studies have demonstrated prevalence rates of 25–56% (Whippen and Canellos, 1991; Ramirez et al., 1995; Akroyd et al., 2002; Elit et al., 2004; Grunfeld et al., 2004b; Asai et al., 2006). Multiple factors contribute to stress in oncology clinicians. There is an increasing awareness of the major contribution of workload and life balance issues (Grunfeld et al., 2004b; Shanafelt, 2005): volume overload, difficulty balancing personal and professional lives, inadequate staffing to do the job properly, the challenge of keeping current with medical literature, and pressures to obtain grants and to publish. Mounting administrative issues add to this. Interpersonal conflict and difficulties in relationships with colleagues, junior staff, nurses, administrative staff, and administration are common. To all of these are added the challenges of end-of-life care: dealing and being involved with the physical and emotional suffering of patients, delivering bad news, and having to deal with distressed, angry, or blaming relatives. Oncologists must deal daily with stressed patients and families, disproportionate hopes and expectations, emotionally laden dialogues with patients and families, and the limitations of treatments that are unable to deliver cures.

Regarding the contribution of end of life on oncologist burnout, a European Society for Medical Oncology survey of almost 900 medical oncologists regarding their attitudes to and involvement with the management of advanced cancer (Cherny and Catane, 2003) found that just over a third of respondents reported that they felt emotionally burned out by having to deal with too many deaths. This predilection to burnout was associated closely with negative attitudes to involvement in supportive and palliative care and low levels of actual involvement or referral to palliative care colleagues. This study suggests that burnout from end-of-life care was not so much associated to over-exposure rather to poor attitudinal preparedness and aberrant role definition. These finding suggest that positive attitudes and involvement in palliative care are all resilience factors that helps prevent burnout caused by exposure to advanced cancer.

In a survey of 81 French general practitioners (Schaerer, 1993), 86% endorsed the assertion that encounters with death were a cause of physician suffering. The major causes of physician suffering were the end of the doctor–patient relationship (58%), feelings of uselessness (55%) and failure (38%), increased awareness of their own mortality (49%), and the presence of 'questions without answers' (31%). The most commonly reported feelings that were experienced by these physicians at the bedside of the dying patient were sadness (94%), helplessness (89%), failure (61%), disappointment (59%), and loneliness (51%).

Nursing distress

Studies of nurses working in palliative care have yielded mixed results; an international study evaluating stress levels and coping mechanisms among professionals who work with illness and death found that palliative care and hospice workers had less stress and better coping than those in other fields (Vachon, 1995; Hackett et al., 2009; Martins Pereira et al., 2011). Despite this, the potential for exhaustion and burnout is well described (Vachon, 1995; Astudillo and Mendinueta, 1996a; Peterson et al., 2010). Major sources of stress include perceived deficiencies in symptom control, deep emotional involvement in work, dealing with young patients, dealing with the emotional needs of distressed relatives, and conflict with the participating physicians over the goals of care (Harris et al., 1990; Newton and Waters, 2001; Wilkes and Beale, 2001; Hackett et al., 2009; Peterson et al., 2010).

Research among nurses has demonstrated both vulnerability and resilience factors. Personality characteristics such as perfectionism and over-involvement with patients may contribute to compassion fatigue or burnout. Self-esteem, sense of mastery, purpose in life, and a clear philosophy of life are protective factors.

Younger nurses with fewer years of experience report higher levels of distress (van Staa et al., 2000). A qualitative study of palliative care professionals found that less experienced clinicians focused on the technical aspects of care. Clinicians with more than 10 years' experience focused on their commitment to patient and family and developing trusting and open therapeutic relationships. They were also likely to recognize the stressful nature of end-of-life care and to understand the experience from the perspective of the patient and family, as well as the meaning of the experience to themselves, both personally and professionally (Farber et al., 2003).

Assessment and planning

An effective approach to the alleviation of suffering for patients with incurable or terminal illness is predicated upon careful case

assessment, identification of care needs, formulation of a multi-disciplinary therapeutic intervention to address those needs, and the provision of ongoing monitoring with readiness to re-evaluate the care plan as problems arise or needs change.

Assessment

An appreciation of the full diversity of factors that may contribute to suffering underscores the need for a methodical approach to the assessment of each individual case. The objectives of the assessment are to identify current problems that are a source of distress to each of the parties, to assess their care needs, and to evaluate the adequacy of the available resources. This evaluation must incorporate medical variables in the patient, family, and available community medical system; psychological variables in the patient, family, and psychosocial community supports; and social and financial variables in the patient and family. Since both the patient and the family are part of the unit of care, assessment requires discussion with both. The clinician must maintain a clinical posture that affirms relief of suffering as the central goal of therapy, and which encourages open and effective communication about perceived problems.

Patient assessment

The prevalence of poorly controlled pain and other physical symptoms, and the impact of these factors on the lives of all involved, emphasize the importance of addressing these issues at the earliest opportunity. The early establishment of good symptom control conveys concern, builds the trust of patients and their families, and facilitates the ability to address other important issues.

Patient variables that must be assessed include the disease status, expected disease progression, present functional level, symptoms, current therapies, and anticipated future problems. Of particular importance is the patient's level of function, reflecting his or her mobility (e.g. fully bedbound or fully mobile without aids), ability to communicate (from severe as with brain tumours to minimal impairment), ability to perform activities of daily living, bowel and bladder function (from incontinence to full self-care), and level of alertness (from coma to full alertness). The use of validated pain and symptom assessment instruments can provide a format for communication between the patient and health-care professionals and can also be used to monitor the adequacy of therapy.

It is important to ascertain the patient's and the family's understanding of the nature and extent of the illness and their expectations of treatment and outcome. As part of this process, the clinician must develop an understanding of the patient's prioritization of the sometimes conflicting goals of care: optimization of comfort, function (interactional function in particular), and duration of survival.

Family assessment

Family assessment should encompass medical variables, psychosocial concerns, and the adequacy and availability of supports. Evaluation of the willingness and ability of home carers to provide home care and the availability of supports are essential. Concurrent medical problems in a family member, particularly a primary caregiver, need to be evaluated since the viability of the home care plan may depend upon the family member's ability to participate in care. Since the ability of families to cope with home care is largely determined by the nature of the available home-care supports (Kristjanson et al., 1997b; Redinbaugh et al.,

2003; Limpanichkul and Magilvy, 2004), the family assessment must include an assessment of available health-care professional and community supports.

It is important to ascertain the family's understanding of the nature and extent of the patient's cancer and their expectations of treatment and outcome. Discrepancies between what is known and understood by the patient and the family should be identified, and the reasons for these discrepancies should be tactfully explored. Knowledge deficits may have been deliberately maintained: the family or patient not wanting information overload, the patient protecting the family from knowledge of poor prognosis, or the family protecting the patient from the impact of such information (Dalla-Vorgia et al., 1992; Mystakidou et al., 2005). This part of the assessment requires a non-judgemental posture, and sensitivity to psychological and cultural factors that may influence the transmission of information.

Health-care professional assessment

Evaluation of the professional caregiver supports usually requires greater detail than that which can be provided by the patient and family alone. To effectively plan for ongoing care, the clinical coordinator must understand the limitations of the involved health-care professionals (knowledge, experience, and availability for home care), their difficulties in coping with the situation, and their perceived needs to improve the care outcome. As previously described, the coping of professional caregivers may be severely strained by issues pertaining to communication; conflict with the patient, family, or colleagues; perceived therapeutic failure; excessive workload or emotional strain; and difficult therapeutic or ethical decisions.

Awareness of this interrelated construct enables the clinician to construct a series of critical questions regarding each of these domains, the answers to which constitute the basis of a patient assessment.

The patient

Several tools gave been developed to help evaluate patient suffering or distress (Krikorian et al., 2013) (see section 7).

Who is the patient and what is their social context? It is critically important to be aware of who the person is who is now needing care. This includes collection of information about basic demographics, family structure, other significant relationships, professional and education history, and place of dwelling. This phase should also incorporate past medical history and significant elements of family health and social history.

What is the patient's illness and where is the patient in the natural history of the condition? More often than not, this information will be available from the referring clinician and the patient's medical record. Specific information is required regarding the diagnosis, sites of disease, active medical problems, and anticipated prognosis. Anticipated prognosis relates not only to life expectancy, rather a broader concept that incorporates the projected course of illness and anticipated complications or problems.

Is the patient clear headed, if not why not? Cognitive impairment is very common among patients with advanced cancer and among other patients needing palliative care (Minagawa et al., 1996; Breitbart et al., 1997; Pereira et al., 1997). The presence of delirium impairs the ability to obtain direct information from the patient and will impair the ability to directly address many of the

subsequent assessment issues without involvement of family and health-care providers. When cognitive impairment is identified, efforts should be made to identify reversible contributing factors. The chronology of the problem must be assessed, including pre-morbid level of function, the time course of the deterioration in cognitive function, precipitating or alleviating factors, and other features of co-morbidity that may help identify the underlying problem. In this setting, the clinician will need to obtain the greater part of the clinical information from the family members or other involved observers. Since iatrogenic cognitive impairment caused by centrally acting drugs is common, it is important to review the patient's drug chart and to ask about the ingestion of any other substances (such as 'medicinal' mushrooms) which may be implicated.

What does the patient understand of the illness? Care planning and further evaluations require that the clinician is aware of the extent of the patient's familiarity with his/her condition and what the patient's communication preferences are. Although there is extensive data indicating that most patients want accurate information regarding their medical status, this is not universal (Walsh et al., 1998). Some patients want only limited information and a few want no information (Walsh et al., 1998). Excessive candour in the setting of impaired coping or in a patient who expresses a desire not to receive information may constitute a maleficent assault (Campbell and Sanson-Fisher, 1998; Girgis and Sanson-Fisher, 1998; Walsh et al., 1998).

What are the current goals of care? The goals of care are often complex, but can generally be grouped into three broad categories: (1) prolonging survival, (2) optimizing comfort, and (3) optimizing function (Cherny et al., 1994b). The relative priority of these goals provides an essential context for therapeutic decision-making (Fins et al., 1999). The prioritization of these goals is a dynamic phenomenon which changes with the evolution of the disease. For some patients requiring palliative care the optimization of comfort, function, and survival may share equal priority whereas the provision of comfort usually assumes overriding priority as death approaches.

Awareness of goals has major implications for care and therapeutic decision-making and it influences the evaluation process. When patients equally prioritize optimal comfort and function, the therapeutic intent is to achieve an adequate degree of relief without compromising cognitive and physical function. In this setting, impairments to physical, psychological, or social function require careful evaluation in order to guide care needs. When, however, comfort is the overriding goal of care, and the overriding intent is to achieve relief of discomfort, there may be areas of function or of disease status that are no longer an essential part of the assessment.

What are the physical consequences of the illness? Is the patient coping? Are there physical problems that are not well controlled? Patients needing palliative care are typically polysymptomatic and often have severe limitations in activities of daily living. Data from a number of studies have demonstrated that patients commonly have six to ten active distressing symptoms (Teunissen et al., 2007). Symptom assessment aims to identify the active symptoms, their severity, and the degree of distress that they are engendering for the patient. Several well-validated tools have been developed to help screen patients for physical and psychological symptoms and to monitor their severity (Kirkova et al., 2009).

Pain in particular needs detailed evaluation; this is addressed in greater detail in Section 13.

Symptom evaluation must be accompanied an evaluation of function. This should incorporate activities of daily living such as ambulation, toileting, dressing, eating, sleeping and sexual function (if clinically appropriate).

The extent of the physical examination will be determined, in part, by the patient's prevailing condition and the goals of care. The physical examination often helps refine the differential diagnosis of problems indicated by the clinical history. Details of physical examination are beyond the scope of this introduction: suffice it to say that special attention must be paid to common problems associated with advanced illness including mouth care and skin integrity as well as to sites affected by the patient's symptoms or which may be commonly involved in the disease from which the patient suffers. When the patient suffers from pain or from neurological symptoms, the valuation should incorporate a neurological examination.

All relevant pre-existing diagnostic investigations should be reviewed. These often reveal important information that may explain current symptoms or help focus the need for any future diagnostic interventions.

Psychologically, how is the patient coping? What is he/she thinking? What are his/her active fears or concerns? Fear, anxiety, sadness, depression, and sleep disturbance are among the most common symptoms of advanced cancer. They are a substantial cause of distress, undermine coping, and are a major contributing factor for suicidal ideation and the desire for death. Patients should be asked how they are coping. This serves as a useful opening to explore more specific psychological and social issues. Inquiry about coping conveys concern. This, in turn, contributes to the development of trust and facilitates development of the therapeutic relationship. Specific enquiries should be made regarding feelings of sadness, anxiety, or persistent fears. If acknowledged, these symptoms should be further evaluated to identify the contributing factors, severity of the symptoms, and the impact of the psychological distress on patient function.

When patients express fears or anxiety, it is important to clarify the specific fears. Often fears are based either on misinformation or on anticipated problems that are very unlikely to occur. In other situations, patient fears are appropriate but are magnified either by poor communication or by a lack of communication. Patients with advanced cancer often harbour fears of uncontrolled pain, dyspnoea, or some other form of uncontrolled suffering at the end of life. These fears can be addressed through counselling, a commitment to continuity of care and to adequate palliation, and meticulous clinical follow-up with implementation of those commitments.

On a day-to-day basis, how is the patient coping and do they have adequate supports? Effective day-to-day coping requires an integration between physical, psychological, and disease-related factors in coordination with environmental factors related to family, friend, and health-care supports. This complex interaction must be evaluated. Asking patients about their day-to-day coping is a technique to open a dialogue regarding this complex interaction. Similarly, one can ask the patient if they have adequate supports. Support and coping are deliberately general queries that may evoke responses relating very diverse issues and concerns. Commonly expressed concerns include financial concerns, fears of family

burnout, lack of availability of medical and nursing staff, difficulties in obtaining parking at the hospital, communication concerns with clinical staff, and inadequately controlled symptoms.

What are the deeper thoughts that the patient harbours? What sort of life have they had? Do they have unfulfilled dreams or aspirations? What have been the things that have made them sad or happy? How do they see the future? Existential and spiritual issues may relate to the past, present, or future. As people approach the end of life, they commonly have many thoughts relating to the life that they have lived, issues of legacy, the life that they are currently living, and concerns about the time that remains ahead of them. Additionally, many patients harbour transcendental thoughts relating to their place in the world, their relationship to God, and thoughts related to an afterlife. These concerns are universal, cross-cultural, and are probably intrinsic to mortal life. The relative weight of these issues is influenced by culture, past, cognitive function, and the place in the life cycle at which the patient is confronting their mortality.

Evaluating these deeply personal issues requires the prior development of a trusting relationship. Exploration and disclosure of these issues is usually undertaken over time. In many instances the patient may choose to disclose and discuss different issues with different staff members. This may reflect interpersonal dynamics, specific clinical skills, or perceived roles. Information sharing, with the patient's permission, with other members of the interdisciplinary team helps sensitize other participating caregivers to the specific cares, concerns, and sensitivities of the patient. When patients feel understood, they are more likely to feel trust in the care team and environment.

Life-review techniques can help identify points of meaning about important issues of legacy as well as unresolved issues related to the past such as remorse, unfulfilled ambitions, or guilt. Direct questioning can be used to evaluate the patient's coping in the family, at work, and in significant relationships.

Fear of death is commonplace. Specific death-related fears may include fears of pain, dyspnoea, loss of control, medical abandonment or overtreatment, oblivion, and concern for surviving family members. Frequently, specific goals or uncompleted tasks will be identified. This information may be critical for life planning in the time that remains for the patient.

What future problems are anticipated? What provisional steps can be taken to cover contingencies? Careful contingency planning can help avoid crises. Contingency planning should relate to specific anticipated physical problems (such as pain, dyspnoea, immobility, wound breakdown, or bleeding), psychological problems (such as anxiety, sleep disturbance, or delirium), and home-care problems (such as failing supports, family burnout, or access problems). By identifying probable contingencies one can implement and prepare a back-up plan. Examples of this sort of planning include provision of opioids and antipsychotics if pain or delirium is anticipated, oxygen if hypoxaemia is anticipated, and bathroom railing if immobility is anticipated. When home death is anticipated, it is helpful to have a prepared programme for the family of who needs to be called with all phone numbers prepared and any paperwork ready and available.

In some circumstances, the nature of the anticipated contingency may be such that it may impact on the immediate care plan. This is especially true when catastrophic bleeding from a carotid or femoral blow-out is anticipated. If the patient lives alone or with a companion who may be significantly traumatized by this sort of horrid event, anticipatory admission to a hospital or palliative care unit may be appropriate. This is true for patients who may suffer asphyxiation from upper airway tumour.

Family

Screening tools to evaluate the distress and needs of family caregivers have been developed (Shim et al., 2010; Ewing and Grande, 2013). These tools address components of the following eight domains (see Chapter 7.4).

Who is the family and what is their social context? This is well achieved using a family map. Critical issues for assessment of each family member include age, place of residence, health status, occupation, nuclear family relationships, and geographic and emotional proximity to the patient. Some family members may have unresolved past issues with the patent and, as far as is possible, it is helpful to identify these.

How is the physical and psychological well-being of the family member? Since advanced and incurable illnesses are most commonly a problem of the elderly, often the caring family member may be in poor physical health. Similarly, significant illness in a family is a major emotional stress and indeed, family members often suffer from anxiety, depression, and adjustment disorder or difficulty. It is important that the members of the care team be aware of these factors as they will impact on the ability of the family member to participate in care and they indicate specific care needs of their own.

What do the family members understand of the patient's condition and the goals of care? Discrepancies between the patient's and the family members' understanding of the patient's diagnosis, treatments, anticipated outcomes of treatment, prognosis, and goals of care are commonplace (Purandare, 1997). It is only by asking family members what they understand of the illness that these discrepancies can be identified. When discrepancies are identified, the clinician must evaluate if there is a specific reason that they exist. Occasionally the patient may have specifically requested that information not be disclosed to family members or to a specific family member. When this has been the case, the reasons for concealment of this sort should be explored with the patient.

Emotionally, how are they coping with the prevailing situation? Are they adequately supported? Are they coping?

Life-threatening disease in a family member is a major life stress. Coping with this sort of stress is very variable and it has both psychological and physical dimensions. When emotional coping is difficult or when failure of coping occurs this impacts on everyone else involved in the care dynamic including the patient, other family members, and the professional health-care team (Vachon, 1998). Coping with physical care needs can be severely compromised when there is a failure of emotional coping. It is, therefore important to explore issues of emotional coping of the family members. Common issues include anticipatory grief, anxiety, and depression. Changes in the patient's condition commonly precipitate a transient adjustment disorder that may manifest as anxiety, panic, depression, psychomotor retardation, or acting-out.

Physically, how are they coping with the prevailing situation? Are they adequately supported? It is important to evaluate the family members' ability to cope with the patients care needs, to

identify the role of pre-emptive or remedial assistance when available, and to identify impending breakdown in coping (which may require urgent intervention such as respite admission) (Bramwell et al., 1995; Astudillo and Mendinueta, 1996b; Karlsen and Addington-Hall, 1998). This process aims to evaluate the limits of the family's coping resources for home care. If the patient's care needs exceed these limits, other care plans will need to be activated. Coping with physical care needs can be supported by the provision of appropriate physical supports (such as a wheelchair, hospital bed, or toileting equipment), education in care provision, and professional or volunteer assistance.

What are the deeper thoughts that the family member harbours? What sort of life have they had? Do they have unfulfilled dreams or aspirations? What have been the things that have made them sad or happy? How do they see the future? Life-threatening illness in a spouse, sibling, or parent threatens a significant relationship, and it impacts on the way family members relate to their past, present, and future. Family members may suffer the same spectrum of existential issues as the patients themselves (Carson, 1997). As with the patient, life-review techniques may identify unfilled ambitions, regrets, and remorse related to relationship issues with the patient, as well as help highlight positive aspects of their shared experiences. The patient's illness may have altered the structure of the family relationships. Often, evaluation of future goals can identify specific targets that may not be achievable with the involvement of the patient unless they are brought forward. In many instances, discussion of these issues has brought forward major life events such as weddings, long-distance travel, or family reunions.

What are their concerns for the future? Family members often have specific fears regarding anticipated future events in relation to the patient. Common fears include fears of uncontrolled pain, confusion, incontinence, loss of ambulatory function, bleeding, addiction, abandonment, and lack of supports. Once identified, these fears are often amenable to intervention either through counselling, information transfer, family meetings, or the development of clear contingency plans and lines of communication.

Have they suffered other losses in the past? In what circumstances? How did they deal with them? How are these losses impacting on what is happening now? Previous grief experiences impact on the distress of impending bereavement (Janson and Sloan, 1991; Murphy et al., 1997). Knowing about the experiences of previous losses can help the professional caregiver address issues related to the current situation. Family members who have experienced multiple grief experiences may be suffering from cumulative losses. In other situations, family members have fears based on previous death experiences. Consequently it is important to ask family members about previous death experiences: what happened? How did they cope? Did the experience leave them with any specific fears or hopes regarding death and end-of-life care?

Health-care providers

Who is involved in the patient's care? Patients commonly have multiple professionals involved in their care. It is critical to identify them, their roles, the limits of their availability, the cost of their services, and the extent of their communication. Contact details should be made available and clear lines of communication and responsibility established. A clinician should be nominated as the coordinating clinician who is ultimately responsible for the coordination of professional caregiver activities.

What is the experience and expertise of the professional health-care providers with the prevailing problems? Health-care professionals constitute a heterogeneous group. Professionals vary greatly in their experience, training, and attitudes regarding palliative care and end-of-life care. Since knowledge deficits are endemic, it is important to understand the specific professional background of each of the participating clinicians. Where lack of experience or lack of knowledge in palliative care is identified in the care team, special provision for expert backup or remedial education may be required.

What do the professional health-care providers understand of the illness and of the goals of care? It is important to clarify the understanding of all participating caregivers regarding the goals of care and of their specific care goals. Miscommunication of the goals of care or lack of concordance between professional caregivers on this issue can contribute to conflict and confusion.

What are the limits of care that they can reasonably provide? Do they have adequate human resources to deal with the prevailing problems? Are they coping? Usually, there are limits to the professional services and personnel resources available for the care of patients. These limits need to be determined. Once determined, it is important to assess the likelihood that they will be adequate to meet the patient's and family's care needs. When the care needs are great and the professional caregiver resources are limited, it is important to assess professional caregiver coping. When there is mismatch between care needs and available services, particularly in the setting of home care, alternative care arrangements in hospital or a palliative care department or hospice may need to be considered.

How are they coping with the emotional impact of the situation? Caring for incurable patients and their families places a great stress on the emotional coping resources of health-care professionals and sometimes professionals feel inadequately prepared for the emotion-laden nature of this work. Consequently, it is important to assess the coping of the members of the care team with the emotional issues to which they are being exposed. As part of this assessment, it is important to check that the emotional care burden is being distributed between the professional carers and that there is provision for debriefing.

Do they have adequate physical resources? Home care of patients needing palliative care often requires equipment such as a hospital bed, ambulating assist devices (such as a walking frame or wheelchair), toileting equipment, oxygen, suction device, or specific medications. It is incumbent to evaluate what resources are needed and the evaluate availability and cost (if any).

What future problems are anticipated? What provisional steps can be taken to cover contingencies? The issue of contingency planning was addressed as part of the patient assessment. The evaluation of the care services must include an evaluation of the implementation of the contingency arrangements. Lines of communications should be clarified and the extent of available cover for emergencies checked. If the need for admission is foreseen, communication including a letter of introduction should be prepared in advance. When it is anticipated that the patient will die in the near future, there should be clear instructions for the family indicating who to contact, including the details of funeral company contacts.

Table 2.1.1 The dimensions of patient distress, management approaches, and potential therapeutic resources

Dimension	Distress	Intervention(s)	Therapist(s)
Physical	Pain	Comprehensive pain management	MD, Nur, Anaesth,
	Other physical symptoms	Comprehensive therapy	PCS, Physiat,
	Physical disability	Physiatric review and therapy	OT, PT.
Psychological	Anxiety	Careful assessment for reversible factors	Onc, Nur, SW,
	Depression	Psychotherapy ± pharmacotherapy	Psych, Neur, PCS
	Adjustment difficulties	Cognitive or behavioural interventions	
	Cognitive impairment		
	Unresolved previous loss or separation		
	Control		
Social	Strained family relationships	Family assessment, supportive intervention	MD, Nur, SW,
	Unsatisfactory communication regarding illness or treatment	Assessment and facilitation	Psych, PCS
	Economic	Assessment and support	
	Family related	Address issues of family distress	See Table 2.1.2
	Feeling an excessive care burden		
	Feeling an excessive emotional burden		
	Feeling an excessive economic burden		
	Doctor related	Evaluate limits of available medical supports	PCS, Psych, SW,
	Lack of MD attention to current problems	Expert consultation	Nurs
	Lack of empathic support from MD		
	MD excessively hopeful or pessimistic		
Existential	Current personal integrity	Attention to reversible factors	MD, Nur, SW, Phys,
	Changes in body image and function	Use of prosthetic, cosmetic, orthotic or functional supports	Psych, Chap, PCS,
	Changes in intellectual function	Cognitive, behavioural and supportive psychotherapies to enhance coping	Physiat, OT, PT, ST,
	Changes in social and professional function		Cosmet
	Changes in attractiveness as a sexual partner		
	Retrospective distress	Cognitive restructuring	SW, Psych, Chap, MD,
	Disappointment	Life-review techniques	Nurs, PCS, MT, RecT
	Remorse		
	Anticipation	Cognitive restructuring and goal reprioritization	Psych, SW, MD, Nur,
	Hopelessness	Identification of short-term achievable goals	Chap, PCS, ClinEth
	Futility	Abandonment of unachievable goals	
	Meaninglessness	Addressing fears associated with death	
	Death concerns		

Anaeth: Anaesthetist; Chap: Chaplain; ClinEth: Clinical ethicist; Cosmet: Cosmetician; MD: Doctor; MT: Music therapist; Nurs: Nurse; OT: Occupational therapist; PCS: Palliative care specialist; Physiat: Physiatrist; Psych: Psychiatrist; PT: Physical therapist; RecT: Recreation therapist; SW: Social worker.

Formulating a care plan

Based on this assessment one can formulate a care plan that addresses all aspects of the care trilogy: patient, family, and caregivers. The formulation can be summarized in a document or report that describes the following:

1. The medical condition of the patient and the goals of care.

2. Description of the involved family and professional carers.

3. Patient issues: physical, psychological, existential, social, communication, understanding.

4. Family issues: physical, psychological, existential, social, communication, understanding.

5. Professional carer issues: staffing, training, resources, resource/need match, emotional coping.

Table 2.1.2 The dimensions of family member distress, management approaches, and potential therapeutic resources

Dimension	Distress	Intervention	Therapist(s)
Patient related	Patient in physical distress.	Treat patient and support family	MD, Nurs, Psych,
	Patient in psychological distress.	Treat patient and support family	Chap, ClinEth
	Patient in existential distress.	Treat patient and support family	
Physical	Illness	Comprehensive therapy	MD, Nur,
	Physical disability	Physiatric review and therapy	
Psychological	Anxiety	Psychotherapy ± pharmacotherapy	MD, Nur, SW,
	Depression	Cognitive or behavioural interventions	Psych, Neur, PCS
	Adjustment difficulties		Chap
	Unresolved previous loss or separation		
	Uncertainty		
Social	Alteration in roles and lifestyles	Acknowledge difficulties	MD, Nur, SW,
	Unsatisfactory communication regarding illness or treatment	Explore specific problems of family and supports Assess information needs and address them	Psych, PCS
	Lack of comfort and support from family members	Provide sensitive information and express readiness to provide appropriate supports	
	Lack of support and comfort from health-care professionals	Express readiness to deal with whatever difficulties may arise	
	Non-convergent needs among family members	Identify family members in need of psychological or psychiatric support	
	Economic/employment		
Personal resources	Excessive physical demands	Optimize home supports	SW, Nurs, MD
	Excessive complexity of care	Provide effective backup	
	Exhaustion	Consider alternative care arrangements	
		Consider respite care	

Chap: Chaplain; ClinEth: Clinical ethicist; Cosmet: Cosmetician; MD: Doctor; MT: Music therapist; Nurs: Nurse; OT: Occupational therapist; PCS: Palliative care specialist; Physiat: Physiatrist; Psych: Psychiatrist; PT: Physical therapist; RecT: Recreation therapist; SW: Social worker.

6. Coping assessment: patient, family, and professional staff.

7. Contingency planning: anticipated contingencies, planned interventions.

Tables 2.1.1 and 2.1.2 illustrate interdisciplinary care plans to address patient and family needs in each of the dimensions of care.

Implementation of ongoing assessment

Advanced incurable illness leading towards death is characterized by the potential for rapid and dramatic change and the overall tendency for change, increasing dependency, and an increasingly complex confluence of physical, psychological, existential, ethical, and social concerns. Just as care for the palliative care patient is a longitudinal commitment, so is assessment. Consequently, this assessment must be repeated at appropriate intervals which will be determined by the rate of change in the patient's clinical condition or at points of major change in goals, care plan, or the patient's condition.

Family meetings

A common source of distress for patient, family, and professional carers occurs when there is a lack of coordination in the desired goals of patient care. The goals of care are often complex, but can generally be grouped into three broad categories: (1) prolonging survival, (2) optimizing comfort, and (3) optimizing function. The relative priority of these goals provides an essential context for therapeutic decision-making. The prioritization of these goals is a dynamic phenomenon which changes with the evolution of the disease: whereas the optimization of comfort, function, and survival may share equal priority during the phase of ambulatory palliation, the provision of comfort usually assumes overriding priority as death approaches. When patients equally prioritize optimal comfort and function, the therapeutic intent is to achieve an adequate degree of relief without compromising cognitive and physical function. When comfort is the overriding goal of care, the overriding intent is to achieve relief. In the latter circumstance, there is a willingness to continue therapies that may impair function, or even foreshorten life expectancy.

Family meetings, with relevant members of the professional health-care team, provide a useful format for discussing the needs of all parties involved, clarifying care goals, sharing and exploring concerns, and developing a therapeutic plan that adequately addresses those needs (Rabow et al., 2004; Weissman, 2004; Fineberg, 2005; Lautrette et al., 2006). The participants should be determined on an individual case basis. Since the family is an appropriate unit of care, and its members have a right to confidentiality, it may be appropriate, on occasion, to meet without the participation of the patient to address their concerns and needs. Meetings with the participation of all people who are involved can open communication, improve coordination in the formulation of a care plan, and facilitate better personal coping for each of the individuals involved.

Formulation and implementation of a care plan

Coordination of the many participants in this sort of multidisciplinary care requires an identified leader for each case. This role is usually filled by either a physician or nurse, and the specific person may change in the course of an illness as the predominant care needs change. For example, with the progression of a cancer from a diagnostic stage to a palliative stage, the responsibility may shift sequentially from a surgeon, to a medical oncologist, and finally, to a palliative care nurse. The coordinator, or case manager, is responsible for monitoring the degree to which care needs are being met, and for facilitating change when necessary. Similarly the well-being and function of the health-care professionals must be monitored, ensuring the availability of appropriate manpower and expertise to effectively manage the prevailing problems. For security and safety in the event of a clinical crisis, it is essential that the patient and family have access to a contact person with 24-hour availability. This model represents a family-centred, multidisciplinary, collaborative approach between physicians, nurses, social workers, other therapists, and community supports.

Conclusion

An understanding of the nature of suffering and of the factors that contribute to it are essential to the task of palliative medicine. Suffering is a complex human experience which requires evaluation in order to construct an effective therapeutic response that is appropriate to presenting problems. An effective approach incorporates careful case assessment, identification of care needs, formulation of a multidisciplinary therapeutic intervention to address those needs, and the provision of ongoing monitoring with readiness to re-evaluate the care plan as problems arise or needs change.

The epidemiology of death and symptoms: planning for population-based palliative care

Megan B. Sands, Dianne L. O'Connell, Michael Piza, and Jane M. Ingham

Introduction to the epidemiology of death and symptoms

The epidemiology of the end-of-life experience

Epidemiology is defined as 'the study of the distribution and determinants of disease frequency' (Hennekins et al., 1987). Epidemiology is central to the development of strategies for the prevention and management of disease in populations and for the planning of health services. Epidemiological data can also provide information about the nature of the progression of specific diseases and treatment outcomes. For palliative care, epidemiology can provide important information about disease and symptom occurrence as well as health-care needs. In this chapter, we take a broad view of the epidemiology of 'disease' towards the end of life and discuss epidemiology as it relates to the 'human experience' with an emphasis on disease, symptoms, psychosocial experiences, and access to health services. Areas where information about a population is available and where it is needed, but lacking, are highlighted. Examples of the way in which epidemiological data have informed planning, policy, or patient care are highlighted throughout this chapter. Epidemiological studies on populations at the end of life are relatively few. Where data from large or whole population studies are unavailable, smaller studies such as those derived from service-based data, have been used to illustrate aspects of the human experience towards the end of life. The attainment of high-quality population-based data is essential to understanding the needs that inform service development and provision of care across settings.

Important definitions

The population base for palliative care

The World Health Organization (WHO) has defined palliative care. A definition of the palliative care population is important as it helps to articulate what palliative care is, who needs it, who should provide it (Rosenwax et al., 2006), and how well it is provided across health systems. A definition of the palliative care population is therefore a vital part of planning for palliative care service delivery. Notwithstanding this, defining the 'palliative care population' has been problematic. To date, among the approaches to defining the population have been the use of specific conditions, patient needs, and all deaths (Rosenwax et al., 2006). Definitions of the palliative care population may vary but it is essential to identifying who would benefit from palliative care and therefore remains a core challenge. The focus of research in this area has more recently centred on identifying markers of 'palliative care needs' as a basis for defining 'the palliative care population' (Boyd and Murray, 2010; Waller et al., 2010). Defining appropriate quality indicators is another important area of research. The type of diseases encountered as well as the socioeconomic, cultural, home, and natural environments that patients inhabit are all important variables that influence the spectrum of a population's palliative care needs.

Incidence and prevalence

Incidence and prevalence are two important epidemiological measures. 'Incidence quantifies the number of new events or cases of disease that develop in a population of individuals at risk during a specified time interval' (Hennekins et al., 1987) and can be summarized as:

$$\frac{\text{Number of new cases}}{\text{Total population at risk}}$$

'Prevalence quantifies the proportion of individuals in a population who have the disease at a specific instant and provides an estimate of the probability (risk) that an individual will be ill at a point in time' (Hennekins et al., 1987) and can be summarized as:

$$\frac{\text{Number of cases}}{\text{Total population at a given point in time}}$$

Epidemiology of death worldwide

Limitations of mortality statistics

Mortality statistics provide information on death rates and causes of death in populations and therefore provide important

epidemiological data for palliative care. In reviewing mortality data, it is important to have an understanding of the limitations of data which are derived from diverse sources, each with its own limitations. The Global Burden of Disease (GBD) study, which was initiated in 1993 to provide comprehensive mortality and morbidity data, has been a collaboration involving the WHO, the World Bank, and other organizations. This study is ongoing, and since its first publication in 1994 the GBD data has been updated (Lozano et al., 2012; Murray, 2012; WHO, 2013a). Estimates of mortality relating to deaths in 2011 were published in 2013 and were largely obtained using the same methods as those used to produce previously published mortality estimates but were derived from more recent information from vital registration data (WHO, 2013b) (see Box 2.2.1).

Mortality estimates from the GBD are obtained from four general sources (Lopez et al., 2006):

1. Death registration systems: these provide information, not always complete, on the causes of death for most high-income countries as well as many countries in Eastern Europe, Central Asia, Latin America, and the Caribbean (Maudsley et al., 1996).

2. Sample death registration systems: these register a sample of the population and establish death rates within the sample population which are then extrapolated to estimate data about the broader population. They are used to estimate mortality data in areas where deaths are not registered for a large proportion of the population, and are frequently necessary, for example, to estimate deaths in rural areas. Sample death registration systems contribute particularly to statistics regarding deaths in China and India, which together have more than one-third of the world's population (WHO, 2013a).

3. Epidemiological assessments: these provide estimates of deaths for major diseases, such as cancer, HIV/AIDS, malaria, and tuberculosis, for countries in the regions most affected by these conditions. Epidemiological assessments deduce case fatality rates (i.e. people who have a specified disease and who die as a

result of that disease within a given period of time) from surveys on the incidence or prevalence of a specific disease over a specific period of time combined with knowledge of the usual mortality for that condition.

4. Cause of death models: these are used to estimate deaths according to broad cause groups in regions (including most of sub-Saharan Africa) with non-existent or incomplete mortality data.

Only a third of the world's population resides in regions where complete civil registration systems exist that provide adequate, cause-specific mortality data. In most of Africa, South East Asia, the Middle East, and parts of the Pacific, where over one-quarter of the world's population resides, there has until recently been little or no mortality monitoring (Rao et al., 2005; Lopez, 2006). Notable increases in the collection of data have been reported in Thailand and South Africa in publications from the WHO (2011).

It can be seen therefore, that reporting errors and inaccuracies relating to cause of death are a worldwide problem. Even in countries where deaths are reported with reasonable consistency, significant proportions of reports of death contain reporting errors (Maudsley et al., 1996; Rao et al., 2005; Mathers et al., 2006a). There are many reasons why death data may be unrepresentative. For example, in an effort to reduce complexity, mortality data are usually reported by single cause of death despite the fact that several co-morbidities and health risks may significantly contribute to death. This may introduce biases. These include, but are not limited to, economic constraints on various capacities for data collection and reporting, as well as political and other factors; these factors must be considered when assessing the limitations of global health data (Murray et al., 2004; Lopez et al., 2006; Mathers et al., 2006b; Wang et al. 2012).

Coding and reporting systems also influence the data available but increased adoption of standardized reporting systems such as the International Classification of Diseases (ICD; WHO a), by the majority of countries (from four countries in 1994 to more than one hundred in 2014) has resulted in improvements in 'real-time' availability of data relating to cause of death (WHO, b). Cumulative developments in information systems have potential for fostering further improvements in the comprehensiveness and accuracy of mortality statistics. Despite this, significant reporting delays exist in many regions in cause of death, location of death, and co-morbidities. The absence of these can impact on the service planning that is critical for optimizing the delivery of population-based care at the end of life (Wang et al., 2012).

Life expectancy

Life expectancies vary greatly worldwide (see Fig. 2.2.1) (Institut national d'études démographiques (INED), 2012). These variations are associated with demographic characteristics such as occupational, political, cultural, and lifestyle risks as well as ethnicity, gender, and genetics (Commission on Social Determinants of Health, 2008; WHO, 2009, Institute for Health Metrics and Evaluation, 2010; Lim et al., 2013). Populations from low-income countries have not experienced the increase in life expectancy observed in the rest of the world, and communicable diseases and conditions of the newborn continue to be a significant cause of death. For several countries of sub-Saharan Africa,

life expectancy in the 1990s had declined to 40 years or below (WHO, 2006). There have been some areas of notable improvement since that time; however, data demonstrate that countries in some regions have life expectancies less than or close to 50 years (INED, 2012).

Globally, life expectancy for 2012 has been estimated as 66 years for men and 71 years for women. In more developed regions the life expectancy at birth for both sexes is currently estimated to be 76.9 years and, in the least developed regions, 58.4 years (United Nations, 2013).

In addition to life expectancy, it is important to consider infant mortality. Within countries and across regions of the world, infant mortality varies. Across the world, the infant mortality rate has been projected to be 41.5 deaths per 1000 live births (INED, 2012). Two types of figures are reported for this very young age group—infant mortality per 1000 live births and infant deaths under the age of 1 year—and great variability exists for both. Afghanistan has, for example, had a very high infant mortality with projections of 123 deaths per 1000 live births in 2013 whereas projections for Iceland for the same year were for two deaths per 1000 live births (INED, 2012). In the contemporary era many countries have seen a decrease in child mortality. Others have been slower to achieve a decrease (Gapminder, 2010; INED, 2012).

Leading causes of death

In 2011, there were approximately 54.5 million deaths estimated throughout the world (WHO, 2013b). Fig. 2.2.2 presents the ten leading causes of death worldwide for 2011 (WHO, 2013c). As reports reflect individual cancers the general diagnosis of 'cancer' itself does not rank among the leading ten causes although lung cancers rank 6th with 1.5 million deaths (WHO, 2013d). The

leading reported causes of death vary among regions at different levels of economic development and illustrate some of the health disparities associated with economic issues. The World Bank now classifies countries into four income groups: low, lower-middle, upper-middle, and high. The most recent data on causes of death by income categories are for 2011 (see Box 2.2.1). Globally, adult mortality rate declined from 204 per 1000 population in 1990 to 160 per 1000 population in 2011 (WHO, 2013a).

Disparities in causes of death between countries reflect divergent levels of economic development. More specifically, communicable diseases and conditions of the newborn are the predominant causes of death in low-income countries. These causes of death also vary between demographic groups within countries defined, for example, by socioeconomic status, gender, age, and ethnicity. The disparity in global mortality is greatest for low-income countries which constitute 11.4% of the world's population but account for 16.3% of the world's deaths (WHO, 2008).

Another example of where differences in health status, life expectancy, and causes of death exist is between ethnic groups within some high-income countries in which some indigenous populations have comparatively higher rates of death and morbidity from diseases including cancer, respiratory disease, stroke, injury, and diabetes when compared to the non-indigenous population of the same country (see Box 2.2.1) (Stevenson et al., 1998; Horton, 2006; Australian Bureau of Statistics, 2011a, 2011b; WHO, 2011).

Differences in the ranking of causes of death between time periods have been demonstrated, most notably by the data presented in the GBD study which presented comparative data from 1990 and 2010. For instance, while many communicable diseases have decreased in frequency, death from HIV/AIDS has moved from

33rd ranking to 6th, and road injury and self-harm have remained significant causes of death at 8th and 13th rank in 2010 (cf. 10th and 14th rank in 1990). Over those two decades, lung cancer has increased in frequency changing from 8th rank to 5th and diabetes has changed from 15th rank to 9th (Institute for Health Metrics and Evaluation, n.d.). WHO estimates comparing cause of death between the years 2000 and 2011 are available online (WHO, 2013d).

Projections for the future: leading causes of death

Mortality projections can assist in the planning of services that will be required to meet the needs of populations in the future and provide insight into requirements for the spectrum of knowledge and skills needed by palliative care clinicians (K. Strong et al., 2008).

Recently updated projections of mortality and cause of death have been released by the WHO and are summarized in Table 2.2.1. The death rates from various causes were estimated using data from 2011 (WHO, 2013d). An in-depth discussion of age-standardized mortality projections of cause of deaths for 2030 using 2002 data has been published by Mathers and colleagues. Among other estimates, they present data demonstrating expected increases by 2030 in deaths from HIV/AIDS, lung cancer, diabetes, chronic respiratory diseases, road traffic accidents, violence, and war (Mathers et al., 2006a). These 2002 projections for 2030 provide three kinds of estimates: baseline, pessimistic, and optimistic (Mathers et al., 2006a). Under the optimistic scenario, 64.9 million deaths worldwide were projected and under the pessimistic scenario 80.7 million. With respect to HIV/AIDS, a baseline projection estimates

deaths from this cause will increase from 2.8 million in 2002 to 6.5 million in 2030. Deaths from other infective conditions or perinatal conditions are projected to fall. Over the same time period baseline projections of deaths from cancer suggest an increase from 7.1 million to 11.5 million, and cardiovascular deaths from 16.7 to 23.3 million. Combined deaths from cancer and chronic non-infective and non-cancer illnesses are expected to account for 70% of deaths in 2030. The third major mortality grouping is related to deaths from injury and accidents and notable in this group was a 40% expected increase predominantly accounted for by road traffic accidents which were projected to increase from 1.2 in 2002 to 2.1 million in 2030 (Mathers et al., 2006a).

Projections are developed to reflect various contributing factors including the success of preventive action. Projections may vary if behaviours related to disease incidence or disease related-mortality change. Examples of important factors that may impact projections include tobacco use, the incidence of obesity, the incidence of infective causes of death, and whether prevention efforts have a greater or lesser impact than expected (Olshansky et al., 2005; Strong et al., 2008; Wang et al., 2012; WHO, 2012). For example, deaths attributed to tobacco use are estimated to be likely to account for 8 million deaths worldwide annually (WHO, 2013f); if preventive efforts are less or more successful than predicted, the death rates for tobacco-related diseases will change. Given the uncertainties that exist concerning influential variables including economic, environmental, social and, technological factors variations can be expected between actual and projected mortality (Mathers et al., 2006). Deviations from the projected mortality will affect palliative care services planning.

Table 2.2.1 Projected leading causes of death in 2030 (based on 2011 data)

Low-income countries			Lower-middle-income countries			Upper-middle-income countries			High-income countries		
Cause	Deaths (000s)	%	Cause	Deaths (000s)	%	Cause	Deaths (000s)	%	Cause	Deaths (000s)	%
Stroke	905	8.9	Ischaemic heart disease	3544	13.4	Stroke	3701	16.8	Ischaemic heart disease	1393	12.1
Lower respiratory infections	810	7.9	Stroke	3105	11.8	Ischaemic heart disease	3528	16.0	Stroke	867	7.6
Ischaemic heart disease	780	7.6	Chronic obstructive pulmonary disease	2213	8.4	Chronic obstructive pulmonary disease	1573	7.1	Alzheimer's disease and other dementias	728	6.4
HIV/AIDS	650	6.4	Lower respiratory infections	1509	5.7	Trachea, bronchus, lung cancers	1268	5.8	Trachea, bronchus, lung cancers	627	5.5
Diarrhoeal diseases	422	4.1	Diarrhoeal diseases	1064	4.0	Diabetes mellitus	782	3.6	Lower respiratory infections	525	4.6
Road injury	421	4.1	Diabetes mellitus	971	3.7	Liver cancer	717	3.3	Chronic obstructive pulmonary disease	446	3.9
Diabetes mellitus	369	3.6	Road injury	940	3.6	Stomach cancer	712	3.2	Colon and rectum cancers	403	3.5
Chronic obstructive pulmonary disease	336	3.3	HIV/AIDS	629	2.4	Lower respiratory infections	692	3.1	Diabetes mellitus	342	3.0
Preterm birth complications	327	3.2	Cirrhosis of the liver	557	2.1	Hypertensive heart disease	547	2.5	Hypertensive heart disease	252	2.2
Malaria	247	2.4	Falls	517	2.0	HIV/AIDS	463	2.1	Kidney diseases	249	2.2

Place of care: where are palliative care services and support needed and where do we die?

One aim of health-care service providers is to offer care, where possible, in a location that matches the patient's preference. Data reporting concordance between preferred place of death and actual place of death has been much less common than data that simply reports place of death (Pritchard et al., 1998; Gomes et al., 2012a).

Data reporting 'place of death' are for the most part collected only in high-income nations. In general, it is clear that for many individuals in low-income countries hospital care is not available, which would suggest that the vast majority of people in these regions die outside the hospital setting (English et al., 2006). The opposite is true in many high-income countries where death in hospital is common. The available data suggest that more than 50% of deaths in England, the United States, Germany, Switzerland, and France take place in the hospital (Gomes, 2013). Significant variations in place of death nonetheless exist among high-income countries, with lower rates of hospital death reported in the Netherlands (35%), Ireland (30%), and Italy (35%) (Klinkenberg et al., 2005; Beccaro et al., 2007).

Some studies have provided projections of where people in high-income populations are likely to die in the future, and suggest that the rate of death at home will decline over time (Gomes et al., 2008). Despite this, other data indicate that this trend may not necessarily continue and reports from several countries suggest there will be an increase in the proportion of patients who die at home, at least with respect to cancer deaths in populations which are served by specialist palliative care (Gomes et al., 2012a).

When asked about preferred place of death, the overwhelming majority of well people indicate a preference for care at home up until, and including, the time of death (Foreman et al., 2006; Beccaro et al., 2007; Gomes et al., 2012b; Gomes, 2013). This contrasts with actual place of death for the majority (McNamara et al., 2007; Gomes et al., 2012a; Gomes, 2013). The reasons for this disparity have been investigated, revealing that many factors, including access to care, influence this observation. For example, where inpatient beds are available, more inpatient care occurs (Pritchard et al., 1998; Higginson and Costantini, 2008). Recent research that has focused on 'preferred place of care' rather than only on 'place of death' takes into account the observation that the preferences of ill patients may change along the illness trajectory, and may be different to the preferences elicited from well people with or without life-threatening illness (Storey et al., 2003; Munday et al., 2007; Agar et al., 2008; Gomes et al., 2008; Gomes, 2013). These types of data illustrate some of the subtle, less acknowledged, reasons behind patients' changes in their preferred 'place of care' (see Fig. 2.2.3). When collected longitudinally, rather than at a single point in time, data that compares actual place of care to preferred place can also help to inform planning and support flexibility in service provision up until and including the time of death (Agar et al., 2008). Further research is required to explore factors associated with the disparities between desired place of death and actual place of death that have been identified (Gomes, 2013).

The availability of, and access to, palliative care expertise

Epidemiological data related to the provision of palliative care are important for understanding whether there is population-wide access to appropriate care. It also helps to identify populations in need of palliative care and, in relation to care towards the end of life, whether care is available in the patient's preferred place of care. These types of data allow for designing and refining models of palliative care delivery that aim to provide appropriate care and, where possible to provide it in patients' locations of choice. The WHO has endorsed palliative care as an essential component of health care (see Box 2.2.1) (WHO, 2014). To achieve this, it is vital that generalist and most specialist health practitioners have fundamental competencies in symptom management towards the end of life (Dudgeon et al., 2008; Shipman et al., 2008). It is generally accepted that there is also a need for patients to have access to specialist palliative care services when needed (Field and Cassel, 1997; National Institute for Clinical Excellence, 2004; WHO, 2007; Martin-Moreno et al., 2008; Temel et al., 2010; National Gold Standards Framework Centre, 2012).

It is evident that specialist palliative care services are becoming available for cancer and non-cancer diagnoses in most high-income countries through mainstream health services in community, inpatient, and acute hospital settings but availability is much more limited in middle-income and low-income countries (Fig. 2.2.4) (Morris, 2011). In high-income countries, many tertiary-referral centres accommodate integrated consultative, specialist palliative care services within acute and subacute settings (Glare et al., 2003; Mercadante et al., 2008). Studies have highlighted that palliative care specialist services in most middle-income countries are available but only for some of the patients in need, and are frequently unavailable for the poor and those living in rural and remote regions (Morris, 2011). Specifically, in low-income countries, the majority of those dying do not have any access to specialist services and those services that do exist reach only a very small proportion of the people in need (Kikule, 2003; Morris, 2011). The majority of dying people in these areas are cared for at home and in communities by family and/or neighbours. Regarding needs in these countries, one cross-sectional study identified three main areas of palliative care need in low-income areas —symptom management, counselling, and financial assistance (Kikule, 2003).

Despite the availability of services, for a significant proportion of patients with far advanced disease, even in high-income countries there are limits on access to symptom management and end-of-life care (Higginson, 1997; Pritchard et al., 1998; Rosenwax et al., 2006; Beccaro et al., 2007; Goldsmith et al., 2008). As an example of the impact of epidemiological data supporting this claim, a West Australian study showed that patients dying from illnesses other than cancer are less likely (8%) than those with cancer (68%) to receive specialist palliative care (Rosenwax et al., 2006). Studies elsewhere have raised similar access issues when considering palliative care (Solano et al., 2006; Murray et al., 2008).

Examples of the wealth of information that can be provided by generating epidemiological reports from carefully collected clinical data are reports such as those from Seow et al. (2012) and Laugsand et al. (2011) that describe components of multidisciplinary service provision, symptom management, prognosis, diagnoses, and co-morbidity. While not necessarily generalizable to other regions, these data provide information that could be highly useful in planning and tailoring regional services for the areas in which data was collected. Of note is that local needs assessments, using defined criteria, such as performance status, symptom prevalence, and prognosis, may also allow further comparison and

benchmarking in relation to palliative care access—an approach such as that recommended by Kaasa and colleagues and others (Kaasa et al., 2008; Boyd and Murray, 2010; Currow et al., 2012).

Studies such as those just mentioned can assist identifying the extent to which people and populations with palliative care needs are accessing services. Methodical enquiry into this matter is important especially where disparities exist and/or access is not clearly defined as needs based. An emphasis on needs-based care, rather than on diagnosis- or prognosis-based provision of care, has been advocated by many (Davies and Higginson, 2004;

Rosenwax et al., 2006; Young et al., 2008; Boyd and Murray, 2010; Waller et al., 2012); however, presently there are limited epidemiological data to inform practice in regard to this area. The routine collection and systematized reporting of data relating to care needs is crucial to this and the review, identification, and refinement of tools to help in identifying those who would benefit from palliative care will assist this process (Boyd and Murray, 2010; Waller et al., 2010; Weissman et al., 2011).

The epidemiology of symptoms experienced towards the end of life

Symptom data and health-care needs in palliative care

In the previous section, access to health services in relation to care needs was discussed. Importantly, specific research questions in relation to how well those specific needs are being addressed within populations generally warrant epidemiological investigation. Health-care needs at the end of life have a direct relationship with symptoms experienced during that time; in the context of palliative care (Franks et al., 2000; Mirando, 2004; Higginson et al., 2007), and in relation to many specific diseases at the end of life (Edmonds et al., 2001; Elkington et al., 2005), symptom management is also generally acknowledged as an important need, among many palliative care needs. Some data which quantify and describe various aspects of the symptoms experienced towards the end of life in particular populations and to a certain extent are available (Solano et al., 2006; Teunissen et al., 2007). In relation to health-care needs, data relevant to palliative care have been reported but prevalence has not necessarily been well quantified.

Currently in palliative care there is a focus on developing and describing appropriate processes that can be used to identify, compare, and contrast the palliative care needs of different people and populations (Higginson et al., 2007; Currow et al., 2008a; Waller et al., 2010; Currow et al., 2012). Illness trajectories, as discussed below, are one useful way of mapping population-based functional support needs over time. Aside from the importance of addressing symptom burden and care needs from a health-service perspective, epidemiological data are also needed to provide adequate answers to questions that come from individuals in clinical settings such as 'Am I likely to have pain that cannot be managed?' (Franks et al., 2000; Edmonds et al., 2001; Currow et al., 2004; Davies and Higginson, 2004; Mirando, 2004; Elkington et al., 2005; Higginson et al., 2007) and 'Who will care for me if I can't care for myself?'. In essence these questions that may be asked by patients and carers are the corollary of questions asked by palliative care providers, that is, 'What needs are best met by specialist palliative care providers?' and 'How can we ensure that people who may not require specialist palliative care have their needs at the end of life met?'

With respect to symptom management, biomedical ethics and contemporary liberal philosophy suggest that there is not only justification for symptom management at the end of life, but an ethical (Sen, 1993; Freeman, 2007) and legal (Brennan, 2007) imperative for it. Within health services and/or specific populations, it's important to develop benchmarks to assess outcomes and quality of care and to carefully describe study populations so as to facilitate comparisons across settings.

Methodological issues and limitations of data relating to symptoms

When reviewing and interpreting symptom-related epidemiological data there are a number of important aspects that must be considered. A summary of the key points to take into consideration in the interpretation of data reporting the epidemiology of symptoms follows:

1. *It is crucial to consider symptom-related epidemiological data in the context of the availability of effective symptom management.* This is especially important for patients and caregivers. For example, a prevalence estimate of 70% for severe pain can be alarming for patients and caregivers unless placed in context. While this figure may reflect the true point prevalence it does not convey the important information that the overwhelming majority of pain can be appropriately treated (Meuser et al., 2001), or that for the 10–15% of patients who respond poorly to initial pain management, standard multidisciplinary approaches are available to improve the refractory pain, suffering, and symptom burden (Hanks et al., 1992).

2. *Defining the population from which data are obtained is extremely important.* Care must be exercised when interpreting findings and, for the most part, extrapolation beyond the source population is best avoided. Heterogeneity in patient characteristics, such as primary disease, disease stage, and access to care, may render generalizations about the symptom-experience itself, or the factors contributing to the outcome under investigation, inappropriate (Hearn et al., 2003; Kaasa et al., 2006; Currow et al., 2008b). For example, some studies of patients with far-advanced disease have been conducted in the last year of life, others in the last days of life, and in many studies the prognosis of the population or the 'time to death' in relation to the point of data collection are not presented. Some symptom reports may reflect pooled data from patients at various disease stages. For example, a study of cancer patients may include patients undergoing adjuvant treatment for cancer, and/or those with early- or late-stage metastatic disease. Another major problem in the symptom-related literature is that a diagnosis of 'cancer' without further detail (e.g. lung, colon, etc.) has been the unifying 'diagnosis' that has identified the subjects in many studies of end-of-life needs and symptoms. While common symptoms occur across different diseases, the nature of the symptom experience and health-care needs may vary across and among disease states (Edmonds et al., 2001). Interpreting data gained from a study of heterogeneous patients even with respect to a specific primary malignancy (e.g. 'breast cancer') can present significant problems (Greenwald et al., 1987; Kaasa et al., 2006).

3. *The patient experience is personal and subjective*—attempts to characterize it may require a diverse spectrum of research methods and when a type of method is selected, it should be standardized and consistent to allow comparison with other studies using the same or similar methodology; this has not always been the case (Payne et al., 2008). With respect to symptom occurrence studies, for instance, although for each symptom a number of studies may be identified, heterogeneous target populations and/or poorly described characteristics of the populations, can mean that it is very difficult to compare

studies or to pool data in meta-analyses (van den Beuken-van Everdingen et al., 2007).

4. *The accuracy of data is dependent on the accuracy of information communicated between subject and researcher.* For example, the accuracy of the medical record as a source of data and the use of proxy symptom ratings will affect the data and limit interpretation (Addington-Hall, 2002; McPherson et al., 2003; Higginson, 2013). No matter which tool is used within a study, the validity of the tool in the context in which it has been used must be considered carefully (National Institutes of Health, 2004; Higginson, 2013).

In addition, patient symptom reports are different to clinical diagnoses of syndromes. For example, with respect to delirium, if a study reports categories such as confusion, cognitive symptoms, and neurological symptoms separately rather than syndromal delirium, conclusions about the presence or absence of delirium become difficult to draw. Patients or proxies cannot be asked to rate the presence of 'delirium' which is a diagnosis not a symptom. Meta-analyses cannot reverse the impact of poorly defined symptoms or syndromes as the categories reported are determined by the methods used in the individual studies. The importance of study methods in terms of choosing the correct tools to address the hypothesis and carefully describing the population is again emphasized (Kaasa et al., 2008).

5. *An individual's symptom experience changes over time and the burden imposed by a particular symptom may change over time* (Hwang et al., 2003; Sharpe et al., 2005). The temporally isolated nature of point prevalence data does not reflect the dynamic changes of the symptom experience over time. Likewise, health-care needs at the end of life are dynamic and longitudinal studies are required to adequately describe them.

6. *The symptom experience is multidimensional, inter-relates with the bio-psychosocial, spiritual, and cultural domains, and may have characteristics linked with particular populations.* Some studies have addressed this by investigating symptom burden or distress in addition to symptom prevalence and/or incidence (Hwang et al., 2003; Potter et al., 2003; Strong et al., 2007; Blinderman et al., 2008). Other experts have reviewed and highlighted important priorities relating to care at the end of life and identified approaches and directions for future research that relate to measuring complex, and/or multicomponent interventions towards the end of life (National Institutes of Health, 2004; Higginson, 2013).

7. *Despite the limitations and challenges of study in this area, and considering the overall experience of symptom burden and distress towards the end of life, questions still exist as to which symptoms or health-care needs are the most common and/or most burdensome in the context of particular conditions or within particular health systems, and whether the common symptoms or needs are appropriately addressed* (Hearn et al., 1999). The management of uncommon but troubling symptoms is also of clinical importance; however, there is a paucity of epidemiological data for uncommon symptoms. Meta-analyses have been used to address the problem of small sample size, although as highlighted previously, the heterogeneity of studies included in meta-analyses is also problematic.

Collaborative, multi-centre studies with attention to inclusion criteria that carefully define the population reported can go a long way towards improving case recruitment as well as maximizing the homogeneity of the data (Currow et al., 2008a; Kaasa et al., 2008). Electronic record linkage has proven to be a powerful tool for palliative care health service research in areas such as estimating patients' needs, service utilization, cost, and place of care (Fassbender et al., 2005; Rosenwax et al., 2006; McNamara et al., 2007) but not in exploring the symptom experience as such.

The aim of this section has been to illustrate the relationship between empirical data and the symptom experience, and the uses, limitations, and challenges inherent in the interpretation of symptom-based epidemiological data. The following sections review existing epidemiological data related to symptoms and health-care needs at the end of life in the light of their incidence and prevalence, severity, frequency, associated distress, and in relation to impact on function and global burden for patients as well as caregivers.

Symptom occurrence by cause of death: what symptoms can be expected over time?

Until recently, symptom prevalence studies in the palliative care setting have focused predominantly on patients with cancer diagnoses. There are now a number of good quality studies that have explored the prevalence of symptoms in patients with life-threatening and far-advanced chronic lung disease (Elkington et al., 2005; Walke et al., 2007) and cardiovascular disease (Addington-Hall et al., 1998a; Solano et al., 2006; Young et al., 2008). Large population-based data sets describing symptom prevalence are lacking; however, two systematic reviews of studies reporting point estimates of the prevalence of different symptoms have provided excellent overviews of symptoms experienced near the end of life (Solano et al., 2006; Teunissen et al., 2007).

Although generalizing is problematic, the available evidence suggests that for people with advanced, progressive life-limiting illness, there is a core group of symptoms, including pain, depression, dyspnoea, and fatigue, experienced across disease states in the last days, and probably the last year of life. Table 2.2.2 presents the data from a meta-analysis which included 64 studies across progressive cancer and non-cancer illnesses (Solano et al., 2006). The authors defined the study time-frame in the included patients' end of life care and targeted 11 predicated symptoms. Studies restricted to the last hours of life were excluded. Notably this meta-analysis did not include cerebrovascular disease (stroke), now ranked the second most common cause of death worldwide, or Alzheimer's dementia which is now reported as the fourth most common cause of death in high-income countries according to 2011 data (WHO, 2013e).

Physical symptoms during the last year of life: what will it be like?

In a meta-analysis of 26 223 patients (Teunissen et al., 2007), studies relating to two time periods were analysed independently and data were presented in two groups relating to the time periods. The two groups were studies prior to the last 2 weeks of life (identified as 'group 1' in the original article) and studies

Table 2.2.2 Symptom prevalence in specific life-threatening diseases

Symptoms	Cancer	AIDS	HD	COPD	RD
Pain	35–96%[7,8,11,19,33–47]	63–80%[48–50]	41–77%[22,34,51,52]	34–77%[4,22,53]	47–50%[54,55]
	N = 10 379[a]	N = 942	N = 882[a]	N = 372	N = 370
Depression	3–77%[7,11,19,20,33,36,41,43,45,47,56–63]	10–82%[50,61,64,65]	9–36%[52,66]	37–71%[4,53]	5–60%[67–72]
	N = 4378[a]	N = 616[a]	N = 80[a]	N = 150	N = 956[a]
Anxiety	13–79%[19,33,36,41,45,47,58,62,63]	8–34%[12,64,73]	49%[52]	51–75%[74]	39–70%[67,68]
	N = 3274	N = 346[a]	N = 80	N = 1008	N = 72[a]
Confusion	6–93%[7,19,20,34,36,39,42–47,60,75–81]	30–65%[76,82]	18–32%[22,34,52]	18–33%[4,22]	–
	N = 9154[a]	N =?[a]	N = 343[a]	N = 309	
Fatigue	32–90%[8,24,35,41–43,45,47,63,83]	54–85%[50,84]	69–82%[8,22,52]	68–80%[22,53]	73–87%[71,85]
	N = 2888[a]	N = 1435	N = 409	N = 285	N = 116
Breathlessness	10–70%[7,8,11,19,33–36,39–47,61,86–88]	11–62%[50,88]	60–88%[8,22,34,51,52,61]	90–95%[4,22,53,61]	11–62%[55,89]
	N = 10 029[a]	N = 504	N = 948[a]	N = 372[a]	N = 334
Insomnia	9–69%[7,8,11,19,33,39,41–43,45,47]	74%[50]	36–48%[8,52]	55–65%[4,53]	31–71%[55,85,90]
	N = 5606	N = 504	N = 146	N = 150	N = 351
Nausea	6–68%[8,11,19,33–36,39–47,61,91–93]	43–49%[50,94]	17–48%[8,34,52]	–	30–43%[85,95,96]
	N = 9140[a]	N = 689	N = 146[a]		N = 362
Constipation	23–65%[7,11,19,33–35,39–45,47,50,93]	34–35%[50,94]	38–42%[34,52]	27–44%[4,53]	29–70%[97]
	N = 7602[a]	N = 689	N = 80[a]	N = 150	N = 483
Diarrhoea	3–29%[11,33,39–41,43,44,47,61,92,93,98]	30–90%[50,61,98,99]	12%[52]	–	21%[71]
	N = 3392[a]	N = 504[a]	N = 80		N = 19
Anorexia	30–92%[7,8,11,19,33,35,39–46,92,93,100]	51%[50]	21–41%[8,52]	35–67%[4,53]	25–64%[89,96]
	N = 9113	N = 504	N = 146	N = 150	N = 395

1. Minimum–maximum range of prevalence (%) is shown.

2. HD = heart disease; COPD = chronic obstructive pulmonary disease; RD = renal disease.

3. *N* refer to the total number of patients involved in the studies found for each symptom in a given disease (e.g. there are 372 patients involved in the three studies on pain prevalence in COPD).

4. Superscripted numbers relate to the reference source[b] and indicate the number of studies for each symptom in a given disease (e.g. there are three studies on pain prevalence in COPD patients). In two occasions, a single study reported a prevalence range rather than a single point prevalence—anxiety for COPD and constipation for renal failure. '–' was displayed when no data were found for a specific symptom and condition (e.g. confusion for renal failure).

[a] The number of patients is underestimated or unknown because prevalence figures given by textbooks were considered (for which the number of patients was not provided).

conducted 'in the last 1–2 weeks of life' (identified as 'group 2' in the original article) (see Table 2.2.3 and Table 2.2.4). Despite the limitations discussed above, studies such as these help to define symptom experience over time and can be useful in service planning. As already discussed, point prevalence data and severity data for symptoms are influenced by, but do not provide detail of, access to quality care.

Data on the prevalence of specific symptoms, even in the setting of malignant disease, is more scarce than expected. With regard to the prevalence of pain, Bonica's landmark review (Bonica, 1985) reported a prevalence of 71% in patients with advanced/metastatic/terminal cancer (Van den Beuken-van Everdingen et al, 2007). In addition to providing prevalence

data, Bonica's study highlighted methodological considerations in studies of symptom occurrence, including the presence of serious pain at all stages of cancer, its amenability to effective management, and the variation in pain experience over a day and over longer periods (Greenwald et al., 1987).

Other important studies have presented data relating to the experience of pain in cancer (Hearn et al., 2003; Holtan et al., 2007) and non-cancer (Solano et al., 2006; Murray et al., 2012) settings, or both. Most studies have also noted that effective management of pain can be achieved with adherence to the WHO ladder recommendations for management. An unexpected consequence of understanding available pain prevalence data is that it may also provide reassurance to some individuals as these statistics suggest

Table 2.2.3 Summary of symptom prevalence in cancer *prior* to the last 1–2 weeks of life[a]

Reprinted from *Journal of Pain and Symptom Management*, Volume 34, Number 1, Teunissen, S.C. et al., Symptom prevalence in patients with incurable cancer: a systematic review, pp. 94–104, Copyright © 2007 U.S. Cancer Pain Relief Committee, with permission from Elsevier, http://www.sciencedirect.com/science/journal/08853924

that there is a proportion of patients with advanced cancer who do not report pain and that although pain is a significant problem for many, it is not an inevitable consequence of a cancer diagnosis. Communication of information about pain to patients and carers benefits from attention to these factors.

Van den Beuken-van Everdingen and co-authors (2007) provided pooled estimates of prevalence for four subgroups of patients based on different stages of the cancer care pathway. They report pooled prevalences of pain of (a) 33% (95% confidence interval (CI) 21–46% (from studies including patients after curative treatment), (b) 59% (95% CI 44–73%) from studies including patients under anti-cancer treatment, (c) 64% (95% CI 58–69%) from studies including patients with disease characterised as advanced/metastatic/terminal, and (d) 53% (95% CI 43–63%) from studies including patients at all disease stages. They also report that for one-third of patients pain was graded as moderate or severe. The pooled estimates of prevalence of pain were greater than 50% for the six cancer groups they examined. Age, continent of origin, and date of study did not contribute to statistically significant variation.

Pain is not only among the most common symptoms in terms of incidence, but it ranks highly with regard to intensity (Tishelman et al., 2007) and distress (Bruera et al., 1991; Portenoy et al., 1994; Hwang et al., 2003). Other common and distressing symptoms for which specific point prevalence data are available include fatigue (Solano et al., 2006; Tishelman et al., 2007), depression (Hotopf et al., 2002; Mitchell et al., 2011), delirium (Leonard et al., 2008), breathlessness (Elkington et al., 2005; Solano et al., 2006; Teunissen et al., 2007; Walke et al., 2007; Currow et al., 2010), disturbed bowel function (Clark et al., 2012), and psychosocial distress (Addington-Hall et al., 1998a; Hynninen et al., 2005; Jacobsen et al., 2005; Averill et al., 2007; Holland et al., 2007; Blinderman et al., 2008; Hill et al., 2008).

The evidence suggests that neuropsychiatric symptoms and syndromes are also particularly common toward the end of life (occurring in up to one in two patients) (Derogatis et al., 1983) and that under-recognition, misdiagnosis (Fallowfield et al., 2001), and under-treatment persist (Lloyd Williams et al., 2003). In the setting of far-advanced cancer anxiety (Roth et al., 2007), sleep disorders (Mercadante et al., 2004), post-traumatic stress disorder (Breitbart, 1995; Leonard et al., 2009), demoralization (Kissane et al., 2001), and suicidal ideation have all been identified as prevalent and distressing neuropsychiatric syndromes.

Symptom occurrence in the last days of life: what symptoms can be expected in the very last days of life?

Much has been written in recent decades about the mandate for optimum care for all dying patients at the very end of life (Field and Cassel, 1997; National Institute for Clinical Excellence, 2004; WHO, 2007; Martin-Moreno et al., 2008) (see also Chapter 1.1). Recently, health-funding bodies, locally and nationally, have invested in comprehensive programmes to assist generalist and specialist clinicians to improve care for patients in the last days of life, regardless of setting or diagnosis. Epidemiological data about symptoms and health-care needs during this period of life can inform care provision and assist in defining priorities for the education of clinicians.

There are several problems inherent in reviewing data regarding symptoms at the very end of life. Fatigue, weakness, and lack of energy along with dyspnoea and pain are reported as highly prevalent in most studies examining symptoms at this time of life (Teunissen et al., 2007) Many of these symptoms and/or the distress associated with them are amenable to treatment and as a result, symptom prevalence data must be interpreted in the context of an understanding that some or many symptoms are amenable to treatment. It is important to note that point prevalence data alone do not give insight into the level of treatment provided. It must be noted that in some studies, data on symptoms such as fatigue and those symptoms related to delirium are conspicuous by their absence. This may result from bias of a particular tool (some tools have excluded fatigue) or, for example, the absence of delirium in an inventory of symptoms at the end of life. The omission of a symptom from a specific tool will unavoidably bias outcomes, so it is important to understand how a symptom assessment tool has been developed.

Reports from hospice programmes and pain studies suggest that despite the prevalence of symptoms, most deaths can be peaceful (Saunders, 1948; Lichter et al., 1990; Seeman, 1992; Hinkka et al., 2001). Although an early but informative study of this time of life was published in 1904 by Osler (Osler, 1904; Hinohara, 1993), studies on symptoms towards the end of life, especially in the very final days of life, have been rare until recently and often limited to small case series that relied on proxy reports. Table 2.2.4 provides pooled prevalence estimates from a comprehensive meta-analysis of cancer-related symptoms in the last 1–2 weeks of life (Teunissen et al., 2007). Symptoms during the last days or weeks of life have also been captured by other studies (Foley et al., 1995; Pritchard et al., 1998).

Longitudinal, population-based data relating to the experience of specific symptoms occurring at the very end of life are essential for planning service provision and setting training and research agendas but have only rarely been published. A study from Western Australia documented patient dyspnoea in 5862 patients who had rated their dyspnoea over time in a routine collection of symptom data in a clinical palliative care setting. Data were reported from patients over time, with a median of 48 days of data collection, up until the day of death. In the last days of life the proportion of patients with 'no dyspnoea' fell to 35% but those who rated dyspnoea as greater than 7 out of 10 rose to 26%. Moderate to severe dyspnoea in patients with respiratory failure was sustained over many months before death, and mild to moderate dyspnoea was also reported in other patients in the months preceding death (Currow et al., 2010). This study is a good example of how data collected in a standardized manner in a clinical setting can be analysed to provide important information about some groups and inform the development of treatment and support interventions, as well as patient, caregiver, and provider educational strategies.

Despite significant advances in palliative care treatments and interventions, there are data that suggest that, at the very end of life, unmet symptom-related health-care needs amenable to palliative care interventions persist (Okuyama et al., 2004; Goodridge et al., 2008; Rustoen et al., 2008; Laugsand et al., 2011). For example, the findings of the Study to Understand Prognosis and Preferences for the Outcomes and Risks of Treatment (SUPPORT) were published in a number of papers in the mid 1990s. This study followed 9105 adults hospitalized in the United States with at least one of nine life-threatening diagnoses. One finding was that proxies reported that 50% of conscious patients were in moderate to severe pain for more

Table 2.2.4 Summary of symptom prevalence in the *last* 1–2 weeks of life[a]

CI, confidence interval.

than half the time during the last 3 days of life (SUPPORT Principal Investigators, 1995). Epidemiological studies of cancer patients from other countries reveal similar rates of inadequate pain control (Laugsand et al., 2011) and unmet symptom management needs are also evident for patients with non-cancer, life-threatening conditions (Covinsky et al., 1996; Goodridge et al., 2008; Rustoen et al., 2008). As discussed above, unmet symptom management needs are important research findings; however, as previously emphasized, data must be interpreted in the context of access to skilled care as well as the amenability of symptoms to treatment and the ability of multidisciplinary services to meet complex needs (Meuser et al., 2001).

Another aspect of the physical experience that has been rated as highly important by cancer patients is the area of communication, consciousness, and mental acuity towards the end of life (Steinhauser et al., 2000). Few epidemiological studies have reported on the longitudinal trends in the level of consciousness towards the end of life. The large National Mortality Followback Study in the United States addressed many aspects of health care including the end-of-life experience (Seeman, 1992). This study sought the perceptions of family carers in regard to decedents and, with respect to cognitive function at the end of life, reported that 68.9% of patients 'never or hardly ever' had trouble in recognizing

family members or friends during the last year of life (Seeman, 1992). Delirium is reported to frequently accompany the last hours of life for patients with cancer and non-cancer-related illnesses (Conill et al., 1997; Teunissen et al., 2007), but, as with other symptoms, such data must be considered in the context of the availability of effective management (Seeman, 1992; Lawlor et al., 2000).

Trajectories of functional decline towards the end of life: what can be expected over time?

Functional decline in the months before death has been described in several studies, including one by Glaser and Strauss (1968) that described the trajectories of dying. More recently, Lunney et al. (2003) described four general patterns of functional decline (see Fig. 2.2.5). Of note, these 'general patterns' of care needs are supported by detailed epidemiological data, in this case from US Medicare data sets (Lunney et al., 2003). It is important to acknowledge that while general trends exist, these trajectories are not necessarily applicable to individual patients. Functional decline can be viewed to some degree as a 'proxy' for health-care needs in that it has implications for personal care, physical support in the home, and caregiver supports. Clearly, on a national, regional, or institutional level it is important for health-care planning to accommodate the care needs of populations implied by trajectories of functional decline.

On an individual level, this type of epidemiological data about performance status and function can assist in facilitating discussion about an individual's projected symptom experience and can help in answering such questions as: 'Is it likely I will have months lying in bed unable to speak or get up?', 'Is it likely I will need someone to look after me?', or 'Is it likely I will be able to stay at home?'. As an example, it may appear almost redundant to many clinicians to state the general differences between the functional decline and care needs of a patient with Alzheimer's disease and the needs of a patient with acute myeloid leukaemia.

For patients and carers this is most often far from obvious, and rather than being left to draw their own conclusions based on what they have observed in others, in the literature, and/or the media, patients and carers may benefit from timely and skilled communication with a health professional who has a good understanding of common functional trajectories.

Health administrative data sets: how can these be used to assess needs and quality of care?

Some information about population health-care needs at the end of life has been provided by a number of large, well-designed epidemiological studies (Seeman, 1992; Addington-Hall et al., 1995; McNamara et al., 2007; Coupland et al., 2010; Seow et al., 2012). Further information about the longitudinal trajectory of functional and other needs would be helpful for service planning.

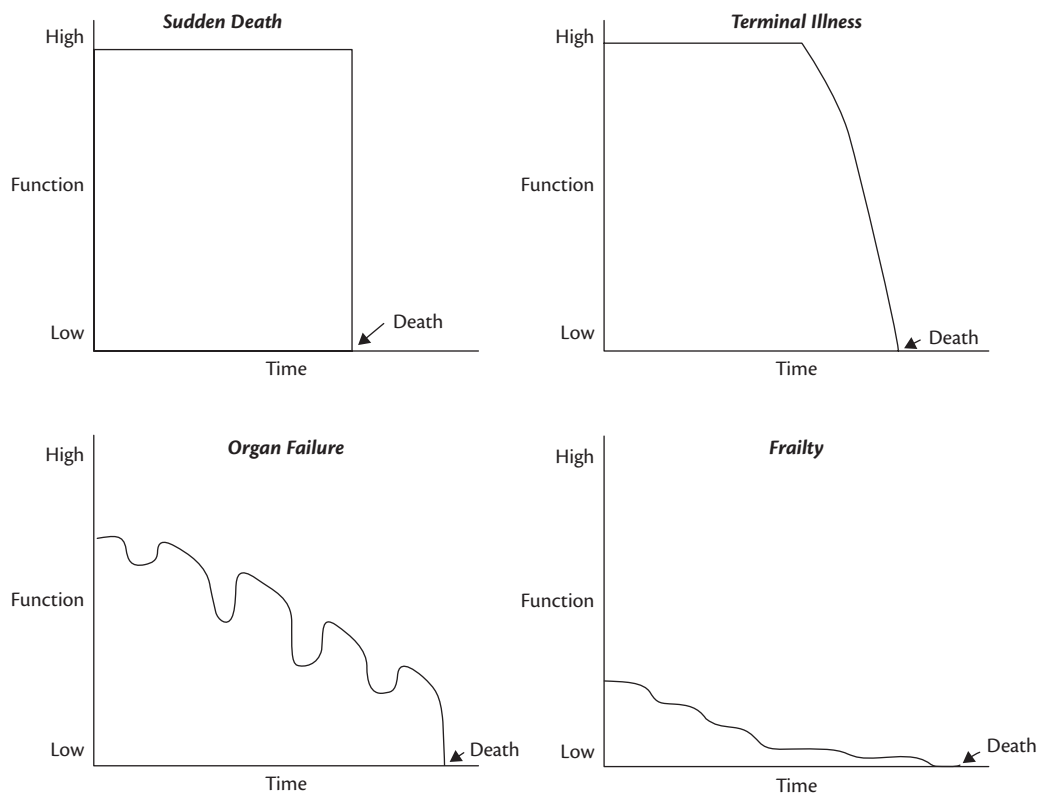

Fig. 2.2.5 Functional trajectories at the end of life.

With an increase in the potential to analyse large health-care administrative data sets through record linkage, there is increased discussion about the role that information extracted from these datasets can play in assessing the quality of care. Many studies of this nature have been carried out in recent years looking at the period towards the end of life including large epidemiological studies that have provided information about health-care utilization over the period near to the end of life. Although a full review of these studies is beyond the scope of this section, these include studies looking at costs of care (Fassbender et al., 2005; Yabroff et al., 2007), palliative care service use (Fassbender et al., 2005; Rosenwax et al., 2006), place of death (McNamara et al., 2007), and hospital and community health experiences including physician visits, procedures, intensive care admissions, emergency department presentations, and length of stay in hospital (Kaul et al., 2011; Unroe et al., 2011).

A recent Canadian study illustrates the types of findings possible in these studies. This study examined the public provider costs associated with the last 6 months of life for all cancer deaths in Ontario. Investigators found that 75% of costs associated with end of life and palliative care were incurred in the acute hospital setting (Walker et al., 2011). Other investigators found that 26.6% of costs were borne by family/carers (Dumont et al., 2010).

Increasingly, investigators have sought to explore the question of how to use data points within health administrative data sets to develop indicators of quality of care at the end of life and, to achieve this, have used methods including seeking expert opinion and patient and carer feedback about such indicators through focus groups (Earle et al., 2005; Grunfeld et al., 2008). It is becoming clearer with time that indicators could, with widespread use and further work on appropriate benchmarks for various regions, be used within and among health services to inform planning and predict service needs (e.g. home care, emergency room services, etc.) (The Dartmouth Atlas of Health Care, 2007). The ability of indicators in these data sets to truly capture the appropriate endpoints relating to quality of care remains complicated. Limitations include the challenge inherent in non-subjective indicators to provide a clear representation of many aspects of the patient's experience. These data sets cannot generally answer questions such as whether patients' preferences were honoured, and whether patients and carers were satisfied with care (Grunfeld et al., 2008). In summary, while there is a wealth of data related to health-care utilization there is a need to both refine validated quality indicators, and to develop systems to measure and record patient-reported outcomes to ensure information is meaningfully recorded to inform patient-centred care (Grunfeld et al., 2008; Higginson, 2013).

Caregiver concerns

A single death affects many others in terms of informal caregiving and grief (see Chapter 17.6). Documentation of the caregiver's experience towards the end of life is therefore an important aspect of the epidemiology of the end-of-life experience.

Many caregivers willingly provide care, and indeed report that they find the role of carer a rewarding and an important part of family experience (Andrén et al., 2008). Notwithstanding this, research conducted across diagnoses and in various countries has tended to focus on the significant demands and burdens that arise from caring for patients with life-threatening illnesses and despite the positive aspects of the role, one in 13 carers in one study (7.4%) indicated that they would not take on the caring role again (Currow et al., 2011). Caregiving has been shown to affect both the physical (Christakis et al., 2006) and psychological (Zivin et al., 2007) health and the social and financial (Carmichael et al., 1998; Emanuel et al., 2000; Berecki-Gisolf et al., 2008) situation of caregivers (Aoun et al., 2005; Burton et al., 2012). Population-based sampling such as that undertaken by Addington Hall et al. (1998b) can provide important information about carers of patients with a particular diagnosis. For instance, the study by Addington-Hall et al. presents data from a representative sample of carers for a person who died from stroke and state that 43% of carers reported to have needed more assistance with personal care and 31% reported unmet needs regarding financial issues. For further information about caregivers, readers are referred to Chapters 6.1, 6.2, and 16.1 and to studies such as the 1999 National Long Term Care Study (NLTCS) (Wolff et al., 2007) and the SUPPORT study (Covinsky et al., 1996).

In addition to the impact of caregiving on physical and psychological health, from a societal and epidemiological perspective, the financial and social impact of caregiving is also significant. As an example, in the SUPPORT study, in which care in the United States was investigated, it was reported that 31% of families caring for patients near the end of life lost most or all of the family's savings and, in 20% of cases, the caregiver had to resign from work or make another major life change to continue to provide care (Covinsky et al., 1996). Informal carers and their households are certainly at risk of suffering loss of income, and indeed epidemiological studies have demonstrated the significant impact that caregiving has on workforce participation (Carmichael et al., 1998; Berecki-Gisolf et al., 2008). Such data raise questions about availability of resources and policy to address the needs of carers. The importance of assessing the impact of caregiver interventions on carer burden beyond financial and health concerns is supported by existing literature. There is evidence suggesting that carers regard information, emotional support, practical care, and patient comfort as most important (Addington-Hall et al., 1998b; Burton et al., 2012).

The array of studies reporting on the needs and experiences of caregivers from high-income countries contrasts with the paucity of data relating to this from low-income countries. While less research has been done in low-income areas, an interesting small study by Grant et al. reported that for advanced cancer 'the emotional pain of facing death was the prime concern of Scottish patients and their carers, while physical pain and financial worries dominated the lives of Kenyan patients and their carers' (Grant et al., 2003). While more data are needed worldwide on the caregiver's experience, the overlapping needs of caregivers and the contrasting needs reported in this study provide some insight into the spectrum of needs and the disparities that exist among caregivers.

Cultural experiences and the existential context

Death is laden with emotional, social, and cultural significance (see Chapter 2.5). A diverse spectrum of beliefs exists about the spiritual/existential and cultural aspects of death and the period prior to, and after, death. Despite much being discussed in the popular media

and the fact that many hold strong beliefs relating to this time of life, and the time before and after death, there is a paucity of epidemiological data concerning perceptions about the 'metaphysical' domains of experience near to the end of life with few publications in the peer-reviewed literature. Cultural factors are important in relation to symptom experience, distress, and communication at the end of life and addressed elsewhere in this textbook. Well-designed epidemiological studies investigating cultural aspects of the end-of-life experience within and across different social, geographical, and cultural groups would serve to illuminate this aspect of the end-of-life experience.

Conclusion

The study of the epidemiology of the end-of-life experience is an evolving and important field with an increasing number of studies being published that shed light on the experiences of those within populations who are nearing the end of life, and the experiences of caregivers. The use of validated tools, carefully designed studies, and record linkage will, it is hoped, shed more light on this important area over time. It is important for epidemiological enquiry that the symptoms and health-care needs at the end of life be a subject of focused study throughout the world if health policy is to truly reflect the spectrum of needs of individuals who are near to the end of life.

2.3

Predicting survival in patients with advanced disease

Paul Glare, Christian T. Sinclair, Patrick Stone, and Josephine M. Clayton

Introduction to predicting survival in patients with advanced disease

Diagnosis, treatment, and prognosis have long been recognized as the three cardinal skills of clinical medicine (Hutchinson, 1934). Prior to the twentieth century, when few effective treatments were available for any disease, offering a prognosis was about all the physician could do. Due to progress in diagnosis and treatment in the twentieth century, the need for this kind of prognostication has—thankfully—largely disappeared (Christakis, 1997). In the twenty-first century, the growth of palliative medicine has led to a renaissance of interest in predicting survival in patients with fatal diseases. But nowadays they are chronic, incurable conditions such as advanced cancer, end-organ failures, and dementia, and not acute, medical diseases such as pneumonia.

There are many reasons why palliative care clinicians need to be proficient at prognosis:

◆ It provides patients and their families with information on what to expect so they can set meaningful goals, priorities, and expectations for care.

◆ It is a key technical prerequisite for many clinical decisions.

◆ It determines eligibility for the hospice benefit in the United States and admission to inpatient units in other countries.

◆ It is important for the design and analysis of clinical trials.

Despite the importance of prognosis as a clinical skill in palliative care, most clinicians are not trained how to do it well. Prognostic issues may be covered in a class on 'breaking bad news' which typically uses disclosure of a poor prognosis as an example of difficult physician–patient communication. But most students are not taught how to formulate a prognosis or how to use it appropriately. Being poorly trained in the prognosis skills, it is not surprising that physicians find it difficult to prognosticate and do not like doing it (Christakis and Iwashyna, 1998). They also find it stressful because they believe patients desire too much certainty and accuracy from their predictions. They also feel intimidated by being judged by patients and other clinicians if their prognosis is wrong—although not as badly as for getting the diagnosis wrong. As a result, various norms of prognostication have evolved within mainstream clinical medicine:

◆ Avoid prognosticating.

◆ Wait to be asked rather than volunteering a prediction, especially if the clinical situation is atypical.

◆ Be optimistic, especially if the patient is also optimistic.

◆ Avoid being specific.

◆ Do not use prognostication for survival in treatment decision-making.

These behaviours emphasize the need to improve both education and clinical research in prognosis. There have been advances in the science of prognostication in the past 10 years that are teachable to physicians to improve their confidence to make predictions. Palliative care specialists should have special expertise in this area because it will guide care planning, diagnostic and treatment decisions, as well as communication with patients and families.

In *The Book of Prognostics*, Hippocrates wrote that the physician who was a good prognosticator was highly esteemed among his colleagues and trusted by his patients. This secular perspective contrasts with many religious traditions which insist that only God knows the hour of an individual's death. As a result, in many non-English-speaking cultures, such discussions have traditionally been avoided, although this situation may be gradually changing (Bruera et al., 2000). Patients, family, and staff who wish to defer discussing prognosis to the idea 'God only knows' may use it as a way to culturally identify the acknowledged uncertainty of prognostication.

Even in cultures that accept that predicting survival is allowable, questions are asked about the importance of prognostication. Unlike modern diagnosis and treatment, prognostication remains inherently inaccurate. Nevertheless, we believe prognostication is necessary and inevitable, and in the best interests of all involved. There may even be a moral duty for clinicians to prognosticate (Broeckaert and Glare, 2008), striving to formulate as accurate a prediction as possible, and to communicate it and use it appropriately. This means deeply embedding the clinical acts of prognostication in an open, flexible, dialogical, patient-centred approach (Glare, 2011).

Scientific principles of prognostication

Domains of prognosis

Although the focus of this chapter is on predicting survival, it is important to remember that the word prognosis is defined more broadly by clinical epidemiologists as the 'relative probabilities of the various outcomes of the natural history of a disease' (Sackett et al., 1991). To categorize the many different outcomes of a disease

which can be predicted, the '5Ds of prognostication' has been proposed (Fries and Ehrlich, 1981):

◆ disease progression/recurrence

◆ death

◆ disability/discomfort

◆ drug toxicity

◆ dollars (costs of health care).

All five of the 'Ds' are relevant to palliative care, and patients may be more interested in predictions other than survival, such as response rates and side effects of palliative therapies (Steinhauser et al., 2000). However, because remaining survival time is so central to establishing patient-centred goals, making decisions about treatment and end-of-life decision-making, the focus of this chapter is on predicting death.

Three components of prognostication

The clinical act of prognostication is in fact a composite of three skills that palliative care clinicians should be competent in. These are formulating the prognosis, communicating the prognosis, and using the prognosis when making clinical decisions. To date, prognosis research has focused on good formulation and communication. With the exception of the Study to Understand Prognosis and Preferences for the Outcomes and Risks of Treatment (SUPPORT) study (The SUPPORT Principal Investigators 1995), there have been few studies of how clinicians use prognostic information when making decisions.

Formulating the prognosis: two approaches

A prognosis can be formulated in one of two ways. The first, called clinical prediction of survival (CPS), involves the use of subjective judgement and formulation of the prognosis in the clinician's head. The other way, referred to as actuarial judgement, relies on statistical data such as median survivals and hazard ratios and eliminates the need for the human judge (Dawes et al., 1989). Research from clinical psychology indicates actuarial judgement is generally superior to clinical judgement in predicting human behaviour (Steyerberg and Harrell, 2002), but this is not yet the case for predicting survival.

Irrespective of how the prognosis is formulated, it may be expressed as a temporal prediction or a probabilistic one. A temporal prediction estimates the time to the event (that is, death) and is normally expressed as a continuous variable (i.e. actual number of days, weeks, or months) but may also be a categorical variable (e.g. < 3 weeks, < 6 months, > 1 year). A probabilistic prediction estimates the chance of surviving to a certain time point, for example, percentage chance of being alive in 6 months.

The question of which is the best way to formulate and express the prognosis raises the topic of research in prognosis and the methodological challenges that are encountered when designing or appraising a prognostic study, and they are very different to the methodological issues arising in a clinical trial of a therapy (Laupacis et al., 1994; Altman, 2009). There are many different research questions in prognosis, including evaluation of predictive factors, development and validation of prognostic models, and systematic reviews of the two. Some of the characteristics of a well-designed study to evaluate the association of a prognostic factor with survival are shown in Box 2.3.1.

***

Box 2.3.1 Characteristics of well-designed studies to evaluate the association of prognostic factors with survival

◆ A well-defined study population

◆ Inception cohort design

◆ Prognostic factors selected are appropriate and clearly defined

◆ Sample size is adequate for sufficient statistical power

◆ Clearly defined end point

◆ Complete follow-up of all patients

◆ Data analysis is appropriate to test associations between the study factors and survival

◆ A measure of agreement between the predicted and actual survival

◆ The definition of accuracy is explicit and appropriate

◆ The prediction tested mirrors clinical language or practice (i.e. not hazard ratios).

Subjective judgement: clinical prediction of survival

Little is currently known about what goes through a clinician's head when they are using subjective judgement. Are they being truly subjective, are they recalling previous patients similar to the one before them, or are they using a kind of actuarial judgement and weighing clinical and other factors? A survey of Italian oncologists found they mainly utilized tumour-related factors when formulating the prognosis in advanced disease (Tannenberger et al., 2002), even though factors such as performance status, symptom burden, and laboratory tests are more relevant in this setting (Hauser et al., 2006). For the clinician who wishes to be more systematic with their CPS, a semi-structured approach has been posited (Mackillop, 2006), beginning with the general prognosis which is based on the clinical and pathological findings (e.g. median survival of 6 months for stage 4 lung cancer). This is then customized to the patient's clinical situation, taking into account their co-morbidities, symptoms, and laboratory abnormalities, as well as their psychosocial issues.

Studies of the accuracy of CPS in advanced cancer indicate that temporal CPS are typically inaccurate, with less than one-quarter of predictions falling within 33% either side of the actual survival, and most being in the over-optimistic direction (Christakis and Lamont, 2000; Glare et al., 2003). Probabilistic CPS are often more accurate (typically in the 60–75% range) and have less of an optimistic bias. Factors influencing the accuracy of CPS have been evaluated. Improvements may be achieved with repeated estimates or asking multiple clinicians to predict. Few differences have been found between disciplines, although physicians may make better initial predictions and nurses may be better in the last few days of life—perhaps because of the amount of time they spend with the patient (Oxenham and Cornbleet, 1998). Experience matters, but a strong physician–patient relationship has been shown to lower prognostic accuracy (Christakis and

Lamont, 2000). The accuracy of CPS in non-malignant diseases is less well studied, but clinicians may be less likely to overestimate prognosis in these populations. Other terminology from the science of measurement, such as calibration and discrimination are also relevant to survival predictions. Predictions discriminate well if the patients in one prognostic group have a different survival to those in another prognostic group. Predictions are well calibrated if patients with better prognoses live longer than patients with worse prognoses.

In an attempt to improve CPS, national organizations in the United Kingdom and the United States have offered clinicians guidance on this subject. In the United Kingdom, the National Health Service's Gold Standards Framework prognostic indicator guidance consists of general 'triggers' for identifying patients and then some more specific guidance for individual diseases (Gold Standards Framework, 2011). In the United States, where incorrectly recommending hospice can result in charges of fraud, the National Hospice and Palliative Care Organization (NHPCO) has developed guidelines to help physicians determine if American patients meet the 6-month prognosis rule 'if the disease follows its usual course' to be eligible for the hospice benefit. These guidelines have been shown to be not very accurate, especially for patients with non-cancer diagnoses (Fox et al., 1999).

For physicians facing difficulties with formulating a CPS, an alternative approach is to ask oneself the 'surprise question', namely 'Would I be surprised if the patient died in the next . . . ?'. Rather than needing to definitely conclude that the patient is dying, asking if they would be surprised if the patient died before some future time point may be more intuitive and feasible. In a study of 826 patients with breast, lung, or colon cancer being followed at a US university cancer centre, 41% of the 'No, I would not be surprised' patients had died at 12 months, while only 3% of the 'Yes, I would be surprised' group had died (Moss et al., 2010). Patients in the 'No' group in this study were older, more likely to have stage IV disease, more likely to have lung cancer, and more likely to have completed an advance directive.

Actuarial judgement: predictive factors in advanced disease

Performance status
Performance status has long been recognized as a predictor of various oncological outcomes, including survival. Multiple studies in the 1980s and 1990s confirmed that cancer patients with a low score on the Karnofsky Performance Status (KPS) scale—developed in the 1940s to assess the effects of chemotherapy on functional level in cancer patients—had a short survival.

One limitation of the KPS scale is that the definitions for scores below 50 depend on the patient's need for hospitalization. The rapid development of community-based palliative care and home hospice programmes over the past 30 years that strive to keep the patient at home has made the KPS scale difficult to apply in these settings. To overcome this problem, the Palliative Performance Scale (PPS) was developed. Multiple studies have shown that the PPS score is a strong predictor of survival in cancer patients already identified as palliative. A meta-analysis of four studies demonstrated that each PPS level is distinct and without grouping (Downing et al., 2007). A large study of PPS scores in ambulatory cancer patients found that the average PPS score declined slowly over the 6 months before death, starting at approximately 70 and

ending at 40, declining more rapidly in the last month (Seow et al., 2011). Prognostat is a web-based tool for survival prediction in palliative care patients which is based on the PPS (Health Terminology Group, n.d.). It includes a calculator, survival tables, and a nomogram for cancer and non-cancer patients.

Symptoms
Most of the research on the impact of symptoms and survival has involved cancer patients. Various individual symptoms have been consistently associated with poor survival in multiple studies (Vigano et al., 2000). The strongest association is with the anorexia-cachexia complex, which has been called the 'final common pathway of terminal cancer'. Dyspnoea and confusion are also associated with a short survival in most studies. In hospice patients with a better performance status (above 40 on the KPS scale), a high symptom burden helps identify the subset with a worse survival outlook (Reuben et al., 1988).

Somewhat surprisingly, pain is not usually identified as one of the predictors of a poor survival in studies of prognostic factors, even though it is known to be a progressive problem in cancer patients. This discrepancy is likely to be explained by lead time bias. Most of the studies of prognostic factors in advanced cancer do not utilize a true, disease-based inception cohort. Instead they study patients who have been referred to palliative care services or hospice, in whom pain is usually the trigger for referral. In a recent study, the use of strong opioids, rather than pain per se, was shown to be prognostic (Gripp et al., 2007).

Various symptom scores have also been shown to be associated with survival, including the Symptom Distress Score (Degner and Sloan, 1995), Rotterdam Symptom Checklist (Earlam et al., 1996), the Memorial Symptom Assessment Scale (Chang et al., 1998), and the Edmonton Symptom Assessment Scale (Seow et al., 2011). In ambulatory cancer patients with end-stage disease, more than one-third of the cohort reported moderate to severe Edmonton Symptom Assessment Scale scores (i.e. 4–10) for most symptoms in the last month of life. Average scores for pain, nausea, anxiety, and depression scores remained relatively stable over the final 6 months. Conversely, shortness of breath, drowsiness, well-being, lack of appetite, and tiredness increased in severity over time, particularly in the month before death.

The association between symptoms and survival is less well studied in non-cancer patients. A systematic review of the prevalence of 11 common symptoms among end-stage patients with cancer, acquired immunodeficiency syndrome, heart disease, chronic obstructive pulmonary disease (COPD), or renal disease found that symptoms were widely and homogeneously spread across the five diseases (Solano et al., 2006). Pain, breathlessness, and fatigue were found among more than 50% of patients, for all five diseases. The authors concluded that the concept of a 'final common pathway' towards death featuring fatigue, anorexia, weight loss, and dyspnoea applies as much to non-malignant diseases as it does to cancer.

Mood, quality of life, and self-rated health
While several physical symptoms are associated with a poor survival, the impact of psychological symptoms is less clear. A systematic review of depression, cancer, and survival identified 25 relevant studies and concluded that mortality rates were significantly higher in depressed patients, but the effect size was small. Mortality rates were up to 25% higher in patients experiencing

depressive symptoms and up to 40% higher in patients diagnosed with major or minor depression. The effect of depression remains after adjustment for other prognostic factors, suggesting that depression may play a causal role (Satin et al., 2009). Intriguingly, accelerated cellular aging as indexed by short telomere length has emerged as a potential common biological mechanism linking various forms of psychological stress and diseases of aging, including cancer (O'Donovan et al., 2012).

Quality of life (QOL) scores generally are not associated with survival, especially when measured with instruments developed for palliative care that focus largely on non-physical domains. The Therapeutic Impact Questionnaire developed in Italy for use in hospice/palliative care, rates four major components of QOL—physical symptoms, function, psychological state, and family and social relationships (Tamburini et al., 1996). Global well-being is also evaluated. Only the patient-rated perception of cognitive function and global well-being showed independent prognostic value. Patients had median survivals of 137, 50, and 17 days for impairment of neither, one, or both scales, respectively.

Self-rated health (SRH) is increasingly being recognized as a valid measure for predicting future health outcomes, including survival. Global SRH, the most commonly used measure to rate overall health, is an important predictor of mortality. An unfavourable assessment of overall health has been associated with increased risk of death, even after controlling for socioeconomic status, physical health, functioning, chronic conditions, and health risk behaviours. In a study of ambulatory advanced cancer patients with a median survival time of 10 months, SRH was the strongest predictor of survival from baseline (Shadbolt et al., 2002). The risk of dying was greatest for patients rating their health as 'poor', intermediate if they rated it 'fair', and lowest if they rated it 'good' or better.

Co-morbidities

Cancer patients often have other diseases or medical conditions in addition to their cancer, especially when they are older. Multiple studies have shown that early-stage cancer patients with co-morbid conditions have worse outcomes than patients without co-morbid ailments. The prognostic impact of co-morbidities is greatest for patients with cancers associated with a long natural history, such as prostate cancer, and least in patients with aggressive cancers, such as lung cancer (Read et al., 2004). Co-morbidities have been shown to influence the survival of critically ill cancer patients (Soares et al., 2005), but have rarely been evaluated in studies of prognostic factors in less severely ill palliative care patients. A notable exception is the SUPPORT prognostic model (Knaus et al., 1995), which included cancer as a co-morbidity in patients with other diagnoses (see later section).

Biomarkers

The possibility of taking a single blood sample to provide a precise, accurate, objective estimate of prognosis is tantalizing to clinicians. Pro-inflammatory cytokines such as interleukin-6 (IL-6) are implicated in the genesis of the anorexia-cachexia syndrome (Lee et al., 2004), and C-reactive protein (CRP) is a readily available, inexpensive blood test that is highly correlated with IL-6 levels for inflammation. Other parameters that have been evaluated include elevations of serum alpha-1-acid glycoprotein, alkaline phosphatase, lactate dehydrogenase, and pseudocholinesterase.

Several simple, objective prognostic scores incorporating CRP levels have been developed in advanced cancer. The Glasgow Prognostic Score uses CRP and albumin levels, with elevated CRP levels and hypoalbuminaemia being awarded prognostic points. It has been shown to predict survival in patients with advanced lung cancer (Forrest et al., 2005) and gastric cancer. The vitamin B_{12}/CRP Index (BCI) takes the product of the serum vitamin B_{12} (in pmol/L) and CRP (mg/mL). A retrospective analysis of BCI scores in Swiss geriatric cancer patients who were terminally ill showed that a high score (> 40,000) was associated with a poor survival, that is, less than a 10% chance of surviving 3 months (Geissbuhler et al., 2000). This finding has been validated by others (Kelly et al., 2007; Tavares, 2010), and shown to be as accurate as CPS (Tavares, 2010).

Biomarkers may be prognostic in other diseases. In heart failure, brain natriuretic peptide (BNP) levels may indicate an increased risk of sudden death (Tannenberger et al., 2002), either alone or combined with troponin levels and CRP. In 44 patients dying suddenly versus 89 other patients who died more slowly within 3 years of first diagnosis of heart failure and ejection fraction less than 35%, multivariate analysis showed that log BNP level was the only independent predictor of sudden death (P = 0.0006), with a cut-off point of log BNP less than 2.11 (130 pg/mL) (Berger et al., 2002).

Prognostic tools and models

Models for cancer patients

There is the potential to combine the simple clinical and laboratory factors described above to provide physicians with accurate information about prognosis. Yet caution is needed in interpreting any studies or systematic reviews on survival prediction and prognostic models. Firstly, it is important to distinguish those based on the general population at large from ones within a defined palliative or hospice population. A strong consideration must be given to the inception cohort issue, which requires patients to be at a uniform, disease-based point in time when the measurements of survival begin. Secondly, even in a defined palliative population, attempting to compare published data to one's own palliative programme requires attention to the demographics and inclusion/exclusion criteria. There is often a difference between patients admitted directly to an acute tertiary palliative care unit and those cared for at home or admitted to a hospice facility. The former admissions are usually for urgent symptom assessment and management and as such, may have shorter survival data due to patient complications and difficult symptoms. Hospices will have a somewhat more stable population at least on admission. Thirdly, prognostic scores with statistical significance will follow a Kaplan–Meier curve for the subset analysed but the location on that curve for each individual's death is less obvious, and is in fact indeterminate without other factors being taken into consideration.

Models for terminally ill cancer patients

Many studies over the past decade have developed multiple regression models to determine the association between prognostic factors and survival in patients with far advanced cancer, but few have tested the predicative accuracy of their final models, a key step in prognostic model building. Some of the better developed models are discussed in more detail here.

The SUPPORT study

The SUPPORT study (Knaus et al., 1995) was designed to identify deficiencies in the care of hospitalized patients with various eventually fatal illnesses. The SUPPORT model was developed for this study, with the aim of providing prognostic information as the cornerstone of improved decision-making about end-of-life care in hospitals. Based on the APACHE system for prognostication in critically ill patients in intensive care units (ICUs), individuals' clinical and physiological parameters were utilized in a complex algorithm that was computer generated and gave a probability for the hospitalized patient being alive in 2 and 6 months' time. Only some of them had cancer, making it difficult to compare this model with others developed in patients with terminal cancer. The mathematical model is complex and not suitable for routine use by the clinician at the bedside. The information provided (chance of being alive in 6 months) is relevant to only a small minority of cancer patients referred to hospice/palliative care. Nevertheless, the SUPPORT study is important because it was the first large study to demonstrate the potential of using actuarial judgement to provide the clinician with accurate prognostic data.

The Palliative Prognostic Index (PPI)

This model was originally developed in Japanese cancer patients enrolled in palliative care programmes (Morita et al., 1999). The PPI is calculated by attributing partial scores to five clinical variables (performance status, oral intake, dyspnoea, delirium, and oedema). In the initial study, the total PPI score was used to define three groups with differing prognoses and these results were subsequently replicated in an independent validation sample. A PPI greater than 4 predicted death within 6 weeks with a positive predictive value (PPV) of 83% and a negative predictive value (NPV) of 71%. A later study by the same group confirmed the effectiveness of the PPI at predicting 6-week survival and also demonstrated that the accuracy of clinicians' estimates was improved if they were provided with PPI scores prior to making a prediction (Morita et al., 2001). Further evidence for the validity of this instrument has been provided by Stone and colleagues (Stone et al., 2008) who reported that among patients referred to their palliative care service in Ireland, the PPI had a PPV for predicting death within 6 weeks of 91% and a NPV of 64%.

The Palliative Prognostic (PaP) score

The predictive model from which the PaP score is derived was developed in Italian home hospice patients with advanced cancer (Pirovano et al., 1999). The model consists of six variables that are easily measured at the bedside, namely Karnofsky performance status, anorexia, dyspnoea, total white blood count, and lymphocyte percentage plus the CPS measured in 2-week intervals out to 12 weeks. These factors were independently predictive of survival, and the model is able to split a heterogeneous sample of patients with far advanced cancer into three groups with differing probabilities of being alive at 30 days (group A > 70%, group B 30–70%, and group C < 30%). To calculate the PaP score, points are allocated for each of the six factors, the points for each being based on their parameters in the model. The individual points are then summed to give a final score, which can range from 0 to 17.5, with higher scores representing worse survival. In the original clinical validation study, group A had a score of 0–5, group B 5.5–11, and group C, 11.5–17.5 (Maltoni et al., 1999).

The PaP score is the most robust prognostic model in hospice and palliative care, having been validated in a variety of populations and settings (Glare and Virik, 2001; Glare et al., 2003, 2004; Naylor et al., 2010; Tarumi et al., 2011). The largest validation study, in a mixed cancer and non-cancer palliative care population at a Canadian acute care hospital, involved 958 patients, 18% of whom had non-cancer diagnoses (Tarumi et al., 2011). In this population, PaP group A had a 78% probability of 30-day survival, group B had a 55% probability, and group C had an 11% probability. These results are in keeping with the original development studies for the PaP and generally support its validity as a prognostic tool in palliative care patients. Although the PaP is the most widely validated of the palliative prognostic scales some investigators have expressed dissatisfaction with its over-reliance on subjective clinician estimates (the clinician's intuitive guess accounts for approximately 50% of the total PaP score) and with the omission of cognitive function (which is known to be a poor prognostic factor) from the scoring algorithm

Prognosis in Palliative care Study (PiPS) models

The PiPS models attempt to address the limitations of the PaP score. A large, prospective, multi-centre study involving over 1000 advanced cancer patients newly referred to palliative care services in England identified 11 core variables (pulse rate, general health status, mental test score, performance status, presence of anorexia, presence of any site of metastatic disease, presence of liver metastases, CRP, white blood count, platelet count, and urea) which independently predicted both 2-week and 2-month survival (Gwilliam et al., 2011). Four other variables had prognostic significance only for 2-week survival (dyspnoea, dysphagia, bone metastases, and alanine transaminase), and eight further variables had prognostic significance only for 2-month survival (primary breast cancer, male genital cancer, tiredness, loss of weight, lymphocyte count, neutrophil count, alkaline phosphatase, and albumin). Separate prognostic models were created for patients without (PiPS-A) or with (PiPS-B) blood results.

These models were able to reliably identify those patients with expected prognoses of 'days', 'weeks', or 'months/years' (St George's, University of London, 2011). The median survival across the PiPS-A categories was 5, 33, and 92 days and survival across PiPS-B categories was 7, 32, and 100.5 days. All four PIPs models performed as well as, or better than, CPS. The area under the curve for all models varied between 0.79 and 0.86. Absolute agreement between actual survival and PiPS predictions was 57.3% (after correction for over-optimism). The models can be used in either competent or incompetent patients and in circumstances when blood results are available and when additional investigations would be inappropriate. The prognostic models were shown to be at least as good as a multi-professional clinical estimate of survival; when blood results were available, the models were significantly better than either a doctor's or a nurse's prediction (but not a multi-professional estimate). The instruments have not yet been independently validated, nor has the performance of the PiPS been compared to the performance of the PaP score or the PPI.

Feliu prognostic nomogram

Feliu and colleagues (Feliu et al., 2011) have developed a nomogram to predict survival of terminally ill cancer patients at 15, 30,

and 60 days. The prognostic index is generated from a weighted combination of Eastern Cooperative Oncology Group (ECOG) performance status, albumin, lactate dehydrogenase, lymphocyte counts, and time elapsed between initial diagnosis and development of a terminal disease. The nomogram correctly classified survival in 70% of patients in the development study and in 68% of the validation cohort. The authors tested their nomogram against the PaP score and found the nomogram to be significantly more accurate. A potential limitation of the Feliu nomogram is its reliance on the concept of the 'time to terminal diagnosis'. This is a very subjective concept, potentially open to the same limitations as using CPS in the PaP. To assist validation studies of the nomogram, standardized definitions of the onset of a terminal diagnosis, for example, progression through third-line chemotherapy, are needed.

Prognostic tools for less seriously ill cancer patients receiving palliative care

There is currently no prognostic model for predicting survival from cancer that has been validated in the setting of an outpatient palliative care clinic, where patients often don't have many of the symptoms and other problems incorporated in the above models and often survive for several years. A vast amount of prognostic information is available for individual cancers within the oncology literature but is not easily accessible; PubMed has no single MeSH term for 'prognostic index' (Yourman et al., 2012). A tool that is applicable to the heterogeneous patient population seen in the palliative care outpatient clinic is urgently needed. As more palliative care programmes offer ambulatory clinics for patients with months–years to live, a tool for predicting their survival is an important innovation.

A prognostic tool has been developed for ambulatory patients receiving palliative radiotherapy (Chow et al., 2002). It has subsequently been simplified (Chow et al., 2008), the simplified model utilizing just three variables—primary cancer type, site of metastases, and performance status—to divide patients into three independent prognostic groups with median survivals of 12, 6, and 3 months, respectively. This simple prognostic model may be applicable to the broader palliative care population (Vij et al., 2012).

Prognostic tools and models for other life-limiting diseases

End-organ failures
Congestive heart failure (CHF)

The prognosis of CHF may be as bad, if not worse, than many cancers (see Chapter 15.3). Overall, 1-year and 5-year survival rates in the Framingham Heart Study were 57% and 25% in men and 64% and 38% in women, respectively (Ho et al., 1993). The New York Heart Association (NYHA) classification category is the major gauge of disease severity in CHF, and is the cornerstone of the criteria for hospice admission for CHF in the United States. Based on data from the Framingham Heart Study and other studies, NYHA Class IV (severe symptoms) CHF has a 1-year mortality of 30–40%. However, providing more accurate predictions of 6–12-month mortality has been nearly impossible, due to the unpredictable disease trajectory of CHF. On the one hand it is highly mutable by application of evidence-based therapies, yet it is also marked by a high incidence of sudden death, in the vicinity of 15–20%.

A limitation of the current US hospice admission criteria for CHF is that they are outdated. Written by the NHPCO in 1996, 'optimal treatment' is specified as angiotensin-converting enzyme inhibitors, diuretics, and vasodilators when contemporary optimal treatment includes beta blockers, aldosterone antagonists, and device therapies. The increased use of left ventricular assist devices as 'destination therapy', that is, until death in patients who are non-eligible for transplants, also makes prognostication in CHF increasingly challenging, as do the placement of pacemakers and intra-cardiac defibrillators.

Although it does not predict 6-month mortality, the Seattle Heart Failure Model is a well-validated model that provides an accurate estimate of 1-, 2-, and 3-year survival with the use of easily obtained clinical, pharmacological, device, and laboratory characteristics (Levy et al., 2006; Mozaffarian et al., 2007). Caution should be noted in application in the very elderly, as it is given to greatly overestimating prognosis in this group. A dynamic web version is available which shows changes in Kaplan–Meier survival curves as various parameters are inserted (University of Washington, n.d.). Enhanced Feedback for Effective Cardiac Treatment (EFFECT), a Canadian consortium, has validated another online prognostic model (Canadian Cardiovascular Outcomes Research Team, n.d.).

The prognosis for survival to discharge after cardiopulmonary resuscitation (CPR) is also important, as it is the typical starting point in a discussion of code status. The outcome of in-hospital arrest has not changed since the early 1990s, even though there have been major improvements in the outcome of out-of-hospital cardiac arrest during this period. For the general hospitalized patient experiencing an in-hospital cardiac arrest, a return of spontaneous circulation can be achieved with CPR approximately 50% of the time, but less than 20% of patients survive to discharge (Ehlenbach et al., 2009). The neurological outcomes of those who survived to discharge were generally good, and most patients admitted from home pre-arrest were able to return there. Having multiple co-morbidities pre-arrest is associated with a worse outcome, as are extreme age, poor functional status, and admission from a nursing home.

Chronic obstructive pulmonary disease

COPD also has a poor prognosis with men aged 65 with stage 3 or 4 COPD who continue to smoke dying 10 years before non-smokers without COPD (Shavelle et al., 2009) (see Chapter 15.2). Traditionally, the two most important prognostic factors in COPD have been forced expiratory volume in 1 second (FEV_1) and age. More recently, the level of dyspnoea, graded by the Medical Research Council (MRC) dyspnoea scale, has been found to be a better predictor of survival than the FEV_1 (O'Donnell et al., 2007). For example, a Japanese study of mortality predictors in 227 outpatients with COPD of whom 73% were alive at 5 years found that dyspnoea was significantly correlated to the 5-year survival rate and the level of dyspnoea had a more significant effect on survival than disease severity based on FEV_1 (Oga et al., 2003).

Factors other than age, dyspnoea, and FEV_1 have been evaluated in prognostic models of dyspnoea. The BODE Index incorporates *b*ody mass index (BMI), *o*bstruction (FEV_1 %), *d*yspnoea (MRC dyspnoea scale), and *e*xercise capacity (6-minute walk distance) (Celli et al., 2004). Similarly, the HADO score includes *h*ealth (5-point self-assessment), *a*ctivity (self-reported), *d*yspnoea, and

*o*bstruction (FEV$_1$ %) (Esteban et al., 2006). The BODE Index and the HADO Score have both been identified as good predictors of all-cause and respiratory mortality in COPD. In patients with severe COPD (FEV$_1$ < 50%) the BODE Index may be more accurate (Esteban et al., 2010).

Two major clinical issues related to prognosis in COPD are the identification of patients who are eligible for hospice and the outcomes of mechanical ventilation. COPD patients most likely to die within 6–12 months include those with severe, irreversible airflow obstruction, severely impaired and declining exercise capacity and performance status, older age, concomitant cardiovascular or other co-morbid disease, and a history of recent hospitalizations for acute care (Hansen-Flaschen, 2004). Clinicians' predictions in COPD found underestimation of survival after admission to the ICU. For example, the quintile of patients with the lowest expected prognosis (10% probability to survive 6 months) had a group survival of 40% at 6 months (Wildman et al., 2007). The reason for the underestimate is not elucidated in this study but the issue is important for further study as it may impact decisions to admit to the ICU that may be overweighted towards futility arguments. This is an excellent illustration for how prognostication can have profound impacts on policy and utilization of resources, and should be a critical area for more research to serve patients best.

Prognostic models for the frail elderly

Prognosis in the general geriatric population

Failure to consider prognosis in the context of clinical decision-making in the elderly can lead to poor care (see Chapter 16.3). Healthy older patients with good prognosis have low rates of cancer screening, while hospice is underutilized for patients with non-malignant yet life-threatening diseases. Guidelines increasingly incorporate life expectancy as a central factor in weighing the benefits and the burdens of tests and treatments, but prognostic indices offer a potential role for moving beyond arbitrary, age-based cut-offs in clinical decision-making for older adults.

Many geriatric prognostic indices have been published. An excellent recent systematic review of this literature has identified 16 indices that predict risk of mortality from 6 months to 5 years for older adults who do not have a dominant terminal illness such as CHF or dementia, and who are in a variety of clinical settings (Yourman et al., 2012). The review focuses on the accuracy, generalizability, potential for bias, and usability of these indices. To enable clinicians to find the right tool from the 16 available that best fits their patient's situation, the review's authors have created a website which provides an online repository of each of the indices in the review and advice about when to use them (Yourman et al., n.d.).

Dementia patients

The illness trajectory for Alzheimer's dementia follows a generally predictable decline in functional and cognitive status (see Chapter 15.4). The onset of inability to walk unaided indicates the patient is entering the final phase of the illness. However, the final phase of the illness can be protracted and the event that precipitates the death is often unclear. The current NHPCO hospice admission criteria for dementia requires the patient to be stage 7C on the FAST (Functional Assessment Staging Tool; Reisberg 1988) classification system—defined as dementia with impaired activities of daily living (ADLs), incontinence and loss of ambulation—plus the onset of a major medical complication such as aspiration pneumonia, urinary tract infection, or decubitus ulcers in the previous 12 months. Two small studies (Luchins et al., 1997; Hanrahan et al., 1999) have reported that the NHPCO guidelines did appear to identify patients at higher risk of dying within 6 months, but in one study, 30% patients with dementia aged more than 90 years who had been referred to a US hospice programme were still alive 3 years later (Aguero-Torres et al., 1998). Several other studies have found the guidelines had a predictive ability 'no better than chance' (Schonwetter et al., 1998, 2003; Mitchell et al., 2004). Furthermore, many bed-ridden dementia patients do not progress through the earlier stages of the FAST system in an orderly fashion. They are not technically at stage 7C and therefore not hospice eligible. Hospice has been shown to benefit people dying with dementia (Teno et al., 2011), but these studies indicate that prognostication is difficult and may be a barrier to hospice enrolment (Jayes et al., 2012).

In view of the inaccuracy of the NHPCO criteria, several other tools have been developed to improve on them. Of them, the Advanced Dementia Prognostic Tool (ADEPT) has been specifically developed to be more accurate than the FAST 7C criteria used for hospice eligibility, and validated against them (Mitchell et al., 2010). Unlike FAST, ADEPT includes scores for age, male gender, weight loss/BMI, performance status, ADLs, symptoms, and continence. When benchmarked against FAST, it performed slightly better (58% vs 51% accuracy).

Communicating a prognosis

Multiple surveys show most patients with cancer want information about their prognosis (Kutner et al., 1999; Butow et al., 2002; Hagerty et al., 2004, 2005; Parker et al., 2007; Innes and Payne, 2009), whether it be good news or bad (Fallowfield et al., 2002) (see Chapter 6.1). But talking to patients about prognosis is difficult and clinicians are poor at this type of communication. There are large discrepancies between patients' and healthcare professionals' perceptions about how much information is needed, how much information has been given, and what such information means (Hancock et al., 2007). Clinicians tend to underestimate patients' prognostic information needs and overestimate how much they had understood about their illness and its likely outcome (Beadle et al., 2004).

Giving patients prognostic information is also important in terms of the effects it can have on patient outcomes. Advance care planning for patients at the end of life requires frank disclosure about prognosis. In one large cohort study (Wright et al., 2008), explicit discussion of end-of-life issues was associated with less aggressive medical care near death, earlier hospice referrals, and improved outcomes for bereaved family members. Without such explicit prognostic information patients may find themselves being managed in the acute care setting at the end of life rather than a more appropriate environment (Innes and Payne, 2009; Mack and Smith, 2012).

Physicians and patients may, to some extent, enter into a level of collusion about avoiding any discussion of prognosis (The et al., 2000). Consultations tend to focus on treatment options and the results of investigations rather than on questions of prognosis, often involving 'false optimism' about the prospects of recovery. This optimism may be fostered both by doctors' reluctance to give clear information about prognosis and patients' avoidance of asking direct questions.

What prognostic information do patients want?

Patients both crave and dread prognostic information. They are caught between wanting to know what is going on and fearing the answers they might receive. Therefore, they want the prognosis to be given by someone whom they perceive to be an expert, and they find inconsistent information or evasiveness on the part of the professional to be distressing and unhelpful. Patients also want hopeful messages, even when they accept the terminal phase of the illness (Kutner et al., 1999; Kirk et al., 2004). Strategies clinicians may use to facilitate hope when discussing prognosis include retaining professional honesty, avoiding being blunt or giving more detailed information than desired by the patient, pacing of information, respecting patients' need to follow alternative paths/treatments, and exploring and facilitating realistic goals and wishes where appropriate.

Many studies have stressed the importance of individualizing the content of prognostic discussions, but few patient characteristics have been identified to predict how much information patients want or how such information should be delivered (Kutner et al., 1999). Patients have different needs from one another and individual patients' information needs and preferences can change during the course of their illness. While many want to discuss prognosis when they were first diagnosed with metastatic disease, others want to negotiate with the clinician about when such issues were discussed. In one study, more than half the patients wanted the physicians to initiate discussions about prognosis, less than a quarter only wanted the physician to tell them about survival 'if asked', and approximately 10% of patients never wanted to discuss likely duration of survival (Hagerty et al., 2004). In general, women want more information than men (Fallowfield et al., 2002) and older patients request less information than younger patients. Cultural differences may also be important (Parker et al., 2007). Likewise patients tend to want less information as their underlying disease progresses and they approach the terminal phase of their illness.

How to communicate the formulated prognosis to the patient?

Although patients generally indicate they want information about prognosis, it is not always clear what is the best way to communicate such information. Guidelines and other recommendations for the best way to deliver the information are available (Clayton et al., 2007; Back et al., 2009; Kiely et al., 2010). They stress the importance of communication occurring within the context of a caring, trusting relationship, consistency of information within the multiprofessional team, and the need to communicate prognostic information to other members of the family. As highlighted above, not all patients want to be provided with an estimation of their life expectancy. Hence it is very important to first clarify the person's understanding of their medical situation and the information they desire. Any information provided about prognosis should then be tailored to the individual needs of patients and their families.

Most patients want to be informed of their likely survival duration in a straightforward and clear manner. For patients who would like to be provided with a numerical estimation of their life expectancy the following approach has been advocated for patients with advanced cancer (Kiely et al., 2010). The first step is to use a prognostic tool to estimate the median survival of a group

Fig. 2.3.1 Using the median survival to make other probabilistic survival predictions.

with similar characteristics. The survival curve of patients with a variety of advanced cancers typically approximates an exponential function—as would be predicted for a heterogeneous population (see Fig. 2.3.1) (Stockler et al., 2006). In the case that follows, assume that the median survival is 6 months.

◆ Explain that a median survival of 6 months means that 50% will live longer than 6 months.

◆ Use simple multiple of the median to estimate and explain the typical, best case, and worst case scenarios:

- Typical—about half of similar patients would live for somewhere between 3 and 12 months (half to double the predicted median).

- Best case—about 10% of patients could expect to live beyond 2 years (three to four times the predicted median).

- Worst case—about 10% of patients will experience more rapid decline and will die within 1 month (1/6 of the predicted mean).

Using multiples of the median to estimate and provide typical, best, and worst case scenarios as outlined above may offer a way of conveying more realism and hope than a single point estimate of the median survival. Finally after providing patients with information about life expectancy it is important to explore and acknowledge the patient's and family's emotional reaction to the news and to check their understanding about what has been discussed.

Conclusion

Prognostication remains a challenging topic in palliative care. In the past 20 years, much research has been undertaken to identify ways of improving the accuracy and precision of clinicians' estimates and as presented here many tools are now available to improve prognostication.

While we are now in a better position to give the patient 'x % chance of surviving for y weeks/months', we are not yet able to posit any of the existing tools as the ideal one to be recommended for widespread use. Most of the existing tools focus on performance status, symptoms, and simple laboratory markers; while these are helpful, they are no more accurate than the subjective judgements

of experienced clinicians. Novel objective prognostic factors need to be identified, and biomarkers such as CRP and the proinflammatory cytokines are the main focus of current research.

Clinical judgement remains important, in our opinion. The clinical data needed to use a tool to calculate the prognosis (e.g. recent laboratory parameters) may not be available, tools may not provide the prognostic information required, and they may not have been validated in the population to which the individual patient belongs. Clinical judgement alone may be sufficient if the issue is acknowledging a probability of dying from an illness in the foreseeable future. The SUPPORT study showed patients will change their planning behaviour once they understand the chance of surviving beyond 6 months is small. Furthermore, models predicting survival should be thought of like any diagnostic test, that is, they should not be interpreted in isolation but as a way of improving the pre-test probability of survival, which is based on clinical judgement.

Even if precise and accurate predictions of survival duration become available, this alone should never drive treatment plans. What ultimately is needed is not so much an accurate prediction of time but an acknowledgement of the possibility of dying, communicated carefully by the compassionate and skilful physician.

Defining a 'good' death

Karen E. Steinhauser and James A. Tulsky

Introduction to defining a 'good' death

Woody Allen often commented that he was not afraid to die, but did not want to be there when it happened (Allen, 1983). This is emblematic of our society's ambivalence towards the notion of a 'good death' (Rousseau, 1997; Steinhauser et al., 2001). Its inherent irony is instructive for palliative care clinicians. While death may be inevitable, for patients, it is rarely the goal. Therefore, naming deaths 'good' or 'bad' should be met with caution.

There is a long historical and literary tradition discussing the 'good death'. In some of the best known work on evolution in Western attitudes towards death, social historian Philippe Aries uses cemetery iconography, notary records, wills, art, and literature to explore changing patterns in cultural norms of dying and death over the last 1500 years (Aries, 1980). For example, we learn that contemporary preferences for sudden death or death during sleep stand in contrast to previous eras in which populations literally prayed, in the Anglican Great Litany, not to die, 'suddenly and unprepared' (Aries, 1980; Vig and Pearlman, 2004). Aries' work demonstrates the plasticity of how we view circumstances of death and the relativism of the terminology 'good' and 'bad'.

Extraordinary variation exists in the social construction of the meaning of dying and death and the social organization and cultural norms surrounding end of life (Aries, 1980; Hart et al., 1998; Seale, 1998; Kim and Lee, 2003; DelVecchio Good et al., 2004; Long, 2004; Radley, 2004; Hirai et al., 2006). Recent work describing end-of-life activities in diverse regions such as Japan, North America, the Netherlands and Papau New Guinea, and spanning contemporary, classical, and biblical eras (Seale and van der Geest, 2004) finds that humans create and enact cultural scripts in ways that describe death as either 'good' or 'bad' (Seale and van der Geest, 2004).

While these cited works provide in-depth sociocultural and historical exploration of how we define the meaning of death, the focus of this chapter is on the reappearance in the last 40 years of attempts to define a good death in the medical context, the empirical investigation of the construct, the clinical implications of using the terminology 'good death', and an alternative framework for language defining preferences at end of life.

Context of contemporary exploration of 'good death'

In 1908, William Osler conducted a study of 486 deaths at Johns Hopkins Hospital reporting that 90 patients experienced pain, 11 anxiety, and for the majority, death was 'nothing more than falling asleep' (Kring, 2006). Deaths in this era occurred all across the life course spectrum and were the result of either old age or catastrophic illness with limited medical intervention capable of extending life. Despite the site of Osler's investigation, the majority of deaths at that time did not happen in the hospital.

Rather, deaths in the nineteenth and early twentieth centuries occurred primarily at home with support of family, church, and community (Sudnow, 1967; Aries, 1980; Hart et al., 1998). However, by the second half of the twentieth century the primary site of death had shifted to the hospital. Moreover, by the 1960s, the landscape of death in Western culture had changed dramatically as medicine had experienced a variety of therapeutic and technological revolutions resulting in the capacity to extend life, including antibiotic therapies, artificial nutrition and cardiopulmonary resuscitation. In this latter twentieth-century hospital setting, death's meaning was narrowed primarily to a physiological event. As such, death was defined less as an expected and natural part of the life course and more as a failure of medical technology and intervention (Byock, 1996).

By the late 1950s, social reformers, such as Cicely Saunders, began to critique conventional medical care for dying patients, arguing that hospitals lacked both the specific expertise in palliation of symptoms as well as the multidisciplinary perspective that attended to social, psychological, and spiritual aspects of care (Saunders, 1978). In 1967, after returning to medical school to supplement her nursing, social work, and divinity training, she opened St. Christopher's hospice as a multidisciplinary care centre that emphasized palliative versus curative therapies and promoted quality of life over quantity of life.

Amidst this social reform movement, in-depth inquiry of death and dying began to appear in the medical, nursing, and social science literatures. Seminal qualitative accounts were published in the few years following the opening of St. Christopher's. Prominent sociologists Glaser, Strauss, and Sudnow were among the first to refocus study on end of life and to conceptualize trajectories of dying (Glaser and Strauss, 1965; Sudnow, 1967). Emerging from a tradition of grounded theory, Glaser and Strauss became participant observers in hospital settings and described four 'contexts of awareness surrounding the dying experience: closed awareness, suspicious awareness, mutual pretense, and open awareness' (Glaser and Strauss, 1965). Their conceptualization reflected an era during which patients often were not informed of terminal diagnoses or poor prognoses. Their sociological critiques were heavily counter-cultural in their scrutiny of the power dynamics of the paternalistic hospital culture.

A few years later, Elizabeth Kubler-Ross called further attention to the unmet needs of patients and the personal evolution of people coming to terms with a terminal diagnosis (Kubler-Ross,

1969). Though the stages of grief—denial, anger, bargaining, depression, and acceptance—were never tested empirically, her theory of dying and death is perhaps the best known and most frequently cited to this day. In fact, after her work, investigation of death and dying would receive scant attention until the 1990s.

The subtext of many of these investigations was that conventional medical care settings often played host to 'bad' deaths, typified by excessive use of technology, with patient and family wishes ignored, lack of patient knowledge and autonomy in decision-making, the patient reduced to a physiological system versus whole person, and quality of life devalued.

The hospice movement, both in its British foundations and its importation to the United States, arose within this context and was part of a larger 'death with dignity' movement of the 1960s and 1970s. Those involved in hospice and early palliative care worked to reclaim the experience of dying and death beyond a biomedical event. In this context, a 'good' death was the obverse of the previously described situations. The goals were to increase awareness of end of life as a part of a natural life course and to acknowledge dying patients as whole persons in the context of fuller lives lived, as well as family and community nexus. 'Good death' connoted a model of care more closely matching patient and family preferences, with the terminology designed to serve as a vision of improved experience for dying persons.

Empirical investigations of a 'good death'

Despite the popularity and growth of the hospice movement, widespread, systematic attempts to define a 'good death' empirically did not appear in the medical literature until after the publication of the Study to Understand Prognosis and Preferences for the Outcomes and Risks of Treatment (SUPPORT) findings. This large multi-site study documented poor care of dying patients and their families in five top US medical centres and redefined the landscape of end-of-life and palliative care (The SUPPORT Principal Investigators, 1995). SUPPORT described hospitalized patients dying in pain, without their wishes known, and in isolation. The results provided empirical evidence of what was wrong with hospital deaths.

Care of dying patients became a priority in the United States and organizations such as the American Medical Association, the Veterans Health Administration, and The Robert Wood Johnson Foundation committed funding to improving education and quality of care (Field and Cassel, 1997). Efforts to develop and evaluate hospice and palliative care became expanded in US and international journals. If clinicians and administrators were to provide quality of care and quality of life at the end of life, they must first define quality. If SUPPORT had given empirical evidence of 'bad' deaths, what was the empirical evidence regarding the definition of a 'good' death?

In the 17 ensuing years, over 400 Medline articles include the construct 'good death'. A smaller subset of independent studies have attempted to define the construct through analyses of qualitative and quantitative data gathered from patients, family members, and health-care providers. These have been reviewed systematically in both the medical and nursing literatures (Morris et al., 1986; King and Bushwick, 1994; McNamara et al., 1994; Asch et al., 1995; Layde et al., 1995; Low and Payne, 1996; Payne et al., 1996; Lynn et al., 1997; Ellington and Fuller, 1998; Emanuel and Emanuel, 1998; Singer, Martin, and Kelner, 1999; Steinhauser

et al., 2000a, 2000b; Kristjanson et al., 2001; Mak, 2001; Cohen and Leis, 2002; Curtis et al., 2002; Hanson et al., 2002; Hopkinson and Hallett, 2002; Masson, 2002; Pierson et al., 2002; Ganzini et al., 2003; Kim and Lee, 2003; Tong et al., 2003; DelVecchio Good et al., 2004; Leichtentritt, 2004; Long, 2004; McNamara, 2004; Vig and Pearlman, 2004; Borbasi et al., 2005, 2006; Ferrell, 2005; Goldsteen et al., 2006; Hirai et al., 2006; Kring, 2006; Rietjens et al., 2006; Miyashita et al., 2007a; Hales et al., 2008). While each study lends a unique population or conceptual nuance, some common features exist among attempts to define a 'good death'.

Mutlidimensionality

The social reformers propelling the 'good death' movement of the 1960s and 1970s were responding to the narrowing of the patient experience to the biomedical realm. Recent empirical investigation suggests that perhaps the most important feature to recognize about a 'good death' is its multidimensional nature.

In 2008, Hales et al. reviewed 17 studies defining quality at end of life (Hales et al., 2008). Five of the studies were conducted with health-care providers only; five were conducted among only patient populations, three were studies of non-patient, non-health-care provider populations; and the remaining included both patients and or families, and providers. Seven common broad domains were found: *physical experience, psychological experience, social experience, spiritual or existential experience, the nature of health care, life closure and death preparation*, and *circumstances of death*.

Expectedly, *pain and symptom management* was the most commonly identified theme. Yet, variation exists in how individuals prefer this domain to be addressed. For example, some patients may wish to balance analgesia with lucidity to allow meaningful personal interactions, and thus may tolerate some pain to achieve a higher state of alertness, if necessary. More recent studies suggest that physical dimensions include not only pain and symptoms but attention to *functional status*, which is highly correlated with continued independence and quality of life (Walke et al., 2007).

This body of work confirms that the physiological aspects of end-of-life experience are only a point of departure in overall definitions of a 'good death' or quality at end of life (Steinhauser et al., 2000a). Attention to emotional or *psychological* and *social* well-being are crucial. Patients experience their illness living a variety of roles and inter-relationships that need to be sustained as part of whole-person care. Interestingly, earlier sociological theory proposed that dying patients, and older adults, in general, experienced a natural 'disengagement' as end of life loomed. However, this theory has been debunked by empirical evidence showing the desire for and power of continued role engagement. Although dying patients usually experience physical decline or limitation, they may experience growth in social and emotional areas.

Similarly, attention to *spiritual* or transcendent aspects of experience are reported as central to quality experience and hold opportunity for growth (Daaleman and Nease, 1994; Byock, 1996; Cohen and Leis, 2002). This domain may be expressed in traditional religious terms, via connection with nature or as overall sense of meaning and purpose in life. There is some evidence of it increasing in importance as death nears (Byock, 1996). Of note, the absence of this domain in traditional quality of life measures was a main factor limiting their reliability and validity when applied to the context of dying.

While physical, social, psychological, and spiritual domains had been predicted by some of the pre-empirical literature, several new domains emerged from empirical investigation. These include *preparation for death or end of life, nature of health care*, and *life completion*. In contrast to settings of 'closed awareness' reported as common in the 1960s, 'good death' investigations of the 1990s and early 2000s suggested many patients with advanced serious illness wanted an opportunity to know what to expect about the course of their illness, to put personal affairs in order, to make financial arrangements and personal business, to not be a burden to family, to prepare their families for the future, and, for some, to plan one's own funeral. It is important to note the contradiction found in the literature whereby populations within the same study report valuing 'dying in their sleep', 'dying suddenly', and 'being prepared' (Vig and Pearlman, 2004).

These studies show that *preparation* is not limited to patients. Families also need to be prepared for what to expect about the course of illness and decision-making.

> I can't tell you how many times, working in the emergency room, [that I saw] families [take a patient home]; this patient was going to die at home. And, when the last breath came, the families panicked. They brought the patient into the emergency room and went through the whole process [resuscitation]. Preparing the family, assessing what they actually know, and figuring out what you have to teach them is essential. [Nurse] (Steinhauser et al., 2000b)

Finally, some have also described the importance of provider preparation, coming to terms with their own fears about mortality and the emotions generated in caring for those who die (Steinhauser et al., 2000a).

Another less expected domain revealed in the 'good death' studies was the *nature of health care*. This domain focused on issues such as the appropriateness of level of technological intervention—levels in keeping with patient and family wishes, as well as communication with health-care providers, knowing how and where to get answers to questions, and overall relationship with the provider (Steinhauser et al., 2000a, 2000b; Perkins et al., 2008). The latter issue of relationship included maintaining patient dignity and treating patients as whole persons rather than as diseases.

Finally, the domain of *life completion* has been central to many investigations conceptualizing a 'good' death (Steinhauser et al., 2000b; Vig and Pearlman, 2004; Hirai et al., 2006; Rietjens et al., 2006). Attributes of completion include life review, closure, coming to peace, resolving conflicts, contributing to others, spending time with family and friends, and saying good-bye. Completion may involve personal reflection or individual spiritual practice, or may be more explicitly communal including family or a wider social circle. Of course many organized religions denote particular rites of spiritual completion for both the dying and the mourner. As with all domains, cues regarding specific expression should come from the patient or family. Within this domain, the attribute of contributing to others reminds family members and providers the importance not only of what patients may need to receive but also what they need to give to experience wholeness as they face the end of their lives.

Importance of role

Studies attempting to define a positive end-of-life experience reveal the importance of role in perception of what constitutes 'good'. For example, studies show that physician perspectives tend to be more narrowly biomedical. And the data suggest a discrepancy in physician versus family and patient ratings of the importance of spirituality and completion attributes such as prayer (Byock, 1996; Cohen and Leis, 2002). In one survey asking participants to rank order nine attributes of end of life, families' and patients' rankings of being at peace and freedom from pain were statistically equal in importance (Steinhauser et al., 2000a). In contrast, physicians rated coming to peace as a distant third. Patients also were more likely to rate higher the importance of mental alertness and a desire not to be a burden to family or society.

In this same study, non-physician providers were more likely than patients to rate as important, 'talking about the meaning of dying'. Family members were more likely than patients to rate the importance of discussing personal fears or meeting with clergy. Again, it is instructive to take cues from patients about how they want to discuss this issue. Qualitative findings suggest patients may wish to discuss purpose and life more than meaning of death.

In a survey of hospice nurses definitions of a 'good death' McNamara and colleagues found that definitions of 'bad' deaths included those in which the patient did not internalize hospice philosophy, leaving staff frustrated (McNamara et al., 1994). Non-internalization included not accepting the imminence of death, allowing non-palliative therapies to continue, and the family wanting 'everything done' despite terminal diagnoses. Such circumstances were thought to compromise a peaceful 'natural' death.

Importance of culture

In addition to individual and family variation in preferences for end of life, cultural scripts also predominate (see Chapter 2.5). While this is expanded upon more fully elsewhere in this textbook, studies relating to minority and majority population variation suggest a desire for clinician awareness of cultural issues, particularly heightened attention to the role spiritual beliefs play in decision-making, and attention to individual interpretation of minority culture scripts (Tong et al., 2003). Within the US population, a growing literature has demonstrated increased preference for life-sustaining therapies among Latino and African American populations (Tulsky et al., 1997). However, in one study African Americans were more likely to 'want all available treatments' but less likely than Caucasian participants to want to be 'connected to machines' (Steinhauser et al., 2000a). These varying responses among groups sensitized providers to patient and family differential interpretation of medical jargon, and true variation in preferences for treatment. As many sources have noted, when working with populations of patients traditionally denied access to care, withdrawing and withholding treatments are met with understandable apprehension.

Much of the empirical work defining a 'good death' has involved English-speaking Western populations in which individual decision-making and autonomy is culturally rewarded. However, more recently, a number of studies have explored the meaning of a 'good death' in a variety of cultural contexts (Munn and Zimmerman, 2006; Rietjens et al., 2006; Miyashita et al., 2007, 2008; Sanjo et al., 2007; Yao et al., 2007; Spathis and Booth, 2008; Murakawa and Nihei, 2009; Nelson et al., 2009; Iranmanesh et al., 2011; Wilches-Gutierrez et al., 2012; Wilson et al., 2009a, 2009b).

For example, Asian cultures with normative scripts including notions of filial piety will display markedly different preferences

for treatment and communication on the part of patients and families. A noteworthy study of Korean attitudes towards patient autonomy showed that while 42% of respondents knew of their terminal condition, approximately 22% made treatment decisions primarily on their own with approximately 36% leaving their treatment decisions to others. Higher individual decision-making was associated with lower quality of life and quality of death scores, including assessments of physical and psychological comfort (Mo et al., 2012). More familial or communal decision-making models, though prevalent, are less well represented in the research literature, and therefore deserving of future study.

A study of Mexican culture found increased mortality rates around holidays, such as Christmas and All Saints Day, and accompanying higher ratings of quality of dying at these times (Wilches-Gutierrez et al., 2012). Respondents discussed the belief in a greater presence of religious deities on such holidays, ensuring a more 'beautiful death'. Such interpretations stand in contrast to other cultural scripts which consider holiday deaths to be imbued with a greater sense of loss. Social construction of the meaning of death is varied and often in direct opposition to the palliative care's normative views of grief and loss.

Importance of timing

In addition to cultural variation, clinicians must take note of the importance of timeframe in patient and family preferences. The literature reveals little consensus on what time frame constitutes the end of life. Furthermore, preferences will likely differ by stage of illness and evolve over time with definitions of 'good experience' living with advanced serious illness being distinct from 'good dying', as distinct from a 'good death'. For example, immediately after a diagnosis of metastatic disease *preparation* may include discussions of possible courses of treatment, the combination of curative and palliative therapies, and helping patients remain integrated with normal work and social roles. As illness progresses, preparation may include discussions of decreasing the use of curative therapies and increasing palliative approaches, discussion of hospice, and increased attention to issues of completion. As dying becomes imminent, preparation may involve working with the family about expectations of care, location of care, and education regarding the very end of life.

Developmental stage

Most 'good death' studies have been done within adult populations. The Initiative for Pediatric Palliative Care and the National Hospice and Palliative Care Organization, among others, have spearheaded efforts to improve care of children at the end of life (Feudtner, 2004; Welch, 2008). Towards that end, investigators have gathered perspectives of families and providers to identify whether childhood death can ever be considered 'good', what elements might be associated with better and worse scenarios, and whether these are applicable to the nearly 55 000 childhood deaths in the United States (Feudtner, 2004; Welch, 2008). Full reviews of efforts to improve paediatric palliative care are covered elsewhere in the textbook. We limit our brief discussion to definitions of the construct of good death.

Some of the domains considered essential to 'good' end-of-life experiences in children are similar to those found in adult populations, such as pain and symptom management, emotional and spiritual support, maximizing quality of life, need for family respite, continuity of care across settings, and making care match individual values and preferences (Feudtner, 2004; Welch, 2008). Other domains are similar to adult populations but entail special considerations due to developmental and population complexities of paediatrics. For example, Feudtner outlined the importance of addressing the total population in need; in paediatrics that may include those children born with the expectation of impending death, those who acquire illnesses after birth, and those with a sudden death due to trauma (Feudtner, 2004). The leading causes of death after the age of 1 year include unintentional injuries followed by congenital abnormalities, malignant neoplasms, and intentional injuries. Research also shows the importance of collaborative decision-making and supportive decision-making which in paediatrics includes the family as well as informing and involving children to the extent to which they are developmentally capable and desiring involvement. An additional domain of 'managing trade-offs adroitly' refers to the potential caregiver tension between a desire to limit suffering and take therapeutic risks given a child's age, life yet to be lived, and biological resilience (Feudtner, 2004). Additionally, investigators note the importance of maximizing safety and effectiveness, largely around polypharmacy, and finally, attending to timely introduction of bereavement services. The latter domain acknowledges that nearly all paediatric deaths are viewed by familial caregivers as untimely, adding to the complexity of grief. The sense of a death being on or off time in an expected life course applies to most deaths not experienced during old age. While investigation of the unique developmental needs are obvious in paediatric populations, the field would benefit from additional research examining social construction of the meaning of death across the lifespan and various adult developmental stages (Erikson, 1982).

Importance of diagnosis

Early hospice and palliative care populations were comprised, primarily, of patients with cancer. As such, literary, cultural, and empirical definitions of a 'good death' grew from the experience of living and dying from advanced cancer. Realizing the limitations to generalizability for broader end-of-life populations, investigators began seeking the perspectives of those living with a variety of life limiting illnesses (Steinhauser et al., 2000a, 2000b; Pierson et al., 2002; Walke et al., 2007; Chattoo and Ahmad, 2008; Chattoo and Atkin, 2009; Kaufman, 2011). Though sample size often precluded in-depth investigation of experiences unique to various illness types and disease trajectories, more recent work has been designed specifically to learn about the particular constructions of a 'good death' for those with congestive heart failure, chronic obstructive pulmonary disease, dementia, end-stage renal disease among others (Russ et al., 2007; Gott et al., 2008; Spathis and Booth, 2008). Two studies in heart disease (Gott et al., 2008; Chattoo and Ahmad, 2008; Chattoo and Atkin, 2009) demonstrated that both the heightened levels of uncertainty and increased possibility of sudden death among those with congestive heart failure, posed a challenge to conventional palliative care beliefs regarding values of patient 'open awareness' and even autonomy and individuality. They revealed conflict between cardiologists' culture of 'living with heart failure' and palliative care's attention to 'dying with heart failure' calling for different and more nuanced engagement with patient and illness uncertainty. Similarly, research in patients with chronic obstructive pulmonary disease highlighted notions

of uncertainty and reported definitions of 'good' end-of-life care not precluding life-sustaining interventions.

Location of death

The seven domains listed earlier often are referred to under the general rubric of the biopsychosocial and spiritual model of care. The model, as just described, enjoys significant empirical support. In addition, two recent studies expand the notion of elements that contribute to the quality of end of life for patients and families. Casarett and colleagues highlighted advanced cancer patients' preferences for 'supportive services' even over traditional hospice services (Casarett et al., 2008a). Supportive services included vouchers for practical assistance at home, transportation, peer support, meal delivery, case management, and family care. Perkins and colleagues emphasize additional supportive services such as emergency contacts and case management (Perkins et al., 2008). While much of the 'good death' literature was built on investigation into improving care of hospitalized patients, we must recognize that a majority of care in the dying trajectory occurs in the outpatient, home, and community settings. Therefore, newer models of good end-of-life experience must expand beyond the individual inpatient model of care.

The most recent research extending investigation beyond hospital end-of-life experiences has focused on defining a 'good death' in long-term care settings. Studies identify domains such as adequacy of staffing, facility environment and size, and the capacity of staff to 'be there' for residents and family (Munn and Zimmerman, 2006). Other studies identify the importance of creating 'family-like' bonds between staff and residents and family and improved communication. In this setting, definitions of a good death confirm previously identified interpersonal and more quality of life domains and extend those domains to include facets of resident and family experience directly related to quality of care.

In addition, a literature trend is the transition from identifying what constitutes a 'good death' to implementation of such definitions. One of the broadest examples is the efforts by the Department of Veterans Affairs to introduce and fund policy and clinical care initiatives to ensure quality end-of-life care for veterans across their nationwide health-care system (Edes et al., 2007; Casarett et al., 2008b). In these efforts, researchers wrestle with measuring the interconnected yet distinct concepts of 'good death', quality of life at end of life, and quality of care at end of life (Hales et al., 2010).

Opportunity for growth

Ira Byock has described the benefit of adopting a life cycle model when providing care at the end of life (Byock, 1996). The medical model begins assessment and treatment by generating a problem list. From the time a patient presents with symptoms, the clinical interviews and choice of diagnostic testing is determined by these problems. While this approach brings focus and efficiency to diagnostic testing and treatment, it is best suited to acute medicine and has limitations when applied to the context of care of incurably ill patients. Incurably ill patients surely are met with the daunting challenges of physical symptom exacerbation and functional decline; however, a purely problem-based approach offers less guidance in helping patients navigate areas of experience in which

they may experience improvement or growth. A life cycle model assumes death is the natural end of a life course. And, building on the work of human development by Erikson, Bulter, and Cassell, Byock notes the expected developmental tasks associated with this phase of life (Cassell, 1973; Butler, 1974, 1980; Byock, 1996). These tasks include attention to life review, resolution of conflict, forgiveness, acceptance and generativity. Most importantly, this framework allows one to conceptualize end of life, like other phases of the life course, as holding opportunity for growth rather than only the decline predicted by the medical model. Growth will most likely occur in emotional and spiritual domains (and areas like preparation and completion) and is hypothesized to account for discrepancies in patient versus observer ratings of quality of life.

Measuring a 'good death' and quality of death and dying

Attempts to measure a 'good death' can be found among assessment tools specifically reflecting this name, (e.g. The Good Death Questionnaire, The Good Death Inventory) and also in a larger body of work assessing the quality of dying and death (Hales et al., 2008). A recent review showed extensive variation in measures rigor with regard to design and reliability and validity. Of the 18 measures reviewed, half reported no reliability of validity information, five were single-item measures, and fewer than half reported definitions of quality of death and dying. All measures were designed for retrospective accounts of family or professional caregivers. This is the soundest way of assessing last days of life and moment of death in populations with significant percentages unable to respond, yet requires additional efforts to understand direction and strength of proxy bias among domains as well as surrogate characteristics (Steinhauser et al., 2002; Hales et al., 2008). Additionally, most research demonstrates few measures allow for weighting response preferences to match individual circumstances of changing values over time. Measures of sensitivity to change over time also is an area in need of refinement.

Because this chapter focuses on definition and measurement of a 'good death', we have not discussed the vast literature on quality of life or quality of care at the end of life. The former is best suited to periods in the palliative care trajectory preceding periods of imminent dying and allows for real-time, prospective patient-rated assessments (Steinhauser, 2005). Quality of care may rely on patient, family, or provider perspective as well as administrative and organizational data of clinical benchmarks (Ferrell, 2005).

Clinical implications of the term 'good death'

In this article we have reported on research which sought to define a 'good' death. Yet, it is important to discuss the clinical implications of using such language. In one of our studies, 'In search of a good death: observations of patients, families and providers' we concluded that there is no one 'good death' (Steinhauser et al., 2000b). Rather, each end-of-life experience is a process to be negotiated and renegotiated in the context of that patient's and family's values, preferences, and life course. We were strongly cautioned by nurses, for example, that it was important to know there was 'no one right way to die' and warned against implying to patients that

'you're not dying the right way, because you're not dying the way we think you should'.

While early hospice founders used language of a 'good' death to rally reformers to a new vision of care, in recent years the language of a 'good' death often has taken on a denotation of specific expectations of what should occur at the end of life. The zeal driving the early movement has risked imposing a sense of a 'right way' to die. Its components include being free of pain, surrounded by family, free of conflict, acceptance death, stopping curative treatment, being at peace, and preferably dying at home. While those may be components many or most would define as positive, the implication is that one can define a good death, and should achieve it. Unfortunately, though propelled by positive intentions, such definition risks imposing an unintended paternalism. Furthermore, data of patient and family preferences at end of life exhibit far more nuance and variation.

For example, a national survey revealed that only about 50% of respondents ranked dying at home as important (Steinhauser et al., 2000a). In related qualitative research linked to the survey, while many valued dying at home, other patients and families described circumstances of caregiver frailty, superstition, or fear of bad memories as dissuading them from wanting the death to occur at home. Family members and non-physician health-care providers were significantly more likely than patients to identify 'talking about the meaning of dying' as important. And though coming to peace often is highly valued by patients, working to resolve conflicts can be complex and contain periods of great uncertainty, for patients, families, and providers hoping to guide them. And, by the time of death, everything is not always resolved. Again, there is caution to those working with dying patients that these uncertainties and lack of resolution do not represent failures on the parts of patients and families, but merely illustrate rich variation in the way people live their entire lives.

Health-care providers are most likely to be challenged by patients whose conception of a good death includes the use of medically non-beneficial treatments in the setting of clearly imminent death (e.g. parenteral nutrition or attempted cardiopulmonary resuscitation). In some cases, such preferences are reflective of unresolved loss or other emotional distress, and the best response may be empathy and support, which often leads to a change of treatment course. For other patients, these views are rooted in deeply vitalist traditions and are consonant with a broader set of values and goals. When that is true, an honest respect for individual choice compels us to honour such preferences. In the rare cases where health-care providers cannot find a way to reconcile these actions with their own sense of the goals of medicine, mediation via ethics consultation or other processes may be required.

Alternative language—defining goals at end of life

Therefore, rather than promoting a construct of a 'good' death, we favour the language of helping patients and families define and meet goals at the end of life. This paradigm has several advantages. First, in the medical context, we expect that goals vary between individuals. Second, we expect that they may change over time. Therefore, they require ongoing communication and negotiation. Third, the language of goals engages patients as active participants. Drawing from the self-management literature, the clinician may be the expert on the disease process, but the patient is the expert on their life. Fourth, it acknowledges a future orientation and ongoing contributions. Fifth, for the clinician, it is action oriented and moves beyond the idea (not common in palliative care) of having nothing more to offer. There are always additional goals.

Although we favour the paradigm in general, it does have some disadvantages, and points of caution. First, the language of goals may imply achievement and productivity, and risk imposing such expectations on patients. This would be counterproductive. Second, culturally we may think of goals as 'doing'. Yet, we do not want to understate the importance of offering a sense of presence to patients and simply 'being' with them in their illness.

Being with patients and families may involve offering assurance, through words and actions, that the provider will be present through the course of treatment and illness. It may involve deep listening and necessary silences, in the presence of powerful emotions. And, it may involve assurance of commitment to negotiating and renegotiating preferences for care that attend to domains of physical, social, emotional, spiritual well-being as well as issues of preparation and life completion. Together, acknowledging that the quality of end-of-life experience is dependent upon attending to the multiple dimensions of whole persons facing illness in the context of an entire lifetime of values and choices and the web of family and community.

2.5

Ethnic and cultural aspects of palliative care

LaVera Crawley and Jonathan Koffman

Introduction to ethnic and cultural aspects of palliative care

The goal of this chapter is to identify 'differences that make a difference' (Parens, 1998) among individuals and groups when they negotiate institutions and practices for palliative and end-of-life care. Culture is but one of several typologies of difference that has been used to signify diversity among individuals and groups. If narrowly defined from an anthropological perspective, culture can be thought of as that which refers to the 'patterns, explicit and implicit, of and for behaviour acquired and transmitted by symbols, language, and rituals (Kroeber and Kluckholn, 1952). Seen as a 'recipe' for living in the world, this conceptual framework for culture explains the means of transmitting these 'recipes' to the next generation (Donovan, 1986). However, this is a limited understanding of culture that, if used here, risks minimizing discussions of cultural aspects of palliative care to an interpretive list of end-of-life beliefs and practices from a range of so-called cultural groups. This has also been referred to as the 'fact-file' or 'checklist' (Gunaratnam, 2003a) approach that, while informative in regards to interpreting behaviours, symbols, rituals, and other cultural practices of certain ethnic or religious groups that may be important and meaningful at the end of life, runs the risk of encouraging generalizations about individuals and groups based on cultural identity. This in turn may then lead to the development of stereotypes, prejudices, and misunderstandings.

Culture is not static because identity, be it cultural, ethnic, religious, or using other categories, is in a constant process of adaptation and change, often in response to interactions with yet 'others' who are different in multitudes of ways. Culture is not the sole possession of those who are considered 'ethnic' minority groups. All people, the health-care practitioner included, brings his or her own cultural self into the medical or nursing encounter—a self that holds assumptions about the world and engages in practices and behaviours learned from their family and society of origin and, in the case of the health practitioner, from Western scientific and professional ideologies. Cross-cultural or intercultural interactions are not merely interpretative where each party needs only to translate the language, signs, behaviours, or practices of the other. Ideally, these exchanges are also dialogical and relational. All parties enter into some transformational 'third space' (Bhabha, 1988) where meaning is negotiated and new understandings emerge. Therefore programmes in 'cultural competency' that

merely utilize an interpretive approach, emphasizing technical competencies utilized during the clinical encounter (such as communication skills), may miss the opportunity to teach skills needed for attitudinal transformations (such as sensitivity and humility) that are critical for 'developing mutually beneficial and non-paternalistic . . . partnerships' with patients and families (Tervalon and Murray-Garcia, 1998).

Understanding identity

In addition to culture, self- or group identification may be based on race, ethnicity, tribal or clan affiliation, nativity, generational status, citizenship, gender, religion, politics, sexual orientation, social and economic class, and other categories (Koffman, 2006). Race, a rather contentious category of identity, has its roots in social Darwinism, and relies heavily on an expectation of perceived (versus real) biological differences between people and populations (*Collins Concise Dictionary*, 2001). Historically, race has been used to describe geographically separated populations (such as the African race), cultural groups (Jews), nationality (the English race), and mankind in general (the human race). Racialized research in science has a long and inglorious history (Gould, 1981; Stepan, 1982). In the mid-nineteenth century, the cephalic index, a method for describing the shape of the skull, became a popular way of describing and dividing races. Under the influence of phrenology, a hierarchy of races was devised with white Europeans at the top and black Africans at the bottom. Intelligence, physique, culture, and morality were all placed in an order, the so-called Great Chain of Being philosophy used to justify slavery, imperialism, anti-immigration policy, and the social status quo (Singh, 1997). Biological determinism also became prominent in medicine and medical practitioners frequently contributed to racialized science (Ahmad, 1993) with the theory of racial hygiene in Nazi Germany being a horrific and notorious example. However, differences that do exist between peoples and populations are very minor and largely reflect superficial physical characteristics such as facial features, hair, or skin colour. Many researchers have therefore now discredited race as being inaccurate and misleading (Karlsen and Nazroo, 2002b).

Less controversial but equally misunderstood is the concept of ethnicity (Chaturvedi, 2001; Afshari and Bhopal, 2002). As a category of identity, it reflects the social grouping of people on the basis of historical or territorial identity or by shared cultural patterns and

traditions maintained between generations (Senior and Bhopal, 1994; Crawley, 2005). One's ethnicity can be defined by language, such as the Spanish language that unites Hispanic peoples in Central and South America and the Caribbean who are otherwise separated by geography, history, and politics. It can also be defined by shared ancestry, such as subgroups of diasporic black people who are descendants of slaves from West and Central Africa. There are also subcategories used in identifying certain ethnic groups. For example, among ethnic black people, further delineations can be made by nativity and citizenship: African Americans who are descendants of slaves and of multiple generations born in and holding citizenship in the United States may be ethnically distinct (e.g. in language or culture) from black Haitians, Cubans, Jamaicans, or other descendants of African slaves who reside in the Caribbean, South America, the United Kingdom, or other diasporic locations. Other ways in which people express their identity include kinship by tribal or clan affiliation which can be extremely influential (and potentially volatile) in intergroup dynamics.

Identity is both internally (self-) defined and externally (structurally) imposed (Karlsen and Nazroo, 2002a) which has bearing not only in how an individual or group sees oneself but also in how they are treated by society. Needless to say, the politics and social science of identity is complex. Furthermore, semantic confusion is very common when the concepts of identity are used in clinical and research settings. Race, ethnicity, and culture are often used interchangeably, subject to misuse, or confused with other social metrics, such as social class or education (Hillier and Kelleher, 1996). The manner in which these concepts are used may change due to prevailing fashions and politics (Gunaratnam, 2003b).

Structural factors, defined as rules, roles, and institutions derived from dynamic social, economic, political, and historical processes, may play an important role in creating and maintaining cultural, racial, and/or ethnic identities themselves, or various aspects associated with those identities. An example can be seen with the conflation of ethnic identity with class: in places or situations where institutional racism or other forms of discrimination constrain freedom and development for certain segments of a population, such as on the basis of racial or ethnic visibility, these structural factors may produce patterns (e.g. poverty, poor education, crime) that become erroneously attached to the identity of that group (Karlsen and Nazroo, 2002a). The same can be said for structural factors that privilege other segments of the populations.

To compound the confusion, there is no uniformity in how people are classified across national boundaries. For example, the National Health Service and census in the United Kingdom identify five different categories of 'ethnicity' (white, mixed, Asian, black, or Chinese) that are further broken down into different subgroups based on countries of origin (e.g. Indian, Pakistani, Bangladeshi, or other for Asian; Caribbean, African, or other for black people, etc.) (Office of National Statistics, 2003); while the US census collapses many distinct populations into one dichotomous category of 'ethnicity' (Hispanic or non-Hispanic) and five single broad categories of 'race,' (white, black or African American, American Indian or Alaskan Native, Asian, and Native Hawaiian or Other Pacific Islander) (Office of Management and Budget. Revisions to the standards for the classification of federal data on race and ethnicity. Federal Register, 1997; 62(210): 58782–58790). The South African census uses five population categories based on self-classification (Black African, Colored, Indian or Asian, White, or Other) (Lehohla, 2003). Canada collects census data based on ethnic origins (defined by ancestry) and on a category called 'visible minority' status, defined as 'persons other than Aboriginal persons who are not white in race or colour' (Statistics Canada, 2001). Lastly, there is evidence that many people change their assigned identity over time, as is their prerogative (Bhopal, 1995). US-based research has shown that at least 35% of respondents altered their self-assignment over a year and in the validation study following the 1991 British census, 12% of 'black' people altered their ethnic group, as did 22% of 'other' category (Pringle and Rothera, 1995).

This mutability attests to the fact that people inhabit multiple identities which are expressed or perceived differently as needs and circumstances change (Karlsen and Nazroo, 2002a; Crawley, 2005). The relevance of this discussion for palliative care is to caution the clinician and researcher to be mindful of the difficulties in interpreting events at the bedside or reports in the literature related to culture, race, ethnicity, or other identifiers. Employing clearly and rationally defined demographic categorizations of identity in studying epidemiological patterns of morbidity and mortality has usefulness for policy implications, such as determining what systems of care are needed or measuring inequities in quality of care delivered across population groups. However, employing essentialized notions of preferences or behaviours at the bedside runs the risk of compromising an individual's 'needs and concerns [that] may not conform to preconceived or stereotyped patterns' (Crawley, 2005). What best serves the needs of all patients is knowledge of the particular individual's beliefs, values, preferences, and practices—knowledge gained by asking the patient or family directly or by utilizing resources that promote patient-centred and relationship-centred care.

The special case of immigration

Throughout human history, individuals, families and groups have emigrated from their native homes to other places for many reasons: the prospect of educational, economic or social advantage; the need to escape war, political torture or other conflicts; or the desire to reunite with other family members. Globalization has brought with it an unprecedented increase in the numbers of people who have migrated to developed countries. As of 2010, there were an estimated 214 million immigrants worldwide: nearly 70 million of these immigrants arrived in Europe and over 50 million in North America—an increase of nearly 40% in these regions compared to 20 years earlier (United Nations, Department of Economic and Social Affairs, Population Division, 2009). This trend is expected to continue and to increase. In the United States, for example, it is estimated that by the year 2050, nearly two-thirds of the population will be immigrants.

The International Observatory on End-of-Life Care that monitors the global development of hospice and palliative care services around the world reports that such services are unavailable or are uneven at best in resource-poor and medium-resource countries when compared to European and English-speaking countries (International Observatory on End of Life Care, 2006). Subsequently the immigrant may not have had much exposure to or knowledge of palliative care services provided by hospices or other health-care institutions in their home country. For example, the Observatory documented misperceptions about and stigmas regarding palliative care in Mexico (Clark, 2006). As

such, expectations for palliative care may thus be lowered among Mexican immigrants who bring from their country of origin misperceptions or lowered priorities for this type of care (Crawley and Chaudhary, 2006). In addition, some immigrants may find accessing quality care and finding funds for hospice, palliative care, and other end-of-life health services to be a complex and potentially confusing process that may be compounded by unfamiliarity with laws and regulations of the host country. The immigrant's knowledge of and preference for palliative or other health care may be influenced by factors related to immigration itself. For example, refugees and asylum seekers who have experienced violence, or who may have been exposed to torture or other state-sanctioned or war-related trauma, may be mistrustful of government-run health-care or social service institutions and authorities (Gavagan and Martinez, 1997; Gavagan and Brodyaga, 1998). They may also face fears and uncertainties that accompany their experiences as an immigrant.

Immigration also impacts the workforce that provides caregiving for those who are dying. Foreign health-care workers are motivated to leave their native countries for reasons general to all immigrants—educational, economic or social advantage; family reunification—or they may leave due to inadequate health-care infrastructures and technologies (Crawley et al., 2007). The result in some receiving countries is a growing immigrant workforce who bring their own unique cross-cultural issues to health-care delivery systems. On the one hand, an increasingly diverse health-care workforce may help improve outreach to diverse communities, particularly with access issues such as language barriers. On the other hand, these workers will represent a spectrum of acculturation or assimilation of the language, customs, values, and perspectives of the host country. Just as there can be 'native' providers who lack cultural competency and sensitivity towards immigrant patients, there can be those immigrant providers who lack these skills with 'native' patients. Central to this issue is communication capability.

Cultural versus moral relativism

Cultural relativism or multiculturalism is defined as 'a social-intellectual movement that promotes the value of diversity as a core principle and insists that all cultural groups be treated with respect as equals' (Macklin, 1998). In social, economic and political arenas, this is a laudable goal, although it may seem as narrow in the sense of applying limited or narrow definitions of culture or identity as what is discussed above. Efforts for ensuring equitable access to societal goods across all populations, including quality care for the seriously ill and dying, requires attention to salient differences within and among groups. However, blindly embracing this principle does carry an inherent risk of mistaking cultural relativism with moral relativism. Respect for diversity does not mean one should tolerate actions that violate another's human rights. A case example is warranted: a young adult immigrant from Yemen with advanced metastatic cancer required large doses of opioids to control his pain. The patient described his pain as unbearable and requested relief from his physician. The patient's family, traditional Muslims, strongly objected to the prescribing and administering of opioids required to relieve the patient's pain and suffering, quoting scriptures that held that pain was to be endured as test of faith (Al-Jeilani, 1987).

Cultural relativism indeed requires us to respect the role that religious and other cultural beliefs and practices hold; however, it may be difficult to be tolerant of practices if doing so forces us to violate moral principles such as non-maleficence (to avoid doing harm) or beneficence (serving what is in the patient's benefit). If the patient, rather than his family, acknowledged this preference to forego treatment of his pain, then the moral dilemma between the doctor and patient may need to be addressed. In this case, however, the patient did request relief and thus the provider might feel the prima facie obligation to address the patient's request for pain relief with respect for his autonomous right for health-care decision-making. The moral dilemma then, is truly between the patient and his family.

However, one may counter argue that such moral principles are not culturally neutral to begin with and, rather, reflect a Western bias of what counts as right or wrong. Respect for individual autonomy is a Western ideal. Among other populations, the family or community is thought to be the unit of autonomy. For example, among some Asian or Hispanic populations, it is believed that the family should be the decision-maker and in some cases patients should be shielded from information deemed potentially disturbing. This is a classic dilemma brought to ethics committees or consultations for deliberation and an example of why cross-cultural or intercultural interactions should be seen as dialogical and relational. The goal for all parties in such interactions is not to condone or to condemn the 'other' but rather to seek understanding and to co-create resolutions that are mutually acceptable. Understanding goes beyond interpretation of beliefs and values; it also means looking at the structural aspects of a practice: what purpose it serves in the cultural group or society. If a group values family autonomy over individual autonomy while the physician or medical system values the reverse, then a mutually acceptable solution might entail asking the patient if he or she would autonomously prefer the family to make decisions, thereby autonomously relinquishing autonomy. In summary, as ethicist Ruth Macklin has written, blind tolerance, which she calls 'extreme ethical relativism', is not useful. However, Macklin reminds us that neither is Western cultural imperialism. The middle ground is the following: cultural, religious, and ethnic groups should be treated as equals—conforming to the principle of justice as equality—while at the same time this should be balanced with intolerance of practices that are unjust and oppressive (Macklin, 1998).

Differences that make a difference

How we understand the influence of diversity in patterns of advanced disease, illness experiences, responses to treatment, and the use of specialist palliative care services is important given increasing evidence that we are not all equal in death and dying (Oliviere, 1999; Crawley et al., 2000; Karim et al., 2000; Firth, 2001; Koffman and Higginson, 2001; Gunaratnam, 2003a). Race- or ethnic-based disparities in mortality and in diagnosis, quality of care, referral patterns to specialist palliative care, and treatments for pain and other physical symptoms have been documented in many developed countries (Berthoud and Modood, 1997; Harding and Maxwell, 1997; Department of Health, 1998; Farrell, 2000; Karim et al., 2000; Gibson, 2001; Karlsen and Nazroo, 2002a; Koffman et al., 2003, 2005; Mooney, 2003; Smedley et al., 2003; Casas-Zamora and Ibrahim, 2004; Crawley, 2005; Paradies, 2006).

In the United States, a comprehensive review of evidence of unequal treatment, commissioned by the US congress and produced by its Institute of Medicine (IOM), documented race- or ethnic-based inequities in pain and chronic disease management, cancer care, and other clinical care settings and suggested that inequities may be due to patient-level, provider-level, and/or health system-level variables, alone or in combinations (Smedley et al., 2003). Patient-level factors would include ethno-cultural, social, or other beliefs, preferences, or knowledge about health options. According to the IOM study, patient-level factors were thought to be the least likely contributor to disparities. On the other hand, both provider stereotyping and bias, and how health-care systems are organized as well as the degree to which people have access to care were shown to more likely influence health outcomes for minority patients.

The existence of prejudice and stereotyping by health-care providers may be difficult for many non-minority providers to accept, as we all presume to consciously abhor such discriminatory attitudes and behaviours. The important contribution of the IOM report in thinking about this issue was its suggestion that it is not conscious attitudes that drive discrimination but rather those unconscious or implicit attitudes that may compel us when we are under duress. As Fyodor Dostoyevsky stated:

> In every man's memories there are such things as he will reveal not to everyone, but perhaps only to friends. There are also such as he will reveal not to friends, but only to himself, and that in secret. Then finally, there are such as a man is afraid to reveal even to himself, and every decent man will have accumulated quite a few things of this sort. That is, one might even say: the more decent a man is, the more of them he will have. (Dostoyevsky, 2003)

Health system-level factors such as poor access to health-care services have been reported by black and minority ethnic groups in the United States and the United Kingdom (Harding and Maxwell, 1997; O'Neill and Marconi, 2001). This is also an issue for end-of-life care where the impact of ageing on the black and minority ethnic groups now means larger numbers of older members within these communities will require health services for advanced disease. A limited number of reports have levelled criticism of care at the end of life for these communities and poor access to appropriate care. Low rates of cancer were seen as one explanation to account for low uptake of service provision, but the figures were likely to have been inaccurate because of inadequate ethnic monitoring (Aspinall, 1999). The authors concluded 'some black and Asian patients and their carers are very disadvantaged, as they do not know what they are entitled to, and hence what to ask for by way of benefits and services' (Hill and Penso, 1995). More recently, a study in an inner London health authority demonstrated that African Caribbean patients with advanced disease experienced restricted access to some specialist palliative care services compared to white British deceased patients (Koffman and Higginson, 2001), yet an analysis of local provision revealed no lack of palliative care services (Eve et al., 1997). This may be due to poor knowledge and awareness of palliative care and related services (Koffman et al., 2007). This example of under-utilization of palliative care services by the black Caribbean community at the end of life supports other recent research among minority ethnic communities (Farrell, 2000; Skilbeck et al., 2002). The explanations to account for this build on work conducted by Currow and colleagues (Currow et al., 2008) among others (Ahmed et al., 2004; Koffman and Higginson, 2004), all of which may operate

in combination, and are highlighted in Fig. 2.5.1. Identifying and eliminating health inequities in the delivery of quality palliative care is a critical mandate. Institutional standards for monitoring and ensuring the cultural sensitivity and competency of the palliative medicine workforce should be employed, as should strategies to increase community-based partnerships. Ultimately, it is incumbent on service providers to redress these disparities by active processes rather than imagining that people who are often already marginalized can improve their own access to services.

Providing equitable, culturally appropriate palliative care

The World Health Organization definition of palliative care specifies two goals: improving quality of life (QOL) of patients and families and preventing and relieving suffering. It identifies three strategies for meeting those goals: early identification, impeccable assessment, and [appropriate] treatment. Lastly, the definition addresses four domains of care: (1) problems related to pain, (2) other physical conditions, (3) the psychosocial, and (4) the spiritual. The remaining sections of this chapter addresses these goals, strategies, and domains in relation to delivering quality palliative care in cross- or multi-cultural settings.

Goals of palliative care in cross-cultural contexts

Quality of life

The World Health Organization defines QOL as 'an individual's perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards and concerns' (World Health Organization, 2006). When applied to palliative care, the focus is on maximizing the quality within the time remaining in a patient's life. Because quality should be subjectively defined by patients and their families, cultural factors relevant to the individual and their family need to be addressed when assessing their QOL preferences and requirements.

Many QOL assessment instruments include broad areas representing key domains such as physical symptoms, functional status, interpersonal relations, emotional well-being, and the experience of spiritual or existential transcendence. However, the subjective nature of the concept of QOL and instruments used to measure it must also consider variations in meanings of these domains across cultural groups. Recognizing the need to address cultural components in assessing quality, the World Health Organization initiated the WHOQOL project to 'develop an international cross-culturally comparable quality of life assessment instrument' (Murphy et al., 2000).

The psychometric properties of the WHOQOL instrument were tested in several stages and across multi-cultural field sites to ensure cross-cultural validity including:

◆ agreement on the definition of QOL

◆ standardization of questions or items and of scale construction

◆ field testing final instruments.

Both the 100-item instrument (WHOQOL-100) and the shorter 26-item version (WHOQOL-BREF) are available in many

Attitudes to palliative care: Barriers to general health care that the poor and the disenfranchized have traditionally encountered may affect their receptivity to palliative care (Gibson, 2001).

Ethno-centralism: Demand for services may be influenced by the 'ethnocentric' outlook of palliative care services, discouraging BME groups from making use of relevant provision (Smaje and Field, 1997).

Gatekeepers: Some health-care professionals 'gatekeepers' to services among minority ethnic groups contributing to lower referral rates (Smaje and Field, 1997)

Awareness of specialist palliative care services: There is a growing body of evidence that BME groups are not aware of specialist palliative care services available to them, a situation magnified by poverty (Koffman et al., 2007; Currow et al., 2008)

Mistrust: BME groups are less likely than white patients to trust the motivations of doctors who discuss end-of-life care with them (Kagawa-Singer & Blackhall, 2001).

Social deprivation: Low socioeconomic status has been positively linked to an increased likelihood of hospital deaths although this would apply equally to all population groups (Gomes and Higginson, 2006).

Dissatisfaction with health care: Uptake of health and social services among certain minority ethnic communities and has revealed lower utilization of services due to dissatisfaction of services. (Lindsay et al., 1997; Koffman and Higginson, 2001)

Fig. 2.5.1 Possible explanations to account for under-utilization of specialist palliative care among black and minority ethnic (BME) groups.

languages and can be used clinically for individual patients as well as in cross-cultural research for inter- and intra-group comparisons (World Health Organization, 2006). The initial field sites, located in Australia, Croatia, France, India, Israel, Japan, the Netherlands, Panama, Russia, Spain, Thailand, the United Kingdom, the United States, and Zimbabwe, each adapted the standardized instrument to their population-based needs. To date there are now over 30 sites worldwide and more continue to field test and adapt the instrument to the unique cultural needs of their countries.

Preventing and relieving suffering

Cultural factors mediate the ways in which symptoms associated with advanced disease are identified and interpreted. Examples include the appropriate modes of expression of pain and other symptoms, and the associated suffering, whether an illness and

symptoms are stigmatized, and whether the dependencies that accompany advanced disease are considered an acceptable part of the normal life cycle. The evidence of the influence of cultural and ethnic factors on symptom interpretation is fascinating and frequently raises more questions than it answers. In the 1950s, Zborowski demonstrated differences among old American, Irish, and other migrant communities' perceptions of their pain (Zborowski, 1952). Most recently, Koffman et al. observed significantly higher levels of symptom-related distress among black Caribbean peoples compared with native-born white United Kingdom patients with advanced cancer living in south London. This finding was only partly explained by simple variations in treatment levels between the two groups (Koffman, et al., 2003). Along with other researchers (Lasch, 2002; Cintron and Morrison, 2006), the authors suggest that the language of expressing symptom-related distress may be reinforced by

cultural expectations (Koffman et al., 2003). Expressions of suffering have been shown to serve a purpose. It has been observed in some African American communities that suffering is perceived to be redemptive, bringing those who experience it closer to God (Crawley et al., 2000).

In other communities the actual language used to describe distress and suffering has implications for the delivery of palliative care. Krause revealed that the expression in Punjabi, 'Dil *me* girda hai,' used by Panjabis in Bedford, often translates as the 'sinking heart' to reflect a range of psychological and somatic conditions (Krause, 2005). In addition, she suggests that the 'generalized hopelessness' which characterizes depressive disorders in women living in London would not be regarded as abnormal among Hindu, Muslim, and Buddhist women who would regard 'hopelessness' as an aspect of life which can only be overcome on the path to salvation. Ahmed takes the view that while South Asian patients may be well aware of their own psychosomatic symptoms, general practitioners (GPs) (including Asian GPs) tend only to acknowledge physical symptoms and do not recognize psychological distress (Ahmed, 1998). The ongoing challenge is for health-care professionals to explore and acknowledge culturally determined understandings and expressions associated with advanced disease that do not mirror their own.

Strategies of palliative care in cross-cultural settings

Early identification

Problems with late referrals to hospice or for palliative care in general are a concern for all populations. To avoid the appearance of medical abandonment, it is important to integrate the goals of hospice and of palliative care early in the disease process, particularly for those illnesses that are predictably fatal. This is particularly important for immigrants or members of ethnic or cultural communities who may already feel marginalized or vulnerable due to their minority status. Myths or misunderstandings about the goals of palliative care should be addressed where possible early on through culturally effective communication—which can also enable the palliative care team to learn about and incorporate the unique perspectives of the patient into the multidisciplinary management of their care.

Identifying preferences for medical care in advance of untoward or terminal circumstances can be a difficult and emotional process. The decision-making model of advance care planning derived from bioethics practices assumes that choices made by the individual can be arrived at through rational processes that are unchanged by time, shifting social consequences, or disease and illness progression; good advance care planning permits for changes and shifts overtime for an individual or a community. Such a model may only appeal to certain subsets of people, thus limiting the utility of instruments used for advance planning (living wills or durable powers of attorney for health care).

For some groups, speaking about the dying process or planning for death may represent a transgression of a strong cultural taboo and could create additional distress. Other patients, unfamiliar with or mistrustful of the legal system, may misconstrue the purpose or nature of formal advance care planning documents. In all cases, rather than abandon the goals of advance care planning, strategies should be sought that facilitate understanding. For example, a generic discussion to identify a health-care proxy need not be cast as a discussion of death, but rather an opportunity to determine desired roles of various family members and support persons. Discussions about patient preferences for end-of-life care should be culturally and linguistically appropriate and reflect sensitivity to patients' values and beliefs.

Impeccable assessment

Critical to assessing and monitoring palliative care needs is the ability to communicate clearly and effectively. The inability to do so not only affects access to palliative care services but has been shown to be a source of serious problems in clinical consultations and the cause of misunderstandings among patients, family members and health-care providers (Nazroo, 1997; Koffman and Higginson, 2001). Important communication difficulties arise where there is an over-reliance on a patient's relatives acting on their loved ones' or dependants' behalf. While this may well be simpler than accessing an interpreter, it can potentially disadvantage both the doctor and the patient (Crawley et al., 2000).

The family interpreter may filter, abbreviate, or omit very important information, or inform the doctor or the patient what he or she thinks the doctor and patient needs to know. Important medical information may not be understood adequately or conveyed in full (Butow et al., 2011). Further, the use of children as interpreters is considered inappropriate. Details about an illness may be very intimate and it places an unfair burden on them (Yee, 1997). Using friends or untrained lay interpreters from the local community can be even more problematic since there can be issues of confidentiality and fear of gossip in the wider community (Firth, 1997). Moreover, communication is not only an issue of spoken language. It also involves body language, cultural rules as to what is courteous (such as not looking the professionals—especially of the opposite gender—in the eye), and appropriate behaviours in an unequal gender and power relationship (Firth, 2001). People who speak English with a different accent or dialect can also be judged to be less intelligent or fail to be understood or understand what is being said to them (Firth, 1997).

Appropriate treatment

It is widely acknowledged that management of physical and psychological symptoms associated with advanced disease can be difficult in mono-cultural interactions between clinicians and patients because of differences in perspective between Western biomedicine and lay health beliefs and practices. However, the design and assessment of effective health care for culturally diverse patients, both long-term residents and new immigrants and refugees, is even more complicated. New immigrants increasingly come to the United States and the United Kingdom, among other countries, from regions such as Southeast Asia, Latin America, and Africa, and are even more heterogeneous than their European predecessors (Lasch, 2002). Within the same ethnic group, individuals come from all walks of life with differing educational, occupational, and economic status, ties to their country of origin, and geographical background. All these factors affect their ethnic identity and their cultural responses to health and illness. Understanding and controlling patients' symptoms in a health-care system where the dominant imperative is for economic efficiency represents a challenge. When clinicians look to published research to acquaint themselves with the ways in which

ethnicity or culture may impinge upon the experience, expression, or behaviours related to responses, they find a vast array of disciplinary lenses and diverse theoretical approaches that are often not made explicit, thus generating inconsistent findings.

Domains of palliative care for culturally diverse populations

Albert Schweitzer is noted to have said 'Pain is an even worse master than death' (Marcus and Arbeiter, 1994, p. 4). Pain is a common and often distressing symptom associated with cancer, with a prevalence of over 90% in the more advanced stages of the disease (Solano et al., 2006). Although treatments to manage this symptom have improved dramatically in recent years, some patients still experience severe pain due to its refractory nature, poor management, or a reluctance to take medication. In recent years, the number of research articles that have examined the interface between pain and ethnicity have increased (Bonham, 2001; Morris, 2001). This has particular relevance given that ethnic and cultural diversity is more common in countries around the world; health-care professionals are now more likely to care for patients from backgrounds that differ from their own.

Whilst pain is an individual experience that may affect people differently, it is also plausible that biological markers which may be shared within a group may contribute to reported pain severity. If this is so, ethnic differences in experiential pain sensitivity could help explain group differences in clinical pain. However, the evidence base that has attempted to explore this complex aspect of pain presents a mixed picture. An early study conducted by Chapman and Jones reported lower heat pain thresholds and tolerance among African American study participants compared to non-white Hispanics (Chapman and Jones, 1944). Whilst other studies present similar findings (Woodrow et al., 1972), more recent (and more sophisticated) studies that have utilized several different methods of assessment to compare pain among African Americans and non-white Hispanics, have not identified marked differences in pain ratings across groups (Edwards and Fillingim, 1999; Campbell et al., 2003).

It is important to recognize that pain has the potential to affect all, regardless of biological, ethnic, or cultural differences. Comparative studies on pain thresholds across population groups—identifying which group experiences more or less pain under given conditions—are potentially racist and without clear clinical value. However, what would be clinically relevant is individual patient assessment of pain levels. While there has been enormous progress in the field of pain in recent years, the actual delivery of care of individuals in pain is still far from adequate. In 1990–1991, a study of 1308 outpatients with cancer noted that 67% reported pain with 62% of those in pain reporting pain severe enough that ability to function was impaired (Cleeland et al., 1994). However, as we focus on pain and why it is too often ineffectively treated, it is evident that certain minority populations are at higher risk for ineffective or sub-therapeutic treatment of pain. Evidence from recent studies, principally conducted in the United States and the United Kingdom, paints the clear picture that one's ethnic background matters in the treatment of cancer pain; the studies' most poignant findings are related to the disparity in treatment of minority ethnic patients compared to their white peers. Moreover, the studies, when reviewed as a group, identify that these disparities exist across a number of types of health-care facilities and treatment settings, from the community hospital to the nursing home.

The cultural meaning and shaping of pain

Pain is never the sole creation of our anatomy and physiology. Rather, as Morris (2001) suggests, it emerges only at 'the intersection of bodies, minds and cultures'. Pain attributions and meanings may be learnt by the members of a particular culture and then transmitted to others. Cancer-pain 'meanings' have frequently been identified as invoking religious beliefs. For example, recent research among black Caribbean and white British patients observed that beliefs about pain were mediated by religious beliefs that influenced attitudes towards medication and the accommodation of distress; a number of black Caribbean cancer patients regarded their pain as representing a test of religious faith or a justified punishment. In this religious context, these patients believed that cancer suffering was part of life, to be endured in order to enter heaven (Koffman et al., 2008). Although these findings may appear to be inappropriate and even anti-therapeutic (Bendelow and Williams, 1995; Juarez et al., 1999), health-care professionals should remind themselves of Helman's three propositions about pain, all of which have resonance in such a clinical encounter:

1. Not all social or cultural groups respond to pain in the same way.

2. How individuals perceive and respond to pain, both in themselves and others, can be largely influenced by their cultural background.

3. How, and whether, people communicate their pain to health professionals and to others can be influenced by cultural factors (Helman, 2007, p. 185).

Assessment and communication of pain in the clinical encounter

At its core, pain represents a subjective experience. It therefore relies heavily on impeccable assessment and communication between health-care professionals and patients. Although patients from minority ethnic groups share many of the same concerns that limit pain control with majority populations, data from a number of studies suggest that the manner in which pain is communicated varies from one group to the next (Cleeland, 1989; Anderson et al., 2002). Several important issues therefore warrant consideration. First, patients with serious medical conditions such as advanced cancer may under-report their pain and its severity and this may be culturally determined. For example, African American and Hispanic cancer patients have reported stoicism and the belief that their pain is an inevitable part of their illness experience and must be accepted (Juarez et al., 1999). Second, the most frequently studied factor that has been shown to influence pain assessment involves its actual severity. When pain severity is low, patients and health-care professionals report good agreement in rating of this symptom (Grossman et al., 1991; Tait and Chibnall, 1997). However, when patients rate higher levels of pain there is evidence that health-care professionals do not concur with their assessments (Chibnall et al., 1997). In addition, there is also evidence that patients reporting high pain severity also experience prejudiced stereotyping which may be amplified by racism (Tait and Chibnall, 1997).

Like QOL measures, a range of cross-culturally validated instruments for assessing pain can be employed at the bedside.

Pain intensity scales and multidimensional tools have been translated into several languages; however, mere translation of standardized instruments into the language of a given patient may not ensure its efficacy for that patient's cultural group. The selection of a scale or tool should be based on the patient's literacy and ability to understand numerical ratings, images, or sensory, affective and evaluative descriptors used in numerical rating, visual analogue, or multidimensional scales.

Health-care system factors

Racial and ethnic differences in the utilization of health-care services in general and palliative care in particular are well documented (Spruyt, 1999; Koffman and Higginson, 2001; Koffman et al., 2007). Specific examples can also be cited in relation to the management of cancer-related pain. For example, in examining a randomized selection of pharmacies located in New York City, Morrison and colleagues observed that 50% of pharmacies located in neighbourhoods with proportionately larger minority residents did not stock adequate supplies of opioids to treat severe cancer pain (Morrison et al., 2000). In the United Kingdom, several studies have identified disparities in the uptake of specialist in-patient and community-based specialist palliative care among black and minority ethnic groups (Koffman and Higginson, 2001; Ahmed et al., 2004).

Other symptoms

Like pain, symptoms of anxiety, depression and delirium, common in the advanced and terminal stages of dying, may be expressed and understood differently across various ethnic and cultural groups. Symptom formation can be influenced by sociopolitical factors in conjunction with biological and environmental variables. Behaviours considered normative within the psychospiritual belief systems of a given culture (e.g. spirit possession, visions of spirits or ghosts, etc.) may be considered delusional or otherwise pathological within a Western biomedical model. Conversely, certain culture-specific patterns of anxiety or distress that do not fit medical classifications (so-called culture-bound syndromes) may be missed in evaluating the mental health of patients and their families.

Psychosocial domains

Social support networks are crucial factors in the psychological well-being of the seriously ill and the dying patient (Koffman et al., 2012). Within those networks, informal caregivers perform an essential role for both the patient and for the health delivery system. The emphasis on care in the community rather than institutions, and the growing awareness that in some communities, people would prefer to die at home given the choice (Gomes and Higginson, 2006), means that informal caregivers are indispensable partners of health and social care professionals. Many assume responsibilities of care that were previously confined to specialist in-patient settings and community hospitals (Rhodes and Shaw, 1999). Caring for family members is regarded as an important obligation in many ethnic communities (Koffman and Higginson, 2003; Koffman et al., 2012). Further, for many ethnic minority families, caring for dying relatives at home when possible is considered a matter of honour and integrity as well as a means of ensuring the death occurs in a holy place (Spruyt, 1999). Karim et al. refer, in addition to Currow and colleagues, to the stigma and loss of face from not caring for close family relatives (Karim et al., 2000; Currow et al., 2008). In the Hindu tradition, the concepts of karma and sacred duty may place the family of a loved one or dependant under additional stress in order to do the right thing (Firth, 1997). Spruyt found that east London Bangladeshi children became actively involved in the care of dying patient and in interactions with professionals, and had to act as interpreters. This had a negative impact on them subsequently. A number of children were required to give up formal schooling and older sons gave up work to help with care of relatives. When there is home care the burden often falls upon one person, but without ready access to outside support (Spruyt, 1999). For example, in the United Kingdom, multigenerational Pakistani and Bangladeshi families who wish to provide traditional support may also be in situations with high unemployment and poverty, and large families of young children (Blakemore, 2000). Home care is also not without problems when outside help is needed, because many ethnic minorities would regard this as a sense of failure in the eyes of the community, and it may also be regarded as an invasion of privacy (Firth, 2001). Smaje and Field also point out the tensions which can arise when an elderly person needs and demands care from a female relative who may have quite different expectations, especially if the carer also has children born in the host country (Smaje and Field, 1997). However, it is important to bear in mind that expectations of care from family relatives may change in coming years as patterns of family life and social networks evolve through a process of acculturation.

Spiritual domains

The experience of advanced disease can have a profound effect on patients and their family and friends. Indeed, during their illness, many patients may raise questions that relate to their identity and self-worth as they seek to find the ultimate meaning in their life. Some patients attempt to answer these questions by examining their religious or spiritual beliefs. Formal religion is a means of expressing an underlying spirituality, but spiritual belief, concerned with the search for existential or the ultimate meaning in life, is a broader concept and may not always be expressed in a religious way.

Hope is an important spiritual resource that has been correlated with one's ability to adapt and cope with serious illness. Thus it is an essential assessment and intervention tool in palliative care. A comprehensive review of the multidisciplinary theoretical and empirical work on hope has produced the following definition: hope is a future-directed positive emotion or expectation constructed from biological, psychological, and social resources. This understanding of hope, however, is 'culture-bound,' reflecting a specific Western cognitive-temporal and affective-behavioural concept based largely on an expectancy-value psychological model. To date, there is a paucity of studies on hope across cultures and those that exist may be hampered by the use of measurement tools that reflect a specific Western bias. The most commonly reported tool, the Herth Hope Index, was developed in the United States and validated among American patients of European descent who were predominately Christian. This tool is based on a three-factor model that presumes hope is future/time oriented, influenced by expectations, and involves a sense of interconnectedness with self and other. As such, this definition may not capture the unique cultural aspects needed to accurately assess the spiritual needs of patients

who hold a different understanding of relationships and responsibilities (i.e. holding a collectivist vs individualist expectation of decision-making or other outcomes). The 'future-directedness' of hope may not translate across cultural groups that hold a different orientation toward time (time as cyclical or circular compared to linear). For example, Chinese folk wisdom or beliefs grounded in Confucianism may promote a stance of hope in the present as opposed to the future; or hope in the ancestral afterlife as opposed to this life. It has been suggested that concepts such as optimism or keeping faith, rather than hope, may be more culturally appropriate for people holding traditional Chinese values. Understanding the diverse multicultural norms around hope is especially salient among individuals and groups that favour non-disclosure of terminal or other bad prognostic information in order to preserve 'hope'. Identifying what hope means to these patients and families will allow providers to incorporate a culturally responsive model of hope and to identify appropriate strategies for its promotion among multicultural patient populations.

Conclusion

The palliative care movement has assumed a role in addressing the health and social care needs of patients and families facing the inevitability of death. It has only been recently that attention has focused on the importance of providing care for increasingly diverse societies, including in the United States, United Kingdom, Canada, Australia, and New Zealand among others. This has now become a demographic imperative. This chapter has shown that the language of understanding difference is complex yet fascinating. When considering its influence in the provision of care at the end of life and during bereavement, perhaps we should hold a double lens: one that applies a framework of equity to understand and serve population needs of specific communities; and another that never loses sight of the individuals and families before us—those with clinical, psychosocial, and spiritual needs and concerns that may not conform to preconceived or stereotyped patterns. Always, we should be mindful that an individualized approach to palliative care with a focus on quality is paramount for any patient, regardless of their ethnic or cultural background.

2.6

The economic challenges of palliative medicine

Thomas J. Smith and J. Brian Cassel

Introduction: the reasons to do palliative care

The compelling reasons for palliative care continue to be better symptom management, better advanced care planning and medically appropriate goal setting, and transitions to hospice care (Morrison and Meier 2004). Since the first edition of this book, over 80% of hospitals in the United States now have palliative care programmes (Center to Advance Palliative Care, 2014), the United Kingdom has strongly endorsed palliative care in the End of Life Care Strategy as a way to allow more patients to die at home with better quality of care (Department of Health, 2008), and the American Society of Clinical Oncology has endorsed concurrent palliative care for all seriously ill cancer outpatients (Smith et al., 2012a). Other new-found compelling reasons include better survival with hospice care, better survival with concurrent palliative care, and lower cost to hospitals and government and insurance funders. In every study to date, hospice and palliative care have been associated with equal or better survival and lower cost. A compilation of the available studies, in Fig. 2.6.1, shows that the group that receives palliative care has lower in-hospital or total costs.

In this chapter, we will define the various types of cost and clinical studies and discuss the available data about the economic challenges of palliative care, how to apply the available data, how to collect and present some useful and useable data, and new directions for research. We have summarized the key learning points in Box 2.6.1.

Why is cost important?

The United States is an example of uncontrolled health spending. Currently the United States spends 18% of the gross domestic product (GDP) on health care, which translates into $8000 per person per year; Canada and most other countries spend $4000–5000 per person per year and have equivalent health outcomes (Organisation for Economic Co-operation and Development, 2012). Insurance premiums for a family of four have risen from $6000 in 2000 to over $15,000 in 2011, with co-payments rising from $1000 to over $4000 (Claxton et al., 2010). There are over a million medical bankruptcies each year, with over half amongst insured people (Himmelstein et al., 2009). Almost one-quarter of Medicare spending (the single payer system for those over age 65) is in the last year of life and over 9% in the last month of life

(Riley and Lubitz, 2010). There is great variation in end-of-life care in the United States, such that over half of patients die in the ICU at some hospitals, and the use of hospice care varies from 20% to 40%, when it should be over 60% (The Dartmouth Institute for Health Policy and Clinical Practice, 2014).

Other countries have different issues. In the United Kingdom, and much of the world, the dramatic rise of deaths in the hospital has driven up health-care costs. Before the Second World War this rarely happened but at present 58% of people die in hospital, which has increased the need for beds, with attendant costs (Gardiner et al., 2013). The barriers to better palliative care are familiar: lack of discussions about palliative care, avoidance of discussions to maintain false hope, and lack of mechanisms for a smooth transition (Gott et al., 2011). Over half of all complaints about medical care in the United Kingdom relate to poor end-of-life care, which the National Health Service (NHS) is addressing with the End of Life Care Programme. In the Middle East and countries like Portugal there has been an even more rapid shift, with over half of all patients now dying in hospital within the past generation, which is simply unsustainable financially. In most cultures, when people are given a choice, they prefer to die at home. Despite the large percentage of deaths in UK hospitals, current UK data show an increase in deaths at home and decline in deaths in hospital, which suggests that such programmes can be successful (Gomes et al., 2012).

Types of cost studies and how they are used in decision-making

The traditional ways of balancing cost and health outcomes are reviewed briefly in Table 2.6.1. In decades past, clinical outcomes alone were sufficient. But with palliative drugs now costing over $100,000 a year it is critical that we ascertain if the benefit is affordable. Some examples include palliative sipuleucel-T for metastatic castrate-resistant prostate cancer (survival benefit 4 months, cost US$90,000), and palliative treprostinil (Remodulin®, US$120,000/year) and epoprostenol (Flolan® US$100,000/year) for pulmonary hypertension, with better exercise tolerance, but no clear cut improvement in overall survival (Macchia et al., 2011). It is clear that the problems of balancing cost and effectiveness will persist.

Clinical outcomes alone

When a drug is much better than any other treatment, for instance, imatinib mesylate (Gleevec®) in the treatment of chronic
Fig. 2.6.1 Representative studies that show reduced costs with palliative care. Key: IDPCT, interdisciplinary palliative care team; VCU IP, Virginia Commonwealth University Inpatient Unit; DC, discharges; Decedents, patients who died during that admission; OP, outpatients randomized to usual care versus usual care and interdisciplinary palliative care team; IP, inpatients randomized to usual care versus usual care plus and interdisciplinary palliative care team; Medicaid, Alive Medicaid-eligible patients discharged alive. The Gade and Brumley trials are randomized controlled trials.

Box 2.6.1 Key learning points about palliative care finances

The imperatives for palliative care include financial issues, but the main goal is better patient care.

The evidence for cost savings or cost avoidance in hospice is strong.

The evidence for cost savings and cost avoidance in acute palliative care is strong, particularly in integrated health systems such as a national health insurance or health maintenance organization.

The economic outcomes of palliative care programmes are not limited to cost-avoidance and include cost savings, best use of scarce resources such as the intensive care unit (ICU), good will, and profit.

Data that illustrate good care and positive financial impact on the institution are relatively simple to collect.

---

myelogenous leukaemia or gastrointestinal stromal tumour, medical care decisions are clear-cut. It is a lifesaving drug but the cost ranges from $32,000 to $98,000 per year depending on dose. With such blockbuster drugs, the only real issue is how to make room in the budget; another issue is that patients who bear some or all of the financial cost will stop taking expensive drugs in an economic downturn (Kelley and Venook, 2010). The second and third drugs on the market for the same indication were priced even higher and to date there has been no price competition (Tuma, 2007), so alternative strategies on cost control will continue to be needed. The NHS in England is trying several, including 2 free months of the drug (paid for by the manufacturer), and the NHS only pays if the drug is successful (Rawlins et al., 2010; Yong et al., 2010).

Cost alone

Very few, if any, new drugs cost less than the treatment they replace. Knowing that a drug or treatment is inexpensive does not help decision-makers without some indication that a treatment actually works. For example, a widely used anti-nausea remedy lorazepam (Ativan®), diphenhydramine (Benadryl®) and haloperidol gel ('ABH gel') costs pennies for each dose, but is not absorbed, so cannot be effective (Smith et al., 2012b).

Cost minimization

Cost minimization combines clinical results with cost. Two equally effective strategies are compared, and the one that has

Table 2.6.1 Types of studies and application to palliative care

Type of study	Advantages and disadvantages	Application to palliative care
Clinical outcomes alone	Easy to perform Ignores costs	Traditional way to make decisions, e.g. imatinib mesylate (Gleevec®) works for chronic myelogenous leukaemia. Find a way to pay for it
Cost alone	Ignores clinical outcomes	Rarely used to make decisions, unless the medical outcomes are similar (cost minimization, below)
Costs and clinical outcomes together		
Cost minimization: assumes two strategies are equal; lowest cost strategy is preferred	Easy to do if there are direct comparisons	For instance, if methadone gives equivalent pain relief to sustained-release morphine, then use the less expensive option
Cost-effectiveness: compares two strategies; assigns $ per additional year of life (LY) saved by strategy	Requires a trial that directly compares strategies, and economic analysis alongside that trial. 'Only accept treatments that gain a year of life for under $100,000/LY	Palliative care usually adds no additional LYs, so rarely applicable. May be most appropriate in chemotherapy or other interventions that prolong life
Cost utility: assigns $ per additional LY saved by strategy, then estimates the quality of that benefit in $/quality-adjusted life year (QALY).	Compares two strategies, with their quality of life comparisons converted to utility, or the value placed on time in a health state, e.g. time spent on chemotherapy = 0.7 compared to a healthy individual whose utility = 1.0	There are few interventions that make a large difference in utility Also, there is rarely one simple yardstick of utility that covers all health states.
Cost–benefit: compares two strategies but converts the clinical benefit to money, e.g. a year of life is worth $100 000	Possible but rarely done due to difficulty in assigning $ value to human life	Would almost certainly be unfavourable to most palliative interventions, as patients rarely work or generate income
Special considerations		
Cost avoidance: measure the costs saved by not doing procedures, or by moving from an expensive place of care to a less expensive place	Can be easy to calculate (moving from ICU bed to regular or hospice bed) or difficult (avoided CAT scans, for which there is no financial record)	Hospital-based programmes routinely show cost savings to the health system. Important to know who is avoiding the cost and who may be absorbing the cost. For instance, if palliative care transfers sick patients to hospice, it will save the hospital money but cost the hospice money if the daily costs are above the per diem given to the hospice organization, typically US$150 per day (Passik et al., 2004)
Opportunity cost: the cost of performing one action rather than another. For instance, the opportunity cost of a patient staying in the ICU when appropriate for palliative care end of life is the high cost of that day plus the lost revenue of the ICU day plus the lost opportunity if a potential patient did not get appropriate trauma or ICU care	Harder to calculate	Familiar concept to most CEOs. They may quickly realize that gaining 200 ICU bed days a year by transferring appropriate patients 1 day sooner would generate $1100/day × 200 days, and prevent the hospital from being on Emergency Room diversion.

the least total cost is preferred. An example is drugs which are designed simply to replace expensive drugs with equivalent ones. In palliative care, Bruera and colleagues showed that methadone was equal to sustained-release morphine in the relief of pain (Bruera et al., 2004); the choice should depend on which is less expensive. This approach is not without flaws. First, it requires that there be a direct comparison of the drugs or technologies. Second, it may put too much emphasis on immediate treatments costs alone, and not enough on long-term costs; for instance, if ABH gel is less expensive than other more effective anti-nausea drugs, one hospitalization for refractory nausea would outweigh hundreds of pounds of savings on the cheaper but less effective remedy (Smith et al., 2012b).

Palliative and supportive care, including home and inpatient hospice care, is a good example of cost minimization. If we assume that survival is equal and the care is at least as good and costs are lower, then we should choose hospice and palliative care. Palliative care consultation improves appropriate hospice enrolment. Morrison et al. compared 1427 patients who did not have a palliative care consult with 296 patients who did, matched in every other respect, and found that if the palliative care team were involved, 30% of hospice eligible patients were discharged to hospice compared with just 1% of patients not seen by palliative care (Morrison et al., 2011). Patients enrolled in palliative care programmes at Sutter Health enrolled in hospice 47% of the time, compared to 20% of similar patients (Meyers et al., 2004,

2011). Appropriate transition to hospice not only improves care (Peppercorn et al., 2011), but is also associated with longer survival (Connor et al., 2007) and lower costs (Pyenson et al., 2004). The most recent data show that hospice saves US Medicare about US$2309 in the last year of life compared to conventional care, and that the savings increase the longer hospice is used (Taylor et al., 2007).

Cost-effectiveness

This method compares two known strategies in both effectiveness (years of additional life gained) and cost, then assigns a cost per additional year of life (LY) saved by the best ('dominant') strategy. For instance, adjuvant chemotherapy for a 45-year-old woman with early-stage breast cancer would be expensive, but would add 5.1 months of additional life at a cost of about $15,000 per year (Hillner and Smith, 2007). Expensive therapies can be 'cost-effective' too if they provide substantial benefit. For instance, trastuzumab (Herceptin®) for adjuvant treatment of breast cancer patients is expensive (over $50,000 in all countries) but the 50% relative reduction in recurrence risk and 1.5 additional years for the average patient makes the cost-effectiveness ratio of $14,000 to $40,000/LY acceptable (Kievit et al., 2005).

There are several assumptions about this method that make it difficult to apply in the real world. First, it implies a limit to resources such that there must be some 'cap' on the cost-effectiveness ratio. The World Health Organization has defined 'reasonable' cost-effectiveness as interventions with a cost-effectiveness ratio that is less than the per capita GDP (Lillemoe et al., 1993; World Health Organization, 2001). Second, it assumes that a single week of added life for 52 persons equals 1 full year of life for another person. Third, it assumes that all people are somehow in the same health system and share a single set of values. Fourth, it requires someone to fund these difficult studies to generate cost-effectiveness data, when many patients are only interested in cure, doctors have a strong interest in benefit, and drug companies are interested in profit, and not usually social justice. Currently, the United Kingdom, Australia, Canada, and most countries use explicit cost-effectiveness to determine insurance coverage, but the United States does not.

Another issue is the question of 'whose costs' are being saved. In the United States and other countries with large hospital infrastructures and large third-party funder markets (e.g. Germany), one must keep in mind that money is changing hands several times. One can reduce hospital costs in ways that do not affect the amount paid to the hospital by the funders. In instances where funders do cut costs, typically this means lower revenue to providers (hospitals and doctors).

Palliative care brings an additional challenge in that very few palliative treatments make people live longer so that additional LYs are not saved. Nearly all the available studies show equal survival, with only one showing improved survival of 2.7 months with concurrent oncology and palliative care (Temel et al., 2010), with about $2000 less overall cost (Greer et al., 2012).

Cost utility adds adjustments for quality of life

In cost-utility analysis the quality of life in a given state of disease or treatment ('health state'), is converted to a utility ratio where 1 equals perfect health and 0 equals death. For example, a patient whose pain has been relieved may have a utility range of 0.90 of 1.00, whereas a patient with continued pain may have a utility range of 0.50. The utility ratio converts 'cost-effectiveness' into cost per quality-adjusted life year (QALY). For example, an intervention that costs $100,000 per year of life gained would be converted to $50,000 per QALY if the treatment doubled the patient's utility score from 0.5 to 1.0. This intervention, however welcomed, would not save money but would cost an additional $50,000 to save an additional QALY with the intervention.

There are several difficulties with the cost-utility method. One is assigning proper utility ratios to the various health states. Controversy exists as to the most appropriate source of values: patients, healthcare workers, or the general population (society) due to differences in perspective. Patients and clinicians place greater emphasis on the issues that matter most to them, such as life, morbidity, or expense. For example, patients are more likely than clinicians to accept toxic treatments in exchange for minor clinical benefits, and a 1% chance of cure or 10% chance of symptom relief may be sufficient for them to choose treatment over supportive care (reviewed by Russell et al., 1996). The most objective source is probably lay people (jurors) whose money is being used (Russell et al., 1996; Smith et al., 2005); the difficulty lies in educating them properly in all aspects of a patient's experience, for example, emotional turmoil, treatment toxicity, inconvenience, and other physical and psychosocial stressors.

A second problem is the magnitude of palliative care interventions, which is usually not enough to change overall ('global') quality of life or utility values. A recent exception was the randomized trial of palliative care alongside usual oncology care versus usual oncology care alone which showed a substantial difference in global quality of life (Zimmerman et al., 2012). Whether the magnitude is enough to change utility scores has not been studied.

Several recent cost-effectiveness or cost-utility studies have produced results that will be of use to decision-makers. Single-fraction radiation for painful bone metastases instead of the usual six treatments was as effective and cost substantially less (van den Hout et al., 2006). Shorter-fraction regimens for palliative treatment of lung cancer, 2×8 Gy versus 3×10 Gy, showed the opposite effect; the cost-utility ratio for the 10×3 Gy schedule versus the 2×8 Gy schedule was acceptable at $40,900/QALY. The longer regimen had an acceptable cost-effectiveness ratio because people lived longer with the 10×3 Gy treatment, offsetting the higher treatment cost (Mason et al., 2011). In countries with nationalized healthcare systems, the QALY is more important and more frequently used (e.g. in the United Kingdom with its NHS) than in other countries such as the United States where there is neither a single, nationalized healthcare system providing care, nor a single, nationalized payer.

Cost–benefit

This method compares two interventions then assigns a monetary value to the added clinical benefit of the best strategy, based on the overall economic productivity of an individual. Therefore, a treatment that costs $50,000 to prolong life 1 year would be acceptable if the person could produce $50,000 of economic worth in that year, but not if the person only produced $10,000 that year. This kind of analysis, while useful in business decisions, is rarely used in clinical studies because of the difficulties in assigning a monetary value to a human life, especially if that value is tied to an individual's socioeconomic status. Since

palliative care patients rarely produce income, even if their symptoms are well controlled, palliative care interventions would be at a distinct disadvantage.

Cost avoidance

This concept has been widely used as an economic argument for palliative care. If a patient can be moved from a US$5000/day ICU bed to a US$1500/day palliative care bed, with equal or better care that meets the patient's goals, *a US$3500 cost will have been avoided each day for each patient.* Taken in aggregate, these costs can be substantial and more than offset palliative care programme costs. For instance, palliative care programmes have reported only a small profit, but annual savings of over US$1 million due to 'cost avoidance' defined as costs saved by transferring a patient from a high-cost venue to a low-cost one, such as from ICU to a regular hospital bed (Brumley et al., 2007; Gade et al., 2008; Smith and Cassel, 2009; Morrison et al., 2011). Similarly, not doing 50 computed tomography (CT) scans each year by careful matching of the goals of care with the diagnostic tests could save up to US$2500 × 50 = US$125,000. In a cost-based system such as national health insurance or diagnosis-related group (DRG) payment system, this would be a desired outcome; however, in a profit-based system this could represent substantial lost profit.

Cost avoidance is relatively easy to measure from usual data bases in US hospitals if there are comparable patients to match before the intervention, because billing systems record what was actually done. A simple historical analysis would show that more patients receive comfort care once a palliative care (PC) programme is established than under standard care. However it is much more difficult to quantify patient-level (or day-level) hospital cost savings in other countries, such as England, where fewer hospitals have invested in systems to do patient-level (or episode-level) cost accounting and cost allocation. In such countries or scenarios, the simplest way to collect data about cost savings is a notebook of 'avoided tests' after palliative care consult, for example, for the first 50 PC consult patients, 50 planned CTs or similar procedures were cancelled. Or to use hospital data on the frequency, duration, and intensity of hospitalizations per patient, comparing PC and non-PC patients.

Large insurers have noted the benefits of enhanced palliative care. In a series of landmark observational trials, researchers at Aetna introduced an expanded access 'Compassionate Care Programme'. They identified cancer patients being treated for terminal conditions through their billing patterns, offered expanded access hospice without having to give up conventional treatment, and offered 24-hour daily help with symptoms by a nurse call-in line. Patients were also assigned a care manager. Hospice use doubled, hospice days doubled, hospital and ICU admissions were dramatically reduced (Spettell et al., 2009), and costs were reduced 22% in the last 40 days of life (Krakauer et al., 2011). Whether the change in resources and costs is due to the PC consult by itself, or the underlying reasons for the PC consult (change in medical goals, change in family or patient perspective, change in physician perspective) cannot be answered from the available data. Since these studies have now been replicated in numerous settings, it seems unlikely that the reduction in resources and costs is unrelated to PC consultation; but, one cannot ascribe all the change to the consultation itself. In the case of PC, the retrospective correlational studies correlate well with the available randomized clinical trials that show equal survival with substantial cost savings (Smith and Cassel, 2009).

Additional considerations

There are a few important other considerations in the economics of PC. The first is *perspective*: whose money is being spent, on whom? In general, health economists take the societal viewpoint; that is, society has limited resources and wants to spend it to gain the most health for the most people. This runs directly counter to the individual viewpoint that only one person's health—'mine'—matters. The societal impact would also take into account work and time lost, and all the additional costs of care that are absorbed by families. Since studies often cannot take all these into account, a common compromise is to take the view of a health system or funder, for example, the NHS in the United Kingdom or Canada or a large insurer in the United States. As an example, a palliative care programme that accepts patients from the hospital will lower the hospital costs; if however, that palliative care programme transfers these patients to hospice, and the patients continue to use more care (IVs, pain medicines, diagnostic tests) then hospice costs increase even though the total costs decrease (Passik et al., 2004). Palliative care programmes for inpatients have consistently shown cost savings of 25–60% (Smith et al., 2003; Naik, 2004; Morrison et al., 2008, 2011).

A second concern is *opportunity cost*, simply defined as the additional revenue that could be gained if money had been used in a different way (this will only be relevant in health systems where third-party revenue is at stake). For instance, an ICU bed that is filled by someone who is not getting better may force the hospital into diversion. In a natural experiment, Oregon Health Center found that every hour of Emergency Room diversion cost the hospital system over $1100 *per hour* in profit, the opportunity cost of diversion. Transferring patients from the ICU to a more appropriate venue may give cost avoidance of $2500/day, *and* open that bed for an additional patient (McConnell et al., 2006). The opportunity cost of filled ICU beds is a sound financial concept that is understandable to most chief executives; if a palliative care programme assists in the transfer of 200 patients 2 days earlier, then the medical staff will have 400 more ICU bed days available.

A third concern is *mortality* in the hospital. If a hospital has a robust palliative care programme, will patients come there, die, and worsen the hospital mortality statistics? The two reports available strongly suggest that mortality is not increased in programmes that have the best palliative care systems (Elsayem et al., 2004; Cassel et al., 2010a).

A fourth issue is who funds palliative care specialists. In the United States, the Veterans Administration healthcare system and the Kaiser Permanente system, both of which have annual healthcare expenditure budgets and do not rely primarily on revenue from third parties, have invested millions of dollars in funding specialists, teams and palliative care units. In other US hospitals, a mixture of direct clinical revenue for specialists and a subsidy from the hospital together fund the teams (see Morrison et al., 2008). In terms of hospice provision, the US Medicare Hospice Benefit provides a reliable funding stream for patients in hospice and hospice touches over 40% of deaths in the United States (National Hospice and Palliative Care Organization, 2013). Other countries have struggled to provide an adequate funding stream

for hospice—for example, in the United Kingdom, a large portion of hospice expenses are paid for through charity, and hospice touches far fewer of the deaths.

The available clinical and economic data

We have organized the available randomized clinical trial data into one table of important clinical effectiveness and cost data (Table 2.6.2). No trial has shown worse care or an increase in costs, or any sort of harm to patients.

Clinical effectiveness

The effectiveness data for palliative care is now sufficient for the American Society of Clinical Oncology to recommend concurrent palliative care alongside usual oncology care for all seriously cancer patients (Smith et al., 2012a). The most recent randomized clinical trial from Canada confirms and extends these findings (Zimmerman et al., 2012). The only negative randomized clinical trials used a model of consultant care outside the usual care team, such that only about 20% of recommendations were followed

Table 2.6.2 Randomized trials of palliative care

Author, year, intervention type	Outcomes					
	Symptoms	Quality of life	Mood	Satisfaction	Resource use	Survival
Pantilat et al., 2010 Study performed 2002–2003 Consultant MD model[a]	No difference	Not measured	Depression not reported, anxiety no difference	Not measured	Not measured	Not measured
Rabow et al., 2004 Consultant MD model	Less dyspnoea, P = 0.01, no change in pain	No difference	Less anxiety (P = 0.05), no change in depression (P = 0.28)	No difference	No difference	Not measured
Brumley et al., 2007 Interdisciplinary palliative care team (IPCT)	Not measured	Not measured	Not measured	Improved, P <0.05	Cost $12,670 vs $20,222, P = 0.03 Hospital days reduced by 4.36 (P <0.001)	No difference
Gade et al., 2008 IPCT	No difference	No difference	No difference	IPCS patients reported greater satisfaction with their care experience (P = 0.04) and providers' communication (P = 0.0004)	Total mean health costs $6766 lower (IPCS: $14,486; UC: $21,252, P <0.001). Net cost savings of $4855 (staffing costs) per patient (P <0.001).	No difference
Bakitas et al., 2009 Nursing education intervention	Improved P = 0.06	Improved P = 0.02	Improved P = 0.02	Not measured	No difference	No difference
Temel et al., 2010 IPCT	Improved P = 0.04	Improved P = 0.03	Less depression P = 0.01	Not measured	Less aggressive care P = 0.05 Costs about $2200 less per patient with PC	11.6 vs 8.9 months P = 0.02
Meyers et al., 2011 Three education sessions in the first month to learn problem-solving skills	Not measured	Patients: no difference. Caregivers: declined at less than half the rate of control, P = 0.02	No difference	Not measured	Not measured	Not measured
Zimmerman et al., 2012 Cluster randomized trial of palliative care alongside usual oncology care	Improved	Improved	Improved	Not reported	Not yet reported	Equal

[a] The model was a consultant physician who was not a member of the team and made recommendations which were not followed the majority of the time. The primary care provider followed recommendations for opioid prescription in 8% of cases, and antidepressant prescription only 17% of cases. This may partly explain the lack of effect

AD, advance directive; ED, emergency department; IPCS, interdisciplinary palliative care service; IPCT, Interdisciplinary palliative care team; OR, odds ratio; PC, palliative care; UC, usual care.

(Pantilat et al., 2010); we would not reject a trial of a new drug if compliance were only 20%.

The impact of hospice and palliative care on cost of care

Hospice was designed to improve care, not save money, but a good side effect has been cost control. The original Medicare hospice benefit was developed with the intent to improve care, not save money, but was required to be 'revenue neutral' (or, not cost Medicare any additional money). As noted above, hospice care saves money compared to usual care at the end of life, and the longer hospice is used, the more money is saved (Taylor et al., 007).

The available studies of palliative care strongly suggested substantial cost savings as shown in Fig. 2.6.1. Originally, Smith et al. reported over 60% hospital cost savings when patients died under the care of the palliative care team, matched to other patients who died in the hospital (Smith et al., 2003; Naik, 2004). The same group subsequently reported substantial reductions in all symptoms measured, if present, within 48 hours suggesting that the care was equal or better than usual care (Khatcheressian et al., 2005). Elsayem and colleagues at M.D. Anderson Cancer Center reported good symptom control accompanied by a dramatic decrease in costs (Elsayem et al., 2004). More recently, Morrison and colleagues showed that in New York State, hospitals with palliative care programmes increased appropriate referrals to hospice by tenfold, and saved over $5000 per admission (Naik, 2004; Morrison et al., 2008).

There are now several randomized trials that show substantial improvements in care associated with equal or reduced costs, as shown in Table 2.6.3. The data from the two randomized trials

Table 2.6.3 Practical palliative care measures and how to collect them

Measure	Data source	Units	Comment
Clinical			
Pain scores	Symptom assessment scale	Visual or linear scale in common use	Use what is in common use at the institution, so that PC scores can be compared to other unit scores.
Other symptom scores, e.g. fatigue, dyspnoea	Symptom assessment scale	Edmonton, Memorial or similar symptom assessment scale	Most other units will not collect data, so PC can accelerate change by showing benefit
Patient and family satisfaction	Survey instruments		Most commercial patient satisfaction firms do not survey decedent families
Stories of patient and family satisfaction	Collected thank you notes and letters		Stories are really important to catch someone's attention. Insert in text boxes in all newsletters. Copy and send to CEO monthly
Economic and other			
Profit margin	Health system financials	Amount contributed to the health system	Most PC programmes will not generate profit, but it is important to be 'cost neutral' to the health system. If the loss is small, it can be made up by contributions
Cost avoidance	$/day saved by transfer to PC team or unit, with resources matched to goals of care	Amount saved for the health system	Each day of transfer from a high-cost to low-cost venue may save $1500 or more. In addition, it will free up the high-cost ICU beds or ED space.
Referrals	By month and year	New patients to the service New patients referred specifically to PC Recurring patients	Documents the amount of work done in understandable terms May document new patients brought to system by PC (new business)
Length of stay	Inpatient LOS for those patients seen by PC team	Days	There may not be much difference. It is important to show that LOS is not increased by PC compared to usual care, in most health-care systems
ICU transfers	All transfers, and LOS before/after	Measure all transfers from ICU after PC consultation	This frees valuable ICU time
Direct ED admissions	All consultations and direct admissions	Measure the LOS, costs of ED consults and admissions	May show a shorter LOS and lower cost than similar patients who are admitted to general service then later to PC
Research grants and funds	Report all submissions and successful requests	All, including $ requested and received	This is a common measure of success for many programmes housed in academic programmes
Scholarly works		Papers, abstracts, presentations	This is the most understandable measure of academic success
Charitable contributions			This may offset losses. Most PC programmes work well with their institutional development officers for fund raising

ED, emergency department; ICU, intensive care unit; LOS, length of stay; PC, palliative care.

Table 2.6.4 Model presentation for palliative care

Clinical	Economic
All symptoms improved from day 1 to day 3 Pain, Nausea, Depression, Anxious, Dyspnoea, Drowsiness, Appetite, Fatigue	1. 1800 consultations done hospital-wide fiscal year 2012 2. 350 outpatient new consultations and 1000 repeat visits 3. 5.2 of 6 palliative care beds filled daily 4. Profit overall $20,000 5. Profit on direct admissions from ER, clinic, hospice $250,000; losses on transfer cases $230,000 6. Cost avoidance $900,000 7. Professional income of $150,000, covering 60% of salaries 8. Additional ICU capacity of 250 bed days 9. Charitable contributions $250,000 10. Grant funding $400,000 11. 5 papers; 3 abstracts; 6 regional/national presentations 12. Two awards for exemplary service

done within the Kaiser Permanente health maintenance organization were so compelling, with better care and $4500–7000 savings per person, that this is now standard care at all their hospitals (Brumley et al., 2007; Gade et al., 2008). The study of non-small cell lung cancer patients randomized at presentation to usual oncology care versus usual oncology care plus concurrent care demonstrated substantially improved quality of life, quality of care, better survival (Temel et al.,2010), and a cost saving of over $2000 per person (Greer et al., 2012). Patients with multiple sclerosis who received palliative care, cost the UK NHS £1200 less than their peers who did not receive it, even incorporating the cost of the care (Higginson et al., 2009) and had better clinical outcomes during and after the trial for up to 6 weeks (Currow et al., 2011).

How to collect and present useable data

A key question before collecting data is to decide beforehand on its use. Is the interested party interested in passing accreditation, improving market share, improving patient satisfaction, reducing health system costs, or increasing profits? The goal will dictate what data to collect and how to present it. In collecting and presenting the data, we have found that the simplest approach is the most effective. Most administrators want to know that the programme is successful, defined as providing good care, keeping busy, and not losing too much money.

We advise programmes to collect useful data that are being requested, and no more. Some common metrics are listed in Table 2.6.3. To collect more data than is actually used, takes time, effort, and money that would be better spent doing clinical care or research.

Presentation of the data should be as simple as possible. We have found that a simple 'improved care at no extra cost' approach is well received, as shown in Table 2.6.4. Again, most administrators will not be expecting palliative care to make a large profit. The goal of this report is fairly and accurately to reflect the activity and impact of the programme.

New directions

Palliative care is now well established as a necessary part of modern clinical care that can improve quality of life and quality of care and can save money. Additional research is needed to confirm results in different diseases, especially non-cancer (Farquhar et al., 2011; Higginson et al., 2011). As a field, we must determine a simple, easy to understand metric of the net benefits and burdens of palliative care in order for funders to justify new and continuing investments (Currow et al., 2011).

Resources

Palliative Care Leadership Center Curriculum (PCLC)—Center to Advance Palliative Care. The PCLC curriculum addresses issues relevant to each stage of palliative care programme development: structural, organizational, and financial. See 'Module 3: Making the Financial Case', available at <http://www.capc.org/palliative-care-leadership-initiative/curriculum>. This curriculum shows a programme how to build a financial case for palliative care, alongside the clinical case. There are core, custom, and advanced modules available.

Inter-Institutional Collaborating Network On End Of Life Care (IICN) website: 'free access to over 4,000 pages of high-quality education materials about end-of-life care, palliative medicine, and hospice care, including the full text of several books'. This includes a very helpful guide to starting PC programmes: TriCentral Palliative Care Programme Toolkit, available at <http://www.growthhouse.org/palliative/>.

Service delivery issues in palliative care

3.1

Barriers to the delivery of palliative care

Barry J.A. Laird

Introduction to barriers to the delivery of palliative care

There are several key barriers to the delivery of palliative care (Lynch et al., 2010). Probably one of the first aspects to be considered a barrier is the definition of 'palliative care'. The World Health Organization (WHO) defines palliative care as:

an approach that improves the quality of life of patients and their families facing the problem associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual. Palliative care:

- ◆ provides relief from pain and other distressing symptoms
- ◆ affirms life and regards dying as a normal process
- ◆ intends neither to hasten or postpone death
- ◆ integrates the psychological and spiritual aspects of patient care
- ◆ offers a support system to help patients live as actively as possible until death
- ◆ offers a support system to help the family cope during the patient's illness and in their own bereavement
- ◆ uses a team approach to address the needs of patients and their families, including bereavement counselling, if indicated
- ◆ will enhance quality of life, and may also positively influence the course of illness
- ◆ is applicable early in the course of illness, in conjunction with other therapies that are intended to prolong life, such as chemotherapy or radiation therapy, and includes those investigations needed to better understand and manage distressing clinical complications. (WHO, 2014)

However, what health professionals and patients consider palliative care may differ both between these groups and/or within them. Some may still regard palliative care as end-of-life care only or associated with cancer. The ideology of palliative care being a concept with which to approach management of patients may still not be fully understood. Furthermore, the differences between generalist and specialist palliative care may also contribute to confusion.

Irrespective of semantics, currently palliative care reaches only a small fraction of those who could benefit from it. Of particular concern is that this situation is likely to become worse.

According to the WHO, in 2008, 7.6 million people died of cancer (approximately 13% of all deaths). Of these, approximately 70% occurred in low- or middle-income countries where palliative care services may be less available. Although survival rates for cancer continue to improve in several key tumour groups, cancer-specific mortality as a proportion of deaths is expected to increase, largely due to a shift from communicable diseases to non-communicable diseases over the next 25 years (Mathers and Loncar, 2006). As a result, death from cancer is going to affect more people and palliative care has to be able to meet the increased demand.

Although palliative care as a concept has largely been embraced throughout the world, its implementation into routine clinical care is lacking. There are many reasons for this but fundamental to improving palliative care access for everyone, is the argument that palliative care should be considered as a human right.

One of the main justifications for this approach is that if palliative care were designated a human right, this would provide the necessary, non-negotiable, impetus for global health policymakers to implement palliative care (Gwyther et al., 2009). Furthermore, it would mean that the obligations for meeting human rights in general, would be adopted for palliative care. This would have several key implications: existing palliative care services which lack the foundation of a secure funding source would have greater bargaining power to obtain robust funding while countries with limited or no services would be encouraged to address this.

The WHO is the key group necessary to develop palliative care worldwide. Strategies developed by the WHO and mirrored by the European Association of Palliative Care (EAPC), the International Association of Hospice and Palliative Care (IAHPC), and the Worldwide Palliative Care Alliance (WPCA) aim to help countries advance palliative care services (Gwyther et al., 2009). Areas of focus include:

- ◆ improving drug availability
- ◆ education
- ◆ policy development
- ◆ quality of care
- ◆ research.

Essential to the change from palliative care being a principle available to the few, to being available to all, and a human right, is the need to address the many barriers to the efficient and effective delivery of high-quality palliative care. These vary with factors such as geographical setting, economic resources, and the availability of education and training. In this chapter, an overview of

these issues is provided, beginning with a global perspective, progressing through social, and organizational, issues, to professional and individual barriers.

Global and economic barriers

Global barriers

The International Observatory on End of Life Care has been monitoring global palliative care development since 2003. Although not wholly exhaustive, a picture of palliative care development on a worldwide scale is slowly emerging. In 2008, Wright and colleagues presented a map of global palliative care development with the aim of categorizing the extent of palliative care services (Wright et al., 2008). From this, it was identified that approximately 50% of the world's countries had a palliative care service; however, only 15% of countries had an integrated palliative care service. This begs the question, what barriers exist globally to prevent palliative care being more widely available?

Advancing palliative care as basic human right may help to improve palliative care access. The role of international palliative care organizations is key to breaking barriers. These include the Asia Pacific Hospice Palliative Care Network, the African Palliative Care Association, the EAPC, the IAHPC, the National Hospice and Palliative Care Organization (United States), and Help the Hospices (United Kingdom). Efforts have also been cemented by the advent of the World Hospice and Palliative Care Day, in 2005.

Building on these strong foundations is the WPCA. Established in 2004, the WPCA is a coalition of key national groups whose aim is the advancement of palliative care towards the ultimate goal of universal access to affordable, high-quality palliative care (Praill and Pahl, 2007). It has been recognized that there is disparity between services nationally and internationally. Furthermore, services are often poorly resourced and of insufficient numbers to meet the increasing needs placed upon them. The WPCA's role is advisory with the remit of developing a better understanding of palliative care policy and disseminating good practice.

Only with greater information about palliative care services, dissemination of good practice, and assistance with policy development can key global barriers to palliative care be broken down.

Economic barriers

Basic health care is becoming less accessible to many (Hsiao and Liu, 1996). This is due to rising drug and health-care costs, in addition to an increased global demand on health-care services; particularly due to the aging population and longer life expectancy.

Palliative care is not immune to these economic constraints; however, one advantage palliative care has compared to other areas of medicine is that the basic drugs needed for symptom control are relatively inexpensive. It has also been shown that pain-relieving medication costs a greater proportion of monthly household income in the developing countries than is the case in the developed world (De Lima et al., 2004). The main economic barrier is resourcing palliative care providers. The intensive medical and nursing support that typifies palliative care is resource heavy.

As non-communicable diseases take precedence, associated with chronicity, there is a marked burden on the health-care system. Developing palliative care services on top of an already burdened health-care system is challenging. Of interest is that

in some countries government expenditure on health care has an inverse relationship with wealth. This means that developing countries which have a high demand for palliative care services also have a high demand for basic health care.

Although better, palliative care services in developed countries are not perfect. For example, in the United States, in the Medicare programme, to qualify for referral to palliative care a patient requires certification of terminal illness, usually only permissible near the end of life; in the United Kingdom, which is a world leader in palliative care, the speciality relies heavily on charitable funding, with full National Health Service integration and financial support not established.

In some countries, an inherent lack of health funding means that key priorities (clean drinking water, vaccination against communicable disease, and so on) are addressed while 'less important' areas such as palliative care are neglected. This is also compounded by unstable governments within countries—frequent changes in ruling parties means that varying health policies are adopted (Lynch et al., 2009).

There is also a variation in the types of palliative care funding that are supported. More cost-efficient areas such as hospice, hospital, or general palliative care can be favoured over more expensive options, such as home care. Health-care provision has also to compete against other areas of social demand. For example, in some countries unemployment, poverty, and war mean that palliative care per se is of low priority. The main focus is on caring for patients in the dying phase, with other areas of palliative care being neglected.

Clearly, areas such as palliative care and health-care provision for chronic and incurable disease are low priorities for some developing countries. Nevertheless there are beacons of palliative care excellence in some developing countries. In Uganda and in Kerala (South India) there is excellent palliative care service provision despite low socioeconomic status (Jagwe and Barnard, 2002). It is grounds for optimism that such networks are possible in the developing world and that they are able to provide models for other countries.

Drug availability

Although palliative care patients can require the use of many drugs, fundamental to the armamentarium are opioids. There can be limitations through government policy restrictions on opioid use and rigid prescribing regulations. There is also a disparity in the cost of opioids between countries which can also result in widespread variation in opioid use. This is all compounded by stigmatization; that use of opioids is still associated in some countries with addiction, side effects, and the end of life.

Inadequate access to opioids and other essential symptom control medication is still one of the primary barriers to global palliative care development. Pain is the most common symptom in cancer patients and the publication of the WHO analgesic ladder for cancer pain relief in 1986 aimed to provide an easily followed and globally applicable algorithm for pain (Azevedo Sao Leao Ferreira et al., 2006). While the majority of cancer pains can be controlled using this ladder, a key barrier is the limited availability of opioids. In terms of medication, morphine is relatively inexpensive but it is still not available to millions who need it.

Reluctance to prescribe opioids by health-care professionals is another factor which has limited their use in palliative care.

To combat all areas aspects affecting drug availability, the WHO has highlighted key points for development: education, government policy, drug availability, and the implementation of palliative care services throughout society (Stjernsward et al., 2007). Clearly further work is need to improve popular, professional, and government understanding about opioids, while education is needed to impart the principles of palliative care prescribing and opioid use to health-care professionals.

Social barriers

Ethnicity

One of the key challenges in a multicultural society, particularly in the Western world, is the integration of palliative care appropriately into groups with different cultural backgrounds. It is known that uptake of palliative care services by patients in minority ethnic groups is less than those patients who make up the majority of the population (Ward et al., 2004). Nevertheless, it is important that palliative care reaches out to these groups as they have the same (and sometimes greater need) for palliative care than majority groups. For example, in people with different religious backgrounds, most palliative care services will struggle to deliver appropriate care (Francoeur et al., 2007). There may be several reasons for this which need to be addressed including limitations on resources, institutional, and sometimes personal, racial, or religious discrimination. There may also be limited awareness among health professionals of cultural or religious issues which could impact on the patient's attitude to palliative care. There may also be limited awareness among patients as to the role of hospices and challenges in discussing death with these groups. Recent migrants, those with language or other communication difficulties, and no family advocate present particular challenges (Worth et al., 2009).

Elderly

The number of people dying in care homes in the developed world is steadily increasing so it is important that this group receive appropriate palliative care. However, residential care, particularly in the elderly, has been described as the last frontier for palliative care (Phillips et al., 2006). Palliative care is strongly advocated, however patients who are in long-term care homes do not always receive good end-of-life care, and indeed it is challenging to provide this. A systematic review suggested there were three main causes: delivery system barriers intrinsic to long-term care settings, barriers related to financial issues, and barriers due to regulatory factors (Huskamp et al., 2012).

One of the ways that palliative care can be improved is to develop the role of a link nurse, a trained nurse with specific palliative care skills, including a role in education. Nevertheless, barriers do exist to the efficient use of link nurses such as lack of management support, frequent changes in the workforce, and lack of adequate preparation (Hasson et al., 2008).

The elderly are also more likely to die in hospital settings in general, so ensuring there is appropriate palliative care access is key. The main challenges to providing this include attitudinal differences in the elderly, a lack of resources, and lack of clarity as to which health-care professionals may be most appropriate to provide care for them (specialist versus general palliative care providers, i.e. care of the elderly physicians) (Gardiner et al., 2011).

Homeless

This group of patients can be a particular challenge in palliative medicine and as the number of homeless people is increasing, this is an area where palliative care needs to be accessible. There are, however, barriers which can prevent the appropriate delivery of palliative care to this group of patients. Homeless people have more physical problems (chronic health problems and increased physical and sexual abuse) which are often compounded by lack of access to health services (Rousseau, 1998). The problem of illicit drug use, which tends to be more common among this group of patients, presents some specific challenges in accessing palliative care. These have been identified as concerns from patients such as how withdrawal from drugs will be managed, and a lack of trust in health-care providers (and vice versa), as well as concerns about prejudice (McNeil and Guirguis-Younger, 2012).

Community

Community health professionals have a major role in delivering palliative care, particularly as a large proportion of patients with life-limiting illness wish to die at home. A Japanese survey of community physicians showed that the majority (92.4%) expressed a willingness to provide palliative care, but this would be limited to consultation (83.4%) and referral to a palliative care service (86.8%) (Peng et al., 2013). Only 42.2% were willing to provide home visits. Home visits were more likely to be provided if physicians were family medicine specialists and older than 50 years. It is of interest that the presence of palliative care knowledge did not influence the likelihood of a home visit. The main barriers to effective palliative care delivery by general practitioners were examined in a study from the Netherlands. These included organizational barriers, coordination of care, knowledge, time constraints, and communication difficulties (Groot et al., 2007).

It is also important that advanced care planning is implemented in primary care settings, particularly as patients often prefer to die at home. However, barriers that exist include prognostic uncertainty, limited collaboration with secondary care, a desire to maintain hope, and resistance to a 'tick-box approach' to health care (Boyd et al., 2010). Challenges also occur in providing palliative care in rural versus urban settings. Nurses working in rural settings providing palliative care were more confident in their abilities, but spent more time travelling, than their urban counterparts (Kaasalainen et al., 2011).

Prisoners

Just as the population is becoming older, so is the prison population. In keeping with this, an increasing number of inmates will die in prison from chronic malignant and non-malignant disease. Challenges in caring for these patients at the end of life are, in general, similar to those in the community; however, health-care systems can vary.

For some, prison may afford more regular contact with health care than in the community. In some cases excellent hospice programmes exist within prisons. Clearly, this varies widely within and between countries; however, in the developed world, there is generally some form of established system.

People in prisons are in general poor, and have often suffered from a lack of adequate health care before incarceration. In countries where there has been a trend towards increased sentences,

determinate sentences, and mandatory minimum sentences, the average age of the prisoners has also increased. Together these often result in the prisoners suffering from several medical problems and disorders—such as chronic obstructive pulmonary disease (COPD), coronary disease, end-stage renal and liver disease, hypertension, and diabetes—and often in need of palliative care (Linder and Meyers, 2007). Increasing numbers of convictions for drug possession and use have also led to an increase the number of prisoners suffering from HIV and AIDS due to drug injection. AIDS has become the leading cause of death in prisons in the developed world. Patients suffering from HIV and AIDS need complex treatment and access to palliative care, and the high numbers of these patients in prisons represents a major challenge.

The poor socioeconomic background of many prisoners also often means increased issues with learning difficulties and limited reading skills. While giving more patient information and an open discussion with the patient has been the focus of palliative care in general, difficulties in reading, understanding, and acting on health information can be limiting for prisoners. The result may be misunderstandings, frustration, and poorer health outcomes. Dying prisoners may need increased medical attention, extended visiting hours with family, access to special foods, and relaxation from routine duties. Some prisoners can be transferred to hospice units at the end of life, where better end-of-life care can be provided. However, this often results in the dying prisoners being further away from their families (Dubler, 1998).

Staff caring for terminally ill inmates may face barriers such as limited facilities, restricted access to medication, and limited autonomy (Linder and Meyers, 2007). In addition, there may be limited specialist palliative care skills among health professionals working in the prison, and more often it will be general staff who provide this service. Nevertheless, in some developed countries there is often good collaboration between palliative care services in the community who support colleagues working in prison health-care systems. Such systems support palliative care in the prison setting to improve slowly.

End-of-life care requires a trusting alliance between the care providers and the patient. To achieve such a relationship in prison is challenging. In contrast to the general population, prisoners do not assume that the system is acting in their best interests. Dying prisoners may not be convinced that decisions to limit care and permit death have been preceded by the full range of efforts to extend and support life.

Professional barriers

There are many factors related to the practices of health- and social-care professionals that impact on the quality of end-of-life care and referral to appropriate palliative care services.

Attitudes

Although palliative care has long been associated with cancer, barriers exist to integrating palliative care into oncology (Abrahm, 2012). Abraham has argued that there are several key reasons for this. Firstly, there is a degree of learned helplessness from oncologists who have been used to a culture where there is a lack of effective medication with which to manage symptoms. Secondly, there may be lack of adequate communication skills to deal with difficult situations. Another aspect which can impair the integration of palliative care into oncology is compassion fatigue. Grief oncologists feel develops from years of caring for patients who despite best efforts succumb to their illness. This may contribute to 'burn out'.

Oncologists may be of the opinion that they already provide 'palliative care' but their skills can be optimized through time spent working with a specialist palliative care team (Wiebe and Von Roenn, 2010). Limitations can be addressed by ensuring that palliative care training is available to oncologists and this may in part reduce compassion fatigue, while improving palliative care delivery to cancer patients. These steps may afford an increased integration of palliative care and oncology.

Palliative care may be underused in patients with haematological malignancy. A systematic review demonstrated that patients with these malignancies were less likely to receive palliative care than those with other cancers (Howell et al., 2011). Possible explanations include ongoing management by the haematology team, and consequently strong bonds between staff and patients, and challenges with transitions (e.g. withdrawal of blood product support).

A structured transition to a palliative care approach for patients although advocated, is not always evident. One study suggested that prognosis was not always discussed with patients while consensus among the clinical team that a palliative approach should now be the main focus of care was not always achieved in practice (Gott et al., 2011). Furthermore, discussions regarding the adoption of a palliative care approach were not often held with patents, resulting in patients being discharged with unrealistic expectations regarding prognosis. Physicians are often supportive of a palliative care approach, the main barrier for patients being prognostic uncertainty (Snow et al., 2009).

Barriers that were identified included difficulty in 'standing back' in acute hospital settings and professional hierarchies impeding junior medical and also nursing staff from being involved in patient management decisions.

Another barrier to the implementation of palliative care is, when there has been a delay in diagnosis (due to a problematic doctor–patient relationships, a feeling of helplessness, strong emotions from patients and families, and time restraints) (Slort et al., 2011).

Although palliative care is not solely associated with end-of-life care, this is an area where specific barriers particularly exist. Three specific areas were identified in a study conducted to assess the views of palliative care professionals (Feeg and Elebiary, 2005). These included a reluctance of other health professionals to refer to palliative care, a lack of familiarity with the availability and suitability of hospice teams, and the association of hospice care with death.

To improve access to palliative care services in the acute hospital setting several key aspects have been identified, including visibility on the wards, informal routes of access, and consensus on the remit of specialist palliative care services (Ewing et al., 2009). In end-of-life care, several further key barriers exist, for example, inadequate medical education, professional uncertainty regarding the difference between stopping life-sustaining treatment and active euthanasia, difficulty in diagnosing dying, and a perception that death is a professional failure. Another issue is that when patients are transferred to a hospice setting for end-of-life care this segregation from familiar health-care providers may provoke anxiety and in itself be a barrier to the delivery of optimal palliative care (Meier et al., 1997).

Treating fellow health professionals can also be a barrier to the delivery of palliative care. One study examined how the challenges of treating doctors who are palliative care patients identified barriers to implementing palliative care (Noble et al., 2008). These include difficulty in health professionals assuming the patient role, raising barriers to psychosocial aspects of care, and late referral to services.

In general, patients with a non-cancer diagnosis have less access to palliative care than patients with a cancer diagnosis. The End of Life Care Strategy in the United Kingdom raised the profile of end-of-life care, suggesting increased planning and delivery is needed to ensure individuals can choose where and how they die. Several reasons exist as to why end-of-life care access is more difficult in non-cancer patients including differing disease trajectories and care planning, all on a background of appropriate funding. These areas are explored further in relation to specific conditions in 'Barriers in key disease groups' (Addicott, 2012).

General barriers to providing palliative care in non-cancer disease include lack of clarity regarding prognosis, hegemony of the curative approach, avoiding words, and the desire to cheat death (Mahtani-Chugani et al., 2010). Indeed provision of palliative care should be tailored to the trajectory of the individual patient.

Knowledge

Lack of knowledge is a key barrier to palliative care among health professionals. This has been compounded by confusion regarding terminology (specialist versus general palliative care), whether or not patients need to be near the end of life, and even whether palliative care is appropriate for non-malignant, life-limiting disease.

Whilst all of these may apply there can be great variation between services which adds to confusion.

Clearly, in an ideal world, differences would not exist; however, it is important that health professionals are aware of the nuances of their local palliative care service. There is an impetus on palliative care services to provide clear guidance on who is appropriate to refer, different services that are available, and also the appropriate time to refer patients. The latter is particularly relevant in the United States since to be eligible for specialist palliative care under Medicare, patients generally need to have a life expectancy of less than 6 months (Brickner et al., 2004).

Which patients are deemed appropriate for palliative care referral can vary between health professionals. One study suggested nursing staff were more likely than medical staff to identify palliative care needs in non-malignant disease; however, this disparity lessened as the patient neared death (Gott et al., 2001). Differences also exist between specialties—for example, oncologists are more likely to refer to palliative care services than other specialists, such as cardiologists.

Barriers in key disease groups

Cardiac disease

Cardiac failure is one of the main areas where palliative care is important (see Chapter 15.3). It is associated with quite marked symptoms including fatigue, breathlessness, and decreased quality of life. In addition to providing good symptomatic relief, palliative care can also provide patient and family support, while assisting in the complex decision-making process that occurs near the end of life. Despite supporting evidence that palliative care is of benefit in patients with cardiac failure, it remains underused (Lemond and Allen, 2011). As with other conditions, prognostic uncertainty is a barrier to access to palliative care in cardiac failure. Furthermore, inexperience among health professionals can contribute to a lack of palliative care access in patients with cardiac failure (Lemond and Allen, 2011).

Respiratory disease

There is a need for the multidisciplinary approach that is used in palliative care to be implemented in chronic respiratory disease. Reluctance to negotiate end-of-life decisions and a perceived lack of understanding among patients and carers regarding the illness trajectory are regarded as key barriers in end-stage respiratory disease (Spence et al., 2009). There is a lack of evidence and guidelines to support palliative care in chronic respiratory disease in comparison to cancer patients (Hardin et al., 2008).

HIV/AIDS

Patients with HIV/AIDS face some similar difficulties to those coping with chronic cardiac failure and COPD, in that prognostication is difficult and communication with professionals involved in care may not be well enough developed to encompass end-of-life issues in a meaningful way (see Chapter 15.1).

In addition, the stigma of the disease can act as a barrier to effective palliative care, as can negative attitudes to homosexuality or substance abuse (Rondahl et al., 2003). Patients with HIV/AIDS often have a heavy, heterogeneous symptom burden which even experienced palliative care practitioners may feel ill-equipped to manage and patients may prefer specialist HIV/AIDS services for this reason.

There are also major issues involved in the care of those who are bereaved and orphaned (Clark et al., 2007). The case of HIV/AIDS care emphasizes the need for palliative care to sit alongside active treatment with highly active retroviral therapy which can itself cause pain and other symptoms.

If palliative care in HIV/AIDS is to be equitable and effective, services need to minimize discrimination, facilitate ongoing improvement in palliative care knowledge and skills for health-care professionals, produce clear referral criteria for specialist palliative care services, and ensure that high-quality palliative care is available whatever the setting (Harding et al., 2005).

Renal failure

Patients who are receiving dialysis have multiple symptomatic needs including pain, fatigue, mood disorders, and cognitive impairment (see Chapter 15.6). It is also difficult to provide accurate prognoses in this group of patients, due to varying disease trajectories, despite this being a clear need of patients. Palliative care input to this group of patients generally occurs infrequently (Kurella Tamura and Cohen, 2010).

Conclusion

Despite the multiple barriers that exist to the delivery of palliative care, there are grounds for optimism. Palliative care as a concept appears to be well understood and received, suggesting this barrier in part been has overcome (Hanratty et al., 2006). The WHO has promoted policies and advice for the rational implementation of pain relief and palliative care (Stjernsward et al., 1996). Palliative

care is now seen as an accepted part of management in many non-malignant, life-limiting conditions and at least basic palliative care education is given to health professionals. As increasing areas develop where palliative care is required, it is important that barriers are overcome to ensure that palliative care as a foundation of good health care is realized.

Palliative care delivery models

Irene J. Higginson

Introduction to palliative care delivery models

Since the initiation of modern hospice and palliative care, led by Cicely Saunders in the United Kingdom, then Vittorio Ventafridda in Europe and Balfour Mount in Canada, palliative care has evolved and is now integrated into mainstream medicine in many countries, with a network of services, the development of a medical specialty or sub-speciality, and creation of academic departments to build knowledge and practice.

In high-income countries, those aged 60 and older bear 35% of the disease burden, a disproportionately high percentage relative to the population distribution, with the leading causes all being chronic diseases (World Health Organization, 2008). As the population in developed countries ages, the disease burden will only increase further and will challenge their health-care systems. Advances in cancer and other treatments leads to patients living longer and experiencing more co-morbidities (Sullivan et al., 2011). Developed countries have to cope with the increasing demand for palliative care services amidst soaring health-care expenditures, tight budgets, and rising patient expectations (Harding et al., 2003; Harding and Higginson, 2005). Each system would have to develop and improve their current palliative care system to meet their future population's needs. As developed countries have varied health financing and delivery structures, contrasting the different models would allow lessons to be distilled that could be applicable to other systems. Thus, palliative care has received growing attention from patients, health-care professionals, and health-care providers in recent years.

Adapted to diverse health-care systems, palliative care services have been developed in more than 100 countries throughout the world. Although originally conceived as something concerned only with the end of life, palliative care has now become more integrated, with services offered throughout the disease trajectory (see Fig. 3.2.1). This chapter considers the different service delivery models and some of the evidence of their effectiveness.

Generalist versus specialist palliative care

One of the challenges for palliative care is the high prevalence of conditions that need palliative care. Every year there are around 53 million deaths worldwide. Of these approximately 80% have a period of progressive illness and/or disability, when the disease becomes unresponsive to curative treatment. Murtagh et al., comparing methods of needs assessment of palliative care, identified that between 69% and 82% of those who die need palliative care (Murtagh et al., 2014). Almost every clinician in health care will encounter patients at or approaching the end of life, those with progressive and symptomatic illness, and bereaved families. Thus, because palliative care needs to be part of every clinician's duties, and because specialist palliative care could not and may not need to expand to care for everyone who has progressive illness or is reaching the end of their life, there is often a distinction between what is called 'generalist' palliative care and specialist palliative care. The former concerns clinical care for all people who have progressive, life-limiting, or end-of-life conditions while specialist palliative care is offered by specialists, and is concerned with patients with the more complex needs.

Generalist palliative care is usually defined as palliative care provided for those affected by life-limiting or progressive illness as an integral part of standard clinical practice by any health-care professional that is not part of a specialist palliative care team (Shipman et al., 2008). In the community, generalist palliative care is provided by primary care teams, district nurses, nursing and residential home care staff, and other community support services. In hospitals, it is provided by general medical and surgical teams, and specialists for specific diseases or circumstances, such as oncology, respiratory, renal, intensive care, and cardiac teams (Shipman et al., 2008). Condition-specific specialist nurses often work across the interface between hospital and community (Aspinal et al., 2012).

In some countries, such as the United Kingdom, improving generalist palliative and end-of-life care has been a major focus of health policy. The UK Department of Health End of Life Care Strategy sought to 'bring about a step change in access to high quality care for all people approaching the end of life' in all care settings (Department of Health, 2008). This is to be achieved with a whole system and care pathway approach for commissioning and providing integrated services, improving coordination. It specifically stated that it involved workforce development including education and training for generalists as well as specialists.

Specialist palliative care is palliative care provided by those who have undergone specific training and/or accreditation in palliative care/medicine working in the context of an expert interdisciplinary team of palliative care health professionals.

Specialist palliative care may be provided by inpatient palliative care units (PCUs) or hospices, hospital palliative care teams, community palliative care or hospice teams, and paediatric specialist palliative care teams. Increasingly, specialist palliative care services need to meet standards developed nationally, work exclusively in palliative care, and have staff who have completed specialist training.

However, a distinction made on the nature of the service is not enough, there needs to be a distinction on the basis of patient and/

or family circumstances and need. A common distinction is the complexity of patients and families. Generalists will provide care for everyone with less complex needs. Specialists in palliative care have a higher level of expertise in complex symptom management, spiritual support, psychosocial support, cultural support, and grief and loss support, and thus care for patients and families with the higher levels of these needs.

Specialist palliative care services usually have three components: (1) directly provide care for the more complex patients and families, (2) provide education and support to generalists, and (3) undertake or collaborate in research to improve the care for patients and families in the future. The provision of education is widely accepted as a role for specialist palliative care, although the nature and level of support is not well defined. The requirement to undertake research is more recent, and at present is not universally provided by all hospices and palliative care teams. The proportion and detailed circumstances of those patients and families with the more complex needs that require 'specialist' rather than 'generalist' palliative care is also not well defined and varies both within and between countries, and within and between diseases (Oliver and Webb, 2000; Johnson et al., 2008, 2011; To et al., 2011).

Currow and colleagues attempted to estimate population wishes for specialist palliative care, and also levels of need among people with diseases other than cancer (Currow et al., 2004, 2008). They found limited levels of unmet need for specialist palliative care according to bereaved relatives. However, the levels of unmet need depend on knowledge of what palliative care can offer, which is varied, especially in some populations and cultures (Calanzani et al., 2013). Research in specific non-cancer populations not referred to palliative care has identified levels of symptoms and problems similar to those among cancer patients who were referred to specialist care, suggesting inequity of provision exists at least in some settings and diseases (Solano et al., 2006; Murray et al., 2007; Selman et al., 2007; Harding et al., 2009; Gysels and Higginson, 2011; Bajwah et al., 2012). Daveson et al., in a population-based survey in seven European countries involving 9344 respondents, found two prominent themes in the responses to open comments: (1) a need for improved quality of end-of-life and palliative care, and access to this care for patients and families; and (2) the recognition of the importance of death and dying, the cessation of treatments to extend life unnecessarily, and the need for holistic care to include comfort and support. The public appeared to recognize the importance of death and dying and were concerned to prioritize quantity of life over quality of life,

also calling for improvement in palliative and end-of-life care services (Daveson et al., 2014).

Joint working and interface between specialist and generalist palliative care is also important. The wide range of health needs of people with progressive or far advanced diseases often requires collaboration and co-working between many sectors, such as specialists in care for older people, oncology, disease specialists, and palliative, primary, and social care. Such joint models are newly emerging in many fields, such as earlier integration with oncology and palliative care—with joint clinics and other initiatives. Such models include outpatient palliative care services, integrated with oncology (Temel et al., 2010); a breathlessness support service run jointly between palliative care and respiratory medicine (Bausewein et al., 2012); and a new short-term service for patients severely affected by multiple sclerosis (MS), offered jointly between neurology and palliative care (Edmonds et al., 2010; Higginson et al., 2011).

Models of specialist palliative care delivery

Delivery of specialist palliative care differs slightly throughout the world but similar structures have evolved: inpatient palliative care is provided in dedicated PCUs or hospices, specialist palliative care teams offer palliative care consultations either in the hospital or in the community within home care programmes, and increasingly outpatient, day care, and respite services. The following subsections consider the most common established and emerging models, and to a limited extent their evidence base. Note that several PCUs offer a combination of services—for example, most inpatient PCUs and hospices also offer other services, such as, if they are based in the community, home care and day care, or if based in a hospital, hospital consultation. It is not that one specific service is better than or preferable to another: community support is essential as evidence consistently shows that most patients want to be cared for at home for as long as possible and often to die there (Gomes et al., 2012b, 2013b) and yet more than half of deaths in most countries occur in hospitals (Cohen et al., 2008; Gomes et al., 2012a).

Inpatient palliative care units and inpatient hospices

The European Association for Palliative Care (EAPC), in its white paper on standards and norms, defines a PCU as a department specialized in the treatment and care of palliative care patients (Radbruch et al., 2010). It can be a stand-alone service (as with many of the inpatient hospices in the United Kingdom) or a ward or unit within or adjacent to a hospital (as is common, for example, in Germany, some parts of Canada, among others). The aim of PCUs and hospices is to alleviate disease and therapy-related discomfort and, if possible, to stabilize the status of the patient and offer patient and carers psychological and social support in a way that allows for discharge or transfer to another care setting.

In her early writing on hospices, Dame Cicely Saunders emphasized the importance of environment—that a hospice should be welcoming, calm, and cheerful, in contrast to most acute hospital wards (Saunders, 2001). St Christopher's Hospice, founded by Dame Cicely Saunders in 1967, followed this guidance, with gardens, a welcoming atmosphere, and sense of peace and cheerfulness.

PCUs and inpatient hospices admit patients whose condition (physical, emotional, social, and spiritual) would benefit from specialist multiprofessional palliative care. Patients can be admitted

for a few days to several weeks; their medical, nursing, psychosocial, or spiritual problems determine this. As mentioned earlier, these units may also provide other services.

Evidence about the effectiveness of specialist PCUs and inpatient hospices suggests that they provide benefits in terms of symptom management, and in particular higher satisfaction with the quality of care from patients and families (Higginson and Evans, 2010). Much of the early evaluation concerned St Christopher's hospice, with quasi-experimental designs showing improved symptom management and satisfaction. Later a randomized trial of a PCU ward found few differences in symptoms but a difference in family satisfaction, although there was contamination between arms, but other studies suggested a benefit of inpatient hospices (Higginson et al., 2003; Gysels and Higginson, 2004). The satisfaction of patients and families with inpatient hospices is much higher than for conventional care, especially hospitals. A national survey of 18 000 bereaved relatives in the United Kingdom in 2011 found that inpatient hospices were reported as outstanding or excellent by 59%, contrasted with 32% for hospitals (NHS Medical Directorate End of Life Care, 2012).

Hospice: a word with different international meanings

The term hospice has different meanings internationally. This has partly arisen because in Latin-root languages hospice sometimes has a very similar meaning to hospital. So Balfour Mount, seeing an alternative word in French-speaking Canada, coined the word palliative, which is more often used nowadays. In many countries, for example, the United Kingdom, the function of an inpatient hospice and a PCU are similar. But, in other countries, a distinction exists—in Germany, for example, patients will be admitted to a PCU for crisis intervention and to an inpatient hospice for end-of-life care (Radbruch et al., 2010). In some countries (e.g. the United States), a hospice, in contrast to a PCU, is a free-standing service which is predominantly home care.

Palliative care consultation teams

Consultation teams provide an additional layer of support and advice for patients and families, working with existing professionals. They can be focused predominantly on hospital patients, or patients at home or both.

Hospital teams

Hospital palliative care support teams provide specialist palliative care advice and support to other clinical staff, patients, and their families and carers in the hospital environment (Radbruch et al., 2010). They offer formal and informal education, and liaise with other services in and out of the hospital. Hospital palliative care support teams are also known as hospital supportive care teams. A core aim is the alleviation of multiple symptoms experienced by patients, and for this the team members will advise on management and sometimes prescribe directly. Teams usually also offer support and education for existing staff, including on pain and symptom assessment and control, holistic care, and psychosocial support. They are usually involved in seeing the patients in all areas of the hospital (Radbruch et al., 2010).

Evidence regarding the effectiveness of hospital palliative care teams comes mainly from quasi-experimental studies. Outcomes considered included symptoms, quality of life, time in hospital, total length of time in palliative care, or professional changes, such as prescribing practices. Most studies indicate a small positive effect of the hospital team, compared to usual care (Higginson et al., 2002; Higginson and Evans, 2010). Multiprofessional teams with more skilled staff may offer greater benefits (Finlay et al., 2002).

Home care teams

Home palliative care teams provide specialized palliative care to patients who need it at home and support to their families and carers at the patient's home. They also provide specialist advice to general practitioners (GPs), family doctors, nurses, and others caring for the patient and family at home (Radbruch et al., 2010). Commonly they reach out to patients in the community wherever they are, including in nursing and residential homes.

The home palliative care team will visit patients and their families in the community at the request of other community professionals, and provides an additional layer of support and help. It has an advisory and mentoring function, and offers its expertise in pain therapy, symptom control, palliative care, and psychosocial support (Radbruch et al., 2010). Advice and support by the home palliative care team is also provided directly to the patient and family, in particular helping with coordination of care, emotional, social, and spiritual support. The extent to which the palliative care team directly decides what treatments should be provided, or advises the GP regarding this, varies. The most usual model is to advise, but in some instances, because the case is complex or because the GP prefers this, the team takes over prescribing for the patient.

Less frequently in many settings, except home hospice care, the home palliative care team provides 'hands-on' direct care, sometimes taking over care (as in the hospice model in the United States) or in collaboration with the GP and other primary care workers. This model approaches that of 'hospice' at home—where all care is provided to patients at home (Grande et al., 2004).

There is very good evidence, from systematic reviews and original studies, regarding the benefits of home specialist palliative care teams. The most recent Cochrane review identified 23 studies, of which 16 were randomized controlled trials, including 37 561 participants and 4042 family caregivers. The patients cared for mostly had advanced cancer but some had congestive heart failure, chronic obstructive pulmonary disease, HIV/AIDS, MS, and other conditions. Meta-analysis showed that a home specialist palliative care team more than doubled the odds of dying at home compared to the conventional care (odds ratio 2.21, 95% confidence interval 1.31–3.71; P = 0.003). In addition, narrative synthesis showed evidence of small but statistically significant beneficial effects of home palliative care services compared to usual care on reducing symptom burden for patients (Gomes et al., 2013a).

Palliative care outpatient services

Palliative outpatient clinics offer consultation for patients living at home who are able to visit the clinic. Palliative outpatient clinics can be offered from hospital or inpatient PCUs or hospitals. There is an increasing variety of such services, with outpatient services being offered jointly with oncology, respiratory medicine, or neurology services. They often meet the need to integrate services and can help to introduce patients earlier to palliative care in a

non-threatening way, providing help with, for example, specific symptoms or advance care planning. To date, however, evaluations are few and these are much needed for the future.

Day care

Day hospices or day care centres are spaces in hospitals, hospices, PCUs, or the community especially designed to provide additional support to patients in the community and their families. For units that have inpatient beds, sometimes the inpatients will also attend day care, especially those who are well enough and are planning to go home. Patients are usually eligible for day care only if they are already in the care of a home palliative care team, affiliated with that particular centre. The nature of services offered varies along a continuum from the more medical/health orientated to the more social and recreational. Quite often day centres offer a variety of complementary therapies.

Evaluations regarding the comparative effectiveness of day care are limited, and those to date have not shown great benefits for the more 'social models' of day care, although it is possible that the outcomes may have been inadequate (Douglas et al., 2000, 2003; Higginson et al., 2010). Although patients in non-comparative studies report high satisfaction with day care, these benefits are not seen when studies use a control group or quasi-experimental design. A recent comparative evaluation of day care appeared to suggest that hope was improved, and more research on this aspect is needed (Guy et al., 2011).

Short-term integrated palliative care

A new model of specialist palliative care is developing in response to the changing needs of patients. In general, palliative care services have accepted patients and kept them 'on their books', even if not as inpatients, until the person died. But better integration with existing services, earlier involvement of palliative care specialists, and providing care for patients with longer trajectories of illness (in both cancer and non-cancer conditions) requires new models of palliative care. In response, the model of short-term integrated palliative care has been developed and trialled at the Cicely Saunders Institute in London and elsewhere.

First developed in the care of people with MS, the integrated service has a definite goal to see patients for a limited time, to set things in order, and then discharge them to the care of existing services. For people severely affected by MS this was usually no more than three visits/contacts. After this, 90% of those referred were discharged to local community and existing services, and 10% were referred to continuing palliative care. The outcomes at 6 weeks and 12 weeks in a phase II randomized trial, showed improved symptom control and reduced caregiver burden (Higginson et al., 2006, 2008, 2009, 2011). Fig. 3.2.2 shows how the service links to others. It is an emerging model of care that now needs further evaluation in demonstration projects and trials.

Principles and structures common to specialist palliative care services

Several principles are common to all the palliative care services. These include attention to the individual and total (physical, emotional, social, and spiritual) needs of the person, and considering the patient and the family as the unit of care (Saunders,
Fig. 3.2.2 Model of short-term early palliative care in multiple sclerosis (MS).

2001; Davies and Higginson, 2004a, 2004b; Radbruch et al., 2010). There is a focus on excellent communication and coordination. Gaertner and colleagues developed with local experts a template for palliative care consultations in a comprehensive cancer centre delineating detailed information of infrastructure, general underlying principles, goals of the palliative care intervention (including symptom assessment and management), and empowerment through patient participation and autonomy (Gaertner et al., 2011). These aspects are captured in some of the common outcome measures specifically developed to assess palliative care, such as the Palliative Care Outcome Scale (Bausewein et al., 2011; Higginson et al., 2012), the Edmonton Symptom Assessment Scale (Watanabe et al., 2012), and the Support Team Assessment Schedule (Bausewein et al., 2011).

Professionals involved

Multiprofessional staffing is central to all palliative care services, as these are needed for the wide ranging problems of patients and families (Fig. 3.2.3) (Davies and Higginson, 2004a, 2004b). Specialist palliative care physicians and palliative care nurses are usually part of all services but other professionals such as social workers, pharmacists, psychologists, physiotherapists, occupational therapies, and chaplains or faith leaders are often involved, especially in inpatient units. The variety of team compositions is certainly related to organizational and resource issues. However, in view of the physical, psychosocial, and spiritual needs of palliative care and its holistic approach, inclusion of professionals other than doctors and nurses should be stressed as palliative care develops for the future.

Target population

The dominant group of patients receiving palliative care services are those with advanced cancer (Gomez-Batiste et al., 2010; Duursma et al., 2011; Farquhar et al., 2011; Gaertner et al., 2012; Jongen et al., 2012; Paiva et al., 2012). More recently, newly diagnosed lung cancer (Temel et al., 2010), glioblastoma (Pace et al., 2012), and prostate cancer (Yennurajalingam et al., 2012) were the focus. Palliative care has begun to extend to include patients with non-malignant disease such as severely affected by MS (Higginson et al., 2009; Edmonds et al., 2010; Higginson et al., 2011), advanced heart failure (Schwarz et al., 2012), advanced respiratory disease or symptoms of breathlessness (Farquhar et al., 2011; Bajwah et al., 2012; Bausewein et al., 2012), or advanced chronic disease (predominantly neurological disease and cancer) (Fernandes et al., 2010).
Fig. 3.2.3 Multidisciplinary palliative care team to respond to holistic patient and family needs.

Conclusion

Palliative care service delivery models operate across all the settings where patients need support. There is a distinction between general palliative care (provided by all clinicians) and specialist palliative care (provided by those with specific training and unique interest in palliative care for the more complex patients). Some models of service—home and hospital consultation teams, inpatient PCUs, and inpatient hospices—are well established and have a strong evidence base. Newly emerging models, with greater integration and short-term and outpatient palliative care, are promising and are beginning to be offered but require evaluation. Some principles and values are common, including a holistic, multi-professional approach based on need, which responds to the individual needs of the patient and their family and considers the patient and family the unit of care.

3.3

Palliative care in the emergency department

Paul L. DeSandre and Karen May

Introduction to palliative care in the emergency department

Training and practice in emergency medicine prioritizes acute illness and life-prolonging interventions. As the elderly population continues to grow, more patients with crises related to illness and debility are expected to rely on emergency departments for help. Severely ill and functionally impaired elderly patients seek emergency care not only for physical concerns, but also for concerns related to psychological or financial distress, and access to care (Grudzen et al., 2010). Clinicians may feel ill-equipped to provide the necessary care for these patients, but they recognize the importance in providing this care (Smith et al., 2009; Stone et al., 2011). There is increasing evidence of the benefit of early palliative care intervention in acute care settings (Campbell and Guzman, 2003; Lustbader et al., 2011).

As the entry point to the hospital and often the health-care system, the emergency department is uniquely positioned for early identification of patients with unmet palliative care needs (Mahony et al., 2008). In addition, the emergency department is often a staging area for negotiating the difficult decisions surrounding life-sustaining interventions and an environment where sudden life-altering events are managed. In recognition of the need to evolve expertise in managing these critical concerns in patient care, there is wide support for improving palliative care practices in the emergency department (American College of Emergency Physicians, 2014; National Consensus Project for Quality Palliative Care, 2013; Emergency Nurses Association, 2013).

Models have been proposed for encouraging the integration of palliative care practices into routine care in the emergency department (Grudzen et al., 2011). Also, resources are available and continue to develop for improving education, clinical care, and research (Education in Palliative and End of Life Care—Emergency Medicine, 2010) Center to Advance Palliative Care, 2011). This chapter will introduce these principles and provide structured approaches to the care of patients with palliative care needs in the emergency department.

Rapid palliative care assessment in the emergency department

The initial assessment of all patients presenting to the emergency department is a triage process based on the level of acuity to direct care to the most critical patients first. Patients with significant unmet palliative care needs may present to the emergency department at any stage of illness and at any level of acuity. The emergency clinician must recognize these patients as early as possible, and assure that their care is not only efficient and effective, but also concordant with the goals of the patient and the family. Two tools have been developed to rapidly guide care in the emergency department. The first developed as an initial screen for palliative care needs in stable patients, the Screen for Palliative and End of Life Care Needs in the Emergency Department (SPEED) assessment tool. The second is the mnemonic 'ABCD', which was developed to assist in the approach to patients in critical condition.

The SPEED tool is designed for use as a brief multidimensional symptom assessment for quick administration in the emergency department. It is a 13-question assessment tool adapted from the previously developed NEST assessment tool (Emanuel et al., 2001). It can be performed rapidly by anyone on the care team (physician, nurse, chaplain, social worker, or other health-care worker), but may have particular utility at the point of triage. This is the first tool designed for use in the emergency department and tested favourably for both reliability and validity in screening for palliative care needs of cancer patients (Richards et al., 2011). SPEED addresses five major domains of palliative care needs: physical, therapeutic, psychological, social, and spiritual. A preliminary study applied the SPEED instrument to 1842 patients in routine emergency department triage and found nearly half of the patients had at least moderate to severe pain, and approximately one-quarter of the patients had at least moderate difficulty with care needs at home, difficulty with medications, were feeling overwhelmed, and had difficulty getting medical care that fitted their goals (Quest et al., 2011). These findings support other emergency department-based efforts to identify patients with unmet palliative care needs (Mahony et al., 2008; Waugh, 2010; Glajchen et al., 2011; Grudzen et al., 2011) with the advantage of brevity and simplicity of application.

Patients arriving at the emergency department in critical condition at the final stages of chronic progressive illnesses are a complex challenge. Despite the inherent chaos of the environment, the emergency clinician must immediately intervene within the context of the patient's illness and goals of care. Therefore, a simultaneous rapid palliative care assessment must occur concurrently with temporizing medical interventions until either goals are clear or life-sustaining interventions are necessary, despite a lack of clarity.

Table 3.3.1 ABCD critical care intervention mnemonic

A	Advance directive:
	Check available records or reports from paramedics or family
B	Better symptom control:
	Attend to symptoms while avoiding invasive interventions to allow time to evaluate whether more invasive interventions would achieve intended goals
C	Caregivers:
	Provide reassurance to patient
	Contextualize patient goals and recent functional and medical changes to foster reasonable discussion of medical decision-making.
D	Decision-making capacity:
	Assess patient's ability to reliably engage in dialogue about medical goals and interventions.

The mnemonic, ABCD, was developed by the Education in Palliative and End of Life Care for Emergency Medicine (EPEC-EM) project (EPEC, 2010) to assist in these situations and is summarized in Table 3.3.1. This approach provides a framework to assess and address the immediate symptom needs of the patient while simultaneously acquiring information to guide medical interventions that can reasonably achieve the goals of the patient and family (B in the mnemonic). There are three remaining elements of the mnemonic: existence of an advance directive (A); the presence of a knowledgeable caregiver (C); and the capacity of the patient to participate in medical decision-making (D). These factors allow the medical provider to place the patient's current condition in the context of the underlying illness, recent functional decline, and goals for medical care. This information can be used to provide recommendations for reasonable medical interventions within the value system of the patient and family.

Rapid titration of opioids in cancer pain

Patients with malignancy often present to the emergency department with uncontrolled pain (Vandyk et al., 2012). Overall, pain is also the most common reason patients seek emergency care, yet analgesics are underutilized, and delays to treatment are common (Todd et al., 2007). Historically, there have been barriers to optimal pain management in the emergency department, including lack of training (Lamba et al., 2012), inadequate assessment (Stalnikowicz et al., 2005), misinterpretation of reasons for seeking care (Wilsey et al., 2008), and disparities in treatment practices among clinicians (Cone et al., 2003; Pletcher et al., 2008). Therefore, patients coming to the emergency department with severe breakthrough cancer pain may be justifiably fearful that their pain may not be addressed in a timely or adequate manner.

Assessing severity of malignant pain in the emergency department using a standardized pain scale such as the numerical rating scale, is an important first step (Todd, 2005). Severe pain in malignancy has been referred to as a 'cancer pain emergency' and rapid titration of parenteral opioids has been demonstrated to provide effective *and safe* control of pain while concurrently addressing

other diagnostic concerns (Hagen et al., 1997; Mercadante et al., 2002; Soares et al., 2003). In addition to severity, initial assessment of cancer pain must also quickly identify underlying patient characteristics, such as prior exposure to opioids or underlying organ dysfunction, which would alter initial dose calculations. Also, new or progressive pain with the potential for emergent interventions, such as spinal cord compression with motor dysfunction, must be pursued concurrently.

In an effort to encourage emergency clinicians to provide timely and effective intervention, a five-step approach was originally introduced through the EPEC-EM curriculum and is based, in part, on recommendations from the American Pain Society (Miaskowski et al., 2005, pp. 39–48; EPEC, 2010; DeSandre and Quest, 2009) (see Table 3.3.2).

Communications in the emergency department

Navigating patients and families through the chaotic experience of the emergency department and negotiating reasonable plans for medical care is a skill required of all emergency clinicians. When patients and families are faced with situations related to mortality in the emergency department, communication requires particular sensitivity and focus. Structured approaches can improve communication by reducing clinician distress in these difficult situations (Baile et al., 2000). A structured approach can be used to address three important scenarios in the emergency department: (1) rapidly establishing goals of care, (2) death disclosure, and (3) family presence during cardiopulmonary resuscitation (CPR) (if it is assessed as appropriate to initiate CPR).

Goals of care

Goal setting is a routine practice of emergency care. Patients present to the emergency department at all phases of illness, and the emergency department is often the staging area for complex medical decisions that set a trajectory for future interventions. Patients are placed on ventilators, sent to surgery, admitted to intensive care units, and sometimes supported symptomatically as they die. Patient and clinician goals must ultimately align in order to ensure medical interventions are likely to be beneficial. Prior to any diagnostic test or medical intervention in the emergency department, the clinician anticipates an outcome. If a test or intervention would not change the outcome, then it would not be medically reasonable to proceed. Other interventions may be more reasonable, in order to limit suffering, or ensure a person can die in a peaceful environment.

'Goals of care' have been defined as 'physical, social, spiritual, or other patient-centered goals that arise following an informed discussion of the current disease(s), prognosis, and treatment options' (Weissman and Meier, 2011). There are several perceived barriers facing emergency clinicians needing to address goals of care prior to intervening with diagnostic evaluations or therapies. Unlike more time-intensive approaches, the purpose of discussing a patient's goals of care in the emergency department often seeks to answer questions about interventions, such as whether or not a ventilator or the intensive care unit will achieve the most appropriate clinical outcome. While it is clear that family meetings are an effective communication strategy for many complex medical decisions (Hudson et al., 2009), emergency clinicians may

Table 3.3.2 A strategy for rapid titration of opioids in cancer pain emergencies

Step 1: assess	◆ Familiar pain or uncharacteristic pain?
	◆ Cancer related or unrelated?
	◆ Progressive baseline pain (> 12/24 hours) or breakthrough pain?
	◆ Medications, dosages, and responses over past 24–48 hours?
	◆ Severity:
	  • if ≥ 7/10 or equivalent and fully alert, initiate step 2
	  • if < 7/10 or not fully alert, further assessment is warranted

Step 2: treat severe pain[a]	Opioid naïve: ◆ Dose: 0.1 mg/kg intravenous morphine or equivalent[b] Opioid tolerant (> 60 mg morphine or equivalent per day for at least 1 week): ◆ Dose: 5–15% of daily morphine equivalents IV[b]
Step 3: reassess (15 minutes if intravenous; 30 minutes if subcutaneous)	◆ Apply same pain scale assessment ◆ Assess for unwanted side effects such as somnolence, nausea, or confusion
Step 4: achieve adequate pain control	◆ If still > 7/10 or equivalent, administer double initial dose[c] ◆ If < 50% improvement, administer same dose[c] ◆ Repeat steps 3 and 4 until pain is adequately controlled or unwanted side effects limit further escalation.

Step 5: disposition and follow-up plan	◆ Consider hospital admission:
	  • inadequate control of pain
	  • persistent side effects
	◆ Collaborate for outpatient continuity (consultants and/or primary providers)

[a] Patients with renal, hepatic, or pulmonary dysfunction should have initial dose reduction of 25–50% or more depending on clinical judgement.
[b] May use subcutaneous route if intravenous unavailable.
[c] Patient is fully alert and without unwanted side effects.

feel ill-prepared for such meetings in the emergency department or the clinical situation is changing too rapidly for a family meeting to occur.

Similar to the guidelines for conducting a family meeting (Hudson et al., 2008), one strategy for effective goals of care discussions in the emergency department uses a seven-step approach:

1. getting started

2. assess what is known

3. explore expectations and hopes

4. suggest goals

5. recommend

6. confirm

7. plan (EPEC, 2010).

Step 1: getting started

Like other communication strategies, start by acquiring sufficient information and limiting environmental distractions in order to conduct the meeting effectively. Have the questions clear in your mind, have the necessary family and support staff present or on the phone, and introduce everyone involved in the meeting along with their relationship to the patient or role in clinical care. Start with reassurance, such as, 'In an effort to provide the best possible care for. . . , we need to determine which investigators and interventions would be most beneficial'.

Step 2: what is known?

In order to proceed from a common perspective, it is important that the patient or family have a similar understanding of the disease and the prognosis. If there are questions or a lack of clarity, it may be necessary to provide or obtain additional information before proceeding further.

Step 3: what is expected or hoped for?

Whenever possible, the patient's goals should be communicated directly from the patient either verbally or in the form of an advance directive. Eliciting the patient's perspectives may be challenging if the patient has lost the capacity to interact, has never communicated these concerns to their family previously, or both. Often, the patient has spoken to family about conditions they would find acceptable or unacceptable, such as 'I want to be at home with my family when I die', or 'I never want to be left on a machine if I won't recover'. In order to preserve autonomy and objectivity, in such situations, it is helpful to ask the family questions from the perspective of the patient, and to imagine what the patient would want or not want in particular scenarios. If the family is unable to imagine or report the patient's direct perspectives, it may be more useful to ask the family if the patient has ever spoken about others who have died or been critically ill in ways the patient found acceptable or unacceptable. Was hospice involved? Were they held on life-sustaining interventions beyond what appeared reasonable? Was there evidence of suffering? Were there things the patient wished were different? Importantly the question 'What do you want for. . . ?' should never be asked. Instead, 'What would be acceptable for. . . under these circumstances?' assuming that there are viable clinical options.

A common fear among emergency clinicians is that questions about hopes and expectations may lead to responses such as 'do everything'. A productive approach to understanding this general hope is to redirect the focus onto specific burdens and benefits of particular interventions. For example, some patients may want to sustain biological existence regardless of the likelihood of ever achieving awareness. This is very uncommon. For most patients and families, 'everything' often refers to any interventions whose benefits would outweigh adverse outcomes and is most often focused in the minds of families on physical comfort. For persistent requests for high-burden interventions that are unlikely to achieve patient goals, a 'harm reduction strategy'

is recommended. This approach attempts to support reasonable medical interventions within the context of patient-centred goals (Quill et al., 2009).

Step 4: suggest goals

In order to offer reasonable suggestions for goals, the emergency clinician should frame the suggestions in the context of prognosis of hours to days, days to weeks, weeks to months, or months to years. An example might be, 'People close to death often are most concerned with assuring comfort, peace, and dignity in their dying process' or 'People with only weeks to months to live often focus on avoiding the risk of dying in an intensive care unit, and may consider treatments that are not too high of a burden, such as a trial of intravenous antibiotics'.

If the expectations or hopes communicated are medically unachievable, reframing hope towards medically achievable goals can be an effective strategy. Examples include controlling physical symptoms, providing access to emotional or practical support, and assuring dignity (Clayton et al., 2005).

Step 5: make a recommendation

Clear recommendations from the emergency clinician can be a powerful source of comfort for patients and families. The recommendations should be based on medically achievable goals from the patient's perspective whenever possible. For example, a patient may present to the emergency department with advanced cancer and severe functional impairment who is demonstrating ventilatory insufficiency, but had previously communicated they never wanted to 'die on machines'. If the patient is unlikely to ever achieve ventilator independence or survival off a ventilator, then a recommendation to focus on controlling dyspnoea and avoiding intubation will be more concordant than a recommendation to proceed with intubation. Likewise, if the same patient were at risk for imminent cardiac arrest and death, an understanding of likely outcomes of CPR would inform your recommendations. Patients and families often have unrealistic understanding of CPR (Heyland et al., 2006). Cardiac arrest itself portends an extremely poor prognosis, and patients with advanced illness with poor function at baseline are unlikely to survive CPR and almost certainly will not regain pre-arrest levels of function (Ebell et al., 1998; Ewer et al., 2001; Peberdy et al., 2003; Reisfield et al., 2006; Young 2009; Sasson et al., 2010). For patients who survive attempts at CPR with such severe underlying disease, dependence on life-sustaining interventions through end of life is the expectation. Therefore, a recommendation in this setting is to avoid CPR.

Step 6: confirm understanding

Once goals and recommendations are established, consensus dictates any immediate interventions. Summarize the available medical options to support the patient's goals, and assure understanding and agreement. If no consensus can be achieved reasonably, the emergency clinician may need to initiate specific life-sustaining interventions to allow the family time to process what is happening to the patient. In such complex situations, further communication with the family will be necessary after the initial attempts to medically stabilize the patient.

Step 7: plan

A clear plan of care sets the course for appropriate disposition and follow-up. The emergency clinician may focus initially on symptom management while other needs, such as psychosocial distress, are being addressed by other interdisciplinary professionals. If life-sustaining interventions are initiated in the emergency department, then a timeframe and conditions for future discussions should be established.

Death disclosure

Informing a family of the devastating news that a loved one has died is particularly challenging in the emergency department, where the death is often relatively unexpected or sudden. Emergency clinicians may feel uncertain of the best approach, yet they are required to have these extraordinarily sensitive conversations routinely (Stone et al., 2011). Death disclosure is a form of breaking bad news, and educational models exist to teach these skills in the emergency department (Quest et al., 2002; Benenson and Pollack, 2003; Hobgood et al., 2005). Each of these models share four common elements:

- attending to survivors on arrival to the emergency department
- unequivocal communication of the death
- allowing for and reflecting on the emotional response
- offering survivors to view the body of the deceased (Quest, 2008).

A nine-step approach incorporates these elements from the educational models and is recommended for managing death disclosure in the emergency department (EPEC, 2010).

Step 1: preparation

When a family arrives in the emergency department, they may not be aware that the patient has died. In order to limit additional emotional trauma to the family, staff should be prepared to receive them on arrival while the clinician is informed of their presence. The room should be quiet and private with adequate seating, away from other emergency department traffic, and equipped with facial tissues. The emergency clinician should be prepared to immediately respond having all available information (including the patient's full name), and assure that the body is being cleaned and prepared for viewing by the family. Relevant staff such as the physician, nurse, social worker, and chaplain should enter the room together. Mobile phones or pagers should be handed over to colleagues until after the death disclosure.

Step 2: engagement

While universal introductions are essential, when entering the room, the appropriate sense of gravitas must be evident. The initial introductions must state the full name of the patient and all involved staff, while unequivocally identifying the primary survivor and the relationship to the patient. If there are children present, depending on their age and maturity, it might be best to communicate first to the parent separately from the children, then collaborate to determine how best to communicate with them.

Sit down, preferable closest to the primary survivor (whether or not they choose to sit down). Maintain awareness of body language to communicate respect, cultural sensitivity, and engagement.

Step 3: transition

The preferred opening communication to a sudden death in the emergency department is to provide information about the immediate circumstances prior to the patient's death. One approach

may be, 'I'm not sure what you know about what has happened, but I'm afraid I have some bad news about [identify deceased patient by name and relationship to the survivor]. . . ' or 'I'm not sure if you are aware that [deceased patient's name] was involved in a serious accident . . . '.

Step 4: 'dead' or 'died'

It is imperative that any euphemisms be avoided at this stage. Survivors are predictably in a state of emotional shock from the transition statements, so unequivocal language must follow to avoid misperception. An example of clear communication would be, 'I'm sorry to tell you that [patient's full name] has died'.

Step 5: reaction tolerance

Emotional response to devastating news is an unpredictable and individual experience. It may be highly expressive as agony or anger, or it may be profoundly withdrawn or stunned. Allowing time, presence, and empathic but clear communication should quickly stabilize the situation and direct further explorations.

Understanding and engaging empathic responses is a skill that can be both taught and practised. Many clinicians may be uncomfortable with the risk of creating an emotionally uncomfortable situation while in the emergency department. With preparation and practice, emergency clinicians can engage in these necessary interactions with both efficiency and compassion. One useful technique for communicating empathy can be performed in under 40 seconds while improving satisfaction and decreasing the anxiety of the emotional experience for the patient (Fogarty et al., 1999):

◆ Acknowledge:
  • 'This is not what you were expecting.'
  • 'You seem angry.'
◆ Legitimize:
  • 'Many people in this situation would feel angry.'
◆ Explore:
  • 'Can you tell me what you are most concerned about right now?'
◆ Empathize:
  • 'I wish the news were better.'
◆ Commit:
  • 'I will make sure we have a good plan in place before you leave today.'

Step 6: information

The surviving family hopes for a lack of suffering. Although it may not be possible to empirically report on the patient's experiences, it is reasonable to assume that the patient was not experiencing physical suffering once unconscious. If the death was violent or otherwise a difficult death, the clinician can speak to the importance of the interventions used to control pain and suffering prior to death.

Information about the patient's underlying medical conditions is often needed to understand and report on the likely cause of death, and may help provide additional closure if related to a known illness. An approach might be, 'To better understand what happened to [deceased patient's name], may I ask you some questions about his/her medical history? I can also tell you what we know and answer any questions you may have'.

Step 7: viewing

Family typically will choose to view the deceased person, and it should be offered. It may work best to have support staff guide the family into the room, and assure ongoing availability nearby.

Step 8: conclusion

Prior to leaving the family, the clinician should offer condolences and provide contact information for any additional questions.

If the deceased is a child, support staff can offer to provide the bereaved something tangible from the child, such as a lock of the child's hair to take with them.

Step 9: self and staff care

Death experiences in the emergency department can be exhausting for everyone involved, particularly if a child has died, or if the death was violent, or if the death triggers transference of personal memories for clinicians or other staff. It can be helpful to ask involved staff how they are managing and to verbalize feelings or distress. Staff should consider a routine debriefing just after the death disclosure and possibly after work, or with other friends and family or with a trusted third party.

Family presence during resuscitation

There is increasing acceptance for allowing family presence during resuscitation in the emergency department in both adults and paediatrics (Kleinman et al., 2010; Morrison et al., 2010). Parents in particular want to be given the choice to be present at the bedside of their child during CPR and those who have lived through the experience were grateful and would repeat the experience if faced with it again. Although family members generally do not create interference, there remains significant apprehension among clinicians and variability in practice. Clinicians vary in their level of comfort or even their perceptions of the appropriateness of including family members in a resuscitation event. Policies encouraging the use of family presence during resuscitation are recommended to promote more uniformity in practice (Dingerman et al., 2007; Tinsley et al., 2008; Dudley et al., 2009).

Although no consensus guidelines are available to provide universal recommendations, certain common themes have emerged from the literature to guide practice (Boudreaux et al., 2002; Agard, 2008; Doolin et al. 2011). First, although family presence should certainly be encouraged, the situation may dictate whether or not to proceed. Certain conditions should be met to assure comfort of the family members and the medical team. The number of family members may need to be limited during the initial phases of resuscitation, while 'final goodbyes' may be encouraged by a controlled process of bringing in other family members as the patient ceases to respond to reasonable resuscitative efforts. A 'family support person' should be identified from the staff, freed of other clinical responsibilities to remain with the family members throughout the resuscitation. The family support person can be a social worker, chaplain, or nurse. They should be trained sufficiently to guide the family members through the medical process by interpreting events and provide psychosocial support, while monitoring behaviours and assuring a controlled situation (Farah et al., 2007).

Given the common discomfort expressed by clinicians regarding family presence, a stepwise structure may help to guide clinicians while also meeting the needs of the staff and the family.

Step 1: introduction

As the essential family members are brought into the room by the family support person, the family support person should introduce the family members. The resuscitation team leader should then introduce themselves as the 'doctor responsible for the care of your [state relationship to the patient, such as "husband"]'.

Step 2: status

Either the resuscitation team leader or a delegate reviews the situation and current status in clear and concise terms. For example, 'Your husband's heart has stopped beating and we are trying to restart the heart'.

Step 3: prognosis

Given the high likelihood of death in cardiac arrest, it is prudent to warn the family members of the seriousness of the situation. A statement such as, 'As you can see, this is an extremely serious situation, and we are worried that your husband may not survive'.

Step 4: plan

State the plan of further care, such as, 'We are giving him powerful medications and electricity to try to restart his heart'.

Step 5: provide

Provide standard resuscitation as indicated by the situation.

Step 6: review

A. Return of spontaneous circulation:

   a. Review: provide a quick summary of the events leading to return of spontaneous circulation.

   b. Plan: state what will be done to maintain the patient's condition while attempting to move the patient to the intensive care unit for further interventions.

B. No return of spontaneous circulation:

   a. Overview: provide a brief summary to serve as a warning communication. For example, 'Mr Jones' heart has stopped and he is not responding to therapy'.

   b. Review: in anticipation of stopping the resuscitation due to lack of response, summarize all the relevant interventions that have been performed to create a clear picture of the course of events for the staff and the family members. An example might be, 'Please allow me to review the course of events. We have a secure airway with good lung ventilation. We have performed effective chest compressions for 30 minutes. With refractory ventricular fibrillation, we have attempted defibrillation multiple times, given a total of 3 mg adrenaline and 300 mg amiodarone, yet we have not achieved spontaneous circulation and (Mr Jones) is now demonstrating asystole on the monitor'.

   c. Recommendations: while continuing resuscitative efforts, the team leader may consider asking for any other recommendations from other team members. This establishes team concordance and assures that all reasonable medical efforts have been performed to the level of comfort of the entire team, as witnessed by the family.

   d. Transition: in a firm but compassionate manner, prepare the family members for the discontinuation of resuscitation. It may be appropriate at this time to tell the family that the heart is not responding. It may also be an important opportunity for any essential family to come into the room to see or touch the patient before death is pronounced.

   e. Pronouncement: the formality of a death pronouncement not only defines a clear time of death to the staff, but it also communicates the unequivocal truth for the family that the patient has died. For example, 'With consensus, the patient is pronounced dead at 22:17 hours'.

   f. Condolence: create silence and the space to grieve by turning off all alarms and monitors, offering condolences to the family, and offering to speak to any remaining family outside of the resuscitation room.

Step 7: acknowledge

It is essential to acknowledge with gratitude the difficulty of the event, the skill of the staff, and effort put forth to attempt to save the life of the patient. For example, 'Thank you team. This is never easy. I appreciate your skill and hard work'.

Step 8: inform

Either offer to inform the remaining family independently, or offer to bring the family members in the room to the others to inform them of the patient's death. As with other death disclosures, this would be an appropriate time to gather additional medical information to better understand the cause of death.

Step 9: self and staff care

The same principle applies as with death disclosure (see earlier subsection). Debriefing after attempts at resuscitation is an excellent method of assuring that all concerns about the resuscitation are addressed. It is also an important time for self-reflection and staff assessment prior to returning to patient care.

Palliative care in the nursing home

Jane L. Phillips, Annmarie Hosie, and Patricia M. Davidson

Introduction to palliative care in the nursing home

Internationally, ageing, technological advances, evolving patterns of disease and disability, and changes in family structures have resulted in nursing homes becoming the final residence for many frailer older people. Many terms are used to describe the nursing home setting, including 'care homes', 'residential homes', 'residential aged care facilities', and 'aged care', 'skilled-care', or 'long-term care facilities'. In this chapter 'nursing homes' are defined as collective institutional settings where continuous care is provided for older people throughout the 24-hour period, 7 days a week on an ongoing basis (Hall et al., 2011). Much of the on-site assistance with activities of daily living in nursing homes is predominately provided by an unregulated or minimally trained carer workforce with registered nurse supervision. Professional nursing and medical care is provided either by on-site or visiting doctors, nurses, and allied health professionals from external services.

In the United States, there are currently 1.6 million older people living in nursing homes ('residents') (Ouslander and Berenson, 2011). The unprecedented demand for institutional care by people aged over 85 years is likely to continue to increase and has significant cost implications and considerations for the health workforce. In Australia alone, during 2009 to 2010, a one billion dollar increase in the aged care budget was needed to fund an additional 4550 nursing home beds just to meet existing demand (Australian Institute of Health and Welfare, 2011). In the United Kingdom, 15 700 nursing homes currently provide care to over 400 000 residents (Mathie et al., 2012). In Canada, nursing home beds now exceed the number of acute care beds (Canadian Institute for Health Information, 2007). Given these trends nursing homes will continue to be major providers of palliative care for the frail aged and for people whose complex care needs exceed available community resources and capacity of family caregivers.

Admission to a nursing home is frequently the consequence of caregiver burden or living alone, care needs exceeding available community resources, or needing end-of-life care (Seymour, 2011). Currently, the majority of all residents are aged over 85 years, with three-quarters having high care needs related to behaviours, activities of daily living, or complex health-care needs (Australian Institute of Health and Welfare, 2011). Whereas residents once lived in nursing homes for longer periods, over a third (38%) now die within a year of admission, with a quarter of these

deaths occurring within the first 6 months (Australian Institute of Health and Welfare, 2011). Between 16% and 30% of all deaths in the developed world now occur in nursing homes: United States, 24% (Goldberg and Botero, 2008); United Kingdom, 17% (Tebbit, 2008); Canada, 30% (Motiwala et al., 2006); and Australia, 16% (Australian Government Department of Health and Ageing, 2010). Despite this unprecedented demand, disparities in resources and infrastructure (Brennan, 2007) continue to impact on residents' access to palliative care.

This chapter details the palliative care needs of older people living in nursing homes and the challenges and opportunities to deliver better end-of-life care to this population; and proposes utilizing the Chronic Care Model as a framework for delivering the elements of a *palliative approach* to improve care outcomes for residents and their families.

Demography and epidemiology of dying in a nursing home

With advancing age comes an increased incidence of chronic co-morbidities, such as stroke, heart failure, chronic obstructive pulmonary disease, degenerative neurological disease, arthritis, dementia, frailty, visual impairment, and hearing loss (World Health Organization, 2011). The six leading causes of death of people aged over 65 years in the United States are heart disease (44%), cancer (29%), stroke (11%), chronic obstructive pulmonary disease (8%), influenza and pneumonia (4%), and diabetes (4%) (Federal Interagency Forum on Aging-Related Statistics, 2008). Approximately two-thirds of all US nursing home residents have two or more co-morbidities (Wolff et al., 2002), with approximately half having a diagnosis of dementia, while in the United Kingdom it is estimated that 40% of all older people admitted to nursing homes have dementia (British Geriatrics Society, 2012). Alzheimer's disease is now the seventh leading cause of death in the United States (Alzheimer's Association, 2011), and people with dementia are more likely to die in a US nursing home, compared to people dying with cancer and/or from other conditions (66% vs 20% vs 28%, respectively) (Alzheimer's Association, 2011).

Alongside the prevalence of multiple chronic conditions, many residents have unrelieved symptoms, have lower use of hospice care and more hospitalization, are the recipients of poor communication, have less capacity and opportunity to participate in advance care planning, and experience more family dissatisfaction (Oliver

et al., 2004; Munn et al., 2006). Residents with advanced dementia are often unable to communicate their needs or participate in decision-making and rely on substitute decision-makers (van der Steen, 2010). They are also more likely than residents with cognition to experience pneumonia and/or eating difficulties (van der Steen, 2010). Residents with cognition have expressed concerns that they often have too little involvement in decision-making, limited access to someone to discuss their concerns, limited access to appropriate information, and that tests and results are often not clearly explained (Wetle et al., 2005).

Older people with dementia nearing the end of life experience significant symptom burden including, but not limited to, pain, breathlessness, discomfort, restlessness, agitation, difficulty swallowing, aspiration, and pressure ulcers (Mitchell et al., 2009; van der Steen, 2010). Up to 83% of people living with dementia in nursing homes experience pain, while between 12% and 32% experience breathlessness at some point in their disease process (Mitchell et al., 2009). Similar to other illness trajectories, these symptoms frequently increase as death approaches (Mitchell et al., 2009). Consequently, many deaths in nursing homes are not considered to be a good death, that is, a death 'free from avoidable distress and suffering for patients, families and caregivers; in general accord with patients' and families' wishes; and reasonably consistent with clinical, cultural and ethical standards' (Field and Cassel, 1997, p. 24). Over the past decade there has been increasing recognition and acceptance of the need to extend palliative care to underserved populations such as nursing home residents.

Challenges

Despite the burden of co-morbidities and prevalence of distressing symptoms in this population, there is still minimal integration of geriatric care, chronic disease management, and palliative care in either the clinical or research context. Advanced dementia has a long and unpredictable illness trajectory, setting it apart from other terminal illnesses. A focus on 'healthy ageing' has made it difficult to draw attention to the policy and practice changes required in nursing homes to provide palliative care (Abbey et al., 2006), while organizational and clinical factors impact on the capacity of nursing homes to manage residents' chronic diseases and their subsequent end-of-life care (Seymour, 2011). There are also few evidence-based guidelines (Australian Department of Health and Ageing and National Health and Medical Research Council, 2006) to assist aged care clinicians effectively manage the multiple co-morbidities experienced by an older, frailer nursing home population (Weiss et al., 2007). The evidence-based guidelines that do exist rarely acknowledge how to effectively manage more than one chronic and complex illness or consider drug–drug and drug–disease interactions in older people (Weiss et al., 2007).

Complex operating environment ripe for reform

Nursing homes have developed separately to palliative care in spite of the importance of these needs (Hockley et al., 2010). Nursing homes are complex care environments, largely constructed as an 'industry' as opposed to a 'service', as a result of many of them functioning in private business models. In many countries, increasing longevity has prompted the transition of nursing homes from a welfare model towards a user pays system, with an economic emphasis to minimize labour costs and maximize profits. A meta-analysis using data from both observational and randomized control trials found that an organization's financial operating status impacted on some aspects of nursing home quality, with not-for-profit homes having more or higher quality staffing compared to for-profit nursing homes; and that not-for-profit nursing homes delivered higher quality care on average compared to for-profit homes (Comondore et al., 2009). Business models and predominance in the private sector have meant reform within this care sector has been difficult to achieve and monitor, with significant change only occurring in response to legislation (Chenoweth and Kilstoff, 2002). However, not all legislative change has impacted positively on residents' outcomes. In countries such as Australia where the legislative need for 24-hour care provided by a registered nurse has been repealed, the resident to registered nurse ratio has been significantly altered (Angus and Nay, 2003). As a result, older people admitted to Australian nursing homes are now largely cared for by unregulated workers (Richardson and Martin, 2004) supported by a smaller ratio of registered nurses, who are relegated increasingly to management duties (Angus and Nay, 2003). This workforce profile presents challenges when palliative care demands a skilled nursing response and resident and family care needs are increasingly complex. These changes in skill mix have also increased the demands on the acute care sector.

Medical care in nursing homes varies considerably across countries and is largely shaped by funding mechanisms and local policy. In the majority of countries, medical care is provided by doctors employed directly by the nursing home (Donald et al., 2008), whereas in the United Kingdom and Australia, general practitioners (GPs) are the main providers of medical care to nursing home residents on a fee-for-service basis (Gadzhanova and Reed, 2007). However, the visiting GP model presents challenges, as the time-consuming nature of nursing home visits, especially when residents are scattered across multiple facilities, onerous documentation, and poor remuneration all impact on GPs' willingness to provide medical care in this setting (Glendinning et al., 2002; Gadzhanova and Reed, 2007). There is growing concern that medical services to nursing homes are inadequate to meet current needs, let alone future demands, with many nursing homes finding it increasingly difficult to secure medical care (Glendinning et al., 2002; Gadzhanova and Reed, 2007).

From the consumer perspective, many residents and/or their families are often forced to establish a relationship with a new GP when admitted to a nursing home, largely because they have been admitted to a nursing home in a geographical area not serviced by their usual GP, their usual GP doesn't have formal links with the nursing home, and/or doesn't provide a nursing home service (Gadzhanova and Reed, 2007). In the United Kingdom, this challenge has been partially addressed through nursing home management entering into ad hoc remuneration arrangements with GPs to secure ongoing medical care for their residents (Glendinning et al., 2002). Limited access to timely medical care often precludes development of appropriate processes to identify and manage each resident's decline (Wetle et al., 2005) and contributes to unnecessary and often distressing hospital admissions (Ahronheim et al., 1996).

Reducing avoidable hospitalizations

In 2005, there were potentially $3.1 billion of avoidable US hospitalizations, with 85% of these total costs related to nursing home

residents being transfers to acute care (Ouslander and Berenson, 2011). In the United States, higher health-care expenditure in the last 6 months of life is associated with decline in functional status, ethnicity, certain chronic conditions, and lack of nearby family support, regardless of regional characteristics (Kelley et al., 2011). Poor transitional care processes also contribute to substantially high readmission rates for residents (Quinn, 2011). It is estimated that one in four older people admitted to a US nursing home directly from hospital has an acute care readmission within 30 days (Ouslander and Berenson, 2011). Hospitalization for older people is dangerous and associated with reduced function, and increased morbidity and mortality (Ouslander and Berenson, 2011). Over the past decade reducing nursing home hospitalization rates has been a policy priority across the developed world (Grabowski et al., 2008), largely driven by the need to reduce both the adverse effects of hospitalization and excessive health-care costs (Kelley et al., 2011). Averting this trend requires multifaceted interventions that strategically build the capacity of nursing homes to better align the resident's goals of care with hospitalization decisions and in the process, change institutional patterns of care, physician practice patterns, and resident and family preferences (Kelley et al., 2011).

Access to hospice and specialist palliative care input

In the United States, the Medicare Hospice Benefit supports the delivery of hospice care across all care settings, including nursing homes where just over a third (36%) of all beneficiaries reside. Three-quarters (76%) of US nursing homes now have an established contract with a hospice provider (Gozalo and Miller, 2007). Hospice care increases the resident's access to palliative care expertise and care protocols, improved pain management (Miller et al., 2002), reduces hospitalization rates during the last month of life (Gozalo and Miller, 2007), and reduces the number of residents who die in hospital (Munn et al., 2006; Gozalo et al., 2008). In contrast, hospitalized patients with dementia are more likely than non-demented patients to have a longer terminal stay (Guijarro et al., 2010) and less likely to receive palliative treatment or have their families involved in decision-making (Afzal et al., 2010). Despite the positive benefits of access to hospice care, the US hospice care eligibility restrictions frequently result in late referrals, especially if families don't fully understand the role and advantages of engaging hospice services (Wetle et al., 2005).

Hospice enrolment substantially reduces care costs (22%) for residents, with shorter nursing home admissions (≤ 90 days) and a small cost reduction (8%) for residents with cancer who have longer stays (> 90 days). Whilst hospice care is cost-neutral for people with dementia, it increases care costs (10%) for people with a diagnosis other than cancer or dementia due to diagnostics (Gozalo et al., 2008). However, access to hospice care is influenced by disease type and proximity to services, with residents with a cancer diagnosis and who live in relatively close proximity to a hospice more likely to be enrolled in hospice (Gozalo and Miller, 2007), than residents with dementia (Munn et al., 2006). In countries with universal health care, access to specialist palliative care services for nursing home residents is underpinned by a population-based approach, where specialist teams provide a consultative service for residents with more complex palliative care needs (Palliative Care Australia, 2005a). However, access to these specialist palliative care teams similarly varies due to geographical or resource allocation barriers.

Opportunities
Promoting a palliative approach in nursing homes

Nursing homes now lie at the interface between continuing care and palliative care (Froggatt, 2001) and increasingly function as slow-stream hospices (Phillips et al., 2006). Given this changing role there is a need to develop new models of care that promote a palliative approach in the nursing home setting. A palliative approach is care that has the potential to improve the quality of life for older people with any life-limiting condition, and their families, by reducing their suffering through early identification, impeccable assessment, and treatment of pain, physical, psychological, social, cultural, and spiritual needs (Australian Department of Health and Ageing and National Health and Medical Research Council, 2006). A palliative approach ensures care is tailored to address residents' and their families' needs, well before the last days or weeks of life. Focusing attention on a palliative approach helps achieve the best possible quality of life for older people and their families by facilitating: (1) evidence-based symptom management; (2) appropriate decision-making support and goal setting, including advance care planning; (3) access to practical aid, community resource, and specialist palliative care advice or support as required; and (4) collaborative and seamless end-of-life care within the nursing home (Davidson and Phillips, 2012).

A palliative approach enables a larger proportion of older people to live and die comfortably in this care setting, as opposed to being transferred to acute care (Reymond et al., 2011). Implementing a palliative approach requires nursing homes to focus on strategies to better manage residents' symptoms, develop an ethos of care that openly acknowledges that death frequently occurs in this setting, attend to residents' spiritual needs, offer caring and appropriate information to residents and their families, attend to the needs of residents' families and friends, and be mindful of the needs of staff (Sander and Russell, 2001). Adopting a palliative approach to care is of equal, if not of more value, to the family than to the person dying (Kristjanson et al., 1996). Given the prevalence of dementia in this population, attending to a resident's substitute decision maker's needs is a high priority, especially as the quality of care at the end of life may be an important predictor of bereavement outcomes (Gauthier and Gagliese, 2012).

A recent Cochrane review (Hall et al., 2011) examining multi-component interventions to enhance the provision of a palliative approach in nursing homes identified weak evidence for the following three elements of care: (1) communication, with a focus on identifying residents who would benefit from a specialist palliative care referral and negotiating this with their treating doctor and family (Casarett et al., 2005); (2) the development of palliative care leadership teams, technical assistance meetings for team members, education in palliative care for all staff, and feedback on performance (Hanson et al., 2005); and (3) targeted symptom control strategies to improve discomfort (Kovach et al., 1996). In addition to these three elements a palliative approach in nursing homes also requires a commitment to: (1) person-centred care; (2) creating a palliative care team for each resident based on need; (3) optimizing symptom control; (4) advance care planning; and (5) timely recognition of dying.

Person-centred care

Person-centred care places the resident at the centre and recognizes individual differences, preferences, and cultural diversity, with cultural and religious beliefs and practices surrounding death and dying integral to providing a person-centred palliative approach to older people in nursing homes (Clark and Phillips, 2010). Mead and Bower (2000) have identified five distinct patient–provider relationship dimensions that shape patient-centred care, which can be equally applied to resident care, including the: (1) bio-psychosocial perspective; (2) 'resident as person'; (3) sharing power and responsibility; (4) therapeutic alliance; and (5) 'physician as person'. Influential factors relating to the resident, health professional, consultation, professional context, and societal 'shapers' all need to be acknowledged and taken into consideration to achieve person-centred care (Mead and Bower, 2000).

When considering a person-centred palliative approach, key priorities of residents nearing the end of life with decision-making capacity are: (1) being active to the very last; (2) having one's will respected and being allowed to die; (3) not being in pain; and (4) being amongst persons close to one (valediction and showing respect) (Pleschberger, 2007). When asked about their end-of-life care expectations, residents with decision-making capacity indicated that they hadn't spoken to aged care personnel about this issue but assumed that their family or primary care physician would take responsibility for making these decisions (Mathie et al., 2012). Other than with decision-making capacity, other factors that influenced residents' ability to discuss end-of-life care was their level of acceptance of living in a nursing home, family involvement in making decisions, and self-efficacy about their capacity to influence everyday decision-making (Mathie et al., 2012). Families have expressed concerns that they were unaware the resident was nearing the end of their life and that dying residents' needs weren't sufficiently addressed, because of difficulties accessing medical care and the limited palliative care capabilities of aged care personnel (Miller et al., 2004; Wetle et al., 2005). While little is known about the end-of-life wishes of residents with cognitive impairment, evidence from the literature suggests that a 'good death' from their families' perspective is a combination of good symptom management, clear decision-making, good preparation for death, completion and affirmation of the whole person, and a smooth transition from usual care to terminal care (Bosek et al., 2003; Gibson and Gorman, 2010).

Creating a palliative care team for each resident based on need

Providing a palliative approach requires the creation of a care team for each resident based on their individual needs. For the majority of residents, the primary aged care team (nurses, care assistants, GPs/physician, family, divisional therapists, and volunteers) can readily provide this care. Residents with complex care needs can benefit from input from external specialists, such as the specialist palliative care, aged care, or psycho-geriatric services (Casarett et al., 2005). In some situations, establishing a shared care model of palliative care, that includes primary health, community-based services, as well as external specialist services, is required to address the resident's and their family's palliative care needs (NSW Health, 2011). Strengthening the linkages between care providers may help to reduce avoidable hospitalizations, especially if community-based health professionals can effectively meet the resident's care needs (Ouslander and Berenson, 2011). There is emerging evidence that a single palliative care assessment shortly after nursing home admission may be the most effective format for optimizing the resident's palliative care outcomes. A recent non-blinded prospective comparison trial involving older people (n = 81) living in three US assisted living facilities found that palliative care assessments conducted at 3-monthly intervals were no better than a single early palliative care assessment in improving palliative care outcomes (Jerant et al., 2006).

Effective team communication is integral to a palliative approach, with case conferencing being an ideal forum to facilitate the delivery of multidisciplinary care. This approach brings together relevant health professionals and the resident's primary decision-makers, usually family members, to discuss the current stage of illness and agree on a person-centred management plan based on best available evidence (Abernethy et al., 2006; Phillips et al., 2013). Case conferencing can improve care outcomes for older people with advanced dementia living in nursing homes through better communication, coordination and engagement of relevant health professionals, residents and their families in a collaborative care planning process, promotion and adoption of more appropriate symptom management strategies, reducing unnecessary hospitalizations, and promoting seamless transitions, if hospitalization is required (Phillips et al., 2013).

Optimizing symptom control

Adopting a palliative approach requires that the symptoms of residents be assessed and managed in a timely and appropriate manner. This is crucial given the symptom burden in this population with approximately (60%) of residents estimated to have dementia, half (40–50%) experiencing pain, and 40% being classified as depressed (The Royal Australian College of General Practitioners, 2006). Older residents with non-malignant diseases and those with cognitive impairment are most at risk of inadequate assessment and management of pain in all care settings, including nursing homes (Abbey et al., 2004). As a commitment to impeccable assessment is an integral component of a palliative approach (World Health Organization, 2003), ensuring aged care providers have access to validated symptom assessment tools that are both sensitive to the needs of older people with multiple co-morbidities and high levels of cognitive impairment is crucial. Selecting assessment tools that are reliably and easily administered by a diverse and largely unskilled carer workforce is also an important consideration (see Chapter 7.1).

Polypharmacy and cognitive, behavioural, and swallowing problems make medication administration in this setting a complex, time-consuming, and potentially hazardous activity, especially if the nurse is unfamiliar with the resident (Thomson et al., 2009). Polypharmacy and adverse drug reactions are common in the nursing home setting, with residents being prescribed an average of ten medications (Patterson et al., 2010). While various strategies have been initiated at an international, national, state, and local level to improve the quality of prescribing and reduce medication errors in nursing homes (Hughes et al., 2011), few clinical trials have evaluated systematic withdrawal of medications among older people (Beer et al., 2011).

The time-consuming nature of medication administration as residents lose their ability to swallow may also influence decisions

to insert a feeding tube for a nutrition and medication administration route, with a complex mix of financial, organizational, demographic, and ethnic factors, as opposed to best evidence (Mitchell et al., 2003), also impacting on feeding tube insertion decisions. Yet, there is little evidence that enteral tube feeding confers any survival benefit for people with advanced dementia and there is little data about its adverse effects (Sampson et al., 2009). In some countries, system-wide incentives are promoting inappropriate use of tube feeding, undermining residents' safety and quality of life (Finucane et al., 2007).

Advance care planning

Whilst death is frequent in nursing homes, advance care planning has traditionally not been raised or discussed in an open and honest manner with residents and their families. In the absence of an up-to-date advanced care plan or previous conversations with the resident and/or their family, aged care personnel often feel compelled to transfer the resident to hospital, as they may be unsure of the resident's wishes, as well as being ill-prepared or unable to manage specific clinical situations. It is estimated that approximately 40% of residents with advanced dementia receive at least one burdensome treatment in the last 3 months of life because they don't have a documented advance care plan (Mitchell et al., 2009). Many of these inappropriately used invasive treatments compromise comfort for little or no survival benefit, whilst impacting adversely on family satisfaction with care (Meier et al., 2001; Givens et al., 2010).

Proactive advance care planning conversations in the nursing home setting offer the multidisciplinary care team, residents, and their family an opportunity to: (1) identify an appropriate substitute decision-maker; (2) clarify resident's values and preferences over time; and (3) to consider what action they would take when the resident's health deteriorates (Sudore and Fried, 2010). These structured conversations are also critical to reducing unnecessary hospital re-admissions (Quinn, 2011). A US study has demonstrated that conducting a structured interview to identify residents with palliative care needs resulted in residents being more likely to be enrolled in hospice within 30 days and fewer acute care admissions. Residents' families also rated the care provided more highly than those receiving usual care (Casarett et al., 2005). In another study, conducting a brief 15-minute advance care planning conversation with families of the resident with advanced dementia's transition to nursing home also increased families' satisfaction with care (Engel et al., 2006).

Timely recognition of dying

In the nursing home setting, death typically follows one of four final pathways: (1) a sudden death; (2) a death following a terminal illness; (3) a death following an acute episode; or (4) a death following a process of general deterioration (Sidell et al., 1997). While older people in the community in the year preceding death experience varying levels of disability, ranging from severe to no disability, the predictable pattern of deterioration identified for residents with advanced dementia is a trajectory of persistently severe disability (Gill et al., 2010). A pattern of deterioration occurring over months and sometimes years adds to the uncertainty of determining exactly when a transition to a palliative approach is indicated for a resident. Reserving palliative care for residents who are dying is of limited value, for the majority of residents will have experienced symptoms and distress as part of their slow and gradual decline (Lynn and Adamson, 2003).

The ambiguity created by this discordance impacts on aged care providers' ability and confidence to accurately determine when palliative care is indicated. In the United Kingdom, the National Health Service has recommended that primary care providers consider the 'surprise question', that is: 'Would I be surprised if this person were to die in the next 6–12 months?' (Lynn and Adamson, 2003). Despite concerns about the suitability of this approach for people with heart failure and chronic obstructive pulmonary disease (COPD) being raised (Small et al., 2010), if used as a screening question, the 'surprise question' can prompt the multidisciplinary team to review the resident's care needs and plan accordingly (Murray and Boyd, 2011).

In planning for the resident's end-of-life care, consideration needs to be increasingly given to deactivate implantable cardioverter-defibrillators, which produce painful shocks at the end of life and are distressing for the family to witness (Goldstein et al., 2010). Similar to hospices, nursing homes need policies and procedures to proactively identify residents with these devices and to ensure that there is an appropriate deactivation plan for when it is deemed appropriate to do so. Conversations about managing these devices needs to be documented in the resident's medical records and goals of care, including such details as how this device will be managed at the end of life, who will be responsible for deactivating the device, and ensuring the device's deactivation instructions are accessible within the nursing home (Goldstein et al., 2010).

A proposed framework for implementing a palliative approach

While there is a growing body of evidence to guide the delivery of palliative care in nursing homes, many aged care providers find it difficult to implement and apply a palliative approach in a systematic and strategic manner. The Chronic Care Model (Wagner et al., 2001) is a useful conceptual model to identify the action required at the consumer (resident and family), health professional, and system levels to strengthen the provision of a palliative approach in nursing homes. The Chronic Care Model has previously been used by a diverse range of health-care organizations to improve health-care delivery to people with chronic and complex illnesses (World Health Organization, 2002). Applying the Chronic Care Model in nursing homes would ensure that the needs of residents and their families remain the focus of care (Fig. 3.4.1 and Table 3.4.1), whilst acknowledging the fundamental importance of the following:

1. Enabling positive policies that promote the delivery of a palliative approach at the systems level, along with executive support and sponsorship at the organizational level.

2. An adequately prepared workforce with the prerequisite geriatric and palliative care capabilities, plus a commitment to maintaining an adequate workforce skill mix in nursing homes to respond to the population's changing clinical profiles.

3. Supporting collaborative partnerships across care settings to better meet the needs of residents, especially those with complex care or symptom control needs.

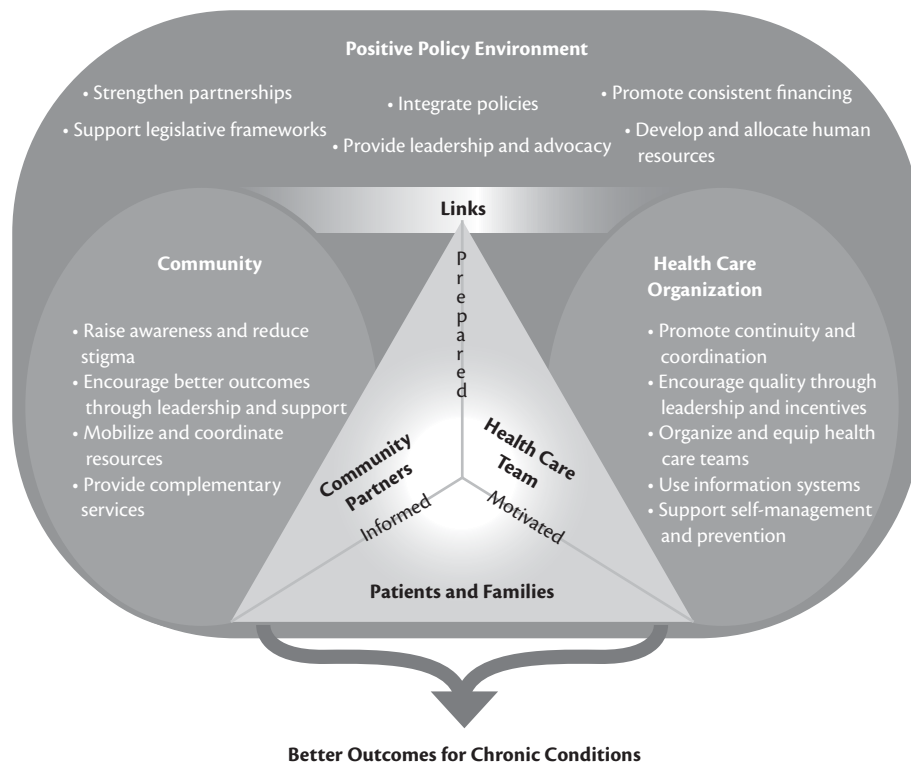
4. Access to decision support tools for aged care nurses, care assistants and GPs so they are able to provide evidence-based care and identify when expert assistance ought to be sought.


Fig. 3.4.1 The WHO Chronic Care Model—'Better Outcomes for Chronic Conditions'. The WHO Chronic Care Model helps identify the action required to integrate a palliative approach into the nursing home sector by addressing the key elements required for change at the systems level (see also Table 3.4.1).

5. Access to clinical information systems, including point-of-care evidence, electronic health records, and electronic prescribing systems to support care delivery.

6. Empowering consumers to take greater responsibility for their health by focussing on engaging residents with capacity and their families in the care planning and decision-making process.

Positive public policy

There are numerous opportunities to reorientate health-care systems through positive public policy to better support the delivery of a palliative approach in nursing homes. For example, while historically US policies such as nursing home regulations which emphasize rehabilitation, a 6-month life expectancy being a hospice eligibility criterion, and external monitoring of hospice referral patterns and contractual relationships between nursing homes and hospice providers were all considered appropriate, these policies are now effectively limiting the enrolment of residents in hospice programmes (Hoffmann and Tarzian, 2005). Similarly, given the uncertain illness trajectory of many residents, the incentive for US hospice providers not to exceed the aggregated payment cap for its beneficiaries is another potential hospice enrolment barrier (Stevenson and Bramson, 2009).

Current nursing home funding regulations also reinforce a task-orientated approach to care delivery, making it difficult to tailor care to meet each resident's individual needs. The frailty and complexity of a resident's care needs demand that care subsidies reflect the actual level of care required. Only with adequate reimbursement will nursing homes be able to employ enough

appropriately trained professionals, including nurses and care assistants, to meet the complex health needs of residents.

An environment of increasing technological complexity, where older people with higher acuity are increasingly being managed within nursing homes for shorter periods of time before dying now demands that a palliative approach be implemented from the moment a person enters a nursing home (Phillips et al., 2007) and be acknowledged as an integral responsibility of the sector. Yet, the fragmented nature of most health systems ensure that traditionally there has frequently been little connection and integration of aged care services and health (Australian Government Department of Health and Ageing, 2010). In Australia, for example, while quality standards for aged (Aged Care Standards Agency, 2001) and palliative care (Palliative Care Australia, 2005b) both exist, neither currently acknowledges the unique and often complex palliative care needs of older people in nursing homes. In the United Kingdom, there has been better alignment of aged and palliative care standards, with a set of national minimum standards that regulate palliative care in nursing homes, while in France there is a legal requirement that palliative care be implemented in all nursing homes (Froggatt and Reitinger, 2013).

A recent mapping exercise across Europe identified over 60 initiatives to support the development of palliative care in nursing homes (Froggatt and Reitinger, 2013). Whilst the diversity of these initiatives reflects differing priorities and opportunities, it affirms the importance of a palliative approach for residents and their families. A summary of these 60 initiatives is available at <http://www.lancaster.ac.uk/shm/research/ioelc/projects/eapc-taskforce-ltc/ltc_initiatives.pdf>. Unfortunately, many of

Table 3.4.1 The Chronic Care Model as applied to improving palliative care outcomes for nursing home residents

Chronic care domains	Elements	Action required
Positive policy environment	Strengthen partnerships	Encourage engagement and input from specialist services
		Promote inter-sectorial collaboration through clinical networks
	Support legislative frameworks	Link standards to funding and accreditation
		Establish minimum registered nursing to resident ratios
	Integrate policies	Align nursing home and palliative care standards
		Promote advance care planning
	Provide leadership and advocacy	Promote and support priority-driven research
		Build health workforce palliative approach capabilities
	Promote consistent financing	Remove perverse incentives
	Develop and allocate human resources	Appropriate ratio of registered nurses
Community	Raise awareness and reduce stigma	Greater community engagement into nursing homes
		Reduce ageism
		Value the care provided in nursing home
	Encourage better outcomes through leadership and support	Promote a palliative approach in the community
		Workforce continuing professional development
	Mobilize and coordinate resources	Pre-admission nursing home clinics
		Establish advance care planning clinics
	Provide complementary services	Embed palliative care volunteers in nursing homes
Health-care organization	Promote continuity and coordination	Promote person-centred care
		Facilitate 'pop-up' shared palliative care teams
		Ensure specialist input for residents with complex needs
		Establish multidisciplinary case conferencing
	Encourage quality through leadership and incentives	Build workforce palliative care capacity
		Role redesign—nurse practitioners and medical input
	Use information systems	Evidence-based guidelines
		Electronic health records
		Appropriate symptom assessment tools
	Support self-management and prevention	Engage residents and families in advance care planning

these initiatives were undertaken as time-limited 'projects' and have not been sustained due to lack of ongoing funding or organizational support (Froggatt and Reitinger, 2013). Demonstrating that like any reform, embedding a palliative approach in the nursing home setting requires improved alignment of relevant legislation, policies, and standards, supported by appropriate funding.

Community

The general reluctance at a societal level to discuss death and dying also shapes the level of community awareness of palliative care and more specifically, the applicability of a palliative approach for residents. Promoting awareness of a palliative approach across the community will make it easier in the future for aged care providers to discuss this issue with residents and their families. Proactively disseminating information about a palliative approach and advance care planning to prospective residents and families contemplating the transition to nursing home

care supports appropriate care (Lowe et al., 2003). This empowering aspect of a palliative approach helps foster greater awareness amongst the resident and their family of the model of care that is offered within the nursing home and the level of support available to address their end-of-life care needs. It also promotes the creation of more supportive care environments and gently encourages better understanding and capacity of aged care providers and families to deal with death and dying (Kellehear, 1999). In Australia, the recent announcement of a national advance care planning advisory service to actively engage and support aged care providers and GPs to initiate advance care planning discussion with residents and families, will raise awareness of the palliative care needs of residents and the importance of regularly reviewing the goals of care as their health deteriorates.

Volunteers

Nursing homes have traditionally often been isolated from the wider community, but there is an increasing need for them

to seek greater community engagement. A structured and well-managed active volunteer programme is one way of engaging interested and suitable community members in the operation of the nursing home. Volunteers are an important adjunct to the interdisciplinary palliative care team (McKinnon, 2002). In specialist palliative care services, these unpaid workers undertake a range of practical, administrative, and supportive care activities in accordance with local service needs, their personal capabilities, and preferences (Palliative Care Victoria, 2010). Extending or establishing a volunteer programme in nursing homes could enhance the delivery of a palliative approach to older people nearing their end of life.

Building workforce capacity

In addition to adequate staffing, appropriate equipment, good medical support, and greater involvement with specialist palliative care teams, building the palliative approach capacity of aged care professionals is an essential element towards improved care for nursing home residents (Phillips, 2008). Over the past decade, many initiatives at both the local organizational and national level have been implemented to expand the aged care workforce's palliative approach competencies (Froggatt, 2001) through: (1) specialist support and ad hoc education; (2) tailored palliative care education programmes, delivered either face to face or online; (3) building clinical champion capabilities; or (4) a combination of specialist support and tailored education (Avis et al., 1999: Phillips, 2008).

Building the aged care workforces' palliative approach capabilities require a strategic commitment to increasing the palliative content in the vocational, undergraduate, and post-graduate health workforce curricula. A range of continuing professional education opportunities are also needed for registered health professionals to increase their symptom assessment and medication management competencies, particularly related to administering opiates; comfort and confidence to initiate and engage in end-of-life conversations and to discuss death, knowing when to initiate a palliative approach and recognizing dying; and communicating effectively with residents and their families about a palliative approach. Any continuing professional education programme implemented for aged care needs to be configured to be responsive to workforce turnover.

Health-care organization

Organizational elements identified as being critical to success for introducing a palliative approach into nursing homes include: (1) strong and committed leadership; (2) active involvement of the medical director; (3) availability of a nurse with palliative care expertise to guide and support the implementation; (4) presence of an onsite clinical champion; (5) combining a 'bottom-up' and 'top-down' approach to organizational change; (6) implementing change in small manageable increments; (7) inclusion of all staff in the effort; (8) regular meetings where discussions of palliative care occur; (9) maintenance of dying residents within the existing unit structures; and (10) capacity to use the programme as a benchmark of quality care and regulatory compliance (Strumpf et al., 2004). The ability of nursing homes to provide a palliative approach will be influenced by all of these factors.

Reorganizing the health-care workforce

A recent literature review identified several models of primary medical care configured to optimize outcomes in the nursing home setting, including the following:

1. Enhanced medical care provided by lead practices.

2. Provision of modest incentive payments to support lead practices to provide anticipatory care to specific nursing homes through a service level agreement.

3. Attached primary care services: general practices within a defined geographical area agreeing to be linked to specific nursing homes and to provide weekly visits, anticipatory care, and regular reviews.

4. Dedicated primary care service: the local primary care organization establishes a dedicated primary care multidisciplinary specialist service to provide primary care services to local nursing homes which focus on medical care and capacity building, including a focus on end-of-life care planning for people requiring palliative care.

5. Integrated primary and secondary care service: the establishment of a multidisciplinary team, composed of an advanced practitioner nurse, GP, and consultants to deliver comprehensive medical care to older people in nursing homes (Donald et al., 2008).

Nurse practitioners are increasingly being utilized in underserved populations, including older people in nursing homes (Aigner et al., 2004). Assessing the impact of nurse practitioners in nursing homes had largely been undertaken using non-randomized trials including before and after studies (Christian and Baker, 2009), with an absence of raw data being reported preventing meta-analysis. While few studies have focused specifically on palliative care nurse practitioners, a reduction in hospitalization rates and transfers to hospital emergency departments for assessment, reduced lengths of stay for hospitalized nursing home residents, and cost savings (Christian and Baker, 2009), suggests that developing the nurse practitioner role offers exciting opportunities to improve residents' palliative care outcomes. Any intervention designed to evaluate the effectiveness of this role ought to be robustly tested and able to generate level 1 evidence to inform future practice. Robust evaluation of all health workforce redesign initiatives is required to determine their cost-effectiveness and capacity to improve care outcomes for older people in nursing homes.

Decision supports

Various symptom-based guidelines have been developed to support the delivery of evidenced-based care and to assist nursing homes to develop and apply suitable policies and procedures (Abbey et al., 2006). The 'Gold Standards Framework for Care Homes' has been promoted in the United Kingdom (Hockley et al., 2010), while evidence-based palliative approach guidelines have been developed for Australia (Australian Department of Health and Ageing and National Health and Medical Research Council, 2006). These decision support tools have contributed to culture change within the aged care sector and resulted in increases in advanced care planning documentation and a reduction in avoidable hospitalization and hospital deaths (Hockley et al., 2010;

Reymond et al., 2011; Horey et al., 2012). These positive trends need to be confirmed using more robust research designs, such as prospective controlled trials (Phillips et al., 2011).

The introduction of information and communications technology solutions into nursing homes globally aims to improve their effectiveness and efficiency within the sector. These technological advances provide opportunities for better decision support, access to counselling and mentorship, communication across care settings, between health-care professionals and between residents, their caregivers, and the multidisciplinary team (Tung et al., 2011; Green and Levi, 2012). The introduction of electronic health records in Australian nursing homes has improved the convenience and efficiency of essential health data processing and empowered aged care providers (Zhang et al., 2012).

Research strategy

Despite the challenges of conducting research in nursing homes (Thompson and Chochinov, 2006), over the past decade there has been an increase in the number of palliative care studies undertaken in this care setting. Yet, as evidenced in this chapter, few of these studies have been designed to generate the high levels of evidence required to change practice (Hall et al., 2011). As a rapidly evolving sub-speciality there is a need to strengthen the palliative care evidence base (Currow et al., 2009). This requires an investment in priority-driven research that will systematically build this evidence base, and to progress from descriptive to interventional research (Sigurdardottir et al., 2010). Research ought to focus on the needs of consumers (older people and their families), providers (aged care and palliative care professionals), and system (nursing homes, policy and reform), in priority areas including:

1. *Consumers*: symptom prevention, recognition, assessment, and management, particularly for people with limited communication, dementia, and frailty (van der Steen, 2010); de-prescribing for older people (Beer et al., 2011); effectiveness of decision support tools and case conferencing for nursing home populations (Phillips et al., 2011); and predictors of older people at high risk of suffering at the end-of-life (Sigurdardottir et al., 2010).

2. *Providers*: effectiveness of interventions to improve the palliative care expertise of aged care providers, and the aged care expertise of palliative care providers (Hall et al., 2011).

3. *Systems*: setting quality standards in palliative care (Sigurdardottir et al., 2010); better aligning policies, standards, and accreditation; eligibility and reimbursement items to promote a palliative approach in nursing homes (Hoffmann and Tarzian, 2005); service intensity, and quality of care across settings (Stevenson and Bramson, 2009); and comparisons of service delivery models (Sigurdardottir et al., 2010).

Undertaking international comparisons of treatment, care, and outcome benefits in different health-care systems, and transnational studies using the same instruments, are required to increase our understanding of the generalizability of the approaches adopted (van der Steen, 2010). Health-care research is required to guide development of models of care (Sigurdardottir et al., 2010) that promote the delivery of a palliative approach. As the palliative care evidence base expands, translating evidence into practice is increasingly important, as evidence-based practice has the potential to redress inconsistencies in care and to improve care delivery, regardless of care setting, and is a key driver for health-care reform (Grimshaw and Eccles, 2004).

Conclusion

Increasing longevity and rising prevalence of chronic and co-morbid illnesses ensure that although more people now live longer with progressive life-limiting illnesses they experience significant disability before dying. Enabling nursing homes to better meet the needs of older people and their families requires multifaceted interventions targeting change at the policy, organizational, health professional, and consumer levels. The Chronic Care Model provides a framework for systematically addressing the policy, community, and health services organizational actions required to ensure the delivery of best evidence-based palliative care in nursing homes.

A palliative approach as a philosophy of care promotes older people's function, whilst maintaining dignity and minimizing discomfort and suffering of older people in nursing homes and their families, making it a policy priority. Integrating a palliative approach from an older person's transition into a nursing home would help to ensure that the many symptoms experienced as a result of multiple co-morbidities don't go undetected or undertreated; and that the unique needs of older people who experience communication problems due to disability or dementia are better acknowledged and catered for. Aligning a palliative approach with the Chronic Care Model offers the opportunity to systematically address the challenges of providing best evidence-based palliative care in this setting, and improve end-of-life care outcomes for older people residing in nursing homes and their families and caregivers.

The interdisciplinary team

4.1

The core team and the extended team

Dagny Faksvåg Haugen, Friedemann Nauck, and Augusto Caraceni

Introduction to the core team and the extended team

Teamwork is an essential component of palliative care. This chapter gives a short overview of the pleasures and challenges of teamwork, and presents and discusses the interdisciplinary palliative care team.

What is a team?

A team may simply be defined as two or more people working together. However, working together is not sufficient to make a pair or a group of people into a team. A widely used definition describes a team as 'a small number of people with complementary skills who are committed to a common purpose, performance goals, and approach for which they hold themselves mutually accountable' (Katzenbach and Smith, 1992). Team members work in an interdependent manner.

Health-care teams

Teams make it possible for health-care professionals to work closely together. *Multiprofessional* teams are employed in areas where patients have extensive and complex needs. Multiprofessional simply means that team members have different professional backgrounds. A multiprofessional team may be multidisciplinary or interdisciplinary.

In a *multidisciplinary* team all team members have their own clearly defined place in the care regimen (Cummings, 1998; Crawford and Price, 2003). Although each professional may provide vital information towards decision-making, generally only one person, usually a physician or nurse, makes the treatment decisions. A common decision-making process demands an *interdisciplinary* approach.

The interdisciplinary team

An interdisciplinary health-care team is described as 'an identified collective in which members share common team goals and work interdependently in planning, problem solving, decision-making, and implementing and evaluating team-related tasks' (Drinka, 1994).

This description will be valid for most interdisciplinary teams, but they still differ with respect to the following:

- Size
- Mix of professions
- The degree of integration or closeness of working between team members
- The extent of collective responsibility, that is, the extent to which the team as a collective is responsible and held accountable for providing the service
- Membership of the team—who is and who is not a member, and what membership means
- The patient pathway through the team—time and process
- Decision-making
- Management and leadership (Øvretveit 1996).

Advantages of teamwork

Health-care teams are more effective than single practitioners and may improve both the quality and quantity of services (Øvretveit, 1996; Mickan, 2005; Lemieux-Charles and McGuire, 2006). Teamwork improves communication and coordination and allows for maximal diversity of professional expertise. These factors lead to organizational benefits like reduced hospitalization time and costs, reduced unanticipated admissions, and better accessibility for patients.

In fact, successful teams may possess combinations of skills that no single individual may demonstrate on his or her own (Crawford and Price, 2003). The type and diversity of clinical expertise involved in team decision-making has been shown to be a major factor accounting for teams' improvements in patient care and organizational effectiveness (Blomqvist, 2004; Lemieux-Charles and McGuire, 2006).

Objectives

The interdisciplinary team should try to achieve the following objectives:

- Accurate and speedy assessment
- Effective, integrated treatment and care
- Efficient communication with the patient and the family, with other professionals and institutions, and within the team itself
- Audit of the team's activities and outcomes.

Team members may give each other valuable feedback and support. On the other hand, working closely together may also precipitate conflicts more easily.

Team performance

Team performance is influenced by factors relating to the *structure* of the team and to *processes* involved in team functioning (Table 4.1.1) (Mickan and Rodger, 2000; Blomqvist, 2004; Mickan and Rodger, 2005; Lemieux-Charles and McGuire, 2006). The structural factors include organizational aspects as well as characteristics of the group and the individual team members.

Team size and membership: core and extended teams

By definition, a team is a small number of people (Katzenbach and Smith, 1992), usually no more than 15, and often between five and ten. A team of five or six full-time members has been suggested as ideal (Kane, 1975). Unresolved differences are better tolerated in larger teams, but it takes more time to reach decisions. Around 20 seem to be the maximum number of team members consistent with efficient teamwork (Kane, 1975; Lemieux-Charles and McGuire, 2006; Maddocks, 2006).

Membership defines the team's boundaries. The most common membership distinction is between *core* and *associated*, the latter belonging to the extended team (Øvretveit, 1990, 1996). Core members are usually full-time members governed by the team policy and managed by the team leader. Associate can mean part-time in the team, not governed by team policy, and having managers outside the team. Each team member must have a distinct and necessary role within the team (Mickan, 2005).

Knowledge and skills

All team members have to be specialists and confident in their own fields to be valid 'instruments' in the interdisciplinary 'orchestra'. However, it is also necessary to have a clear understanding of the other team members' expertise and contributions. Each health-care discipline has its own 'cognitive map' consisting of its conceptual basis, terminology, observational approaches, and theoretical framework. Working together in a team requires some degree of understanding of the 'maps' of the other team members (Reese and Sontag, 2001; Blomqvist, 2004).

Attitudes

Even more important are the attitudes of the team members (Reese and Sontag, 2001; Crawford and Price, 2003). The tendency

to believe that one's own way of framing problems or solutions is the best is a common obstacle to good teamwork (Blomqvist, 2004).

Philosophies of teamwork

The team members' attitude to teamwork is rooted in their understanding of what teamwork really means. Team members' interpretations of teamwork have been shown to be just as important as organizational and group dynamic constraints (Freeman et al., 2000). Freeman and co-workers identified three philosophies of teamwork:

◆ The *directive* philosophy is based on the assumption of hierarchy in the team. One person takes the lead by virtue of status and power and directs the actions of the other team members.

◆ The *integrative* philosophy assumes that each professional's contribution has equal value. All team members are seen as team players, and communication and discussions within the team are given vital importance.

◆ The *elective* philosophy of teamwork is held by professionals who prefer clear and distinct team roles to operate autonomously and only relate briefly to other team members when they see a need for it themselves.

Team processes

Team processes describe how the team handles tasks and interpersonal dynamics to produce the desired outcome (Table 4.1.1) (Mickan and Rodger, 2000).

The development of a team

Research on group processes has shown that teams often go through typical phases in their development (Tuckman, 1965; Katzenbach and Smith, 1992; Payne, 2006).

Forming is the first phase when the group constitutes itself and faces its task for the first time. The team members feel insecure and test out behaviour in the group. The group is dependent on a formal leader. In this phase it is important to develop rules and methods for the work on the team and define the tasks for each team member.

Storming is the characteristic phase of turbulence, critical opposition, and power struggle which often follows once the team is established. Conflicts arise between subgroups, and differences in opinion and competition between team members appear.

Norming characterizes the next phase when the team players finally agree on rules and adapt to common norms. The members resist conflicts and get a feeling of belonging together. There is an open exchange of opinions and feelings, and cooperation develops.

Performing or *adjourning* should be the final, lasting stage of team development. By now the team has developed functional processes for problem solving. The team members know their roles, support each other, and devote their energy to fulfilling the team's objectives (Tuckman, 1965).

This simplified, schematic description is not valid for every team (Drinka, 1994). Still, these common steps might be a help to understand team dynamics and guide your team in the right direction.

Roles of team members

A role is understood as the expectations the individual has of what they are supposed to do in their work, but also what others expect

Table 4.1.1 Characteristics of effective teamwork

Organizational structure	Individual contribution	Team process
Clear purpose	Self-knowledge	Coordination
Appropriate culture	Trust	Communication
Specified task	Commitment	Cohesion
Distinct roles	Flexibility	Decision-making
Suitable leadership		Conflict management
Relevant members		Social relationships
Adequate resources		Performance feedback

from the person (Blomqvist, 2004). The role is linked tightly to the professional identity and gives the owner certain duties and privileges. Role ambiguity and role conflicts threaten teamwork and must be sorted out (Kane, 1975). Clarification of roles first of all concerns the *professional roles* in the team. Who should take on which tasks? Role overlap might lead to competition, or that several team members work on the same task. Some role overlap, however, may be beneficial and actually increase the team's resources, as long as this is agreed upon by all team members (Reese and Sontag, 2001; Crawford and Price, 2003).

In addition to the professional role, other roles will develop in a team. Every team member has a *personal role* rooted in their sex, age, ethnical background, and socioeconomic state (Kane, 1975). In addition, other *formal roles* may be given, like team leader or supervisor.

Informal roles reflect the individual team member's personality and style which have given them a certain position in the group. These informal roles may be more or less conscious and articulated, but roles like 'mother', 'clown', 'messy head', and 'saviour' may be familiar.

Leadership

Team leadership concerns three aspects: management, handling of professional challenges, and motivation and policy. *Management* (administration) is important, but not necessarily a job for the team leader. Although the physician will be responsible for the medical treatment, *professional, task-centred leadership* in the interdisciplinary team should vary from case to case, depending on the nature of the needs of the individual patient and family (Cummings, 1998). The *team leader* should guide the team in the right direction, by:

- keeping purpose, goals, and approach relevant and meaningful
- building commitment and confidence
- strengthening the mix and level of skills
- managing external relations, removing obstacles
- creating opportunities for others
- doing real work (Katzenbach and Smith, 1992).

Leadership is a combination of goal-oriented and interpersonal skills (Kane, 1975; Øvretveit, 1990; Barczak, 1996).

Øvretveit states that the quickest way to establish a close and effective team is to start with a clearly defined team leader role: 'I do not know of any teams which have close teamwork and have survived changes of membership without a clear team leader position. One of the biggest mistakes is to believe that interprofessional and interagency conflicts, rivalries and protectionism can be avoided by not defining a team leader role' (Øvretveit 1990).

Communication and cohesion

Communication is the means through which the team members interact and the work gets done (Jünger et al., 2007). Communication is equally important within the team and between the team and the organization: patients, family members, other health-care professionals, and managers (Kane, 1975; Mickan and Rodger, 2000; Müller and Kern, 2006). Although challenging at times, the patient's and family's right to confidentiality should always be respected and appropriate consent obtained.

Ongoing communication requires commitment of time and energy and is enhanced through physical proximity of offices, common records, and frequent, structured meetings (Katzenbach and Smith, 1992). Meetings provide the main forum and structure within which a team works. Team conferences for assessment, planning, and evaluation of patient care should be held at least weekly, and should be planned carefully, including time for reflection and review (Macmillan et al., 2006).

Cohesion is a feeling of belonging which gives the team members shared enjoyment and pride in their achievements and a wish to remain within the team (Mickan and Rodger, 2000, 2005). This commitment and involvement is generated by working together over time, and is supported by good performance feedback, success in adversity, good communication, and conformity to norms (Vinokur-Kaplan, 1995; Mickan and Rodger, 2000). In their study of Australian health-care teams, Mickan and Rodger found communication and cohesion as two of the categories most able to distinguish effective teams. The other four categories were mutual respect, goals, purpose, and leadership (Mickan and Rodger, 2005).

Decision-making

Decision-making skills are a basis for effective teamwork and a main responsibility for the leader (Kane, 1975). All team members need to contribute to the team's decisions.

Decision-making includes describing the problem, presenting and discussing alternative solutions, prioritizing and choosing among the alternatives, and finally assigning and accepting responsibility and deciding a time frame. In the palliative care team, agenda setting as well as decision-making ultimately must be guided by the patient's and family's needs, wishes, and preferences (Council of Europe, 2003; Maddocks, 2006).

Conflict-solving

Any work group may be subject to stresses and conflicts. Diversity of professional backgrounds presents an additional challenge (Cummings, 1998; Reese and Sontag, 2001; Crawford and Price, 2003). All aspects of teamwork discussed so far may give rise to conflicts. In addition, external factors—scarcity of resources, organizational changes, and work-related strain like working with the terminally ill—may add to the stress. Ability at conflict-solving is an important feature of any successful team (Kane, 1975; Lemieux-Charles and McGuire, 2006).

Any conflict arising in the team should be taken seriously and identified as soon as possible. Investigating the root of the problem is usually more rewarding than focusing just on the symptoms. Possible solutions must be discussed and the necessary steps taken to reach the desired outcome, including clarifying who must be involved (Speck, 2006).

Clinical supervision is recognized as a valuable tool for professional growth and support and should be available to the interdisciplinary team. Supervision has an important role in preventing and solving team conflicts (van Staa et al., 2000; Speck, 2006).

Team building

Teams are dynamic. Appropriate team structures facilitate the development of team processes, but as teams evolve, team processes often shape the structures within which they function best (Mickan and Rodger, 2000). Accordingly, both team structure and processes should be considered when building effective teams (Table 4.1.1).

Shared learning and getting to know each other by spending time together are the core aspects of 'team building' activities (Payne, 2006). A work climate characterized by good social relationships, personal recognition, feedback, and humour influences positively team members' psychological well-being, organizational commitment, and belief in the team's effectiveness (Mickan and Rodger, 2000).

The palliative care team

Teamwork is an inherent feature of palliative care. The palliative care team is an interdisciplinary health-care team with its own characteristics and challenges.

A palliative care team is usually understood as a clinical team, although many teams also are engaged in teaching, service development, and research. The palliative care team should be found in any setting providing specialist palliative care.

The palliative care team: defined and flexible

To be a team, the team members need to be defined (Drinka, 1994; Lemieux-Charles and McGuire, 2006). This is vital for the communication and collaboration within the team, but also for the organization served by the team. A palliative care team should be identified clearly by the name of the team or the programme, and its members should be outlined clearly.

While efficient teamwork demands a defined core team, palliative care also needs to be flexible (Maddocks, 2006). The extended 'team' may consist of some members from the palliative care staff team or consult team in addition to family members, hospital physician, general practitioner, home care nurse, volunteer, etc. In this way a palliative care team is not static. However, although flexibility is needed, loose team boundaries may lead to drifting team members becoming multidisciplinary instead of interdisciplinary.

The core team

Most recommendations for the organization of palliative care services define a core palliative care team consisting of a physician, preferably a consultant in palliative medicine, and a specialist nurse (National Institute for Clinical Excellence, 2004; Doyle, 2009). The UK recommendations specify the physician being supported by other medical staff including junior staff who may be on rotations, and also include secretarial/administrative support in the core team (National Institute for Clinical Excellence, 2004; Booth et al., 2009). Guidelines from the United States include a social worker and chaplain in the core team (National Consensus Project for Quality Palliative Care, 2013).

Having placed the nurse and physician at the core of the palliative care team simply reflects that these are the two professions most often needed by people with advanced, life-threatening disease. Accordingly, the nurse and the physician usually work full time on the team, while other team members often will be part-time or attached staff.

The extended team

The extended palliative care team ideally should be designed to be able to address all the needs of the patients and families served by the team. The team should include psychology, social work, and chaplaincy expertise, and access to specialist pain management, physiotherapy, occupational therapy, and dietetics (Palliative Care Australia, 2003; National Institute for Clinical Excellence, 2004; Norwegian Association for Palliative Medicine, 2004; National Consensus Project for Quality Palliative Care, 2013). Pharmacy expertise is likely to be increasingly important. A number of other health-care providers and therapists may be included as needed (MacMillan et al., 2006; Doyle, 2009). The team must be skilled in care of the patient population to be served (Palliative Care Australia, 2003).

Are the patient and the family team members?

Palliative care interventions must be given with the patient's consent and in accordance with their wishes. The patient may thus be considered a member of the extended team, even if they do not take part in all team conferences (Doyle, 2009).

Likewise, the members of the patient's family can be considered members. They have an important role in the overall care of the patient, and their opinions should be included when formulating plans for treatment and care (Doyle, 2009).

The palliative care staff team

Historical perspective

The establishment of St Christopher's Hospice in London by Dame Cicely Saunders in 1967 is regarded as the foundation of the modern hospice movement (Saunders, 2000). Multiprofessional teamwork was regarded an essential cornerstone of holistic hospice care. Experience has shown that hospice care can be established and implemented in many settings and cultures and in countries with widely different resources (Saunders, 2000).

The dramatic change of focus made it necessary to establish the first hospices outside the acute hospital setting (Dunlop and Hockley, 1998; Hockley, 1999). Gradually the pendulum has swung back. Deficiencies in terminal care for hospital patients prompted the surgeon Balfour Mount to establish the first palliative care unit at the Royal Victoria Hospital in Montreal in 1975 (Mount, 1976).

In some countries, inpatient hospices are very different from palliative care units in terms of funding, length of patient stay, and main task of care (end-of-life care versus crisis intervention and symptom control), while in others they are much more alike. Some countries have chosen not to have 'hospice' as an organizational element—either because of the term's historical associations, or because it is not specific for the contents or quality of the service provided (Norwegian Association for Palliative Medicine, 2004).

Staff teams in hospices and palliative care units

Most members of the palliative care staff team will be defined as core members (National Institute for Clinical Excellence, 2004). This is necessary to provide comprehensive care addressing all the patients' and families' needs.

Recommendations for staffing

The high complexity of problems and the extensive nursing needs demand a higher ratio of staff per patient in hospices and palliative care units, as compared to most other institutional wards. Staffing levels are also influenced by disease panorama and needs for special skills (patients with advanced neurological disease like motor neurone disease are generally very resource intensive), demographics (younger people and families with children often require more support), number of admissions

and rate of turnover, and cultural factors (e.g. need for interpreters and more time-consuming conferences) (Palliative Care Australia, 2003). Care for the dying includes care for their relatives, which often is time-consuming and may require the attention of the whole team.

Recommendations for staffing vary between countries (Council of Europe, 2003; Palliative Care Australia, 2003; National Institute for Clinical Excellence, 2004; Norwegian Association for Palliative Medicine, 2004; Doyle, 2009; Radbruch et al., 2010; National Consensus Project for Quality Palliative Care, 2013).

The extended interdisciplinary medical team

Specialist palliative care may be advanced medical treatment, highlighted in academic palliative medicine units in tertiary hospitals, admitting the most complex cases (El Osta and Bruera, 2006). These units need an extended interdisciplinary medical team to handle any emergencies or complications that may arise. The core staff team should include all relevant professions, including nurses with different specialties. A number of medical specialties must be linked to the team and accessible for consult at short notice. Relevant specialties include orthopaedics, infectious diseases, advanced pain medicine, oncology, urology, gastrointestinal surgery, and psychiatry.

Palliative care units in nursing homes and residential homes

Even though it is undisputed that palliative care should be provided in the settings of care for older people (Davies and Higginson, 2004), this field is poorly developed. However, some European countries have an active policy to establish palliative care units in nursing homes (Francke and Kerkstra, 2000; Norwegian Association for Palliative Medicine, 2004). Many of the patients admitted to these units have palliative care needs due to chronic diseases typical of old age. This creates additional requirements for the staff, for example, pain assessment and symptom control in demented patients and knowledge in a wide variety of chronic and/or neurological diseases. When setting up the team, expertise in geriatrics/nursing home medicine and geriatric nursing should be included.

The palliative care consult team

As hospice practice developed in the UK, many patients admitted to hospices for symptom control were able to be discharged back to their own homes. This precipitated the need for hospices to develop their own home-care teams. From the end of the 1970s, palliative care started to come full circle back into acute care with the formation of hospital palliative care teams.

The typical consult team is found in acute care hospitals (Booth et al., 2009), but teams may operate in different settings, and are especially important as links between the different levels of the health-care system.

Hospital-based palliative care teams

The move of hospice care to acute care hospitals started with the consult teams at St. Luke's Hospital in New York (1974) and St Thomas's Hospital in London (1977) (O'Neill et al., 1992). At that time, 50–60% of all deaths occurred in hospitals, as is still the case in many developed countries today. In later years, services providing palliative care for patients admitted to acute care facilities have developed as an important part of specialist palliative care in many countries.

Team composition and tasks

Team composition depends on the purpose and goals of the service. These are influenced by the hospital characteristics, the patient populations to be served, additional palliative care services inside or outside the hospital, finances, and existing national standards.

Palliative care teams may be linked to a palliative care unit or may operate in hospitals not having palliative care inpatient facilities (Mount, 1976; O'Neill et al., 1992; Norwegian Association for Palliative Medicine, 2004; El Costa and Bruera, 2006).

The following aims are common for most consult teams (Dunlop and Hockley, 1998; Hockley, 1999):

◆ To work alongside the hospital ward team by advising on symptom control and psychosocial/spiritual issues

◆ To support relatives in difficult situations

◆ To support staff in difficult decisions and grief

◆ To educate staff in palliative care

◆ To liaise with hospice /other palliative care services and home care services.

Hospital teams usually have several levels of intervention, from a consulting role to shared care and eventually transfer of care:

◆ Advice and guidance to professionals on the ward team without direct contact with patient.

◆ Single visit for assessment and advice on further plans for care, preferably with referrer. Further contacts specifically at referrer's request.

◆ Short-term interventions with patients or families for specific problems.

◆ Ongoing contact due to multiple, complex problems requiring regular specialist assessment and interventions. In this case the team might temporarily take over patient responsibility.

Consultations are also provided for cancer patients still receiving disease-modifying treatment and patients with non-malignant conditions. This gives the palliative care team a unique role as the interface between palliative medicine and other medical specialties (Glare et al., 2003). Speaking in terms of teams, the consultant, advanced nurse practitioner or other members of the consult team will be part of the extended medical team in the intensive care unit, the department of oncology, and other hospital wards. This is especially important to promote integration of palliative care early in the disease trajectory (Temel et al., 2010).

Community teams

Community teams may be hospital based or community based. Home-care teams must have clear objectives and guidelines for the level of intervention, to ease the cooperation with primary care services.

Services providing extended specialist palliative nursing, medical, social and emotional support, and care in the patient's home, are often known as 'hospice-at-home' (National Institute for Clinical Excellence, 2004). Care may be provided as crisis management or for longer periods of time. By establishing a full range hospice at home, the team assumes full control of the patient and works like a staff team. In such cases, responsibility must be clearly defined and assigned.

Community teams may also serve nursing homes (El Osta and Bruera, 2006), or larger communities may have special teams serving these institutions.

Outcomes of hospital palliative care teams

Although there is a need for more and better quality research in palliative care, palliative care teams have been shown to improve symptom control (Ellershaw et al., 1995; Higginson et al., 2002; Cintron and Meier, 2006; Higginson and Evans, 2010), increase patient and carer satisfaction (Hearn and Higginson, 1998), and have an impact on communication and psychosocial aspects of care (Ellershaw et al., 1995; Hearn and Higginson, 1998; Glare et al., 2003; Jack et al. 2004; Vernooij-Dassen et al., 2007).

Planning the team

The majority of palliative care teams have started from an enthusiastic individual convinced of the needs for and usefulness of specialist palliative care. Although probably no team may come into being without at least one such committed person, a structured planning process will save time and frustration (Dunlop and Hockley, 1998).

The size and composition of the team should be based on a thorough needs assessment which in turn leads to clear task objectives and careful job descriptions. In many cases, the team will be formed from practitioners already employed by the institution, brought together from different departments and grouped into a team. This situation is not ideal and calls for a dedicated team leader, well-defined roles for the team members, and strong support from the institution's management and organization.

Evaluating the team

Audit of the team's activities and outcomes is one of the objectives of interdisciplinary teamwork (Hunt et al., 2004). This demands clearly defined, attainable and measurable goals (Lemieux-Charles and McGuire, 2006). Keeping good records and compiling statistics are first steps to evaluate the service.

Clinical and organizational audit is described in Chapter 19.9. Audit and quality measurement may be applied to three levels of teamwork, and palliative care teams should formulate goals regularly within these three domains:

- Structure
- Processes
- Outcomes.

Structural factors include having job descriptions, systems for referral and feedback, telephone access, symptom assessment tools, and other organizational elements in place.

Processes refer to how the structural elements are used and the teamwork is performed:

- The patient pathway through the team—number of referrals, referral time, time expenditure, use of symptom assessment tools, family meetings, etc.

- Communication and documentation—record keeping, discharge summaries, network meetings.

- Internal processes of teamwork—team functioning, performance and effectiveness—which may be measured by a number of validated tools (Fulmer and Hyer, 1998).

Outcomes relate to results obtained through the team's efforts, auditing the effects of actual interventions in changing ward practice, improving symptom control, patient and family satisfaction, patient and family understanding of disease progression, etc. A large number of questionnaires and outcome scales have been developed to this end (Hunt et al., 2004) (see Section 7).

The interdisciplinary teaching team

Every health-care practitioner is a lifelong learner, and every palliative care team should provide an environment for learning and development for its members. Equally important, is that everyone acting as a specialist practitioner automatically becomes a teacher and a role model.

The advisory role of the palliative care consult team makes it easy to turn almost all clinical contacts into teaching opportunities. The first visit for comprehensive assessment provides an ideal situation to demonstrate communication techniques and involve the junior doctor and ward nurse or general practitioner and home care nurse in discussions on assessment and treatment (Dunlop and Hockley, 1998; Cintron and Meier, 2006). Case discussions, ward rounds, and staff meetings provide similar opportunities. Changes in medication or other treatments should always be discussed with the staff. These are extremely important steps to ensure provision of basic palliative care in all the services the team comes into contact with, inside or outside the hospital.

Every palliative care team must also engage in formal educational sessions. This means that 'teaching the teachers' must be included in the team training. Common, interdisciplinary educational sessions facilitate shared learning for professional groups working together. Separate teaching for each group is also needed, but even so the interdisciplinary approach should be emphasized, for example, in case presentations (Council of Europe, 2003; Jeffrey, 2003; Lawrie and Lloyd-Williams, 2006).

The interdisciplinary research team

Every palliative care team should strive to improve its work through research and development. Unfortunately research often has to give way to pressing clinical activities, and there is a lack of funding and academic chairs and departments in the field. Nevertheless palliative care research is increasing, including some exciting international collaborations.

Translational research, trying to answer questions originating in the clinical as well as in the molecular setting by combined approaches, is one example of true interdisciplinary work (Kaasa and Dale, 2005).

Teaching and training in palliative medicine

Karen Forbes and Jane Gibbins

Introduction to teaching and training in palliative care

Patients die in almost all areas of medicine; it is therefore essential for doctors to be equipped with the knowledge, skills, attitudes, and behaviours necessary to look after patients who need care at the end of life. Both generalists caring for patients with advanced disease, and health-care professionals specializing in palliative medicine require training to enable them to provide the best care for all patients. Whilst there has been progress in providing and improving educational opportunities in palliative care for physicians at all stages of their training, it is suggested that training deficits still lead to many patients receiving poor care at the end of life (Department of Health, 2008; Bui, 2012).

Training needs

The National Council for Palliative Care in the United Kingdom suggests that palliative care is provided by 'two distinct categories of health and social care professionals', those who provide day-to-day care for patients, and those who specialize in palliative care (National Council for Palliative Care, 2012). It is suggested that a 'significant minority' of patients will need specialist palliative care; the remainder need their usual carers to have the necessary skills to provide good 'generalist' palliative care. Training needs for specialists in palliative medicine and those caring for patients within other specialties or in the community will differ, but it has long been recognized that the foundations of the necessary competencies need to be laid down during undergraduate medical training for all future doctors:

> Unlike other specialties, palliative medicine is not concerned with facts and skills needed by a few practitioners but those needed by every doctor, whether generalist or specialist, reminding us that palliative care is the right of every patient and its provision the responsibility of every doctor. (Doyle, 1996)

The literature on palliative care teaching has evolved. Papers on teaching to medical undergraduates were followed only more recently by studies on postgraduates, and education for specialists still features less frequently.

Education for medical undergraduates

Early reports focus on the inadequacy of teaching and the need for the inclusion of teaching about death and dying in curricula (Barton, 1972; Hull, 1991). Subsequent publications are commonly surveys of the teaching available (Field, 1984; Dickinson and Mermann, 1996; Field and Wee, 2002) or present the case for including such teaching and then describe the course developed in the authors' institutions. Initially such papers were descriptive, however once the need for such teaching was acknowledged fully, papers emerged discussing how such teaching should be delivered and by whom and then arguing for the teaching to be evaluated.

A number of authors have carried out sequential surveys of palliative care education within medical schools. Dickinson, and Dickinson and Mermann mailed questionnaires to the deans of all medical schools in the United States at 5-yearly intervals from 1975 to 2010. Increasing incorporation of teaching was demonstrated over the time period, with 100% and 99% offering teaching about death and dying and palliative care respectively in 2010. Whilst the number of separate courses has increased over time, only 21% of schools ran such a course in 2010, the majority offering more integrated teaching, taught in 76% of schools by a multidisciplinary team. In 2010, 28% of schools had a 'terminally ill patient' address the class, and 67% of students spent time with hospice patients. The average number of hours of palliative care teaching was 12 (Dickinson and Mermann, 1996; Dickinson, 2011).

In 2000, Oneschuk and colleagues reported a comparative questionnaire survey of all 16 medical schools in Canada, all 30 in the United Kingdom, and 129 schools selected randomly from the United States and Western Europe; 67% responded. Whilst 64% of schools in the United Kingdom reported palliative medicine experience was part of the core curriculum, this was the case for only 11% of schools in the United States, 14% in Canada, and 19% of schools in Western Europe. Optional experience in palliative medicine was offered in 82% of UK, 71% of Canadian, 62% of American and 30% of Western European schools. Teaching using small discussion groups and case-based learning in small groups was reported for the majority of schools in the United Kingdom and Canada. Other schools continued to use predominantly lecture-based teaching. Oneschuk and colleagues noted that courses were often run by a single academic faculty member and suggested the number of both educational programmes and faculty members needed to increase for palliative care education to improve (Oneschuk et al., 2000). In a more in-depth survey of Canadian medical schools in 2001, Oneschuk and colleagues concluded that there were still barriers to implementing palliative care education and there was a need for increased student exposure,

curriculum and faculty development, and student assessment and evaluation (Oneschuk et al., 2004). Gibbins et al. came to similar conclusions in the United Kingdom (Gibbins et al., 2009).

Field, and then Field and Wee, surveyed all UK medical schools in 1983, 1992, and 2000–2001. The 1983 questionnaire survey indicated that all but four medical schools delivered some teaching on death and dying, but for some this might be a single lecture (Field, 1984). In 1992, all schools taught most of the subjects relevant to palliative medicine. Some students experienced visits to palliative care units or hospices, although only a few schools required this as part of the core curriculum. In 2000–2001, Field and Wee concluded 'the amount of such teaching varied widely and appeared in the curriculum in a variety of manners, times and places'; however, they suggested the integration of palliative care into curricula was positive and should encourage students to apply their palliative care knowledge in other areas of medicine (Field and Wee, 2002).

Undergraduate curriculum development

By 1980, the objectives of teaching on death and dying were relatively consistent in all US medical schools providing teaching; however, the 'course content, faculty and patient roles, learning resources, and involvement in curriculum research did not evidence a systematic development' (Smith et al., 1980). Teaching in palliative care was driven mainly by interested faculty, and indeed Gibbins et al. have found that a 'champion' is crucial to the successful integration of palliative care into, often crowded, undergraduate curricula (Gibbins et al., 2009). National and international palliative care associations often responded to the resulting heterogeneity of teaching by developing national curricula, and finally national or governmental regulatory bodies issued standards related to accreditation of medical schools or the standard a new graduate must achieve which, in turn, drove further development of curriculum, teaching, and assessment.

Undergraduate palliative care curricula

The deans of the Canadian medical schools published a curriculum for the teaching of palliative care to Canadian undergraduates in 1993 (MacDonald et al., 1993). The American Academy of Hospice and Palliative Medicine (AAHPM) first published *Hospice and Palliative Medicine: Core Curriculum and Review Syllabus* in 1998 (Schonwetter et al., 1999). Since 2000, the Liaison Committee for Medical Education, which accredits US and Canadian medical schools, has included end-of-life care as an educational objective in its standards (Liaison Committee on Medical Education, 2013) but made no recommendations as to how these standards should be met. In the United States, the Education for Physicians on End-of-life Care (EPEC) Project began in 1997, aligned with the American Medical Association (Robinson et al., 2004). It proposes a curriculum, trains the trainers, and provides educational resources. Educating Future Physicians in Palliative and End-of-Life Care (EFPPEC) was a similar project in Canada. The EFPPEC website announces it completed its remit in 2008, although resources such as an undergraduate curriculum remain available (EFPPEC, 2008). Both projects have influenced both undergraduate and postgraduate palliative medicine education. In Australia, the Department of Health and Ageing has funded a multidisciplinary Palliative Care Curriculum for Undergraduates (PCC4U) project, in 2011–2014, which is reported to be in use in ten out of 20 medical courses (PCC4U, 2013).

The Association for Palliative Medicine for the United Kingdom and Ireland (APM) published its first curriculum in 1993 (APM, 1993). This curriculum was divided into three sections outlining the curriculum requirements for medical students, for non-specialists, and for those undergoing specialist training. The publication of *Tomorrow's Doctors* in 1993 (General Medical Council (GMC), 1993) required, for the first time, that learning about caring for the dying was included in UK medical undergraduate teaching. In *Tomorrow's Doctors* (2003) the GMC set out the knowledge, skills, attitudes and behaviours expected of new graduates in medicine, and included the recommendation that graduates must know about and understand the principles of 'palliative care, including care of the terminally ill' (GMC, 2003). A consensus syllabus subsequently updated the 1993 APM curriculum through a Delphi study of palliative care experts (Paes and Wee, 2008).

The United Kingdom, United States, and Australasia are recognized as having led the development of teaching in palliative care. In 2007, a European task force on medical education presented the *Curriculum in Palliative Care for Undergraduate Medical Education—Recommendations of the European Association for Palliative Care* (European Association for Palliative Care (EAPC), 2007), although palliative medicine was integrated into undergraduate curricula in German medical schools, for example, only in 2013 (Schiessl et al., 2013). However, curricula are being developed elsewhere, even in countries and regions where palliative care services have been established more recently, for example, a consensus syllabus for undergraduate medical education was published in Japan in 2012 (Kizawa et al., 2012).

Planning undergraduate teaching

The Palliative Education Assessment Tool was developed to 'facilitate curricular mapping of palliative care education' (Meekin et al., 2000). It is suggested seven domains (palliative care, pain, neuropsychological symptoms, other symptoms, ethics and the law, patient/family/non-clinical caregiver perspectives on end-of-life care, and clinical communication skills) should be represented in any undergraduate curriculum. In setting up or reviewing an undergraduate course, this tool could allow faculty to map existing provision, including, in an increasingly multidisciplinary health-care environment, teaching delivered by other health-care professionals, which might otherwise not be obvious. Alternative methods of needs assessment might be using a Delphi technique, focus groups of staff and students, previous student evaluations, or faculty expert opinion. Having identified gaps, teaching and learning experiences to address them can be designed and implemented.

Many undergraduate curricula specify the knowledge, skills, and attitudes that students must acquire prior to qualification. Latterly, most curricula have moved from a knowledge, skills, and attitudes focus towards competency-based objectives. Competencies are a set of observable and measurable behaviours encompassing the combined knowledge, skills, abilities, and personal attributes that make someone able to carry out a given task or do a given job. In designing teaching, the desired learning objectives/outcomes, or competency statements for the student should be made clear. Objectives drive assessment and assessment drives learning, so objectives should be specific, measurable, achievable, relevant, and timely (SMART) and, particularly

for competency-based assessment, should make explicit what the student needs to be able to do, under what circumstances, how well, and when.

Methods of teaching

A variety of approaches to teaching have been taken at different times within different medical school curricula. For many schools, teaching was not part of the core curriculum, and students gained only optional palliative care experience. Many schools continued to deliver a small number of lectures or tutorials. Others were more innovative and introduced learning about death and dying at other opportunities, for example, at the time of anatomy dissection (Marks and Bertman, 1980) or communication skills teaching (Charlton, 1993). As palliative medicine and end-of-life care have gained increasing credibility, more diverse and imaginative teaching methods have been employed. Knowledge-based learning objectives can be acquired through lectures, tutorials, and group discussions. Skills can be encouraged through problem-based learning, role-play (Torke et al., 2004), goldfish bowl discussions (Jeffrey, 2002), consultations with simulated patients (actors) (Kahn et al., 2001), and supported observed hospice visits and clinical attachments.

Knowledge-based learning outcomes and some practical and problem-solving skills are relatively straightforward to teach. Competency-based palliative care objectives are more complex and may need to be met in a number of more inventive or novel ways. Pain and symptom management have been taught with psychological and ethical issues, and teamwork within facilitated multiprofessional workshops involving family caregivers (Wee et al., 2001). In some schools, students are paired with a patient with cancer over a prolonged period (Maughan et al., 2001). Students spend time with patients and their families, attending appointments, investigations, and visiting them at home. Students' learning is supported through tutorials and written reflective portfolios. Whilst such learning is usually evaluated highly, supporting students is important and may be particularly difficult for those students who have personal experience of illness or bereavement. More recent approaches include involving bereaved family members in teaching communication skills (Schillerstrom et al., 2012); the use of literature, drama, and film to teach palliative care competencies (Ring and Reilly, 2003; Dietz et al., 2012; Jeffrey et al., 2012); and the use of combinations of e-learning and simulation to teach spiritual and cultural aspects of care (Ellman et al., 2012).

Teaching attitudes is complex. The *Oxford Dictionary of English* defines 'attitude' as 'a settled way of thinking or feeling' ('Attitude', 2013). Professional attitudes are important in many areas of medicine, but perhaps particularly so in palliative and end-of-life care, where attitudes such as seeing death as failure, therapeutic nihilism in patients with cancer or other end-stage disease, wishing to avoid dying patients, and fears about opioids can all influence patient care adversely. The literature suggests that end-of-life issues are not discussed within the culture of the working environment, and so these attitudes may remain unaddressed (SUPPORT Investigators, 1995; Fitzsimons et al., 2007; Gibbins et al., 2010, 2011).

Lloyd-Williams and Dogra explored the attitudes of second year medical students using a non-validated questionnaire before and after a six-hour course about palliative care comprising lectures, small group teaching, videos and case based discussions (Lloyd-Williams and Dogra, 2004). One hundred and forty-nine students completed the questionnaire which revealed positive attitudes towards caring for chronically ill and dying patients before and after the teaching, and a significant improvement in views of the hospice. These students were surveyed prior to significant exposure to patients and thus their attitudes were theoretical rather than based on experience. Attitudinal change may occur with increased knowledge alone, but it may require also role modelling and facilitated discussion and reflection following clinical or educational encounters. We have described changing students' attitudes towards opioids using e-learning tutorials which prompted reflection, for example (Forbes and Gibbins, 2010).

Postgraduate training in palliative medicine

The UK Department of Health set out a useful classification of healthcare staff who required training to improve palliative care for patients within its End-of-life Care Strategy. These were:

- Group A—staff who work in specialist palliative care and hospices.
- Group B—staff who frequently deal with end-of-life care as part of their role, for example, secondary care staff who work in the emergency department, acute medicine, respiratory medicine, care of the elderly, cardiology, oncology, renal medicine, intensive care, and those who work with patients with long-term neurological conditions.
- Group C—staff who work within other services and who have to deal with end-of-life care infrequently (Department of Health, 2008).

All staff need training in communication skills, assessing a patient's needs and preferences, advance care planning and symptom control. Clearly staff in group A will have their own specialist curricula, and those in group C need mainly to be aware of palliative care issues and empowered to recognize that a patient might be approaching the end of life and where to gain support.

A Royal College of Physicians' (RCP) working party in the United Kingdom suggested that it is the group B professionals whose palliative care continuing professional development is most important; in particular, they need advanced communication skills because they initiate discussions about issues at the end of life (RCP Working Party et al., 2012). Within this group we suggest that recently qualified doctors are generally the clinicians who spend most time with patients with palliative care needs; their early post-qualification period is, therefore, an important time for them to put their undergraduate training into practice and to consolidate their palliative care skills.

Many newly qualified doctors report being unprepared to care for patients with end-of-life and palliative care needs; they lack confidence in breaking bad news, empathizing, discussing prognosis and symptom control (Charlton and Smith, 2000), and managing distress and social issues (Bowden et al., 2013). They often report having received little or no training at medical school, or that it was inadequate for their role, and they want to learn more. For example, in a survey of all first year graduates in the UK (43% response rate, $N = 2062$), 71% felt they needed more teaching about symptom control and 41% in communication skills in caring for patients with cancer (Cave et al., 2007). In the United States, the

authors of a survey of 972 internists and family practitioners concluded that although these physicians provide palliative care, they feel their skills are lacking (Farber et al., 2004). A telephone survey of 1455 students, 296 junior doctors, and 287 senior clinicians from accredited medical schools with response rates of 62%, 56%, and 41% respectively revealed that juniors 'are systematically protected from, or deprived of, opportunities to learn from caring for dying patients. When they do participate in this care, they lack role models with expertise to learn from, as well as feedback and support that facilitate clinical growth'. Many of the respondents did not perceive that dying patients were considered 'good teaching cases'. Students and juniors felt unprepared to provide, and senior and junior doctors unprepared to teach, many key components of good care for the dying; only 17% of senior clinicians reported having taught some aspect of end-of-life care in the past year (Sullivan et al., 2002).

The literature suggests that junior doctors in different countries learn palliative care experientially. A study in Switzerland found 'learning by doing counts strongly for palliative care'; doctors who had more experience with situations involving palliative care had significantly higher competency scores than those with less experience (Mulder et al., 2008). A US study of 20 house-staff reported that formal education in palliative care was not a major source of learning; staff learned mostly on the job, by observing attending physicians, and by making mistakes (Schulman-Green, 2003). Gibbins et al. have reported that students gain little exposure to patients at the end of life during their training, despite increasing curriculum time for palliative care, and report learning by 'trial and error . . . on the job' once they qualify, with nursing staff and hospital palliative care teams being important informal teaching resources (Gibbins et al., 2011).

Few studies consider the skills of senior hospital doctors in caring for patients at the end of life. Many senior consultants have received little or no training in palliative care as undergraduates; they will have learnt by observing others in practice, perhaps from professionals with even less training (Schulman-Green, 2003). Qualitative interviews and focus groups reveal that even caring specialist clinicians find it difficult to face their patients' palliative care needs and to discuss end-of-life issues with them (Fitzsimons et al., 2007). This is significant, since these clinicians will serve as role models to students and junior doctors, potentially informing them, through the 'hidden' curriculum, that palliative care issues can, or should, be avoided. Whilst students, for example, acknowledged learning from end-of-life courses, they found 'patient care experiences guided by teams that acknowledged deaths, role-modelled end-of-life care, and respected students' participation in patient care' far more useful (Ratanawongsa et al., 2005). It is interesting to note that in the RCP Working Party's document on continuing professional development, two-thirds of physicians had not attended any end-of-life care educational event in the last 2 years. Respondents were very confident in their ability to recognize when a patient was approaching the end of life, discuss this with the patient and family, break bad news, control pain, and withhold and withdraw treatment (RCP Working Party, 2012). These results are surprising given ongoing reports of poor care, but are reports of self-rated confidence only, without any proxies for actual skills. It is likely that at least some of these physicians were unaware of their own incompetence. The working party recommended that all physicians caring for patients with palliative care needs attend at least one relevant training event every 5 years.

The literature considering the training of primary health-care or family practice doctors is not extensive, and is often about UK general practitioners (GPs). The skills and training of this group of doctors are important as most patients who know they have life-limiting illness wish to die at home (Gomes et al., 2013). A significant part of early GP training takes place in hospital in the United Kingdom. In a UK-wide postal survey, Low and colleagues reported that while 60–70% of GP trainees had received training in control of pain and other symptoms, only 40–50% had received communication skills training, teaching about bereavement care, or the use of syringe drivers. The median number of patients with palliative care needs they had cared for during their training was five (Low et al., 2006). For most, their deficiencies in training were only remedied once they entered their year in primary care towards the end of their GP training. Their hospital training had thus not provided relevant palliative care training.

Becoming a specialist in palliative medicine

Palliative medicine is recognized in different ways in different countries, for example, in Australia, New Zealand, Hong Kong, and Taiwan it is fully certified. The American Board of Medical Specialties recognized the subspecialty of Hospice and Palliative Medicine in the United States as recently as 2006. In Europe, palliative medicine has specialist status in only two countries, the United Kingdom (since 1987) and Ireland (1995). In five other countries, it is regarded as a subspecialty, that is, doctors seek a second specialization following full certification in another specialty; these countries are Poland (since 1999), Romania (2000), Slovakia (2005), Germany (2006), and France (2007). As of 2006, ten other European countries were discussing certification (Centeno et al., 2007).

Where specialist training is well developed, national bodies have usually agreed on competency-based curricula for specialist palliative care. In the United States, the Accreditation Council for Graduate Medical Education (ACGME) is responsible for accrediting post-MD training programmes. It accredits fellowship training programmes in palliative medicine, but the AAHPM advises on the necessary competencies. In the United Kingdom, such curricula are approved by the GMC, and training programmes are overseen by a specialty training committee of the RCP. Similarly, the Royal Australasian College of Physicians lays out the competency requirements for training in Australia and New Zealand. In many other countries, there are no competency frameworks for training in palliative medicine.

Assessment of palliative care competencies

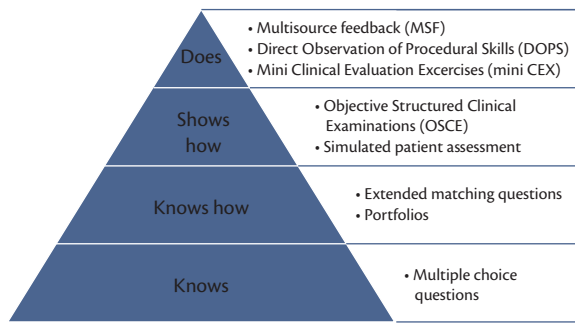
It is useful to consider models of how learners achieve and demonstrate competencies in reviewing the literature pertaining to education in palliative care. In 1990, Miller proposed a model for the assessment of clinical skills, competence, and performance, depicted as Miller's pyramid (Miller, 1990). As a learner's competence increases, they are able to demonstrate that they 'know' what they should do, then 'know how' they should do something; next they can 'show how' to do a skill or task and finally they can perform or 'do' it in practice. Fig. 4.2.1 shows examples of the assessment methods used at each level of the pyramid.


Fig. 4.2.1 Miller's pyramid.

Assessment of undergraduates

Lempp and colleagues suggest that students remain 'orientated strongly towards examinations which are useful in ensuring proficiency in clinical skills but may detract from other learning' (Lempp et al., 2005). Gibbins et al.'s study confirmed this in palliative care (Gibbins et al., 2011). In 2002, only six of 24 UK medical schools assessed teaching about death, dying, and bereavement with some form of examination (Field and Wee, 2002), and a 2008 survey suggested only 30% of US medical schools assessed palliative care outcomes during student clerkships (Van Aalst-Cohen et al., 2008). Where students are assessed, predominantly knowledge-based outcomes are examined, however many schools have introduced objective structured clinical examinations which allow students to demonstrate how they put knowledge into practice and allow assessment of, for example, communication skills and students' attitudes towards patients with end-stage or life-limiting disease. Since students tend to see areas of curriculum content that are not examined as less important than areas that are, assessment of palliative care skills is critical in improving students' and doctors' attitudes towards, and skills in, palliative care.

Assessment of postgraduates: non-specialists

Much continuing professional development in palliative care is evaluated rather than assessed. Where trainees have learning objectives relevant to palliative care within their specialist curricula, these will usually be assessed in similar ways to their other learning objectives, predominantly through knowledge tests and workplace-based assessments. In the United Kingdom there are a number of postgraduate medical degree qualifications in palliative care or medicine available at Diploma and Master's level, however these are optional academic rather than clinical qualifications, and are therefore assessed through essays, presentations, publications, and dissertations, rather than clinically.

Assessment of specialist training in palliative medicine

Accrediting bodies have a responsibility to ensure that doctors awarded specialist qualifications are competent to care for patients, and therefore their training and assessment of competencies must be robust. Whilst competency-based training might be seen as complete once a trainee has gained the necessary competencies, many programmes specify a minimum length

of training also. The United Kingdom probably has the most extensive programme, requiring 4 years of training. The Royal Australasian College of Physicians Chapter of Palliative Medicine Education Committee requires trainees to complete 3 years of training. Fellowship training in the United States is for 1 year. The structures of these programmes differ, however the way that trainees demonstrate their competencies is similar. Most trainees must have satisfactory educational supervisor reports and complete a variety of workplace-based assessments, which allow them to demonstrate their competence in clinical practice, that is, at the 'does' level of competence within Miller's pyramid. In the United States, the Hospice and Palliative Medicine Competencies Project work group has laid out a set of measurable outcomes for hospice and palliative medicine competencies. These, as for other curricula, should 'represent those for the minimally competent specialist palliative care physician, not the expert'. The group refers to the Dreyfus model of skill acquisition where the novice develops into the advanced beginner, before becoming competent, then proficient, then an expert (AAHPM, 2009). These outcomes link to a clearly blue-printed and extensive toolkit of assessment methods, which include fellow self-assessments, attending physician and faculty assessments, chart reviews, assessments of communication skills and professionalism, academic, and palliative medicine structured portfolios and multisource (360°) feedback (AAHPM, 2009).

In the United Kingdom and Australasia, trainees must complete successful case-based discussions (CBDs) and mini-clinical evaluation exercises (mini-CEXs). Mini-CEXs are supervised learning events where an educational supervisor observes the trainee interacting with a patient and/or family, scores the encounter, and provides feedback to the trainee. In the United Kingdom, trainees also have to complete a number of relevant DOPS (direct observation of procedural skills), structured audit and teaching assessments, and seek and reflect upon multisource feedback from the multidisciplinary team. Knowledge is assessed also by trainees being required to pass a best-of-five multiple choice question specialty certificate examination.

Evaluation of palliative care teaching

In a similar way to Miller's pyramid of competence, Kirkpatrick's four-levels model describes how increasingly complex behavioural changes can be evaluated (Kirkpatrick, 1979). The considerations are: at level 1, the learner's reaction to teaching; at level 2, the changes in knowledge, attitudes, and skills the learner has acquired; at level 3, the degree to which participants apply what they learned during training in practice; and at level 4, whether desired outcomes occur because of the learning acquired, at learner or organizational level.

In 1997, MacLeod and James cautioned against a view of palliative care education as too complex, precious, and problematic to evaluate (MacLeod and James, 1997). For some time these issues seemed to hamper good evaluation of palliative care and relegate it to level 1 of Kirkpatrick's evaluation model, that is, the learners' reaction, usually satisfaction with teaching. Palliative care teaching is generally rated highly in studies, but robust evaluation requires more than students enjoying the teaching. Various studies have sought to demonstrate that teaching has led to students gaining knowledge and skills. Knowledge is relatively easy to test;

this is often done using a pre-and post-course assessment model. Whilst it is not surprising that knowledge scores improve immediately after teaching, some authors have repeated assessments to see if these improvements are sustained over time. Assessment and evaluation are not being used synonymously here; an individual may be assessed to see if their knowledge scores have increased following teaching, a group of students' assessments scores may be used to evaluate the effectiveness of that teaching.

Von Gunten and colleagues assessed the knowledge scores of 593 third year students following a taught and experiential palliative care course (von Gunten et al., 2012). Data were available for 487 students before and after the course and at year 4. Students demonstrated a statistically significant increase in knowledge scores (by 23%); these scores had fallen by 6% in the year following teaching. Goldberg and colleagues compared graduating students' knowledge after a 1-week clinical rotation in palliative medicine in addition to the 'interactive didactic' sessions the previous year's graduates had received. Disappointingly, the students' mean knowledge scores were similar (Goldberg et al., 2011).

The large number of medical students makes assessing palliative care skills in clinical practice difficult logistically. Burden to patients and lack of validated tools undoubtedly deter educators from evaluating teaching outcomes in clinical practice in postgraduates, also. Teaching is often evaluated, therefore, by asking participants to rate their confidence and self-assessed competence in carrying out relevant skills, for example, prescribing or communicating with patients and their families. In general, students' confidence and perceived competence improve with palliative care teaching. In medical students who often have little contact with patients approaching the end of life, such judgements may mean little, and what graduates say they will do in theory may not be translated into practice.

Doctors may be poor judges of their own competence; as part of a randomized controlled trial, Dickson and colleagues compared 143 internal medicine trainees' self-assessed ratings of competence with their patients', patients' families', and clinician-evaluators' scores on a questionnaire on the quality of end-of-life communication (Dickson et al., 2012). There was no correlation between these quality scores and the doctors' perceived competence. More worryingly, there was correlation for 'treatment discussions' only, and here the more confident the trainee, the lower the families' ratings were. The authors conclude that 'efforts to improve communication about end-of-life care should consider outcomes other than physician self-assessment to determine intervention success'. There is some evidence that doctors overestimate their own competence. In a carefully carried out evaluation of a faculty development programme in palliative care, delegates were asked to rate their attitudes and knowledge about end-of-life care practices, and their ability to teach aspects of palliative and end-of-life care (Sullivan et al., 2005). The authors used an unusual and potentially very useful approach. They administered questionnaires both before and after teaching, but they asked delegates to rate their pre-programme attitudes and knowledge again after the teaching. As they had expected, delegates rated their pre-course abilities more highly before teaching and reappraised their responses following teaching, that is, before the teaching they did not know fully what they did not know. Delegates rated the teaching highly and qualitative comments suggested changes in approaches to patient care; however,

questionnaires to assess changes in pain and symptom management, whilst showing positive trends, did not meet the authors' criteria for statistical significance.

Questionnaires have been developed to evaluate some of the attitudes relevant to palliative care, such as the thanatophobia (fear of death and dying) scale (Merrill et al., 1998), or knowledge about opioids and the management of pain in patients at the end of life (Elliott et al., 1995). However, there are challenges with such questionnaires. The thanatophobia scale includes statements such as 'dying patients make me feel uneasy', 'when patients begin to discuss death, I feel uncomfortable', 'I feel helpless when I have terminal patients on my ward'. Clinicians caring for dying patients may feel uneasy, uncomfortable, or helpless when talking to or treating patients who are dying or 'terminal'; however, we do not know from the literature whether such 'fears' have a negative impact on doctors' care for patients. More recently, Mason and Ellershaw have developed and studied the psychometric properties of the Self-Efficacy in Palliative Care (SEPC) scale to assess students' perceived confidence in communication, symptom management, and multiprofessional team working, important skills in palliative care. It is based on 'Bandura's theory' which hypothesizes the greater the individual's perception of efficacy (confidence) in a skill and the more rewarding the outcome expectancy, the more likely the individual is to perform the skill or behaviour. This scale has been studied with 140 medical students in one institution before and after teaching about palliative care, and showed an increase in their perceived skills of communication, symptom management and multi-professional team working (Mason and Ellershaw, 2004). Utilizing the SEPC scale and the thantophobia scale the same authors report that, following a 2-week education and clinical placement programme in palliative care, students' beliefs in their ability to practise and their attitude towards palliative care improved significantly (Mason and Ellershaw, 2008). They conclude, 'in accordance with the study's theoretical driver, it is reasonable to propose that the engaged active learning will have a positive effect on the future care of dying patients'. Further work is needed to determine whether the SEPC scale is a robust measure of the outcome of palliative care education in medical students, taking into account doctors' abilities in assessing their own efficacy and competence as described above.

Evaluation: does teaching and learning in palliative care improve patient care?

The best evaluation of palliative care teaching would be that it was shown to improve patient care. This is, of course, the crux of the problem. Ury and colleagues examined pharmacy records and demonstrated improved prescribing practices for pain following an educational intervention, suggesting that attitudes towards opioids and fears about addiction and so on had been changed by education (Ury et al., 2002). However, whether patients' pain outcomes were improved was not examined. Miller and Wee suggest we may need to consider indirect indicators of effective palliative care teaching rather than patient care outcomes; they suggest improvements in appropriate referrals from junior doctors to specialist palliative care teams or the inclusion of palliative care topics within their teaching by the wider medical school teaching community (Miller and Wee, 2006). Whilst these may be useful outcomes, they remain measurable proxy outcomes.

Conclusion

Curriculum development and delivery in palliative care education has come a long way. Despite this, patients at the end of their lives are still let down by doctors without the necessary skills to care for them. A number of challenges remain. Whilst students are receiving more curriculum time in palliative care, they need exposure to and real clinical experience with patients approaching the end of their lives. Junior doctors need support from seniors who acknowledge patients' needs, role model good communication and care, and facilitate their juniors' reflection and learning from these encounters. Perhaps in turn they can become the seniors who acknowledge and celebrate the rewards of caring for patients who cannot be cured, rather than continuing to teach, through hidden and informal curricula, the culture of focus on cure.

We know the research to validate *clinical* outcome measures in palliative care is difficult because of the well-documented problems with research in this patient population. The paucity of robust clinical outcome measures and the multiple potential confounding factors make evaluating the clinical impact of palliative care teaching perhaps even more testing. This does not mean we should not try. In an evidence-based world, our main challenge is to encourage and develop innovative clinical and research partnerships to design, deliver, and evaluate educational packages to demonstrate how education in palliative care best benefits patients and their families.

Nursing and palliative care

Deborah Witt Sherman and David C. Free

Introduction to nursing and palliative care

Although nursing is one of the oldest of the arts, it is one of the youngest of the professions. The origin of the word 'nursing' is derived from the Latin word *nutrire*, which means 'to nourish'. The word 'nurse' has its roots in the word *nutrix*, which means 'nursing mother'. Over the centuries, the meanings of these terms have broadened to encompass the training and education of a person who not only cares for the sick and dying, but also who cares for families, communities, and for humanity (Donahue, 1985).

Nursing has long been defined as both an art and a science. Nursing has moved beyond knowledge gained by reliance on tradition, trial and error, or authoritative statements of experts, to the generation of knowledge based on logical analysis and scientific inquiry. As a humanistic science, the purpose of nursing is to describe, explain, predict, and control phenomenon central to its concern, that of people and our world. The art of nursing is the creative use of the science of nursing for human betterment (Rogers, 1992).

Nursing has been an integral part of societal movements involved in the existing culture, while shaping and being shaped by culture (Donahue, 1985). Although dying and death are universal and part of the human condition, illness and death often can be delayed by science and medical technology. Life-prolonging therapies have assisted individuals to live longer with life-threatening illness, although death ultimately occurs. It has been understood that the care of those with life-limiting illness requires the best of modern science, along with an appreciation of emotional, social, and spiritual needs, and ways to alleviate any associated suffering.

As individuals are living longer with life-threatening or chronic illness, practitioners have realized that patients and families have needs and concerns that begin at the time of diagnosis, and that comprehensive care is needed from the time of diagnosis forward. Furthermore, care must be extended to families during the illness experience, through the death of the patient, and throughout the bereavement period for families. It also has become apparent that patients and their families, who are experiencing all types of life-limiting illnesses, and not only those affected by cancer, need this type of care.

Palliative care may be best understood as evolving from the original model of hospice care, but more explicitly endorses a combination of disease-modifying and supportive therapies intended to promote the well-being of patients and families experiencing serious, chronic, progressive and life-limiting or life-threatening illness. Palliative care not only focuses on pain control and symptom management, but also addresses the emotional, social, cultural, and spiritual needs of patients and families at any time during the illness trajectory, and unlike hospice care, is provided in the context of curative therapies. The ultimate goal of palliative care is to support the best possible quality of life for patients and their families (National Consensus Project for Quality Palliative Care, 2009). The concept of palliation is not new however. The term *palliate* has been seen in early records dating from the fourteenth century. It was in the eleventh century when the first hospices are believed to have originated, initially as refuges for weary travellers and religious pilgrims to Jerusalem in the Crusades, and later, to provide care for the sick and the dying (Connor, 1998).

Nurses, who are educated in palliative care nursing, 'facilitate the caring process through a combination of science, presence, openness, compassion, mindful attention to detail, and teamwork' (Coyle, 2006, p. 5). As members of the interdisciplinary palliative care team, nurses, physicians, social workers, and other health professionals each bring their own specialized competence and expertise gained through education, credentialing, and experience. Through interprofessional collaboration, an effective and compassionate plan of care is developed based on the best scientific evidence available, clinical judgement, and a recognition of the wishes and preferences of the patient and family, known as evidence-based practice.

With close to 19.4 million nurses globally, nursing is the world's largest profession (World Health Organization, 2011). Consistently ranked the most trusted profession both in America (Gallup Incorporated, 2010) and internationally, nurses have a tremendous potential to reform health care and ensure quality care for seriously ill patients and their families. Nurses understand the individual's need for control and can emphasize the patients' and families' active participation in decision-making. Nurses' discussions with patients and families can 'replace uncertainty with certainty, hopelessness with faith and despair with empowerment. Palliative care nursing is an exquisite blend of aggressive management of pain and symptoms associated with disease and its treatment, coupled with holistic and humanistic caring' (Sherman and Matzo, 2006, p. xx). Palliative care nursing requires the integration of empirical, aesthetic, personal, and ethical knowledge in providing patient- and family-centred holistic care. This integration of nursing knowledge assists nurses in reshaping societal perspectives regarding illness, dying, and death. Nurses understand that, when individuals move beyond fear, there is an opportunity for healing and continued growth for patients and families, even as death approaches.

Integration of knowledge in palliative care nursing

According to Coyle, the statement 'I failed to care for him properly because I was ignorant' (Coyle, 2006, p. 5) speaks to the need for health professionals, including nurses, to be educated in palliative care. The knowledge base of a discipline includes information, facts, principles, and theories that are organized according to the beliefs of the discipline. Throughout nursing history, knowledge has been obtained through tradition, expert opinion, borrowed knowledge from other disciplines, and role modelling. Based on an analysis of the conceptual and syntactical structure of nursing knowledge, Carper identified four fundamental patterns of knowing: empirical, aesthetic, personal, and ethical knowing (Carper, 1978).

Empirical knowledge

As nursing has developed as a profession, it has been both recognized and accepted that nursing practice must be based on empirical knowledge, or the science of nursing, which involves problem solving, logical reasoning, and scientific inquiry. Empirical knowledge draws upon a reality that can be observed and measured, and therefore verified by others (Carper, 1978). Qualitative and quantitative research builds and tests theories and provides important insights regarding the health of individuals, families, and communities and the dynamic relationships with the environment. More specifically, nursing is interested in the lives of people in particular environments and their diverse perspectives on promoting health, preventing illness, and managing disease. The goal is to move to greater levels of health and wellness and to improve quality of life. The development, testing, validation, and application of theories through research provide the evidence that informs evidence-based practice. The concept of praxis is often used in nursing to describe the interactive relationship between research and practice—each informing the other (Rolfe, 2006).

With the adoption of evidence-based practice as the standard in medicine and nursing, all levels of evidence from lower levels of evidence such as expert opinion through to the meta-analyses of randomized controlled trials provide the empirical knowledge needed to guide nursing practice in general, as well as in palliative care. The combination of evidence-based practice with humanistic and compassionate care represents the imperative to integrate the science and the art of nursing.

Aesthetic knowledge

Aesthetic knowledge or the art of nursing involves a deep appreciation of the meaning of a situation. Aesthetic knowing is made visible through the actions, conduct, attitudes, narrative, and interactions of the nurse in relation to others. It involves participating in or experiencing another's feelings and the ability to envision valid ways of helping in relation to desired outcomes and the goals of care. Aesthetic knowledge enables a nurse to envision the possibilities and to know what to do and how to be in the moment. Aesthetic knowledge supports the dynamic integration of parts into a whole (Carper, 1978). In the care of those with life-limiting or chronic illness, aesthetic knowledge enables the nurse to see the entire situation related to the interplay of physical, emotional, social, cultural, and spiritual needs and to develop a plan of care that focuses on the whole person within the context of their

family and community. Evidence-based practice involves not only empirical knowledge but also an understanding of the meaning of the situation, which further informs clinical judgement.

Personal knowledge

In addition to the integration of empirical and aesthetic knowledge, the clinician also integrates their personal and professional experiences in the form of personal knowledge. Personal knowledge refers to the inner experience of becoming a whole and genuine person. Personal knowing encompasses knowing one's own self and others (Carper, 1978). Empiric theories can be learned, but their meaning for the individual comes from personal reflection and experience. Personal knowing occurs through entering the world of the person being cared for, understanding their world, and responding to them. Personal knowledge is therefore concerned with the quality of interpersonal contacts, promoting therapeutic relationships, and providing individualized care. Personal knowledge also involves personal integrity and honesty, as well as enthusiasm, courage, and imagination (Carper, 1978). As palliative care clinicians, nurses reflect on their personal and family experiences with illness, loss, and grief, as well as on the experiences of patients and families for whom they have cared. With personal knowledge, nurses respond in loving, and supportive ways to the suffering of patients and families.

Ethical knowledge

Ethical knowledge must be integrated in palliative care. Ethical knowledge or the moral component of nursing is concerned with the right action within a situation. It includes voluntary actions that are deliberate and subject to judgement as right or wrong. Ethical knowing in nursing requires both experiential knowledge and knowledge of the formal principles, ethical codes, theories, and local, state, and federal laws that relate to or govern the discipline and society. It involves advocating for the patient. Ethical knowledge provides insight about which choices are possible and why. It provides direction towards choices that are good, sound, responsible, or just (Carper, 1978). In palliative care nursing, ethical knowledge is very important in assisting patients and families in making end-of-life decisions. Palliative care nurses are often members of ethics committees and grapple with ethical dilemmas in clinical situations.

Emancipatory knowledge

The concept of emancipatory knowledge, a fifth way of knowing, was introduced in 2010 (Kagan et al., 2010). It denotes an awareness of social injustices and disparities, and the ability to investigate their sources, and bring about the changes needed to correct the systemic and underlying causes of injustice and oppression that impact health and society. Each individual pattern of knowing—empirical, aesthetic, personal, ethical, and emancipatory—is necessary, but insufficient alone for achieving the goals of nursing. All of the ways of knowing are important in defining the whole. This is illustrated by considering the response to a common question: 'Which nursing intervention is best to relieve pain?' An *empirical* study can test hypothetical relationships among methods of pain management, each of which is influenced by *aesthetic* meanings of relieving pain, *personal* meanings concerning the experience of pain, *ethical* values that influence how and when pain relief is given and received, and *emancipatory* factors that

address social injustices and inequities that might affect equitable access to the treatment of pain (Carper, 1978). Failure to integrate knowledge within all of the patterns of knowing leads to uncritical acceptance, narrow interpretation, and partial utilization of knowledge. When this occurs, the ways of knowing are used in isolation from one another and the potential for synthesis of the whole is lost. When removed from the context of the whole of knowing, empirics produces control and manipulation; aesthetics produces indulgence in self-serving expressions and lack of appreciation for the meaning in a context; personal knowing produces isolation and self-distortion; ethics produces rigid doctrine and insensitivity to others (Carper, 1978); while emancipatory knowing alone could lead to aimless and ineffective activism. Palliative care nursing, therefore, involves the integration of all patterns of knowing to alleviate suffering and create an opportunity in which illness, dying, and death may become a time of healing or being made whole. In the formal education or continuing education of nurses in palliative care, it is important to recognize the integration of empirical, aesthetic, personal, ethical, and emancipatory knowledge so that nurses can 'practice what they know' and provide a holistic patient- and family-centred plan of care that is effective, evidence-based, compassionate, and equitable.

Palliative care nurses: responding to changing health-care needs

Across the world, there are aging populations, an increase in the incidence and prevalence of HIV/AIDS and cancer, and people living longer with prolonged advanced and chronic illness. The evolution of the field of palliative care has been a response to the changing profile of illness, dying, and death in the twentieth century (Stjernswärd and Pampallona, 2004). In the United States, for example, the number of Americans with serious or life-limiting illness is expected to double in the next 25 years with the aging of the baby-boomers (Morrison et al., 2011). Globally, the percentage of the total population over age 60 is expected to double from 11% to 22%, and the number of elderly over age 80 is expected to increase by a factor of 26 by 2050 (Bloom et al., 2011). In the decades to come, there will be an international imperative to care for aging populations, particularly as palliative care continues to expand its focus upstream from end-of-life care to the care of the patients and families experiencing serious, chronic, progressive, and life-limiting or life-threatening illness.

The increasing demand for palliative care services in the United States has been evidenced by the growth in hospital palliative care teams in the past 10 years. A decade ago, there were virtually no palliative care programmes in US hospitals. Today, palliative care teams can be found in 63% of the nation's hospitals that have 50 beds or more. As such, access to palliative care in US hospitals has more than doubled in the past 5 years (Morrison et al., 2011). Hospice care, as part of the continuum of palliative care, has also experienced a rapid growth in the United States in response to demand. From 1984 to 2010, there was a 110-fold increase in the number of hospices participating in Medicare in the United States, rising from 31 to 3407 (National Hospice and Palliative Care Organization). Worldwide estimates suggest that over 300 million people or 3% of the global population have either palliative or end-of-life care needs each year (Skilbeck and Payne, 2005). The steady rise in the number of patients and families

accessing hospice and palliative care services not only supports this projection of an increased future need (National Hospice and Palliative Care Organization), but also portends an increased need for adequately prepared generalist and specialist nurses in order to provide the care. There has been concern about the ability to meet this projected significant growth in the need for hospice and palliative care services with adequately educated and trained nurses.

In the past, the education of nurses in end-of-life care has been inconsistent at best, and was neglected for the most part, in both undergraduate and graduate nursing curricula (American Association of Colleges of Nursing (AACN), 1998). In 1997, the International Council of Nurses issued a mandate that nurses have a unique and primary responsibility to ensure the peaceful death of patients. In response, the AACN convened a round table of expert nurses to identify the precepts underlying hospice and palliative care. Round-table experts concurred that these precepts should be foundational to the educational preparation of nurses. Based on these precepts, the document, entitled *Peaceful Death*, was developed, which outlined baccalaureate competencies for palliative/hospice care and content areas where competencies can be taught (AACN, 1998). At the same time, the American Nurses Association formulated a position statement regarding the promotion of comfort and relief of pain of dying patients, reinforcing nurses' obligation to promote comfort and ensure aggressive efforts to relieve pain and suffering. National, state, and local indicators also pointed to the need for all nurses to have generalist-level knowledge of palliative care.

Generalist and specialist level of palliative care nursing

Nursing practice is differentiated according to the nurse's educational preparation, and licensure, which ranges from basic/generalist level through an advanced level of competency. Certified at the basic level of competency, the nurse may be licensed as a licensed practical nurse or registered professional nurse who has gained competencies in palliative and hospice care through their general educational programmes, professional work experiences, and ongoing continuing education. By virtue of graduate education and related clinical expertise, the advanced practice palliative care nurse is a specialist who demonstrates greater depth and breadth of knowledge and skill in theory, research, and practice reflected in the standards of care of palliative care and hospice nursing (Hospice and Palliative Care Nurses Association, 2002).

General registered nurses

In the United States, the current expectation is that all registered nurses have a basic or generalist level of knowledge and competency in palliative care. This includes a holistic approach to care including pain and symptom assessment and management, cultural competence, effective communication skills, recognition of ethical and legal aspects of care, and knowledge regarding care of the imminently dying patient. To ensure that all nurses have generalist level knowledge of palliative care, several educational initiatives have occurred. Since 2000, initiatives have included the integration of palliative care content in nursing textbooks, including the seminal textbook *Palliative Care Nursing: Quality Care to the End of Life* (Matzo and Sherman, 2010) and the *Oxford Textbook of Palliative Nursing* (Ferrell and

Coyle, 2010). Furthermore, there has been the integration of palliative care content in associate degree, baccalaureate, and graduate programmes through a project known as ELNEC (End-of-Life Nursing Education Consortium). ELNEC was established in 2000 with initial funding from the Robert Wood Johnson Foundation to develop a national curriculum to address the fact that most nursing students were not receiving adequate training and preparation for end-of-life care during their basic nursing education. Nearly 14,000 nurses and other health-care professionals from the United States and other countries have received ELNEC training to date to provide quality care to seriously ill and dying patients and their families. Those who have received training since the establishment of the ELNEC Train-the-Trainer programme have gone on to train 390,000 additional nurses and other providers in their respective institutions and organizations. Some developed countries are leading the way in terms of integrating palliative care education into their basic nursing education curricula. One notable example is Israel, where all general nursing programmes include a full unit of palliative care nursing.

Specialist palliative care nurses

Specialist palliative care nurses are also being educated and trained. These advanced practice nurses (APNs) must have the appropriate educational preparation to assume responsibility for health-care decisions and are acknowledged as core members, and often leaders of the palliative care team. In 1998, the first Advanced Practice Palliative Care Nurse Practitioner programme in America was begun at New York University in New York, under the leadership of Dr Deborah Witt Sherman. Subsequently, Dr Sherman took this Master's curriculum to Tenshi College in Japan. The first Palliative Care Clinical Nurse Specialist (CNS) programme was begun at Ursuline College in Ohio under the leadership of Dr Denise Sheehan. According to the 2008 AACN Consensus Model for APNs (APRN Consensus Work Group & National Council of State Boards of Nursing APRN Advisory Committee, 2008), advanced practice level preparation for any specialty must be accomplished initially through education in one of four APN roles: CNS, Certified Registered Nurse Anesthetists (CRNA), Certified Nurse Midwives (CNMs), or Certified Nurse Practitioner (CNP) programmes. APNs must also be educated in at least one of six possible population foci: family, adult-gerontology, paediatrics, neonatal, women's health, or psych/mental health.

Today, over 15 nursing schools in America offer specialist/graduate-level palliative care education by combining palliative care with other advanced practice master's programmes such as an adult health, geriatric nursing or paediatric nursing (Hospice and Palliative Nurses Association (HPNA), 2013). While advanced preparation in palliative and hospice nursing can be accomplished in the context of a Master's degree programme as a sub-specialty, it can also be accomplished by completing one of the available post-Master's certificate programmes in palliative care offered at several American schools (HPNA, 2013). Through clinical experience and continuing education in palliative care, APNs in other specialties may also become eligible to take the advanced practice palliative care certification examination, provided they have the required minimum of 500 hours of supervised clinical practice specifically in the area of palliative care. Additionally, a Doctor of Nursing Practice (DNP) programme with a palliative care focus option recently became available at the University of South

Alabama. In addition to the US and Japan, Advanced Practice Palliative Master's programmes are offered in other countries, such as the United Kingdom and Australia.

In the United States and other countries, hospice and palliative care nurses associations have supported the evolution of palliative and hospice nursing. Certification at the generalist and advanced practice levels of palliative and hospice nursing continues to be a critical focus of these organizations. For example, since early 2001, in the United States, the number of registered nurses credentialed at the basic level has risen from 7000 to 11,600 (National Board for Certification of Hospice and Palliative Nurses (NBCHPN)). As of March 2012, 18,000 individuals have been certified in the United States by the NBCHPN as nursing assistants, licensed practical nurses, registered nurses, and APNs.

It is recognized internationally that certification in hospice and palliative care nursing is valued because the individual nurse:

◆ has a tested and proven competency across the spectrum of palliative care and hospice nursing care

◆ has access to a national network of experienced and knowledgeable palliative care and hospice nurses

◆ has demonstrated a commitment to his or her specialty practice by pursuing certification

◆ has demonstrated dedication of professional development in his or her nursing career

◆ is an asset to his or her employer in an atmosphere of increasing awareness regarding quality in health care (Lentz and Sherman, 2006).

The scope and standards of palliative care and hospice nursing

The scope of palliative and hospice nursing continues to evolve as the art and science of palliative care develop. The philosophical precepts of palliative and hospice care emphasize the importance of holistic care offered to patients and families across the life span and in diverse health-care settings. As such, palliative and hospice nurses provide evidence-based care that addresses the physical, emotional, social, and spiritual/existential needs of patients and their families, with the primary goal of promoting quality of life through the relief of suffering along the illness trajectory. Palliative care nursing is provided to patients and families in acute care hospital units; inpatient palliative care units; inpatient, home, or residential hospices; ambulatory palliative care clinics; long-term care facilities and assisted living facilities; prisons; and private practices (Hospice and Palliative Care Nurses Association, 2002).

Relief of suffering and the possibility of improved quality of life for individuals and families are enhanced by:

◆ providing effective pain and symptom management

◆ addressing psychosocial and spiritual needs of patient and family

◆ incorporating cultural values and attitudes in developing a plan of care

◆ creating a healing environment to promote a peaceful death

◆ supporting those who are experiencing loss, grief, and bereavement

- promoting ethical and legal decision-making
- advocating for personal wishes and preferences
- utilizing therapeutic communication skills in all interactions
- facilitating collaborative practice
- ensuring access to care and community resources through influencing/developing health and social policy
- contributing to improved quality and cost effective services
- creating opportunities and implementing initiatives for palliative care education for patients, families, colleagues, and community
- participating in the generation, testing, and/or evaluation of palliative care knowledge and practice (Hospice and Palliative Care Nurses Association 2002).

Advanced Practice Palliative Care Nurses, who have advanced knowledge and skill in palliative care, play a vital role by assessing, implementing, coordinating, and evaluating care throughout the disease trajectory, as well as counselling and educating patients and families, and facilitating continuity of care between hospital and home. APNs also obtain knowledge about ethical issues facing individuals and families, and develop strategies to assist them in defining expected goals of care, as well as accessing and coordinating appropriate care. In addition to clinical expertise, APNs may assume leadership roles in practice, education, research, and administration, which further advance palliative and hospice care as a nursing specialty.

By articulating the scope and standards of professional nursing practice, the specialty defines its boundaries, informs society about the parameters of nursing practices, and develops the regulations for the specialty. As in all nursing specialties, nurses must practice within the scope of their specialty, as outlined by regulation, a professional code of ethics, and professional practice standards (Hospice and Palliative Care Nurses Association, 2002).

The standards of care reflect the values and priorities of palliative care nursing and provide a framework to evaluate practice (Box 4.3.1). These standards are authoritative statements, written in measurable terms, which define the palliative care nurses' responsibilities and their accountability to the public regarding patient/family outcomes. The standards of professional performance describe the competent professional role behaviours of palliative and hospice nurses, including activities related to quality of care, performance appraisal, education, collegiality, ethics, collaboration, research, and resource utilization (Hospice and Palliative Care Nurses Association, 2002). The nursing process includes clinical decision-making and encompasses all actions of the nurse in the care of patients and families. Although the standards, which express the philosophical beliefs of palliative care nursing, remain stable over time, the criteria intrinsic to each standard changes as scientific knowledge and technology are advanced. The standards of care are written both at the basic and advanced practice levels and reflect the nursing process, which involves assessment, diagnosis, outcomes identification, planning, implementation, and evaluation.

Foundational to the standards of care are the following tenets:

- Care should be age appropriate and culturally sensitive.
- A safe environment is to be maintained.

- Education of patients and families is essential.
- Coordination and continuity of care across settings and caregivers must occur.
- Communication and the management of information must be effective (Hospice and Palliative Care Nurses Association 2002).

Competency frameworks have evolved largely from Bloom's learning taxonomy (Bloom, 1956) and take into account how knowledge attainment and skill development occur incrementally based on education and experience. A number of jurisdictions including the United States, Canada, Ireland, United Kingdom, New Zealand, and Australia have developed and, in many cases, validated palliative care nursing competency frameworks. These competency frameworks have been linked to nursing curriculum development in each respective country in order to establish and advance the skills, competencies, values, and standards of care for palliative care nursing (Connolly and Charnley, 2012).

Nurse-generated palliative care research

The science of palliative care and hospice nursing focuses on the generation of basic and applied knowledge in describing, explaining, predicting, and controlling phenomena related to the care of individuals with serious, chronic, progressive, and life-limiting or -threatening illness and their families. The ultimate goal of nursing research is to improve the care of patients and families in areas of symptom management, psychological responses to illness, and the family caregiver experience (Ferrell, 2010). Qualitative studies in palliative and hospice care are important to understanding the subjective experiences of patients and their families and in developing theories for further testing. Quantitative studies are essential for testing theories, determining the incidence, prevalence, and severity of symptoms, and evaluating models of care and palliative care and hospice interventions.

Nurses have historically contributed to the advancement of research and science. Florence Nightingale, known as the 'mother of nursing', was identified as the first nursing researcher as she kept detailed and systemic records of her observations and understood the value of data in informing nursing practice. Early palliative care nurse researchers included Jeanne Quint Benoliel, who in the 1960s, established a programme of research focused on the subjective experience of patients following a diagnosis of life-threatening illness. In the 1970s, Ida Martinson studied the care of dying children, while in the late 1980s, Marilyn Dodd conducted research on patients' self-care management of adverse effects of. In 1992, Elizabeth Clipp examined health transitions and the complexity of human functioning (Lunney, 2011).

Over last 25 years, nursing research has made significant contributions to science. With the establishment of the National Institutes of Nursing Research in 1997 as an Institute within the US National Institutes of Health, interprofessional colleagues, including nurse researchers, have examined phenomenon relevant to the specialty of palliative and hospice care. Similar research institutes in the United Kingdom, Canada, and Australia provide the international community with findings that inform evidence-based practice. Nursing researchers and scholars in academic institutions, particularly research universities and academic medical centres, are submitting research proposals for federal and foundation funding to advance the science of palliative care.

Box 4.3.1 The standards of care for palliative care and hospice nursing at the basic and advanced practice levels.

Standard I: assessment

At the basic level of competence, the palliative care nurse collects individual and family data. At the advanced practice level, the palliative care nurse conducts in-depth and comprehensive assessment based on a synthesis of individual and family health data. Data collection involves information from multiple sources. Assessment is systematic and ongoing. Assessment includes a comprehensive health history, review of systems, physical examination, determination of functional status, information from laboratory data or diagnostic tests, identification of goals of care, and determination of patients' and families' emotional status, spiritual well-being, coping techniques, and resources. The assessment data are prioritized and documented (HPNA, 2002).

Standard II: diagnosis

At the basic level of competence, the palliative care nurse analyses the assessment data in determining nursing diagnoses. At the advanced practice level, the palliative care nurse utilizes an accepted framework that supports palliative care nursing knowledge. Clinical judgement is used in critically analysing data in the formulation of differential medical diagnoses and nursing diagnoses. Diagnoses are derived from multidimensional sources of data; are validated with the patient, family, and interdisciplinary team; actual or potential responses to alterations in health are identified; problems that may be prevented, resolved, or diminished by nursing interventions are identified; and are communicated and documented in the medical record (HPNA, 2002)

Standard III: outcome identification

The palliative care nurse educated at the basic level identifies expected outcomes relevant to the patient and family in collaboration with the interdisciplinary team. The palliative care nurse educated at the advanced level identifies outcomes based on the critical analyses of both complex assessment data and diagnoses. Expected outcomes are mutually formulated with the patient, family, interdisciplinary team, and other health-care providers, when appropriate. Outcomes are culturally sensitive and reflect the patient's and family's values, beliefs, and preferences. Expected outcomes are realistic in accordance with the goals of care and evidence-based practice. Expected outcomes reflect continuity of care across all settings from admission through family bereavement. At the advanced practice level, the palliative care nurse also determines risks, benefits, and costs, as well as modifying the outcomes based on changes in the patients' and families' health status (HPNA, 2002).

Standard IV: planning

At the basic level of competency, the palliative care nurse develops a plan of care that includes interventions to attain the expected health-related outcomes. At the advanced practice level, the palliative care nurse develops a comprehensive plan of care that prescribes evidence-based interventions and reviews the risks and burdens with patients, families, and in consultation with other providers. The plan of care is individualized to the needs, desires, and resources of the patient and family, and is developed in collaboration with members of the interdisciplinary team. The plan is dynamic and is updated regularly, yet provides continuity of care. At the advanced practice level, the palliative care nurse develops strategies that promote quality of life through independent clinical decision-making and provides direction and guidance to other members of the interdisciplinary team (HPNA, 2002).

Standard V: implementation

At the basic level, the palliative care nurse implements the interventions ordered by the physician or APN. These interventions involve the provision of direct care, which facilitate self-care; maximize, restore, or maintain function; enhance well-being; support healthy patterns of living; and provide emotional support and the relief of symptoms. At the advanced level, the palliative care nurse prescribes, orders, or implements medical and nursing interventions. Interventions are evidence-based, implemented in a safe, timely, and ethical manner, and modified based on continual assessment of the patient's or family's response. At the advanced practice level, palliative care nurses supplement interventions at the basic level with sophisticated skills in data synthesis; they may negotiate health-related services and additional specialized care, provide consultation, employ complex strategies, oversee interventions and teaching modalities to promote and maintain health, and makes appropriate referrals (HPNA, 2002).

Standard VI: evaluation

The palliative care nurse educated at the basic level evaluates patients' and families' progress in attaining expected outcomes. At the advanced level, the palliative care nurse critically appraises and comprehensively evaluates all relevant data related to attainment of expected outcomes and goals of care. At the advanced level, palliative care nurses incorporate advanced knowledge, practice, and research into the evaluation process and assume responsibility for the process. Evaluation is systematic, criterion-based, ongoing, and reviewed with other members of the interdisciplinary team. Revisions in the diagnosis, expected outcomes, and plan of care are documented and communicated to the patient, family, and other team members to ensure continuity of care (HPNA, 2002).

In 1998, the Hospice Nurses Foundation in the United States also became a funding agency for palliative care nursing research and published its first research agenda for 2009 to 2012 to investigate the symptoms of dyspnoea, constipation, and fatigue (HPNA, 2012). The HPNA research agenda for 2012 to 2015 (HPNA, 2012) is based on the *Clinical Practice Guidelines for Quality Palliative Care*, developed through the National Consensus Project (National Consensus Project for Quality Palliative Care, 2009). Although there are eight domains of palliative care propounded in the *Clinical Practice Guidelines*, the HPNA research agenda focuses scientific inquiry on the first three domains, specifically on structure and processes of care, physical aspects of care, and psychological and psychiatric aspects of care. The domain of structure and processes of care considers the optimal membership of interdisciplinary teams, the focus on the patient and family as the unit of care, and the locations and models of care delivery. The research agenda related to physical aspects of care focuses on issues related to symptom management and the decline of individuals with multiple co-morbid conditions, as well as a focus on the physical care of patients in special populations. Within the psychological and psychiatric domain, the focus of inquiry is on the needs of individuals with serious mental illness (HPNA, 2012). Other funding agencies are interested in ways of promoting interprofessional education, the value of professional specialty certification, the integration of palliative care concepts into standard care across health communities, the value of concurrent curative with palliative care, and the use of research findings to shape health policy (HPNA, 2012).

As generalists or specialists in palliative and hospice care, all nurses have the opportunity to participate in research dependent on their level of education. Nurses at all levels can identify clinical problems specific to the specialty, serve as members of the research team, participate in data collection for pilot projects, surveys, or formal studies, critique research findings to determine the application of findings in practice and in the development of standards of care and the development of policies (Lunney, 2011).

In collaboration, nursing scientists and clinicians are responsible for evidence-based practice as the empirical findings of research inform clinical practice. The quantity and quality of research are evident in the number of scholarly publications and presentations at national and international palliative care conferences. For example, 14% of the 1073 palliative care English-language, peer-reviewed research articles published in 2010 and found through the CINAHL database identify nurses as either first or co-authors (Lunney, 2011). Nurse researchers, as principal investigators, often lead the interprofessional research team where each provide their specialized perspective to identifying relevant research problems, and offer expertise in quantitative or qualitative research methodologies. As a research team, nurses, physicians, and other health professionals consider ways of overcoming the barriers to recruitment and challenges to retention of such vulnerable populations as individuals who are seriously ill and dying and their family members. All health professionals must be committed to research collaboration to move forward the science of palliative and hospice care as a specialty.

The value of palliative care nursing

APNs play a pivotal role in palliative care (Sherman and Cheon, 2012). Several articles and research studies have examined the role of the palliative care APN. Many of the early studies were conducted outside the United States. Based on a study conducted in Switzerland, Hurlimann et al. (2001) reported that CNSs in palliative care influence patient care by direct care, bedside teaching, and case reviews. Jack et al. (2003) conducted a qualitative study to investigate the role of the CNS within a palliative care team in an acute care hospital setting in the United Kingdom. The results, based on interviews of 23 nurses and physicians, indicated that palliative care Nurse practitioners (NPs) offer support and advice to colleagues, as well as education, which improves the quality of care. Corner et al. (Kuebler, 2004) conducted a longitudinal study in England, which enrolled 76 patients and assigned them to 12 Macmillan palliative care nurses over a 28-day period. Based on the EORTC Quality of Life Questionnaire, significant improvements in emotional and cognitive functioning and in patient anxiety scores, measured by the Palliative Care Outcomes Scale, were reported from baseline to day 7. Patient records further indicated overall positive outcomes of care from Macmillan specialist palliative care interventions in 55% of the cases.

Quaglietti et al. (2004) propose that APNs are uniquely positioned to 'bridge' the gaps in health care based on their independent practice, varied practice sites, and improving reimbursement patterns. Studies have also been conducted regarding the effectiveness of specific roles of nurses in improving the quality of life of patients with life-threatening diseases. Aiken et al. (2006) conducted a randomized trial comparing the PhoenixCare demonstration programme of palliative care and coordinated care/case management for serious chronically ill patients with chronic heart failure ($N = 130$) and chronic obstructive pulmonary disease ($N = 62$), with an equal number of controls who received active treatment from the managed care organizations. Registered nurse case managers provided intensive home-based case management to address disease and symptom management, prepare for end of life, assess physical and mental functioning, and utilization of medical services by patients and families. The results indicated that patients in the intervention group had lower symptom distress, greater physical function, higher self-rated health, and better outcomes on self-management of illness. This novel model of patient care, which combined greatly enhanced palliative care with ongoing managed care organization treatment, was associated with improved quality of life for patients with serious chronic illness.

Additional US studies have clearly demonstrated some of the benefits of APNs in palliative care. Bookbinder and colleagues (Bookbinder et al., 2011) have suggested that NP-based delivery models can increase access to and the availability of specialist-level palliative care in the community. A recent palliative care clinic pilot study (Owens, et al., 2011) demonstrated that NPs by experience and education are ideally suited to manage both primary and palliative care needs of individuals. Other studies (Bakitas, et al., 2009; Dyar et al., 2012) have found that APN interventions in palliative care were not only well received by patients and families, but also demonstrated measurable improvement in patients' quality of life and mood.

The health-care cost-effectiveness and quality of care for NPs in general has been well demonstrated (American Academy of Nurse Practitioners, 2010; Newhouse et al., 2011). The cost-effectiveness of in-hospital and home-based palliative care has been clearly shown by a reduction in health-care spending for America's sickest

and most costly patient populations (Brumley et al., 2007; Penrod et al., 2010). However, there are a limited number of studies that specifically focus on the cost-effectiveness of APNs in palliative care. Nonetheless, nurse coordination of palliative care has been shown to maintain the level of clinical care and outcomes, while saving costs. One study reported a 40% cost savings with nurse-led palliative care (Payne et al., 2002). Further studies are warranted to provide information on cost-effectiveness in the context of quality care, and to obtain further evidence regarding the patient and family outcomes related to care provided by hospice and palliative care nurses, and particularly by those at the advanced practice level. While palliative care has become an economic imperative in reducing the health-care costs, palliative care is, more importantly, 'a humanistic imperative to insure that quality of life is promoted during all phases of the illness experience for both patients and their family caregivers' (Sherman and Cheon, 2012).

Palliative care nurses as health educators and public health advocates

According to Payne, 'Nurses have been and continue to be important in spearheading, introducing and developing hospice and palliative care services internationally' (Payne et al., 2002, p. 21) One of the key roles in the development, advancement and performance of the palliative care nursing is that of educator. The role of the palliative care nurse as educator ideally involves a variety of communications and interactions that may encompass any and all of the following: patient care and families, other health and social care providers, nursing students, institutional decision and policy makers, ethics consultants, community stakeholders and organizations, and political officials.

In the academic setting, palliative care nurses advance the specialty through curriculum development and the inclusion of palliative care teaching units and concepts, as well as through palliative care-focused research, dissemination, knowledge transfer, and research utilization. Palliative care nursing education is being enhanced and made more accessible through programmes such as the ELNEC Train-the-Trainer, which facilitates the dissemination of nursing knowledge to nurses and other colleagues both domestically and abroad (Paice et al., 2007).

In clinical practice settings, palliative care nurses have a role as health educators in promoting optimal patient and family well-being through teaching activities such as pain and symptom management; patient rights and decision-making; informing families of community and social support services; and teaching about other therapies, interventions, and self-care. Palliative care nurses as health-care team members mentor and teach other members of the interdisciplinary team regarding evidence-based approaches in palliative care.

Palliative care nurses are also public health advocates given that palliative care is a public health concern. 'Since death has a universal incidence, the incidence, de facto, makes it a public health concern' (Foley, 2003, p. 25). The aforementioned shifts in population and disease demographics, as well as the aging, dying, and palliative care needs of the 'baby boom' generation will place a strain on health-care systems and resources and will represent one of the key public health challenges of the century (Gott and Ingleton, 2011). The characteristics often seen in public health priorities are now seen with palliative and end-of-life care, such as

major impact, high social and financial burden, and the potential to mitigate illness-related suffering for patients and families (Rao et al., 2002; Foley, 2003).

Globally, here is a tremendous need for increased access to quality palliative care. Only 1 billion people worldwide have access to opioids and some form of palliative care services, particularly in North America, Europe, Australia, and New Zealand. However, more than 5 billion people do not have access to basic pain and symptom management medications and services. The lack of access to pain relief and palliative care an urgent global public health crisis, particularly the lack of equitably access in underdeveloped countries (San Diego Hospice, 2012). By virtue of their numbers, experience, education, time spent at the bedside, and insight into the lived experiences of patients and families, nurses have the potential to play a prominent role in as public health advocates for palliative care at the local, national, and global level (Payne et al., 2009). As both citizens and patient advocates, palliative care nurses work with key decision- and policymakers to inform them about the importance and effectiveness of quality, accessible, and equitable palliative care to improve outcomes, cost-effectiveness (Morrison et al., 2008; Penrod et al., 2010), and to ensure the preservation of basic human rights and dignity. In doing so, palliative care nurses continually serve as advocates for patients, families, and communities, in promoting global health and well-being (Payne et al., 2002) through micro and macro level activities and engagement.

As public health advocates, the role of the palliative care nurse involves the following:

◆ Coordination and continuity of care across settings and caregivers

◆ Education of patients, families, and providers

◆ Promoting and upholding palliative care as a basic human right

◆ Establishing networks of providers

◆ Increasing equity and access to palliative and end-of-life care in developed, and particularly in underdeveloped or resource-poor countries

◆ Developing and enhancing palliative care delivery models

◆ Increasing access to opioids and other symptom management modalities

◆ Increased public and political awareness

◆ Developing integrated care pathways

◆ Actively participating in public policy development, engagement, and social/political activism (Payne et al., 2009).

In addition, palliative care nurses advocate for a new perspective, which includes a focus on health and its promotion, even in the face of serious illness. Palliative care nurses assist patients and families in living life each day to the fullest, with the enhancement and maximization of their potential and the achievement of health even within the context of illness (Skilbeck and Payne, 2005).

Visions for palliative and hospice nursing

Nursing is a way of being in the world which involves a desire to support and care for others and the intention to heal. Nurses witness the suffering of people and are drawn towards them very

often in informal caregiving roles as family members, friends, or members of a community, as well as in professional roles. In witnessing suffering and death, there is often an awakening of nurses' own sense of mortality. Nurses learn of the preciousness of each day, the struggles to find meaning in life and death, as well as the opportunities to transcend the mundane and realize a connection to something larger than self. Though nurses may view living and dying through different lenses because of different cultural or spiritual perspectives, nurses' intentions remain focused on doing good, preventing harm, and being fair and just as they care competently and compassionately for others. As nurses mature as people and in their role as nurses, the egocentric 'I' shifts to a 'We'. The pain or joys of others are felt in a nurse's heart and their intellect strives to gain the knowledge and skills necessary to offer care to the whole person—mind, body, and spirit. Nurses seek to understand the world not only through formal education, but also through their life experiences as they learn about themselves and observe others. Indeed, patients and families often demonstrate a sense of resiliency in the face of adversity and teach others how to die with grace and dignity.

Nurses strive to understand the societal changes occurring at international, national, regional, and local levels that influence health and well-being. Nurses seek to make a difference in the lives of their patients, families, and communities as they work towards human betterment and goals that promote the greater good. The future vision for palliative care and hospice nursing rests on the belief that nurses are a valuable resource in national efforts to improve care and quality of life for patients and their families living with advanced, life-limiting illness. It is through collaborative efforts that the roles of hospice and palliative care and hospice nurses will be fully actualized. Professional organizations in nursing, medicine, hospice, and palliative are called upon to engage in dialogue about the role of APNs, and opportunities and strategies to advance the role. Nursing educators must become knowledgeable about palliative care and develop continuing education programmes, which support palliative care and hospice nursing competencies. Researchers are called upon to continue examining the effects of palliative care education, interdisciplinary palliative care teams, the impact of palliative care generalist and specialist nurses, and the safety, quality, and cost-effectiveness care provided APNs in palliative care. Models of palliative and hospice care delivery in rural areas, in the community, at home, in skilled nursing facilities, and hospital settings, and their impact of patients, families, goals of care, advance care planning, and quality of life are needed. APNs who practise in palliative care and hospice are called upon to document and disseminate the health-care outcomes and engage in interdisciplinary research and translate research findings into practice (Promoting Excellence in End of Life Care, 2002).

Payers of health-care services are called upon to recognize the specialty of palliative care, and provide APNs with adequate and consistent compensation that is commensurate with APNs scope of practice, authority, and responsibility, regardless of practice setting. Regulatory agencies, such as state, national, regional and global nursing organizations, are called upon to work collaboratively and consistently to recognize the scope and standards of advanced practice palliative care nursing. Insurers and legislators are called upon to remove barriers that prevent APNs from practising to the full extent of their education and training, to address challenges related to APN billing processes, and to eliminate inequalities in reimbursement rates for APN services. Health-care systems and providers are also asked to develop or expand practice opportunities for APNs in all settings that care for patients who may experience life-threatening illness. Health-care systems are called upon to develop and maintain interdisciplinary palliative care teams, establish effective policies related to the ethical and evidence-based provision of palliative and end-of-life care, and to work towards the goal of achieving certification where possible, such as through the Joint Commission's new Advanced Certification Program for Palliative Care in the United States.

The vision for palliative care and hospice nursing will be actualized through the collective efforts and commitment of nurses at all levels of practice. Nurses' full potential in health care will be fulfilled by a combination of exceptional knowledge in nursing, clinical skill, sensitivity, originality, ambition, desire, and self-respect. Nurses must continue to nurture their intellect, creativity, and spirit; rely on their own authority and ability to self-govern the profession; value the integrity of human wholeness by offering care which integrates empirical, aesthetic, personal, ethical, and emancipatory knowledge; and have faith and confidence in their personal and professional abilities. Indeed, a universe of infinite potentials arises for palliative care and hospice nurses as they 'Dream Big' and create a reality that improves the quality of care and quality of life of patients with life-threatening illness and their families.

Social work in palliative care

Terry Altilio and Nina Laing

Introduction to social work in palliative care

In 2001, Dame Cicely Saunders authored a commentary entitled *Social Work and Palliative Care—The Early History*. She documents the integration of social work in hospitals in the United Kingdom as early as 1905 and describes her own experience in the 1940s when she trained as an almoner (medical social worker), complementing her nursing education and predating her decision to become a physician. During 1905, in the United States, Massachusetts General Hospital would be the first hospital to employ social workers. This was consequent to the vision and commitment of Richard Cabot, a physician who observed that social and psychological issues were intimately entwined with medical care and health (Gehlert, 2012). Saunders links the reciprocal and enriching work of social work authors by honouring the work of Ruth Abrams, who, as early as 1945, published in *The New England Journal of Medicine* a study of 200 people with cancer receiving end-of-life care. She writes of her discovery of Alison Player's (1954) article 'Casework in Terminal Illness' and credits Margaret Torrie, a social worker in the United Kingdom, with founding Cruse Bereavement Care, a national organization that continues to provide bereavement care at no cost. Additional articles reflecting early social work contributions include Aitken Swan's (1959) report of interviews with families of 200 people with cancer cared for at home and Bailey's (1959) survey of the social needs of 155 people with lung cancer. Lastly, Dame Cicely tributes Zelda Foster, whose writings influenced the care of terminally ill veterans and their families, an impact that extended much beyond the Veteran Hospitals.

This early link of palliative social work clinicians in the United Kingdom and the United States provided a foundation for the evolving specialty which continues to be enriched by social work practitioners across the world. The international nature of the specialty was reflected in the Social Work Summit held in 2005 at the National Association of Social Workers (NASW) in Washington, DC. The Summit included clinicians, researchers, and educators. The *Oxford Textbook of Palliative Social Work* published in 2011 includes an international section honouring the skills, resilience, and diversity of the social work contribution to palliative care around the world. In addition, in the United States, NASW competencies have been established by NASW and in 2007, a monograph titled *What Social Workers Do* was published by the National Hospice and Palliative Care Organization. In Canada, research was undertaken to validate competencies (Bosma et al., 2009) and in the United Kingdom the work of Beresford and colleagues (2007) enhanced our understanding of service users' perceptions of specialist palliative social work.

Palliative care: the convergence

The definition of palliative care selected for this chapter is the most recent World Health Organization definition (World Health Organization, n.d.). In the United States, the National Consensus Project for Quality Palliative Care (2009) defines a similar scope which is informed by guidelines describing core precepts and structures.

Both documents reflect a commitment to psychosocial and spiritual aspects of care. As with other disciplines, the immediate focus of social work intervention and advocacy is often determined by the urgency of needs, resources available, and the challenges presented by social, political, and economic factors. Thus around the globe the contributions of social work will vary. In some settings, palliative social workers may integrate the psychosocial and spiritual aspects of pain and symptom management as a focus of assessment and intervention. However, in many parts of the world where access to opioids is limited, the primary mandate may be advocacy focused on improving access to medications for patients who suffer with unremitting pain during illness and at the end of life. In some settings the commitment to autonomy is actualized by social work participation in the comprehensive work of advance care planning while in other settings this focus on the future may be incongruous with social, spiritual, or cultural values.

Social work and its synergy with palliative care

No matter where in the world social workers practise, there is a unifying code of ethics that speaks of values inherent in the profession many of which are reflected in core principles of palliative and end-of-life care. In 2004, the International Federation of Social Workers (IFSW) and the International Association of Schools of Social Work (IASSW) approved a joint document *Ethics in Social Work, Statement of Principles*. As in palliative and end-of-life care, overarching principles and values frame social work practice and are reflected in the following definition:

> The social work profession promotes social change, problem solving in human relationships and the empowerment and liberation of people to enhance well-being. Utilising theories of human behaviour and social systems, social work intervenes at the points where people interact with their environments. Principles of human rights and social justice are fundamental to social work. (IFSW and IASSW, 2004, p. 1)

As the concepts of relationship, human rights, empowerment, and social justice are operationalized, we begin to identify the perspective and expertise that social workers bring to palliative

practice. Respect for the inherent worth and dignity of all people is related to supporting their physical, psychological, emotional and spiritual integrity, and well-being. Autonomy and participation are linked to a respect for strength and resilience, and treating the whole person within their environments. The social justice focus extends both to the individual and to society as a whole and in elucidating this value; the inherent commitment to diversity and to advocacy is reflected. While the nature of advocacy may be influenced by the population served and the part of the world in which social workers practice, the social justice mandate and commitment to the under-served does not dissipate but rather changes in focus and form. This joint document guides professional conduct and speaks to many common values such as competence, integrity, confidentiality, compassion, accountability, empathy, and critical thinking.

Social work: assessment and intervention

As with other disciplines, social workers listen, think critically, and respond from the perspective of their training. While all palliative care clinicians are expected to provide emotional support and attend to the psychological, social, and spiritual needs of patients and families, there are unique skills brought by each discipline and from these skills flow consequent responsibilities. The ability to identify psychosocial or spiritual distress, while a generic competency of palliative clinicians, does not necessarily assume the skills to intervene, especially in more complex situations. Therefore it is essential to know when to enlist the expertise of interdisciplinary colleagues.

Social work assessment emanates from a systems approach and a view of the person in the multiple environments, internal and external, which influence and inform their experiences. Social workers are therefore, by training, inclined to observe the influence of factors such as illness, medical systems, practical challenges, thoughts and feelings, symptoms, and disability, not only on the person, but on their family constellation and equilibrium. In addition to the environmental perspective the precept 'starting where the client is' (Goldstein, 1983) invites a process of exploration and inquiry whether through tools or conversation. This implicitly demands that we 'listen' to the multilayered communication that frames the patient's story and subsequently focuses intervention. Concurrently this inquiry, which extends beyond the medical to the emotional, social and spiritual life of the patient and their family, leads to a thoughtfulness about the boundaries of confidentiality.

Confidentiality

Inviting a patient to relate aspects of their personal narrative requires sensitivity to confidentiality given the team nature of palliative care. Information that is shared is often private, personal, and family-related, and patients and families are often unaware that information is shared. Hence implicit consent cannot be assumed. Respect for confidentiality and autonomy mandates that team members request consent to share intimate personal aspects of their lives beyond the medical when necessary. For some clinicians, information wields power, for others it represents an exclusive relationship with the patient, and still for others the need to know comes from simple curiosity.

In a specialty based in respect across disciplines, 'a test of trust' rests in an acceptance that honouring patient confidentiality and autonomy means that clinicians receive information that is necessary to do their work and that some information may be held confidential both in team meetings and in documentation (Randall and Downie, 1999; Monroe, 2005). Best practice methods suggest that we inform people that to get optimal care information does need to be discussed at a team level with the patient's permission. Additionally, encounters between a health care professional and patient or family requires a dated entry in the clinical record.

Assessment

Consequent to the environmental perspective, social work attunes to culture, and patient and family's biopsychosocial-spiritual history to identify areas of strength, resilience, and challenge. This helps to grasp the larger context within which illness developed (Cadell et al., 2011). The assessment process may include screening and/or assessment tools. Alternatively, it may be based in questions and conversation designed to validate the person and family beyond the illness, discover or elaborate areas of concern, sources of distress, and practical needs. At the heart of assessment is relationship, communication, verbal and non-verbal, and critical thinking which guides the process. As such, assessment is also an intervention informed by expertise and based in the listening and respect for the experience and perceptions of the patient, family caregivers, and family. The critical thinking that informs questions and comments often serves to uncover the meanings or interpretations attributed by patient and family to the various aspects of the illness experience. Inquiry about mood, sleep, or pleasure may assist in identifying patients who are anxious or depressed, fatigued, or in pain, leading to an interdisciplinary treatment plan which integrates knowledge of evidence, patient and family receptiveness, and available resources. Social workers with knowledge of symptoms bring valuable observations to medical and nursing colleagues for the purpose of exploring aetiology and crafting a treatment plan responsive to the multiple factors that often inform the symptom experience of seriously ill patients (Block, 2006; Cagle and Altilio, 2011; Walsh and Hedlund, 2011). An assessment process embedded in environment and relationship is adapted to the cultural variables that infuse the lives of patient, family, and clinician as well as the institutions in which care is provided.

Culture

Congruent with a focus on environment and strengths, social work assessment includes attention to the role and influence of culture. Culture can be understood as the integrated collection of socially determined and socially transmitted customs and beliefs, which shape the values of a given group of people and influence how they behave and interpret the world around them (Kemp, 2005; Young-Laing, 2009). Therefore, how an individual understands pain and suffering, caregiving, life-threatening illness, and spiritual and social functioning, for example, can be inextricably linked to their cultural background.

While the expectation of social workers and other practitioners is to develop a practice that is responsive to cultural variation, in practice, respect for cultural differences is a continuing and

evolving process. Clinicians develop an awareness that they are not culturally 'neutral', accepting that we bring to bear not only our individual culture, but also, the culture of our profession or institution and all its corresponding biases, preferences, customs, and beliefs. This attentiveness to self-awareness is an integral aspect of social work training and leads to an understanding of how our cultures influence how we receive patients, or conversely, how they may receive us and how this cultural exchange could impact the evolving relationship. Achieving good clinical outcomes in the setting of such a cross cultural exchange requires sensitivity, respect, knowledge, and the humility to ask for guidance from patients and families (Kemp, 2005).

Many practitioners possess generalist understanding of the role of culture in health care. It is also essential to become familiar with the cultural practices and beliefs of specific populations served, both from personal encounters and enquiry as well as from the literature in order to utilize these insights to intervene clinically (Kemp, 2005; Young-Laing, 2009). At the same time clinicians work to avoid a reductionist approach which stereotypes or falsely imposes the role of culture in lieu of more careful individualized assessment of the client–family–practitioner dynamic. Despite common attitudes and behaviours, there is often heterogeneity among cultures and within families and social work observation and enquiry about the family system works to identify such variation. There can be for example, great variation between generations in the perceived authority of a physician which might impact communication style and lead to familial conflict regarding treatment planning or decision-making.

Language differences abound and are an aspect of culture which can often present as a barrier to accessing quality care. Social work attunes to the many variables at play when the clinical team decides how to access translation services. When available, skilled professional interpreters may provide as close to verbatim translation as possible (Butow et al., 2011). Yet, even then, the subtleties of communication can literally be lost in translation and meanings misconstrued. Interpreters who are prepared by the clinical team can be most effective in carrying out their roles. For example, a patient may use the word 'tumour', but never the word 'cancer', something an interpreter should know in advance so as not to risk causing unintended harm. In the absence of professionals who speak the language, trained interpreters, or technological interpreter assistance, family members are often looked upon for assistance. While sometimes necessary, this option creates the possibility that family dynamics, personal beliefs, or individual discomfort with sensitive or difficult discussions could lead to distorted messages, things left unsaid or improperly interpreted with the unintended consequence of increased distress for both the family 'interpreter' and the family system. Equally important is the reality that the treatment team cannot know what is actually being communicated within the family.

Ultimately, culturally informed practice can illuminate and enrich the clinician–patient–family dynamic, identify areas of confusion, and/or clarify perceptions of illness and treatment. Clinicians often discover a path to culturally syntonic ways to intervene and perhaps identify resources within the cultural community, which contribute to positive clinical outcomes and sustain the patient and family as they transition back into their community. This potential reflects the systems approach which is integral to social work and attends to the interaction of people and the many systems of which they are a part. Respect for the power and potential of systems leads to a special affinity for the value and opportunity in team work and family conferencing, two core processes of palliative care.

Family meetings

Palliative care, at its most comprehensive seeks to address the needs of the whole patient, which in many instances includes family who provide continuity and assist in contextualizing the life of the patient. In the most generic sense, family encompasses biological families, families of creation, friends, and other persons of importance the patient identifies as belonging to their extended network. The family also becomes a unit of care as their needs and experiences are often intertwined with that of the patient. As a result, a family meeting can prove to be a powerful intervention to address the multifaceted needs of both the patient and family.

Family meetings are an important tool to enhance dialogue, provide information, respond to emotional distress, and marshal resources to help problem-solve, make decisions, and establish goals of care. Meetings can also help to substantiate a therapeutic relationship, explore patient and family experiences, and create an opportunity for the team to learn about the patient, and the shared values and beliefs which can prove invaluable in providing quality care (Altilio et al., 2008). Consequent to the complexity and the potential for positive outcomes, a well-planned family meeting often takes preparation ahead of time (Cohen Feinberg et al., 2011). By starting where the patient is, social workers utilize their assessment skills to help the team prepare for a meeting.

Understanding who has requested the meeting and the reason it is being held often guides decisions about who will facilitate and who needs to attend; which family members and which practitioners are essential to the process and expected outcomes. These decisions are rooted in sound clinical judgements including respect for cultural values. For example, outcomes are enhanced when the perceived authority of physicians is acknowledged, marshalled, or mitigated, depending on the needs and particular circumstances of the patient. The patient who experiences their care as fragmented or perceives conflicting messages from team members may benefit from a large cohort of involved practitioners in attendance. Alternatively, the patient who struggles to trust or is intimidated by the power of perceived experts may be best served by careful selection of a limited number of clinicians.

While many medical specialists such as intensivists and oncologists are trained to facilitate family meetings, social workers are often the most comfortable and skilled in group and family dynamics. Although social workers are adept at facilitating discourse, negotiation and skilled communication is only made relevant by careful 'listening' on multiple levels. The clinician serving as a 'silent participant' and 'participant observer' of family and group dynamics and communication processes has a responsibility to complement and enhance the process. Interventions designed to facilitate dialogue, interpret non-verbal communications or clarify confusion are chosen based on active ongoing clinical assessment of the patient and family process both within itself and in relation to the clinical team.

During family meetings, social workers use multiple interventions. They may utilize supportive counselling techniques, cognitive reframing, and anticipatory guidance to assist patients

and families as they integrate complex information spoken in the language of medicine and struggle to make decisions which impact the present and the future. They may invite expression of emotion, explore thought and meaning, and enhance informed decision-making and problem-solving as patients and families anticipate and prepare for outcomes or experiences which are unfamiliar and uninvited.

The listening skills implicit in social work training are essential to positive outcomes in family meetings. Indeed, listening is one of the more vital behaviours during a family meeting. The intensive care unit (ICU) is a setting in which family meetings are an assumed part of daily care and therefore much research has focused on palliative and end-of-life care in the ICU and communication with families. While the ICU represents only a portion of the settings in which palliative care is provided, some of the outcomes may have broader implications. Studies suggest that family members feel more positive about communications with physicians when more time is spent listening to the family than speaking to them (McDonagh et al. 2004). Additionally, there have been several studies evaluating the impact of communication in the ICU on the mental health outcomes of family members of patients receiving end-of-life care. While study in this area is ongoing, existing research suggests that there may be a connection between satisfaction with communication and improved mental health outcomes for family members after death (Azoulay et al., 2005; McCormick et al., 2007; Wright et al., 2008; McCormick, 2011). While exclusive to the ICU, this research supports a hypothesis that attention paid by all disciplines to the process of family meetings serves patients and families in the immediate and beyond and thus may be thought of as a pre-bereavement intervention.

Social work: role and responsibility in team

Palliative care as a team-based specialty engages multiple disciplines and different schools of thought in an effort to approach the varied needs of patients. Depending on the setting and resources available, a team can vary in size and constellation. In many practices, the 'person in environment' concept expands team to include family, community resources, and spiritual communities. Single practitioners may develop 'teams of creation' with floating memberships serving the needs of individual patients and families. Even in settings where there are more robust palliative care teams, the needs of the patient and family may be best met by an inclusiveness which invites participation by others who are integral to the patient's life, such as a long-term community physician, a treating oncologist, or a member of the clergy who has known the patient over time.

While a team-based approach is a key component to quality palliative care, how teamwork is translated into practice can vary according to the model chosen and the skills and training of the team members. The interdisciplinary model rests on synergistic and interdependence of clinicians who come with the unique expertise of their chosen profession as well as shared skills. Most palliative care clinicians recognize that individuals do not parcel out their spiritual, psychological, social, and medical needs but often present an integrated experience that requires clinician flexibility, role sharing, and knowledge both of one's own skills and those of others. Consequently, clinicians know when to consult for guidance and when to refer to other team experts. An interdisciplinary team is one in which a cohort of professionals with distinct roles and responsibilities act in concert with one another to produce successful outcomes (Crawford and Price, 2003). By creating an adaptive and interactive team environment, the expectation is that the team as a unit will achieve outcomes that exceed those possible if each practitioner were acting as an individual (Crawford and Price, 2003). However, for an interdisciplinary team to function at its best, it requires mutual respect for the different professionals involved, an environment of trust and safety, a willingness to challenge one another, and a recognition that our varied expertise means that we see patients and problems from differing perspectives.

Within the construct of team, social workers are often uniquely positioned consequent to their training in group dynamics, advocacy, and communication. These skills are essential when working with patients and families, and also when functioning as both a participant and an observer within the group dynamic of team. A social worker will listen and assess from a skill set which often identifies barriers, environmental issues, and patient, family, team, and system dynamics which may either potentiate or impede the goals of patients and families. Plans of care and treatment approaches can then be fashioned from a strengths-based perspective and with an awareness of the unique circumstance of the individual patient and family.

Patient family narrative: an illustration

Whether intervening within a family meeting, exploring decisions related to advance directives or resuscitation, discussing practical needs, or exploring the suffering component of pain, social work interventions have the potential to impact present treatment plans and to influence legacy if death is the ultimate outcome.

Lilie is the 46-year-old mother of Kevin, age 10 and Jamal, age 15. She came from the Virgin Islands to the United States seek medical care after having been diagnosed with breast cancer at the age of 39. She has two sisters in New York. For the past 5 years disease-modifying therapies have contributed to a quality of life that has enabled her to parent her sons, negotiate a fifth-floor, walk-up apartment, and maintain her independence and privacy. When diagnosed with metastatic disease to the bone, unremitting pain necessitated hospital admission and consultation with the palliative care team. Complementing the active pharmacological management of pain, social work assessment included the following:

◆ Understanding the impact of increasing pain and impaired physical functions on Kevin and Jamal, the family structure, and equilibrium.

◆ Exploring the emotional, cognitive, and spiritual aspects of Lilie's pain experience to offer interventions which complement radiation treatments and pharmacotherapy.

◆ Considering the existential, emotional, and cognitive impact as the medical treatments she came to the United States to seek become unable to extend her life.

◆ Exploring practical needs and resources to support her goals related to parenting and sustained function.

◆ Exploring Lilie's values, beliefs, and parental choices related to disclosure of prognosis to her extended family and children; her thoughts about future guardianship and care.

During lengthy hospitalizations Lilie forged a valued and reciprocal relationship with the oncology team. She maintained the structure of her family by parenting from the bed, directing Jamal in his care of Kevin. While she initially chose not to engage family to assist with her children, she consented to social work contact with Kevin's school yet would not allow disease- or prognostic-related information to be shared with her children or extended family. In the course of medical treatment, a lumbar puncture provided an opportunity for the social worker to assist with related distress and pain through a focused breathing imagery exercise which provided relief from procedure-related pain and validated her internal locus of control. It also led Lilie to re-awaken an artistic side of herself she had temporarily lost to disease and pain. She returned to writing poetry and expressing herself through music. She allowed her children to participate in joint videotaped music therapy sessions during which she wore island dress, sang, and played the drums. Concurrent with her choice to withhold information about the extent of illness, she engaged in shared therapeutic work which created a legacy. Her lyrics included the theme of 'going to the top of the mountain' which was understood to be a metaphor for transition and death.

Lilie's disease spread within her bones. As her body became increasingly fragile so did the structure of her family system as she became less able to orchestrate. As she experienced the fragility of her body and was informed of the risk of fractures she realized emotionally and cognitively that she could not return home and allowed the social worker to contact her sisters, extending the system of support. Jamal continued in his parenting role and asked direct questions driven by his observations of his mother's increased debility. Jamal's direct questioning, ongoing psycho-education, and an evolving trust in the social worker and clinical teams created the therapeutic environment wherein Lilie allowed some of Jamal's questions to be answered.

Lilie suffered a pathological fracture of the humerus while being moved by the staff she had come to trust and depend on as she became more disabled. This crisis event occurred amidst subtle signs of an emerging delirium that had not been recognized and created a crisis of relationship and trust with Lilie reporting to family that staff had hurt her and were withholding pain medications. This accusation caused suffering and anger both in the family system and the professional caregivers who cared deeply for Lilie. As the delirium was recognized, pharmacotherapy was initiated. A family meeting was organized to assist family and staff to consider the influence of the delirium on Lilie's perceptions and interpretations of the intent and meaning of staff's behaviours. Lilie's attribution of intentional harm on the part of staff became better understood when days before she died she spontaneously shared with the social worker 'woman to woman' that she had been physically abused by her former husband, an aspect of personal history that had been held private and protected.

Conclusion

Social workers practise in diverse settings and have the opportunity to move palliative care values and processes beyond hospitals and hospices to nursing homes, prisons, and senior centres. While most patients and families grasp the role of physicians, nurses, and chaplains, the functions of social work in health care is often less clear. Palliative care social work skills are a rich opportunity to serve patients, families, teams, and institutions. While social work clinicians may practise from different theoretical models, the work of discovering the individual's perception of their experience is universal. Rather than *informing*, 'starting where the client is' means that we invite patients and families to share what *they* see, their perceptions as well as the meaning they attribute to what has happened in their lives. Listening to the views of others is a primary focus for the social work discipline whose impact is anchored in the critical thinking that informs communication and the interventions they choose.

Social work clinicians whether engaged in direct practice, programme planning, teaching, or research now have access to a burgeoning literature, learning resources, competencies, leaders, and advocates to continue the reciprocal process on learning and enriching the shared work of palliative care. Patients and families living with life-threatening illness are amongst the most vulnerable both to our power and to the skills and compassion we bring to their care. This is a compelling ethical and moral mandate to be the best that we can be.

4.5

The role of the chaplain in palliative care

George Handzo and Christina M. Puchalski

Introduction to the role of the chaplain in palliative care

Spiritual care is an essential domain of palliative care (National Consensus Project, 2004). Spirituality is the essence of one's humanity and therefore a key factor in how people cope with illness and find healing and a sense of coherence (Norris et al., 2013). As Teilhard de Chardin wrote, 'We are not human beings having a spiritual experience; we are spiritual beings have a human experience' (de Chardin, 1976). This is why spiritual care and chaplaincy exist in health care and particularly in palliative care. Health care was founded on compassionate principles with attention to the whole person and emphasis on healing. In the twentieth century, with the rise in science and technology, the care of the patient became more focused on disease and cure. Today, health care is reclaiming its holistic roots, recognizing that the care of the patient requires attention to all dimensions of the patient's life—body, mind, and spirit. Nowhere is this truer than in the practice of palliative and end-of-life care.

Palliative care, as defined by the World Health Organization, 'is an approach that improves the quality of life of patients and their families facing the problems associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial, and spiritual' (World Health Organization, n.d.). This definition is notable for including spirituality as a potential area for diagnosis and treatment. Furthermore, the concept of suffering is included and embraces not just physical pain but also spiritual and existential domains. Thus, palliative care done well must include and take into account the spiritual dimension of the patient, the family, and, we would argue, the clinicians and other caregivers.

In 2004, the National Consensus Project for Quality Palliative Care was created as a task force of the American Academy of Hospice and Palliative Medicine to define and promote clinical practice guidelines for quality palliative care (National Consensus Project, 2004). It determined that spiritual, existential, and religious care is a required domain of care. However, in practice, clinicians did not know how to implement such care. Was this care only to be done by clergy or chaplains? What was the role of other clinicians? To address this issue, a National Consensus Conference (NCC), Improving the Dimension of Spiritual Care within Palliative Care, convened in 2009 (Puchalski et al., 2009). The consensus group developed models and guidelines for interprofessional spiritual care. It determined that all members of the health care team are responsible for addressing patients' spiritual issues within the biopsychosocial-spiritual framework (Sulmasy, 2002). The conference highlighted the importance of board-certified or board-eligible chaplains as the spiritual care experts and essential members of palliative care and other care teams.

The NCC also highlighted the role of spirituality as part of the professional development of all clinicians. Teilhard de Chardin (1976) reminds us that we are all spiritual beings no matter what our role is in health care. The spirituality of the care professional can impact how that person understands health and illness and how they interact with their patients. In fact, as was proposed in the NCC, healing occurs within the context of the relationship between clinician and patient and between chaplain and patient. Spiritual care recognizes this key element of care—the compassionate and caring relationship between any clinician/chaplain and patient is central to whole person care.

Background

The strong contribution of spirituality and religion to health is well documented (Jenkins and Paragament, 1995; Cohen et al., 1996; Tsevat et al., 1999; George et al., 2000; Gail and Comblatt, 2002; Puchalski, 2008; Koenig et al., 2012). Spirituality and religion have also been documented as strong contributors to how people cope with illness and suffering (Pargament, 1997; Balboni et al., 2007; Delgado-Guay et al., 2011). Traditionally, questions have surrounded the application of this knowledge and have focused on the issue of whether spiritual care or spiritual interventions in the process of delivering health care make a difference in coping or whether spirituality is so entwined in the humanity of all people that it is impervious to any intervention, especially during times of stress. There has now been significant research that provides evidence that providing for spiritual and religious needs yields benefits both to the patient and to the health care system. For example, Balboni and colleagues (2011) found that the majority of patients with advanced cancer report a significant spiritual issue. When patients' spiritual needs were met during hospital care, they were less likely to die in an intensive care unit and likely to spend more time in hospice (Balboni et al., 2011).

Another study found that 41% of inpatients desired a discussion of religious/spiritual (R/S) concerns while hospitalized, but only half reported having such a discussion. Overall, 32% of inpatients reported having a discussion of their religious/spiritual concerns.

Religious patients and those experiencing more severe pain were more likely both to desire and to have discussions of spiritual concerns. Patients who had discussions of religious/spiritual concerns were more likely to rate their care at the highest level on four different measures of patient satisfaction, regardless of whether or not they said they had desired such a discussion (Williams et al., 2011). Ai and colleagues found strong evidence for a link between spiritual struggle and poor health outcomes (Ai et al., 2010). Their work suggests that addressing spiritual struggle with patients might improve health-care outcomes.

While the relationship of spirituality and health has long been generally accepted and is now increasingly documented quantitatively, the issue of if and how to best address religious and spiritual concerns has not been clear. Historically, and often still today, the care of religious and spiritual needs has been delegated to faith communities. This model of care, which is still widely used, while providing for the needs of those who belong to organized religious communities, has several deficiencies. Generally, no care is provided for those who do not identify with an organized religious community (Fitchett et al., 2000). One study documented that only 42% of hospitalized patients could identify a spiritual counsellor to whom they could turn (Sivan et al., 1996). Furthermore, the diversity of religious and cultural backgrounds in many health-care settings has increased to the point where people of many groups are not having even their religious needs met.

To address some of these deficiencies there has been a rise in professional chaplaincy care. Recent work comparing chaplaincy care in the United States, the United Kingdom, and Australia concluded that chaplaincy practice in all three countries is moving towards a more multifaith, patient-centred model which, coincidentally, is much more aligned with the preferred role of chaplaincy in palliative care (Orton, 2008). In general, clergy provide religious-specific care while chaplains provide spiritual care within a medical setting, allowing chaplains to meet the needs of religious and non-religious patients and also to extend spiritual care to issues specifically related to medical care, for example, advance directives, family meetings, and addressing spiritual distress in the context of illness.

Training for chaplains

To support this new model, professional chaplains have been clinically and academically trained. In North America, especially the United States, the training for chaplains is foundationally a clinical training programme, clinical pastoral education (CPE), whereas the foundational training for chaplains in Europe is received in an academic setting. Chaplains in North America have the opportunity to become 'board certified' based on a set of clinical competencies. CPE is conducted in clinical settings and focuses on training chaplains in listening skills, forming relationships in order to support patients, and functioning as a member of the health-care team. Chaplains are taught to minister to patients of any faith or no faith as opposed to the traditional model of ministering only to patients of the chaplain's own faith tradition. Since 2013, North American chaplains are able to obtain subspecialty certification in palliative care chaplaincy. In North America, certified chaplains subscribe to a Code of Ethics which, among other things, prohibits proselytizing (Association of Professional Chaplains, 2000). The net result of this training is to recognize and distinguish professional health-care chaplaincy as a discipline separate from other forms of ministry.

Current standards for health-care chaplaincy

The context for chaplaincy in Europe, North America, and Australia can seem different from each other, but most regions of the world where health-care chaplaincy is fairly well developed have standards of practice that are largely congruent (European Network of Health Care Chaplains, 2002; Australian Health and Wellness Association, 2004; College of Health Care Chaplains, 2007; Association of Professional Chaplains, 2009), though the United States and Australia are more particular and clinically oriented.

Spiritual care in palliative care

Chaplaincy is a key component of the interprofessional spiritual care model developed at the NCC in 2009 (Puchalski et al., 2009). Spiritual care in palliative care is based on several premises:

◆ All staff will be trained in and participate in spiritual care at some level appropriate to their discipline.

◆ All patients will have spiritual care fully integrated into their care through spiritual screening, spiritual history, a spiritual assessment if indicated, and the inclusion of spiritual needs in their care plan.

◆ A professional chaplain with specific training in delivering multifaith as well as non-faith specific spiritual care in palliative care will be the spiritual care lead on the team.

Definitions

One of the major issues in this area of practice is a lack of clear definitions. One of the tasks of the NCC on Spiritual Care in Palliative Care in 2009 was to develop a consensus definition of spirituality:

> Spirituality is the aspect of humanity that refers to the way individuals seek and express meaning and purpose and the way they experience their connectedness to the moment, to self, to others, to nature, and to the significant or sacred. (Puchalski et al., 2009, p. 887)

This definition was agreed to by a large group from many faith and non-faith traditions and philosophical backgrounds and disciplines. The focus on 'meaning and purpose' and 'connectedness' are themes in most definitions of spirituality.

Religion is one expression of spirituality:

> Religion is an organized system of beliefs, practices, rituals, and symbols designated (a) to facilitate closeness to the sacred or transcendent (God, higher power, or ultimate truth/reality), and (b) to foster understanding of one's relationship and responsibility to others living in a community. (Koenig et al., 2001, p. 18)

But there are other expressions including nature, art, and humanism, among others.

Another ambiguity in the field is the frequent conflation of 'spiritual care', 'chaplaincy care', and 'pastoral care'. The US Association of Professional Chaplains and others have adopted the following distinctive definitions:

Spiritual care

Interventions, individual or communal, that facilitate the ability to express the integration of the body, mind, and spirit to achieve

wholeness, health, and a sense of connection to self, others, and[/or] a higher power. (Health Ministries Association, 2005)

Chaplaincy care

Care provided by a board certified chaplain or by a student in an accredited clinical pastoral education program, e.g., ACPE. Examples of such care include emotional, spiritual, religious, pastoral, ethical, and/or existential care. (Peery, 2009)

Pastoral care is now understood as a term that comes out of the Christian tradition and generally describes the care given by a faith leader to members of his or her community (LaRocca-Pitts, 2006). As such, it is inconsistent with the current multifaith emphasis.

All members of the health-care team participate in spiritual care to some degree as they all participate in psychosocial and to some degree physical care. Chaplaincy care encompasses those functions which require the spiritual care specialist on the team with the degree of training required. Pastoral care under this definition could be part of what the particular chaplain does when he/she is caring for people from his/her own faith tradition. Otherwise, it is generally part of what Christian clergy do when they care for their own congregants. Pastoral care is still the term used in many parts of the world to encompass what are here called chaplaincy care and maybe even spiritual care. We believe that the definitions proposed here, besides being more commonly accepted, clear some confusion and are useful to the present model and the principles of palliative care.

Model for chaplaincy in palliative care

In the model of interprofessional spiritual care, the role of the chaplain is to be spiritual care lead on the team and, as such, the spiritual care specialist (Handzo and Koenig, 2004). All other members of the team are spiritual care generalists. Thus, social workers would be spiritual care generalists just as chaplains are also emotional care generalists. However, spiritual issues requiring complicated interventions would be referred to the chaplain just as social/emotional issues requiring complicated interventions would be referred to the social worker. This model for spiritual care is aligned with other processes of clinical care.

In a typical case, a patient entering a health-care facility would be screened for spiritual distress along with the rest of his or her screening processes. An algorithm would govern whether or not the patient is referred to a chaplain as a result of that screening. The patient would also receive a spiritual history as part of their total history by the clinicians who develop treatment or care plans. The goal of the spiritual history would be to help the clinician understand their patient in a whole-person context, to identify spiritual resources of strength, and to identify spiritual distress.

Protocols may be helpful to determine whether the patient needs a referral to a chaplain or whether any spiritual needs could be addressed directly by the clinician. Those patients whose screening or history indicates the possibility of spiritual distress would receive a full spiritual assessment by a professional, trained chaplain. The patient's spiritual needs would be included in the patient's treatment or care plan and the patient's discharge plan. This model aligns with current best practice

in health-care chaplaincy (Handzo, 2006; Peery, 2012) as well as best practice in spiritual care in palliative care (Puchalski et al., 2009).

Since the chaplain is the lead on this process, it is the chaplain's responsibility to design the infrastructure that supports this process, oversee its integration, and make sure that other staff are fully trained in its use. The chaplain needs to institute and continually improve systems for spiritual screening, history taking, and assessment including diagnoses, spiritual treatment, and discharge plans.

Spiritual screening

If chaplaincy resources are going to be focused on patients in spiritual need rather than simply those who want to see a chaplain, the goal should be to set up systems which allow chaplains to connect with those in distress as quickly as possible.

The key to this strategy is an effective screen for spiritual distress on admission. According to Fitchett and Canada (2010), screening utilizes one or two questions to find out whether a patient is experiencing serious religious or spiritual distress that then requires an immediate referral to a chaplain.

In the United States, spiritual and religious screening questions are often restricted to asking how the patient wants their religion listed and whether they want to see a chaplain. These questions are focused on identifying those who want to see a chaplain as opposed to those who need to see a chaplain. There is some indication that those with spiritual distress are less likely to ask for a chaplain than others (Fitchett, 1999). For these reasons, the question, 'Do you want to see a chaplain?' should not be used.

The screening questions devised and tested by Fitchett and Risk (2009) are recommended. At this time, they are the only questions with a published validation study (see Table 4.5.1).

Another possible screen is the one question, 'Are you at peace?' tested by Steinhauser and her colleagues (2006). However, while this screen shows some promise in identifying spiritual distress, it has only been tested with patients at the end of life and only as a research tool.

Table 4.5.1 Screening questions

The screening questions are:	
1.	Is religion/spirituality important to you as you cope with your illness? (Yes/No)
2. (If 'yes' to #1)	How much strength/comfort do you get from your religion/spirituality right now? a. all that I need b. somewhat less than I need c. much less than I need d. none at all *Answers 'c' or 'd' should trigger an automatic referral to chaplaincy*
3. (If 'no' to #1)	Has there ever been a time when religion and spirituality was important to you? (Yes/No) *'Yes' should trigger an automatic referral to chaplaincy*

Source: data from Fitchett, G and Risk, J. L., Screening for spiritual struggle, *Journal of Pastoral Care and Counseling,* Volume 62, Issue 1–2, pp. 1–11, Copyright © 2009.

The role of the chaplain in setting up the screening process is to educate staff about why these questions are important and how to make referrals. Given the nature of the screen, there is no need for staff to be trained in clinically interpreting screening results.

Spiritual history

Like screening, history taking is a routine part of admitting a patient to a hospital. Standards for physicians, nurses, and others on the team support the inclusion of spirituality as part of the clinical history. For instance, the American College of Physicians notes that it is the physician's responsibility to attend to all dimensions of the patient's suffering—the psychosocial and spiritual suffering as well as the physical (Karlawish et al., 1999; Lo et al., 1999). As discussed in the NCC, attending to spiritual suffering requires inquiry into spirituality of patients and thus within the clinical history a spiritual history should be included. The history should include an assessment of spiritual symptoms as well. Up until recently, one barrier to this inclusion has been the lack of an evidence-informed spiritual history tool. One history tool, FICA (Puchalski, 2006; Puchalski and Romer, 2000), which is widely used in different clinical settings, has been reviewed (Borneman et al., 2010). The basic format of the FICA tool is shown in Table 4.5.2.

In practice, some primary caregivers feel uncomfortable talking to patients about this domain of the patient's life. Currently this tool is used widely in clinical settings by clinicians who do clinical histories and develop treatment plans. Some chaplains utilize the tool but it is intended for physicians, nurses, social workers, physical therapists, and so on.

The majority of medical schools in the United States have spiritual history taking as part of their curriculum and there is growing interest internationally in this area (Puchalski et al., 2012). On health-care teams the professional chaplain should be involved in ongoing education on spiritual issues with physicians, nurse practitioners, and others who take histories in how to talk to patients about these issues. Most patients want their caregivers to take account of their religious and spiritual beliefs and values in planning their care as was shown in the FICA validation study (Borneman et al., 2010). Numerous surveys have also demonstrated that the majority of patients want their physicians to address patients' spirituality and integrate it into patients' treatment plans (Ehman et al., 1999; McCord et al., 2004). Training materials are available for the FICA tool through the George Washington Institute for Spirituality and Health (<http://www.gwish.org>).

Diagnostic categories

The NCC recommended that all clinicians respond to spiritual distress with the same intensity as to physical pain (Puchalski et al., 2009). The NCC further recommended diagnostic categories for spiritual distress and developing a taxonomy for spiritual distress, including specific and tested treatment plans.

As in other areas of clinical care, a clinician can suggest a preliminary diagnosis based on that clinician's spiritual history. This diagnosis would drive a referral, in this case, to the professional chaplain. The chaplain, like any other specialist, would amend or confirm the diagnosis as warranted based on that chaplain's spiritual assessment.

One set of diagnoses has been posited in the National Comprehensive Cancer Center's Distress Management Guidelines (National Comprehensive Cancer Network, 2012). These guidelines have been vetted yearly for over a decade with providers including many chaplains at NCCN member institutions and deemed appropriate. The diagnoses include:

- guilt
- hopelessness
- grief
- concerns about death and afterlife
- conflicted or challenged belief system
- loss of faith/doubts
- concerns about meaning/purpose in life
- concerns about relationship to deity
- conflict between religious beliefs and recommended treatment
- conflict with/loss of religious community.

Spiritual assessment

Fitchett and Canada (2010) define a spiritual assessment as:

> A more extensive [in-depth, on-going] process of active listening to a patient's story as it unfolds in a relationship with a professional chaplain and summarizing the needs and resources that emerge in that process. The summary includes a spiritual care plan with expected outcomes which should be communicated to the rest of the treatment team.

There is currently no widely accepted or validated chaplain spiritual assessment tool. Further, while whatever outline is used needs to cover some basic issues, the essential requirement is for all chaplains and chaplaincy students within an institution to use the same format so that it can be integrated into the medical record and so other staff learn what to expect from a chaplain note.

Table 4.5.2 Spiritual history tool

F	'Do you consider yourself spiritual or religious?' or 'Do you have spiritual beliefs that help you cope with stress?' If the patient responds 'No,' the health care provider might ask, 'What gives your life meaning?' Sometimes patients respond with answers such as family, career, or nature
I	'What importance does your faith or belief have in our life? Have your beliefs influenced how you take care of yourself in this illness? What role do your beliefs play in regaining your health?'
C	'Are you part of a spiritual or religious community? Is this of support to you and how? Is there a group of people you really love or who are important to you?' Communities such as churches, temples, and mosques, or a group of like-minded friends can serve as strong support systems for some patients
A	'How would you like me, your healthcare provider, to address these issues in your healthcare?'

Reproduced from The George Washington Institute for Spirituality and Health, *FICA Spiritual History Tool*, available from http://smhs.gwu.edu/gwish/clinical/fica/spiritual-history-tool, Copyright © C. Puchalski, with permission of the author.

One option for assessment is presented by Brent Peery (2012) and is based on outcome-oriented chaplaincy. This assessment includes the following:

◆ Needs: relationship with God, support system, meaning/determinism, forgiveness, advance care planning, emotional/relational issues, grieving, other spiritual needs

◆ Hopes: relationship with God, forgiveness, God as comforter, support

◆ Resources: relationship with God, religious/spiritual practices, community support, other.

Another similar system is proposed by Donovan (2012). Pruyser (1976) and Fitchett (2002) have proposed more extensive outlines which have been extensively used over the years.

An outline of issues that could be covered in a spiritual assessment by a chaplain would include the following:

◆ Determinism/meaning:
  • Is everything that happens determined by God?
  • If not, how/why do 'bad things' happen?
  • How does this cause translate into meaning?
  • Differentiating illness as gift or punishment

◆ Grief:
  • Spiritual/existential losses
  • Loss of sense of immortality
  • Loss of sense that God will protect you from all harm

◆ Despair:
  • Rooted in sense of abandonment/hopelessness
  • God does not let 'bad things happen to good people'

◆ God the Judge versus God the Comforter:
  • Is God a 'judging' God?
  • Does God punish people while they are still alive?
  • Or is God primarily a 'comforting' God?
  • Is God's primary role to support people through hard times?

◆ Forgiveness:
  • Sin is what the patient perceives it to be
  • Important to not impose caregiver values and beliefs
  • Religions have distinct ways of expiating sin
  • Explore forgiveness ritual
  • Suffering itself may be seen as a way to 'work off' sins.

Referrals to chaplains

As is done with many other disciplines, referrals to a chaplain in some circumstances should be automatic and even automated if that is possible. The minimal standard in any circumstance is for the chaplain to see every patient who evidences spiritual distress on screening or history. If the palliative care service is small enough and/or the chaplaincy coverage is robust enough, any referral to the palliative care service can automatically generate a referral to the chaplain. This situation does not imply that spiritual screening

or history taking do not need to be done. As with other services, screening functions to direct the chaplain to those with significant need and the history still serves to help the primary care provider come to know the patient in all domains. In any case, the patient and family can refuse the chaplain. However, the chaplain's visit should always be presented as a regular service that is part of what palliative care offers rather than an add-on that is not necessarily central to the team's scope of practice. The inclusion of the chaplain should always be considered when planning a patient/family meeting to discuss care plans and in planning interventions with especially disruptive families.

Tasks of the chaplain

While chaplains certainly are the specialist in helping patients, families, and staff discover and use their spiritual and religious resources in the service of their healing, their most basic skill is listening and fostering clear communication. Learning to listen without bias and reflect what the patient or family member is saying accurately is a central focus of CPE. Chaplains are often regarded by patients and family members as neutral parties. Some options for leveraging this training and skill include the following:

◆ Facilitating goals of care discussions/family meetings

◆ Facilitating palliative care meetings

◆ Facilitating communication when bad news is being delivered

◆ Being present with family members after a death.

In the United States, the chaplain is often regarded as the 'culture broker' on the team (Joint Commission, 2006). As the culture broker, the chaplain assists the patient, family, and health-care team bridge any cultural, ethnic, or religious issue which may hinder communication between and among them. As experts in helping people identify and articulate their beliefs and values, chaplains have expertise in identifying and helping teams accommodate the cultural beliefs and practices families have. It is also part of the chaplain's role to be aware of the religious resources in the community which can be called on as needed.

As already mentioned, the chaplain should be involved in educating other staff on spiritual and religious issues including training staff on administering spiritual screening and spiritual history protocols. Staff education is also appropriate before major religious holidays which might be observed by patients and families so that staff know what to expect in terms of patient and family customs, diet, and other special activities around the particular holiday. The chaplain also provides spiritual care to the clinical team. Clinicians can be affected by the stress of caring for ill patients, conflicts about providing care to patients that clinicians might feel is 'futile', and burnout from over-caring. Spirituality is a critical aspect of clinicians' professional development (Puchalski et al., 2009; Puchalski and Guenther, 2012) because it underlies the vocation clinicians have to service others but it also provides internal resources for support and reflection for clinicians. Chaplains are important resources to clinicians and other caregivers.

Chaplains are unique in that, like community clergy, they are charged with the professional care of those in their own community. That is, the chaplain is the chaplain to the staff as well as to the patients and families (Association of Professional Chaplains, 2009). In this role, the chaplain can help the team, individually

and as a group, process its own spiritual issues and help use its spiritual strengths to provide better care (Puchalski et al., 2009). These activities could include memorial services, meditations as part of staff meetings, spirituality groups for staff, debriefing, and individual counselling.

Chaplain interventions

There is no accepted taxonomy of chaplaincy interventions with patients and families especially as tied to assessments and outcomes. Peery (2012) has proposed an extensive list which covers the universe of what chaplains do. Some research on a selected population also exists (Handzo et al., 2008). As indicated earlier, much of what chaplains do falls under the general rubric of reflective listening and emotional support. Professional chaplains do not generally engage in teaching patients about belief unless the patient specifically asks for it. Any intervention a chaplain would make under the broad category of counselling is, likewise, focused on helping the patients and family members come to their own understandings and conclusions rather than giving them answers.

The chaplain's skill in communication and emphasis on listening and non-judgemental presence comes into play in helping patients and caregivers deal with spiritual distress. The chaplain's primary goal in these situations is to help the patient find their own meaning and discover their own resources through listening to and reflecting their individual life story. The chaplain might use appropriate readings or music to assist in this process. For patients who would like ongoing counselling, the chaplain might refer to community resources such as community clergy, pastoral counsellors, or spiritual directors.

All chaplains are also trained in religious interventions. These fall into two categories. The first is those that the chaplain does as a clergyperson with a person of his or her own faith group. In this case, the chaplain is operating as a clergyperson of that faith group. The second group includes interventions which do not necessarily require the chaplain and the patient to be of the same faith group. For instance, professional chaplains are trained to pray with people of any faith. They also can often read from the patient's sacred texts or help the patient find music or other spiritual resources. Chaplains also occasionally officiate at weddings and funerals—sometimes for patients of their own faith and sometimes not.

Conclusion

Spirituality has been shown to be important in the care of patients, especially those with serious and chronic illness. Data shows an impact of spirituality as well as religious beliefs and practices on health-care outcomes as well as medical decision-making, Spiritual care also describes a whole-person model of care that supports the provision of respectful, compassionate care that honours the inherent dignity of all who receive as well as provide care. Thus spirituality is important for patients as well as family and professional caregivers. Standards for palliative care include spiritual care as a required domain of palliative care. Models and recommendations have been developed to facilitate interprofessional spiritual care where all members of the team attend to the spiritual issues of patients with the professional chaplain being the expert in spiritual care. Health-care providers should be performing a spiritual screening or history with patients to help identify the need for chaplain referral, patient and family spiritual distress or suffering, as well as patient and family spiritual resources of strength. Chaplains function as the spiritual care lead on the team. They do a more intensive assessment and help clinicians with diagnosis of spiritual distress as well as treatment plans regarding spirituality. Chaplains work with patients and families to help them with their spiritual distress or their spiritual issues. Chaplains also provide spiritual care to the team. Chaplains are an essential member of the interdisciplinary care team and should be integrated on all palliative care teams.

4.6

Occupational therapy in palliative care

Jill Cooper and Nina Kite

Introduction: what occupational therapists do and where they work

Occupational therapy aims to help patients achieve their optimum independence in activities that are important to them by using specific treatments and interventions.

In day-to-day use the term 'occupation' refers to an individual's job. But in the context of occupational therapy, occupation refers to:

◆ self/personal care, which applies to all activities we carry out in order to look after ourselves

◆ productivity, which incorporates work-related roles and domestic activities

◆ leisure, which refers to hobbies, sports, and general interests (Hammell, 2009).

Within palliative care, occupational therapists work in a variety of settings including the hospital, community, and hospice and form a significant part of the interdisciplinary team (Squire, 2011). As health systems and resources develop and change, occupational therapy palliative care services are often focused more in the community (Kealey et al., 2005).

As well as playing a vital role in planning for safe discharge home and assessing and prescribing equipment to enable safety and independence, occupational therapists carry out treatment sessions to help patients manage their symptoms and be as independent as possible (Booth et al., 2011).

Occupational therapy services should be accessible for all patients with life-limiting diseases in all settings and at every stage of their illness.

Foundations underpinning occupational therapy

Occupational therapy interventions are underpinned by the following core skills:

◆ Collaboration with the patient: building a collaborative relationship with them that promotes reflection, autonomy, and engagement in the therapeutic process.

◆ Assessment: assessing and observing functional potential, limitations, ability, and needs, including the effects of physical and psychosocial environments.

◆ Enablement: enabling people to explore, achieve, and maintain balance in their activities of daily living in the areas of personal care, domestic, leisure, and productivity as described above.

◆ Problem-solving: identifying and solving problems in day-to-day life (also referred to as occupational performance).

◆ Using activity as a therapeutic tool: using activities to promote health, well-being, and function by analysing, selecting, synthesizing, adapting, grading, and applying activities for specific therapeutic purposes.

◆ Group work: planning, organizing, and leading activity groups.

◆ Environmental adaptation: analysing and adapting environments to increase function and social participation (Creek, 2003).

The foundations of occupational therapy are based within a person-centred approach. This involves the occupational therapist actively listening, encouraging the person to express their wishes and goals, and showing empathy to hear and understand their expectations of the service and points of view (Sumsion and Law, 2006). Overall, it involves working together to achieve what the person wants to achieve (Cooper, 2006).

In palliative care, this requires flexibility to reflect changing needs, for example, as a person becomes more fatigued and dependent, occupational therapy interventions may move away from teaching strategies to manage washing and dressing, and instead focus on liaising with social work or community colleagues to organize a package of care.

It is important to note that occupational therapy is symptom led rather than disease led. Although crisis intervention cannot always be avoided, the occupational therapist will work with the patient and carers to anticipate problems that may arise. The patient does not have to accept the advice or equipment at that early stage, but they will have been made aware of it and can contact the occupational therapist in the future if they deteriorate and require input.

Environment and equipment

The patient and their carers have to live within a physical, social, and emotional environment and great care needs to be taken when adjusting this to enable them to cope at home. For example, a patient's bedroom may be upstairs, but if they have extreme weakness or fatigue, they may not be able to manage the stairs.

Therefore, there might need to be environmental changes such as a patient living downstairs.

Whilst the occupational therapist often provides equipment to help patients manage at home, this must be carefully assessed so they are not cluttered with too much equipment. Apart from overloading them with too much, the risk of altering the environment has huge implications on how the rest of the family manage and how it will affect their memories of the patient's later stages of life at home (see Table 4.6.1).

Planning for safe discharge home

Higginson (2003) reported that of the 56% of palliative care patients who identify home as their preferred place of death, only

Table 4.6.1 Equipment and aids available following occupational therapy assessment, education on their use, and provision (Miller and Cooper, 2010)

Difficulty with	Possible aids and adaptations
Bed transfers	◆ Back rest to support patient in a sitting position ◆ Mattress variator to assist lying to sitting ◆ Leg lifter to enable the patient to lift legs into bed ◆ Blocks to raise bed height ◆ Use of sliding sheets for positioning and moving ◆ Specialist hospital profiling bed, electrically operated and generally required if nursing care is needed ◆ Hoist and slings for safe transfers
Toilet transfers	◆ Toilet seats of varying height and design that are safely fitted and removed ◆ Frames to fit around the toilet and provide patients with something to push up from ◆ Strategically placed grab rails ◆ Other equipment such as commode, male and female urinals
Bath or shower transfers	◆ Range of bathboards that can be easily fitted to assist with transfers ◆ Hydraulically operated bath seats which lift patients in and out of the bath ◆ Strategically placed grab rails ◆ Shower seats, either freestanding or wall-fixed
Chair transfers	◆ Range of blocks to raise chairs and settees ◆ High back, orthopaedic chair with firm armrests and of correct height for safe transfers ◆ Riser recliner armchair enabling patient to sit with legs elevated and sometimes with an option to help them stand from sitting
Transferring in/out of car	◆ Sliding boards may be appropriate here but require full individual assessment and training
Mobility	◆ Joint working with physiotherapist to establish safest mobility techniques ◆ Wheelchairs with detachable sides to enable sliding board transfers. Wheelchair must have correctly fitted and adjusted footrests heights, seat dimensions, and pressure cushion if required
Walking aids whilst carrying out daily activities	◆ If patient uses a frame or stick, they may need a caddy that fits to the frame so that they can carry items, or a trolley on which to carry them
Stairs	◆ Installation of addition handrails or banisters for safety ◆ Stairlifts can be hired or bought privately but this can be expensive and the occupational therapist needs to give advice on this. Social services grants are time-consuming and may not be appropriate ◆ Through-floor lifts are extremely expensive and disruptive when being fitted and it might more practicable to arrange one-floor living or 'micro environment'
Meal preparation	◆ Kitchen aids including jar openers, non-slip mats, specialist cutlery, and adapted crockery and equipment can help in maintaining safety in the kitchen
Personal care	◆ Long-handled equipment such as shoehorns and sponges can help the patient reach their lower extremities. Other adapted equipment helps with poor grip such as button hooks, elastic shoelaces, Velcro fastenings instead of zips and buttons
Manual handling	◆ Hoists, electric and manual, free standing, and ceiling track may be required for safe transfers ◆ Additional equipment includes sliding sheets and transfer boards ◆ All of these require annual training and specialist knowledge and skills
Specific difficulties: spinal cord compression, at risk of falls	◆ Assessment for safety in transfers, identifying need for equipment such as hoist, sling, pressure relief, sliding board, wheelchair and planning for a complex discharge to a suitable place of care if home is not feasible ◆ Falls risk requires assessment for actual and potential hazards and addressing the practical problems

26% achieve this. Enabling patients to die at home requires a well-coordinated, interprofessional team including the discharge coordinator, occupational therapist, ward staff, district nurse, and community support agencies. It is essential that the patient has as seamless a transition as possible between settings of care especially when returning home. This requires establishing what the patient and, separately, their carers want, liaising with community teams, and ordering all the equipment and services. It takes an enormous amount of time and effort by everyone, particularly for complex interventions.

The key responsibilities of the occupational therapist within discharge planning include assessment of the environment, either with or without the patient depending on the circumstances. This will identify access into the property, whether there are difficult steps or doorways, and how professionals and carers will be able to get in if the patient cannot answer the door. The essential facilities such as toilet, washing, and sleeping areas are assessed and whether equipment is required to make returning home feasible.

Meeting carers and families in their own homes often enables them to disclose information which they would not otherwise share with health-care professionals. This helps in establishing the trust and rapport to support and work with them as well as establishing how the services can meet their requirements.

If all the assessments and arrangements have taken place before a hospital admission or discharge is required, it should be seen as a valuable service and treatment option which was offered to the patient and carers. The carers can see that every avenue was explored to try and return the patient home, even if it did not actually take place.

Management of cognitive and perceptual impairments

Cognitive and perceptual deficits, including confusion, manifest themselves in a number of ways. They may be as result of a brain tumour, infection, side effects of medications, central nervous system metastases, or chemical imbalance such as hypercalcaemia. Furthermore, they may be temporary, fluctuating, or permanent.

Although there are numerous standardized assessments which identify neurological deficits such as memory, planning, and problem-solving, their use is almost always inappropriate in palliative care as they are so time-consuming and tiring for the patient. Re-assessment may only confirm to the patient that they are deteriorating.

The occupational therapist observes the patient during functional activities such as washing, dressing, and meal preparation, which then helps them identify any deficits and implications for safety and independence. For example, when a patient is unsafe cooking with gas, handling hot items, and forgetting to take medication, the occupational therapist can address these issues practically. Fluctuating or deteriorating cognitive levels can be extremely distressing for both patients and carers, and the aim of the occupational therapist is to assist the carers in coping with this and maximize the time the patient can be supported at home.

Practical strategies such as the use of memory aids can be explored, and advice can be given about the level of supervision the patient may require, and whether they are safe to be left alone at home.

Rehabilitation in palliative care

The ethos of occupational therapy compliments the World Health Organization's key principles of palliative care:

◆ Relief from pain and other distressing symptoms

◆ Psychological and spiritual care

◆ A support system to help patients live as actively as possible in the face of impending death

◆ A support system to sustain patient's friends and family during illness and bereavement (World Health Organization, n.d.).

Dietz (1981) describes rehabilitation in cancer care as comprising four distinct aspects, the last being palliative rehabilitation. Palliative rehabilitation involves assisting with symptom control and providing comfort and support to patients with advanced disease. The focus continues to be on optimizing independence.

This reinforces how, within the palliative care setting, it is essential that the occupational therapist maintains a flexible approach regarding the varying symptoms that the patient may exhibit as a result of advanced disease and adapting goals as a person's clinical condition changes.

Skills required to manage activities of daily living

A person needs to have certain levels of physical, emotional, and social skills to function independently. When there are problems in any of these areas, the occupational therapist needs to analyse the problems so that they can be addressed with treatment programmes, adaptation, and equipment. These may include the following:

◆ Motor skills which involve the functional use of muscle strength and tone, range of movement, endurance, stamina, and fine and gross motor skills. Disease-related symptoms might result in prolonged periods of inactivity leading to muscle wastage, weight loss, generalized weakness or even weight gain or oedema as a result on steroids.

◆ Sensory skills which involve identification and interpretation of external and internal sensory stimuli, including pain, altered sensation, balance deficits and visual disturbances.

◆ Cognitive skills for which deficits may be as a result of tumour growth, either primary or secondary, or side effects of drugs used for symptom control. The individual may present with altered levels of arousal or exhibit impairment of memory, planning, problem-solving, and communication.

◆ Intrapersonal skills where advanced disease may affect an individual's self-image and identity, which in turn may affect how they behave and participate in occupation.

◆ Interpersonal skills where individuals may experience a loss of control and may feel they are unable to fulfil their existing roles such as mother, breadwinner, or employee. This can have an enormous impact on self-esteem.

◆ Self-maintenance occupations, which refer to activities that one regularly carries out to take care of oneself such as toileting, washing and dressing, feeding and sleeping. Usually these would be carried out with a degree of privacy and the individual is likely to have their own routine. Some people may place enormous value

and meaning on performing these activities independently. If they decline help at home, the occupational therapist then focuses on risk assessment, provision of equipment to facilitate independence and safety, and education in compensatory strategies.

◆ Productivity occupations, in which the individual supports themselves, for example, shopping, cooking, as well as paid employment, housework, and studying.

◆ Leisure occupations, which relate to all activities carried out for pleasure and enjoyment. It is essential that meaningful leisure pursuits are identified and adapted to enable greater participation so that the person can continue with these (Miller and Cooper, 2010).

Goal setting and grading activities

Goal setting is a vital component of therapeutic interventions and its value has been demonstrated within the palliative care setting as a means of focusing the interdisciplinary team (Jennings, 2010). Through collaboration with the patient and their carers, the occupational therapist sets specific, realistic, achievable, and measurable goals for what the patients wants to achieve.

By applying grading techniques to an activity, the occupational therapist can adjust it depending on how the patient is managing. This is done by adapting the environment such as moving furniture or providing equipment. Additionally, techniques such as backward and forward chaining may be used. Backward chaining requires the occupational therapist to complete all the necessary steps, for example, in showering the patient and let them complete the last step. Forward chaining means that the patient completes the first step and the occupational therapist completes the remainder of the activity. Increasing the number of steps which the patient can manage helps build up their stamina and skills. Similarly, if a person deteriorates, a staged decline can be planned to help them adjust to changing circumstances.

Safety is a vital issue which must not be taken lightly. Safety can be improved by providing appropriate equipment, but the patient and carers may be put at risk if a thorough assessment is not carried out and all the potential hazards taken into consideration. For example, a motorized wheelchair or stairlift might sound as though it would be the answer to someone's mobility problems, but the person's cognitive skills, physical balance, abilities, general stamina, and financial situation would all need very careful assessment by the occupational therapist.

Occupational therapy in the management of symptom clusters

Symptom clusters relate to three or more related symptoms that may interact with each other and have a significant effect on the patient's quality of life (Esper and Heidrich, 2005). The combination of anxiety, breathlessness, and fatigue results in such a symptom cluster (Gilbertson-White et al., 2011) and the management of anxiety has a positive impact on the other two symptoms.

Anxiety management and relaxation sessions

It is normal for everyone to experience some degree of anxiety, and in fact by its very existence, it aids everyday survival and performance in certain situations. This natural response is referred to as the 'fight or flight' response which, when activated, enables us to confront and fight the danger or run away from it. Although anxiety may be viewed as an entirely appropriate reaction to advanced disease, prolonged anxiety can cause problems in carrying out day-to-day activities. Therefore, occupational therapy needs to treat the symptom. Exacerbating factors may include pre-existing psychiatric conditions, poorly controlled pain, medication toxicities, and psychological and spiritual issues.

Relaxation is one of the main strategies for managing anxiety and aims to:

◆ understand and recognize the individual's level of anxiety

◆ understand the need for relaxation and recognize certain situations that may trigger tension

◆ experience a variety of relaxation techniques thus enabling the individual to choose the most appropriate one

◆ appreciate the importance of planning time for relaxation as part of the individual's daily activities and lifestyle

◆ improve quality of sleep and performance of physical skills

◆ increase self-esteem and confidence

◆ ease relationships with others

◆ channel and control effects of anxiety and avoid unnecessary fatigue.

Relaxation programmes vary depending on resources available; however, a basic outline would include education and practice using techniques, some of which are outlined in Table 4.6.2.

The focus, as with all occupational therapy interventions, is to promote independence and challenge the loss of control which can occur when patients have to deal with life limiting conditions.

Breathlessness management

Although breathlessness is a common symptom in lung cancer patients, severe breathlessness also affects approximately 30% of the palliative care population in the last weeks of life (Currow et al., 2010). It is a subjective sensation and the overall physical and psychological implications are immeasurable. Interdisciplinary input is vital to manage the patient efficiently as breathlessness needs to be assessed and managed according to the individual's needs. Three main aims of management are to:

1. explore the meaning of the symptom to the patient and carers and families

2. enable activity so that they can achieve optimum independence and control despite their debilitating symptom

3. help patients manage any anxiety and panic attacks, including teaching relaxation techniques as part of the management programme.

Enabling activity for breathless patients

Pacing activities may sound simple but it is often complex (Cooper, 2006: Booth et al., 2011). By working with the patient to use energy conservation, they can take part in activities which they value. Energy conservation is the deliberate planned management of one's personal energy resources in order to prevent their depletion (Barsevick et al., 2002). It includes the following techniques for patients to manage daily activities and cope with breathlessness.

Table 4.6.2 Relaxation programme

Programme	Technique
Assessment	Do you have any previous experience of relaxation? How does anxiety affect your daily life? What are your expectations of relaxation?
Body charts and awareness	Mark on body chart the specific areas of physical tension Discuss increasing awareness of how the body feels when it is tense
Establish programme	Agree treatment plan over set number of sessions, to be reviewed and results recorded at each session
Progressive muscular relaxation	Sequential technique in which each muscle group is tensed then relaxed Structured session in which the individual does not use their imagination but follows logical set of exercises
Passive neuromuscular and release-only relaxation	Releasing tension from muscle groups The individual identifies the muscles which are tense without actively tensing muscles
Autogenic relaxation	A systematic programme which teaches the body and mind to respond to verbal commands to relax
Guided visualization	The participant actively uses their imagination and positive images to induce a feeling of well-being and relaxation
Unguided visualization	This allows more freedom for the imagination, empowering the individual to select their scene or sequence of events to visualize
Challenging negative thought patters	Individual is encouraged to use positive phrases such as 'choose' and 'can' rather than focusing on negative ones which increase stress such as 'should, must, ought to'

Source: data from Ewer-Smith, C., Patterson S., The use of an occupational therapy programme within a palliative care setting, *European Journal of Palliative Care*, Volume 9, Issue 1, pp. 30–33, Copyright © 2002 Hayward Medical Communications, a division of Hayward Group Ltd.

The five Ps:

◆ Prioritize—consider which activities are important to you each day, and prioritize those for which you would like to conserve your energy.

   Try to cut out unnecessary tasks in order to conserve your energy.

◆ Plan—organize your activities as effectively as possible in order to conserve as much energy as you can.

   Consider which times of the day are best for you to be active or at rest.

   Try not to do too much in any one day and plan your activities for the week ahead wherever possible.

◆ Pace—it is important to balance periods of activity with periods of rest. You may need to rest during an activity and allow yourself a little extra time to get things done.

◆ Position—work out a position that is comfortable for you when you feel breathless and practise this so that you can help yourself.

   Think about your posture and try to maintain this so that you avoid becoming uncomfortable and conserve your energy.

◆ Permission—Give yourself permission *not* to do activities which result in your becoming breathless and tired.

   Instead of thinking along the lines of 'I must', 'I ought', try and challenge this negative thinking and way you view this and say to yourself 'I choose to', or 'I wish to do' instead (Ewer-Smith, 2002).

Personal plan for coping with breathlessness

Breathlessness is an anxiety-provoking symptom for both the patient and those who witness it and education is the key to coping with this (Cox, 2002). Once the occupational therapist and other team members have established the most effective way of coping with the individual's problems, a personal plan can be developed to help the patient and carers regain control during such an episode. This includes establishing the following:

◆ How to practice breathing control. This depends entirely on the individual, whether they need oxygen, or a nebulizer, and what technique suits them such as how to position their shoulders.

◆ What to do when they are breathless. Following thorough assessment, the patient will be advised what they need to do, whether to rest, use oxygen, or how to help the upper chest relax.

◆ Positions to use when breathless. The individual may find sitting upright, leaning forward or backwards, or lying on their side most comfortable and the best position for them will be emphasized on the personal plan.

◆ Exercising. What level of gentle exercise will help them.

◆ Breathing control whilst walking. Following thorough assessment, advice will be given on which breathing techniques will help.

◆ Managing daily activities. The occupational therapist will assess whether equipment and different strategies and techniques are required and advise accordingly.

◆ Equipment. A wheelchair may be useful for conserving energy, and other equipment to save energy in the kitchen, bathroom, and around the house may be of help.

These approaches will not totally alleviate breathlessness but can make it easier to manage (Booth et al., 2011).

Fatigue management

Cancer-related fatigue affects more than 70% of patients in palliative care (Ahlberg et al., 2003). It presents as exhaustion and a lack of energy and prevents them taking part in everyday activities which they often previously managed independently. It may also result in insomnia or disturbed sleep patterns, cognitive deficits such as memory difficulties, reduced attention span, and affect their psychological well-being, resulting in impatience and mood swings. It is a multidimensional symptom affecting the patient's physical, social, cognitive, and emotional well-being

The principles of fatigue management are exercise, pharmacological interventions, complementary therapies, and adjustment strategies using psychological and education approaches.

The role of the occupational therapist within fatigue management centres on educative, rehabilitative, and compensatory interventions (Lowrie, 2006) and uses many of the principles already discussed within the anxiety and breathlessness sections:

◆ Fatigue diaries may be used to identify the patient's current level of functioning, highlight which activities and occupations they most value, and establish goals and priorities.

◆ Educating the patient and carers about the nature of fatigue symptoms and means of management can alleviate anxiety and help them to understand this common side effect.

◆ Energy conservation techniques can be explored with the patient and taught, as described within the enabling activity section of breathlessness.

◆ Patients should be encouraged to use goal setting as a means of setting realistic goals by breaking down tasks into smaller, more manageable components, thus enhancing the patient's perception of control.

◆ Equipment can also help alleviate fatigue, as shown in Table 4.6.1.

Memory problems

The patients themselves or their carers may notice short-term memory problems, impaired attention and planning, and problem-solving difficulties. This can impact on the patient's ability to maintain independence with activities which they value and potentially affect their relationships with others. Occupational therapists can advise the patient and carers about minimizing distractions when participating in an activity, assess the implication of such cognitive deficits upon safety, and look into simplifying activities so as to minimize the demands.

Outcome measures

Using outcome measures enables the occupational therapist to measure changes that have occurred as a direct result of intervention although it must be acknowledged that the patient is often seen by a number of members of the interprofessional team so change cannot be solely attributed to one team member.

Outcome data can show areas that need development, as well as areas of particular strength within a service.

Rather than just wanting an outcome measure for the sake of it, Eva (2006) advises that the occupational therapist must be clear about what it is they want to measure. Occupational therapists must be precise about the rationale underpinning the use of an outcome measure and be aware of both the administrative burden and the fact that they are dealing with deteriorating conditions in palliative care.

Goal setting can be used as long as goals are SMART, that is, *s*pecific, *m*easurable, *a*ttainable, *r*ealistic, and *t*ime bound. These can be clearly measured and will provide useful meaningful information regarding their progress and success.

The Canadian Occupational Performance Measure (COPM) (Law et al., 2005) is a client-centred, individualized measure of the impact of physical, sociocultural, mental, and spiritual aspects of occupational functioning. The patient identifies areas of difficulty within the areas of self-care, productivity, and leisure and rates them on a scale of 1–10. Five of these functional problems then become the focus for rehabilitation and determine rehabilitation goals which are then evaluated over a period of time. Its success has been limited in palliative care as the patient, by nature of the life-limiting illness, will deteriorate (Norris, 1999).

The AusTOMs (Unsworth and Duncombe, 2004) is an Australian therapy outcome measure which measures 12 scales for occupational therapy which broadly reflect a patient's status across four domains of health and functioning and are rated by the occupational therapist not the patient. The ratings are based on clinical judgement using knowledge of the patient and how they are functioning. Again, its success may be limited by the palliative nature of patients.

These detailed individual assessments are in contrast to the World Health Organization Performance Scale and the Karnofsky Performance Scale (Cancer Research UK, 2013), which are broad indicators used in clinical research trials. The World Health Organization Performance Scale has categories from 0 to 4, '0' being fully active through to '4' being bed or chair dependent, requiring full care. The Karnofsky Performance Scale ranges from 100, at which there is no evidence of disease and the scale descends down to 10, at which the individual is very ill and unlikely to recover. For the purpose of the occupational therapy assessment, these lack the specific detail required for individual programmes and treatment plans.

Measuring outcomes with numerical scores can show a snapshot of effectiveness, that is, quantitative scores, but will not give in-depth information about how the patient is managing. However, qualitative outcomes provide more meaningful data to the occupational therapists but this may not be of interest to those parties who simply want numbers and scores.

Occupational therapists working in palliative care have not found a completely successful outcome measure, mainly because they have to manage the contrast between enhancing the value and meaning of a person's remaining life while simultaneously supporting approaching death (Eva, 2006).

Conclusion

Occupational therapy aims to enhance the patient's and their carers' quality of life through taking part in activities or occupations that are important to and valued by them. This is achieved by education, equipment provision and adaptations, and treatment programmes. This helps the patient to gain as much control and choice as possible at the advanced and palliative stages of disease.

Whilst the occupational therapist has unique skills and role, they are a vital member of the interdisciplinary team and strive to deliver holistic care for the patient and carers during the final stages of their illness.

4.7

Music therapy in palliative care

Clare O'Callaghan

Music is intricately woven into the fabrics of life and takes on deeper significance during times of transition, loss, and grief.

Introduction to music therapy in palliative care

Music therapists offer musical experiences to improve comfort and enhance the lives of palliative care patients and their families. Music's helpful role in dealing with transition and loss is long evident in tribal rituals and religious and community practices (Laderman and Roseman, 1996). In the 1970s, pioneering music therapists Lucanne Magill and Susan Munro respectively brought live music to patients at Memorial Sloan Kettering Cancer Center, New York, and The Royal Victoria Hospital Palliative Care Unit, Montreal. Music therapists now contribute to holistic patient care in palliative inpatient and home-based services, and other settings caring for people with degenerative conditions, throughout the world.

In palliative care, music therapy can be defined as the creative and professionally informed use of music in a therapeutic relationship with people identified as needing physical, psychosocial, or spiritual help, or desiring further self-awareness, to enable increased life satisfaction and quality. Music therapists, who are university trained and accredited by national registration committees, can often extend the way that music enhances patients' well-being and their connection with who and what matters in their lives. The musical elements and evolving therapeutic relationship can underlie helpful, sometimes transformative experiences. The focus is on therapeutic process rather than musical products and participants do not have to have musical backgrounds to benefit. Music therapists invite patients and families to explore and choose music therapy methods. The therapeutic relationship informs how the music is shared and created. It can be distinguished from music thanatology which is the provision of 'prescriptive music, using harp and voice at bedside' with the compassionate musician's presence (Cox and Roberts, 2007, p. 80). This chapter will describe ways in which music therapists work in palliative care, clarify research supporting its efficacy, and offer strategies for how caregivers may offer music to support palliative care patients when music therapists are not available.

Music therapy in adult contexts: assessment, methods, and effects

Various descriptions of music therapy in palliative care with adult patients, families (including anyone significant in their lives), and staff carers are available (Munro and Mount, 1978; Munro, 1984; Dileo and Loewy, 2005; Hilliard, 2005). Music therapists typically receive referrals from staff, patients themselves, or their families. As patients' conditions fluctuate, sessions may be flexibly scheduled, range from minutes to over 1 hour, and can be offered occasionally to almost daily. Therapists can visit patients at bedsides in hospitals and homes bringing accompanying instruments, sheet music, or recorded music. The author often brings sheet music with up to 7000 songs and classical pieces that she can spontaneously play on an electric piano. Music therapy groups may also be conducted in day hospices, inpatient palliative care, or nursing home settings. Many music therapy departments incorporate extensive recorded music libraries, audio equipment, and tuned and untuned instruments.

Upon meeting patients, the music therapist's assessment includes determining the patient's music preferences, the relevance of music throughout their lives, and biopsychosocial needs or spiritual and aesthetic interests that may be addressed through music therapy. Music therapy methods offered to patients and their families can include (a) replaying the music of their lives, including live performance (by therapist and/or participant), music listening, music and life review, and lyric substitution in familiar songs; (b) exploring 'new' music, including therapeutic song writing, music improvisation, and unfamiliar music; (c) guided use of music, such as relaxation inductions with live or recorded music; and (d) music-based gift or legacy creation, such as song compositions and music-based audio-visual recordings. Ways in which music therapists can support patients and families are listed in Table 4.7.1.

Table 4.7.1 Some music therapy aims in palliative care

Supportive validation	One's feelings and thoughts
	Of a life that has been and is still being well lived
	One's self-worth; spiritual way of being
	Contemplation; a time to 'be'
Increased self-awareness to aid coping	Self-discovery
	Reawakening or reworking of an earlier awareness
Symptom relief and relaxation	Including pain, tension, dyspnoea, nausea, insomnia, restlessness
Connectedness	Those with cognitive impairment
	Those with language barriers and communication difficulties
	Expanded opportunities for interactions with family members, friends, other patients, staff
Aesthetic and spiritual experience	Pleasure
	Diversion; normalcy
	Creative expression
	Transcendence
Support expression of grief, bereavement	Dealing with loss: acceptance of one's own way; reframing regret; helpful catharsis
	Increasing confidence and strength for moving forward

Replaying the music from one's life

Patients often choose to experience music that elicits emotions, messages, or memories of places, events, and people that they want to feel connected with, and supported or inspired by. One patient, for example, consistently asked the music therapist to sing '(You are the) Wind Beneath My Wings'[a] because, she said, no one had ever told that they loved her. Identifications with lyrics associated with themes such as adversity, loss, and hope, and singers who have lived with life-threatening conditions, can enable one to feel understood and part of a wider human experience. People project into music and take from it what is needed because music is polysemous: it can be interpreted in multiple ways. For example, while 'Sailing'[b] may simply evoke happy youthful memories for one patient, another may repeatedly request the song to connect with the lyrics. Music can nurture or sustain in unexpected ways. The day before he died, a patient requested that the music therapist play 'The Prayer'[c] on the electric piano, and then asked for the lyrics so that he could sing it sometime. Although unable to outwardly sing, the invigorating and life-affirming properties of music still allowed him to connect with his non-patient musician identity: he could imagine singing until he died, and possibly felt hope 'singing' the song's lyrical plea of guidance to a safe place.

Patients often request songs once sung by parents or other important people, which can evoke supportive feelings of nurturance. They may also request songs sung at school, that signified courtships, were enjoyed at dances, parties, musical theatre, or concerts, or have spiritual meaning, affirm faith, and enable prayerful contemplation. Music can powerfully elicit emotions and images associated with earlier times. Patients may listen, sing along, or share memories, laughter, and tears, sometimes with their families, other patients, and staff. Elicited stories about their musical memories can reflect the important 'dignity-conserving perspective', 'continuity of self' (Chochinov, 2012, p. 14). Music-based reminiscence can improve communication between patients and those close to them, validate their lives, enhance insight, ethnic and cultural affirmation, and improve self-esteem, sense of worth, and identity (Forrest, 2000). Regrets may also be reframed and reconsidered. Through computerized music scrapbooking, young cancer patients have also arranged meaningful song fragments into new musical works which validate and express important sentiments (Robyn Booth, personal communication, 1 November 2006). Patients' life stories and favourite musical pieces can also be audio-recorded as legacies, perhaps combined with accompanying photo albums. Patients who cannot verbally communicate, for example, through motor neurone disease, can especially find this a meaningful way of sharing their non-patient identity with visitors and staff.

Physical reactions to music therapy may also reveal vital parts of a patient's personhood, arguably reflecting 'dignity-conserving care' (Chochinov, 2012, p. 36). This was evident, for example, in day hospice music therapy groups when one patient held onto a glass of wine in one hand, her wheelchair with the other, and stood up and danced while others waltzed to recorded band music; a seated 90-year-old whose feet could still manoeuvre Scottish highland gigue steps; and when a patient could sing perfectly despite expressive aphasia due to a brain tumour. Music therapy experiences can affirm one's life roles, community contributions, and extend self-awareness and ability to meaningfully express. This is especially evident when patients engage in song lyric substitution, as the music can give impetus to one's creation of personal lyrics, and the hearing of one's meaningful expressions mirrored back through song can soothe, affirm, and inspire self-pride. A particularly useful song for inviting patients to substitute lyrics to is 'One Day at a Time'.[d] When experiencing music one's non-discursive (non-verbal) level of awareness may also be accessed and experienced as a felt, mindful, or a symbolic sensation, possibly enabling longed-for relaxation or peacefulness. This often seems apparent when patients ask for a favourite piece of music to be played repeatedly, or when patients comment, 'You can stay here all day' when the music therapist softly plays their preferred music at their bedsides. The balance of music, discussion, and counselling is therefore monitored and variable in sessions because initiating verbal reflections may shift a patient's focus from a restful or transformative 'feelingful' mode to a less helpful cognitive state.

Patients and families

Music therapy can enable an intimate and comfortable context for patients and families to convey supportive and validating messages through choosing music to enjoy and relax with together and share elicited memories. Affirming messages may also be non-verbally expressed through 'knowing' looks and smiles, hand-holding, massaging touch, embraces, shared singing, and dancing rhythmically with the music, which can involve kicking legs or holding and moving hands together, even when one is in a bed or bed-chair. Music therapy may also help to sustain family members maintaining long vigils at patients' bedsides at the end of their lives. When barely rousable, patients may still smile or squeeze their loved one's hand to acknowledge a significant song

and statement, and when non-rousable, family may continue to communicate with their loved ones through asking for meaningful songs (e.g. 'Love will Go On'[e]) and hymns (e.g. 'Amazing Grace'), and singing or sharing memories. Such good memories of how patients are cared for can ease distress in bereavement (Reid et al., 2006). Music therapy in multi-bed rooms can also inspire shared involvement of patients, families, visitors, and staff in uplifting ways, and through singing together or sharing music-based stories, acknowledge each other's value.

Combining music with allied therapies may also broaden therapeutic benefits of both modalities. For example, patients can use music with physiotherapy exercises, and art therapists have helped patients to create CD covers for songs composed in music therapy and to integrate important aspects of patients' musical backgrounds into their art legacies. Music therapy alongside art therapy in an aesthetically tranquil hospice setting connected with surrounding bush-land contributes to a 'generative community environment' which can enable patients to feel 're-empowered', to creatively regain a sense of identity, and to connect with their faith in a 'sacred place' (Glenister, 2012, p. 91).

Exploring 'new' music

Therapeutic song writing

Through therapeutic individual or group song writing patients and families can express important sentiments in a contained and quick way. People can express what may be difficult to verbalize, and the creative effort may bring pride, spiritual comfort, self-affirmation, or cathartic relief (O'Callaghan, 2005). A music therapist also found that helping cancer patient to create an opera helped them to feel calm, healed, proud, and express fears and grief (O'Brien, 2006). Patients with cognitive impairment can also write songs as therapists provide necessary structure such as multiple choices of lyrics, melodic fragments, harmonies, and tempos. Adding musical accompaniment may extend the therapeutic effect of verbal expressions, because music is a mnemonic and can reinforce emotional meaning. To help palliative care patients write songs: (a) the music therapist invites a patient or family member to consider a topic and then helps them to brainstorm lyrical ideas through encouraging free association or offering prompts and questions; (b) the therapist and patient then group and transform the ideas into a song lyric structure; (c) the therapist invites suggestions for musical elements (melody, harmony, rhythms speed, genre, volume) or offers musical alternatives, line by line, for the patient to choose from, and (d) the therapist, patient, or an extended group record the completed song (O'Callaghan et al., 2009).

Palliative care patients may write songs about their illness journey, for someone important, the general community, or their faith, and experience relationship closure, self-expression, spiritual enhancement, and life review (Dileo and Magill, 2005). Analysis of lyrics of 64 songs written by 39 palliative care patients in music therapy revealed that the patients used song writing to express messages, self-reflections, compliments, memories, imagery, prayers, and reflect about adversity and their significant others, including pets (O'Callaghan, 1996a). Another analysis of 35 songs written by 27 cancer inpatients for their children found that parents' song lyrics included their memories of times spent with their children; messages of love, compliments, and/or hopes

for the children; existential beliefs, such as being available for the children now and in the afterlife; and supportive suggestions, such as who the children can turn to for future support (O'Callaghan et al., 2009). Arguably, these findings indicate that therapeutic songwriting may support parent–child connectedness during the parents' illnesses (O'Callaghan and Jordan, 2011) and, if the parent sadly dies, the child's coping through bereavement as positive associations with the deceased help the bereaved (Raphael, 1984). This is important given the scant information about how to support parents and their children through palliative care (Saldinger et al., 2004).

Improvisation

In music therapy improvisation, the music therapist and participant/s may improvise together on tuned (e.g. keyboard, metallophone, xylophone) or untuned (e.g. drums, rain sticks) instruments, with or without vocalizations. A simple, often effective way of introducing tuned instrument improvisation to patients is through the pentatonic scale. This is a group of five notes which always sound harmonious when the notes are played together. Within this musical relationship, the client musically expresses aspects of their creative self, and the therapist's improvised musical reflections (mirroring) can affirm and extend the participant's musical and holistic way of being. These creative musical experiences can be enjoyable, 'freeing', and transform one's way of cognitively and feelingfully experiencing the world. The ongoing musical dialogue can affirm that the client has been heard and is known, inspiring further creativity, which may lead to further adaptive self-awareness. This has been illustrated in work with a gentleman with motor neurone disease (Salmon 1995) and with HIV-positive men (Hartley, 1999).

Concerts, music appreciation

Music therapists may also organize concerts and music appreciation sessions, where the therapist presents information about singers, bands, or musical genres in response to patients' requests, for those seeking to pursue novel, interesting, and educative experiences for as long as they can. Concerts may include patient, family, or staff performers or good musicians from the community.

Guided use of music

Relaxation inductions and music, and instructions for the use of music, may be used to help patients manage symptoms and feel less stress, including when undergoing scans or procedures. Good relaxation induction scripts are widely available and some include suggestions for music usage (Grocke and Wigram, 2007).[1] When patients are tense and very ill the author sometimes finds that a short relaxation induction followed by about 5–15 minutes of live music can be helpful, for example, 'The Swan',[f] 'Watermark',[g] the *Deer Hunter* 'Cavatina',[h] the *Moonlight Sonata* first movement and *Sonata Pathétique* second movement by Beethoven, and Nocturne in E flat by Chopin. Musical elements need to be steady without extreme variations in tempo, rhythms, and dynamics (loud/soft).

Preferred music is most associated with relaxation response (Stratton and Zalanowski, 1984) and pain reduction (Mitchell and MacDonald, 2006). Music alters mood through activating neural areas involving arousal, pleasure, dopamine production, and opioid transmission, more broadly than those elicited by language

(Levitin, 2006). Theoretical rationales for pain reduction in music therapy include direct physiological response to music stimuli that alter neural components of pain sensation, as well as cognitive and emotional changes aligned with increased self-awareness, thereby altering one's sense of the meaning, and thus perception, of pain (O'Callaghan, 1996b). When playing music to distract from symptoms, therapists often use the isoprincipal, musically matching patients' physical and emotional states, and gradually shifting the musical elements as patients move into more desired states, for example, slowing music down as breathing rate slows with relaxation. When participants have control over the music experienced in sessions, adverse effects are rare.

Specific populations

Children and adolescents

Music is often a central part of children's and adolescents' lives. It enables young cancer patients a connection with 'normalcy' and offers a vehicle for releasing emotions and energy, connecting with family and friends, and identity development (O'Callaghan et al., 2011, 2012). Music therapy can also help to alleviate young patients' distress and symptoms (O'Callaghan et al., 2011), improve coping with aversive procedures like radiotherapy (Barry et al., 2010), as well as improve their mood (Barrera et al., 2002), coping, and initiation behaviours (Robb et al., 2008). Music therapists tailor interventions to the young patients' cognitive abilities and emotional states. Those unable or unwilling to discuss feelings may symbolically express and find self-understanding, such as when a 'miserable and depressed' 8-year-old child was able to express grief and give a message to her best friend through song writing shortly before her death (Daveson and Kennelly, 2000), and when two 13-year-old-patients with brain tumours undergoing radiotherapy required less anxiolytics after experiencing improvisation, song writing, or therapeutic music lessons (O'Callaghan et al., 2007). Families may also have normalized and 'fun' experiences, for example when 4-year-old Peter smiled after a blanket was put on and gently pulled from his face during a Swedish playsong the day before he died (Aasgaard, 2001), and when a grandmother said that the happiest she had ever seen her 14-year-old grandson with AIDS was when he received a trumpet from a hospice on which the music therapist gave him lessons (Hilliard, 2003).

Cognitive impairment

Cerebral areas and neural systems activated during some musical activities are 'relatively independent from the areas used for verbal tasks' (Sergent et al., 1992, p. 108). Furthermore, long-term memories of music are relatively preserved in people with cognitive impairment. Therefore, the therapeutic use of both language and music are more likely to activate preserved neural function in palliative care patients who have brain impairment than when caregivers use language alone. Using both music and verbal language with people with brain impairment expands opportunities for them to have an aesthetic experience and meaningful connections with others. This includes patients with brain cancer and dementing conditions who can sometimes still sing, play instruments, write songs, and share music related interests, reminiscences, and humour with patients and families.

Music improvisation and familiar music can also provide a highly interactive medium for working with patients in low-awareness states following profound brain injury who display minimal and inconsistent spontaneous responses. The diagnosis of 'vegetative state' in one patient, following a severe anoxic brain injury in a cardiac arrest, was revised to a 'minimally conscious state' following purposeful, non-verbal responses in music therapy. Her family, who 'knew she was in there', then worked with the music therapist to find ways that they could leisurely share music with her (Magee, 2005). This work is described as 'neuropalliative rehabilitation'.

Ethnic minorities

Music therapists try and offer a wide variety of musical styles from many cultures. Patients unfamiliar with the dominant language in their care setting may experience reduced isolation, validation, and joy as they experience songs from their language of origin. Culturally significant music may also help patients to reconfirm their identity within their wider socio-historical and ethnic heritage, assist their expression of pain, grief, and memories, and support their preparation for death and their family members' grieving (Forrest, 2000).

Bereavement

Caregivers' music therapy memories shared with deceased family members indicates pre-loss music therapy's role for healthy grieving (Lindenfelser et al., 2008; Magill, 2009). For example, a grandmother caring for her four grandchildren said that memories of family song writing sessions before their mother (her daughter) had died allowed them to remember 'some good feelings, not all sad' (O'Callaghan et al., 2013).

Music therapy groups for 18 bereaved adolescents incorporating song writing, improvisation, or song listening and discussion gave the participants permission to grieve which helped them to feel better (McFerran et al., 2010). Therapeutic song writing also helped six bereaved children to accept loss, and express emotions and memories connected with their loved ones (Roberts, 2006).

Music-based care and the relevance of music therapists

Palliative care workers are encouraged to invite patients and families to consider using music for self-care whenever possible and music-based care suggestions are outlined in Box 4.7.1. Employment of music therapists is, however, recommended for extending music's capacity to enhance life quality. This is enabled through the therapeutic relationship and music therapists' knowledge of theoretically informed and evidence-based methods.

Therapeutic relationship in music therapy

The music therapist's supportive presence may be conceptualized as providing a 'sounding board' or a musical 'human mirror'. Winnicott suggested that in psychotherapy the therapist 'reflects back' aspects about the patient, enabling the person to exist 'as an expression of I AM, I am alive, I am myself' (Winnicott, 1971, p. 56). In music therapy, the patient may be 'reflected back' in a multisensorial manner, that is, musically, verbally, and non-verbally, expanding the potential for creative reintegration and new awareness. Improvisations and familiar music in music therapy are always experienced anew, creatively perceived and expressed, potentially transducing into helpful ways of viewing and coping

Box 4.7.1 Suggestions for staff caregivers offering music in palliative care

◆ Patient choice is imperative, including type of music, its volume, when and where it is listened to, and for how long. Ensure patients can control volume and turn their music off whenever possible; regularly offer to help music access (or to turn it off) when patients are unable to operate music systems when they have a disability. Once a person with anarthria and physical disability from motor neurone disease spelled out on the e-tran board (with eye movements) that the music therapist needed to take her CD player away because busy staff put headphones on her ears and did not inquire about the volume before leaving.

◆ One's preferred music is most associated with relaxation. Hence music therapists do not advocate the indiscriminate use of 'piped' music in palliative care settings: what one person finds helpful may be aggravating for another.

◆ Suggest that patients bring their own music, labelled with their name when coming for inpatient stays or procedures (e.g. iPods/CDs) and have CD players and headphones available as necessary.

◆ When patients intend using music for aversive procedures, suggest that they consider how they would feel if the experience contaminated their enjoyment of that same music in the future. Some people find using preferred music to help them through an unpleasant experience does not impact upon their future enjoyment of that music, while others need to avoid it in the future.

◆ Encourage 'normal' family interactions through sharing music as appropriate. For example, parent inpatients may play children's music CDs/playlist during young children's visits; families can bring instruments to play into inpatient settings; hospices may a have guitar, harmonica, or keyboard available for patients and families to play. Suggest that family members and friends bring in patients' favourite CDs into hospital and listen to music together, or offer to buy a favourite CD instead of flowers. In home-based palliative care, suggest that patients and families consider listening to old music collections; help them consider ways of getting to concerts/ bands if they are concert goers (e.g. borrowing a wheelchair; contacting concert venues about wheelchair access and convenient car parking availability).

◆ Encourage the development of music libraries with diverse music choices in hospital settings that patients/families can access. Perhaps include CD 'samplers' or playlists on MP3 players which offer a range of music styles so that patients and families can explore unfamiliar types of music that may be helpful. As people become more unwell music preferences may change.

◆ Invite patients, perhaps with their families, to consider making CDs or playlists of the musical highlights of their lives. Memories or messages related to the music can be also put on the CD. These 'musical life reviews' can elicit affirming conversations and can be given as gifts.

◆ Inquire about and talk to patients about their music interests which indicates interest in the 'person' beyond the patient. Sometimes talking about music can be just as enjoyable as listening to it.

◆ Consider the presentation of live concerts or background music sensitively in public palliative care settings. Live concerts in palliative care settings, including accomplished musicians and music students, and even patients and families themselves, can be normalizing, interesting, and enjoyable. Performers may suggest that patients and families need to feel free to leave the concerts as needed. Live acoustic ambient music to enhance the environment may be offered in areas where people can move to and from (e.g. foyers). Volume should not be too loud: normal conversations need to be still audible. Avoid presenting music with loss and death themes in this context. Instrumental music, for example, acoustic classical guitar or piano, may be good. Inviting anonymous written feedback to be placed in strategically located feedback boxes can help with understanding what music is appropriate for the context.

◆ When patients have cognitive impairment (e.g. adynamic, memory loss) regularly offer music.

◆ Some patients with memory loss find listening to the same music repeatedly enjoyable.

◆ If patients and families appear 'sad' listening to music this is often ok, especially if they have requested the music. It is important that they can feel free to turn the music off (or leave a concert) if they wish. Consider whether to inquire about the emotion and offer support or leave them to contemplatively be. If a patient or family member is concerned about their music reaction perhaps reassure that varied (and different) responses to music can be normal when one is dealing with serious illness. It is possible that the person is experiencing the 'pleasurable sadness' paradox, that is, enjoying listening to music that evokes sadness alongside positive feelings.[*]

◆ Consider the potential effects of your personal music usage on the wards on overhearing patients and staff.

◆ When patients are unarousable at the end of life, family members may be invited to put soft music on in the room that they believe that patient would like, and softly hum or sing one of their favourite songs, hymns, or melodies. Reassure them that it does not matter if they don't remember the words.

[*]Source: data from Vuoloski, J.K., Thompson, W.F., McIlwain, D., and Eerola, T. Who enjoys listening to sad music and why? *Music Perception*, Volume 29, pp. 311–317, Copyright © 2012 by The Regents of the University of California. All rights reserved.

with illness experience. The therapeutic impetus encapsulated in live musical involvement with a trained music therapist cannot be underestimated as the therapist validates and often improves people's experiences through reflective listening and supportive musical and verbally insight-oriented dialogue.

As patients move closer to death, however, expecting significant psychotherapeutic changes may be inappropriate. The therapist may still softly play the music that has previously enriched the patient's life, and assist family members and friends to continue their supportive presence or expression of messages. This is especially evident, for example, when the music therapist accompanies a spouse singing a favourite courtship song to their dying partner, when children of dying patients ask for songs that they remember their parents loved watching them dance to in school concerts, and when the therapist accompanies family members sing hymns during bedside vigils, such as when one patient's favourite, 'Here I am Lord',[i] was being sung by her children as she took her final breath.

Research and evidence

Extensive music therapy research has been conducted within this field, exemplified by three Cochrane reviews[2] in music therapy palliative care (Bradt and Dileo, 2010), oncology (Bradt et al., 2011), and dementia (Vink et al. 2011). There is also a review, spanning 1983–2009, of 61 research projects in music therapy, cancer, and palliative care encompassing 32 objectivist (quantitative), 26 constructivist (qualitative), and ten mixed methods publications. This latter review found considerable evidence for music therapy improving the life quality of patients and family and staff caregivers in myriad ways. For example, randomized controlled trials (RCTs) and non-controlled quantitative studies showed findings of improved mood, relaxation, spiritual well-being, comfort, and reduced pain, distress, depression, pain, anxiety, isolation, and boredom. Qualitative research findings revealed that music therapy can be a positive social, emotional, and spiritual experience, which provides opportunity for creativity, healing, aesthetic meaning, expanded identity, and it can affirm one's sense of aliveness. Family and staff caregivers also find witnessing and experiencing music therapy's effects personally helpful. (See O'Callaghan (2009) for summaries of these studies and references.)

A Cochrane review meta-analysis on five end-of-life care studies (175 participants) found statistically significant findings in three studies for improved quality of life scales in three domains: functional, psycho-physiological, and social/spiritual well-being (Bradt and Dileo, 2010, p. 2). For example, in one RCT, which examined music therapy's effect on 25 hospice inpatients, anxiety, pain, tiredness, and drowsiness were significantly reduced in the music therapy intervention group compared to the volunteer visitor control group (Horne-Thompson and Grocke, 2008). Another Cochrane review, which examined the effect of music therapy and pre-recorded music listening interventions on physical and psychological outcomes in cancer patients, included 30 trials (1891 participants) (Bradt et al., 2011). The meta-analysis findings also suggested that music may improve life quality and mood, and reduce anxiety and pain. In one RCT, for example, which included 62 patients receiving autologous stem cell transplants for haematological malignancies, the music therapy group scored significantly lower on the anxiety/depression and total mood disturbance score compared with the controlled standard care group (Cassileth et al., 2003). The authors of both these Cochrane reviews, however,

warned that the findings need to be viewed cautiously as most of the studies included high bias risks (Bradt and Dileo, 2010; Bradt et al., 2011). Within Cochrane reviews, findings of 'high bias risk' can mean that one of four criteria for dealing with internal risk domains were not met, that is, (a) adequate randomization, (b) allocation concealment, (c) detail about incomplete outcomes, and (d) blinding of participants, service providers, and assessors (Higgins and Altman, 2008). As, 'it is not possible in music therapy studies to blind participants and those providing the interventions' (Bradt and Dileo, 2010, p. 5), perhaps if the first three mentioned criteria are met (randomization, allocation concealment, and incomplete outcomes addressed) and the assessor is blinded, music therapy trials should be rated as producing high enough quality findings.

Arguably, RCTs and other quantitative studies included in these Cochrane reviews do not produce superior findings to well-conducted qualitative research when investigating music therapy's effect on subjective experiences in palliative care. In RCTs, alongside the problem of non-blinding potentially biasing outcomes, the control of variables is also difficult because (a) music therapy is not a standardized treatment, (b) patient–carer relationships are associated with therapeutic gain (Kain et al., 2004), and (c) conducting studies on representative samples with even distribution of confounders in treatment groups is difficult, especially with small samples. Hence it is suggested that quantitative research only allows logical or conceptual rather than predictive generalizations, just like qualitative research does. Qualitative research on music therapy research questions in palliative care is preferred by some researchers because (a) it can be unethical to withhold (or delay) potentially supportive care through RCTs when patients are assigned to non-experimental groups (Keeley, 1999); (b) RCTs include standardized measurement scales which may provide information important to the researcher but not patients (McGrath, 2000); (c) RCTs do not necessarily support palliative care principles of patient- and-family-centred care (Kvale and Bondevik, 2008): patient-centred practice emerges from listening to patients' reflections; and (d) existing outcome tools are not sensitive enough to detect many of the benefits reported in qualitative studies.

Constructivist (qualitative) research approaches can collect patients' and caregivers' idiosyncratic voices, identifying what they find important. Grounded theory methodology, for example, informed a multisite study which uncovered how 100 oncology staff members, who witnessed music therapy on their wards, were often incidentally supported by music therapy and, as a result, perceived improvements in their care of patients (O'Callaghan and Magill, 2009). Grounded theory methods were also used in a study conducted with six patients with chronically progressive multiple sclerosis. Music therapy provided opportunities for the patients to challenge their disabled identities. Improvisation either validated or reminded them of physical loss, and songs supported coping strategies to deal with the condition's emotional impact (Magee and Davidson, 2004).

Closure

Previously, people lived with shared understandings and ways of how to die and mourn. In contemporary, more individualistic societies people use more privatized ways of dealing with loss (Walter,

1994). Music therapists invite palliative care patients and caregivers to explore how musical attachments from their lifetimes and creative experiences with less familiar music can alleviate physical and emotional distress; nurture and sustain; validate one's unique contribution; restore or continue meaningful connection with who and what is important; and enable new realizations and joy through aesthetic or transcendent experiences. Some of the most profound moments in music therapy are when people apparently experience 'happiness' and 'sadness' in an alternate or simultaneous manner as they relive and reintegrate memories alongside a knowing that their mortal end is near. Almost always, patients want the music to continue. Music can 'carry mourning too heavy for words and preaching' (Roy, 2001, p. 132), provide a familiar 'holding space' (Berger, 2006), and be a vehicle for release. Music therapists are vital members of palliative care teams who are helping to enrich people's lives transitioning from corporeal existence, and the family members, friends, and caring staff accompanying their passage.

Notes

1. Some music therapists with specialized training offer patients with good energy and cognitive capacity the Bonney Method of Guided Imagery and Music. After a relaxation induction clients describe their imagery during musical listening, and then verbally or artistically process their reactions in order to increase self-understanding and personal growth.

2. A Cochrane review is a systematic assessment of a health-care intervention consisting of a systematic review of literature related to the intervention and, if appropriate, a meta-analysis of eligible trials (Higgins and Green, 2008). Cochrane reviews are widely regarded as providing gold standard research findings in health care.

4.8

The contribution of the dietitian and nutritionist to palliative medicine

Rosemary Richardson and Isobel Davidson

Introduction to the contribution of the dietitian and nutritionist to palliative medicine

Nutritional management of patients receiving palliative care is now accepted as an explicit element of care (Finlay, 2001). This includes attempting to manage the nutritional consequences of anorexia and cachexia which are often considered by health-care professionals as milestones of disease progression. Traditionally, the input from those providing palliative care relating to nutrition is one of ethics and centres on the decision to provide food and fluid as treatment or basic care. However, dietary advice spans the entire palliative care spectrum and serves to enhance quality of life as well as nutritional status (Thoresen et al., 2011). Many patients present with and are distressed by the presence of symptoms that affect their ability to eat 'normally', for example, dysphagia, taste changes, xerostomia, and dementia. The consequent deterioration and alteration in nutritional intake promotes weight loss, fatigue, and is associated with poor functional status (see Fig. 4.8.1).

The role of the dietitian may appear simple in attempting to provide sufficient energy to prevent weight loss, but the complexity of the disease process and the barrage of symptoms which influence feeding behaviour profoundly are numerous. In addition, our improved understanding of the metabolic sequelae of disease highlights further the futility of approaches that merely seek to increase patients' nutritional intake (either enterally or parenterally) in an attempt to replete body mass. More realistic goals in nutritional management are nutritional support to maintain body weight and assist in symptom control to optimize physical well-being and support positivity and hope (Seibaek et al., 2011). The key nutritional strategies that may be used to ameliorate or manage symptoms (see Table 4.8.1) have resulted in the recognition of nutrition as a component of holistic palliative care. While research indicates a clear association with loss of body mass and quality of life (Thoresen et al., 2011), the lack of formal and rigorous evaluation (i.e. randomized controlled trials) of nutritional intervention in practice reflects the inherent difficulties of conducting nutritional research in the palliative care environment. The challenge for practitioners remains striking a balance between the application of research evidence and the practical nutritional needs of the individual.

Approaches to increase nutritional intake

Dietary counselling

Dietary counselling should serve to provide the dietitian with an understanding of the patient's nutritional problems, their needs, and an appreciation of limitations and barriers to complying with nutritional advice/prescriptions. Building relationships is an intrinsic, yet vital, component of dietetic consultation. The landscape for dietetic practice has changed significantly and patients are no longer viewed as passive recipients of dietary intervention. Rather they are viewed as partners in their own dietetic management who work in concordance with their dietitian and participate actively in decision-making and goal setting. Therefore, improving and developing communication skills is an essential component of practice and success depends on integrating structure of the consultation and building effective relationships (Kurtz et al., 2003) (see Fig. 4.8.2). Adopting this approach will enable and empower patients to engage actively in their nutritional care (McCorkle et al., 2011) and be conducive to frank and open discussions.

Patients are surprisingly good at providing the information the dietitian wants to hear. While patients may confirm verbally their compliance to nutritional treatment, in utilizing high-level communication skills the practitioner may find adherence may be limited or non-existent. This may account for the disappointing results of one of the few randomized controlled trials that examined the effect of dietary counselling on food intake, body weight, and quality of life in cancer patients (Ovensen et al., 1993). Patients ($N = 57$) were randomized to receive nutritional counselling (twice a month for 5 months) and offered nutritional supplemental drinks. The control group ($N = 48$) ate *ad libitum* and had no counselling. Results showed that, when compared with controls, 5 months of dietary counselling increased total energy intake by 15 kcal/day and 0.6 g protein/day and, not surprisingly, no differences in body weight or quality of life were observed. No details of the structure of the counselling interview were provided, other than that its aim was for patients to achieve recommended intakes.
Fig. 4.8.1 Association between weight and grip strength in patients in hospice.

Similarly, a study (Evans et al., 1987) in patients with advanced colorectal and non-small cell lung cancer showed no differences in intake in patients receiving and not receiving dietary counselling.

There remains a paucity of studies that have examined the effect of dietary counselling in palliative care and in the preceding 3 years there appear to be no new additions to the literature. However, a potential proxy of compliance may be to determine a patient's understanding of appropriate nutritional concepts and the outcomes aimed for through intervention. It is worth noting that currently patients seem to have a limited understanding of their condition, approaches being adopted in its management, and a comprehensive understanding of palliative care (Docherty et al., 2008). A patient is more likely to comply if they have a comprehensive understanding of the rationale that underpins a nutritional intervention (Box 4.8.1). Clearly, undertaking further work in this

Table 4.8.1 Nutritional strategies to improve symptom control

Symptom	Causes of decrease in dietary intake	Management
1. Psychological stress/depression	◆ Poor appetite	◆ Antidepressant, psychological support strategies, counselling, complementary therapies (i.e. aromatherapy, reflexology) small frequent meals
2. Altered taste and smell	◆ Food aversions	◆ Dietary counselling and identification of food aversions/preferences
3. Oral thrush/ulceration	◆ Blunting of taste	◆ Pharmacological treatment of symptoms (i.e. nystatin, lignocaine) ◆ Increase use of nutrient-dense cold fluids ◆ Optimize oral hygiene
4. Reduced flow and altered consistency of saliva	◆ Induce gagging and nausea	◆ Use of artificial saliva and hydrating oral gels ◆ To encourage flow of saliva—chew gum or suck on boiled sweets ◆ Optimize oral hygiene
5. Nausea and vomiting	◆ Physical obstruction ◆ Drugs, e.g. opioids ◆ Radio-/chemotherapy	◆ Pharmacological treatment that is effective at mealtimes ◆ Small frequent meals ◆ Avoidance of food aversions ◆ Consume fluids after meals
6. Dysphagia	◆ Physical obstruction/construction	◆ Altered consistency of food semi-solid → puree ◆ Use of nutrient-dense supplements ◆ Consider initiating PEG feeding
7. Respiratory distress	◆ Focus on breathing rather than food intake	◆ Medication before mealtimes ◆ Ensure patient wearing loose clothing ◆ Relaxation exercises ◆ Small meals and present foods that do not require much chewing
8. Early satiety	◆ Cytokine mediated	◆ Maximize availability of food ◆ Small frequent meals ◆ Encourage food consumption when patient feels at their best/less agitated
9. Altered bowel function: (i) Constipation (ii) Diarrhoea	◆ Feeling bloated ◆ Abdominal discomfort ◆ Abdominal discomfort ◆ Fear of symptom leads to food avoidance	◆ Appropriate laxatives ◆ Encourage fluid intake ◆ Encourage consumption of dietary fibre ◆ If possible optimize mobility ◆ Medication: includes anti-diarrhoeas, pancreatic enzyme supplements as appropriate ◆ Temporarily avoid dairy products ◆ Increase intake soluble fibre (e.g. bananas, oranges, oatmeal)
10. Fatigue/lethargy	◆ Neurological ◆ Loss of muscle mass	◆ Maximize intake when patient feels at their best ◆ Avoid foods that require a lot of chewing

Documentation structure	P (Patient experience, feelings, consent, understanding of dietetic role, relevant social, environmental and clinical information contributing to their 'journey') O (Objective, e.g., biochemistry, medications, observations) N (Nutritional assessment including anthropometry) I (Integration of all relevant aspects from P, O, N to form a patient-centred measurable dietetic goal) P (Plan including how and when to evaluate the nutritional outcome)	Building relationships

Fig. 4.8.2 Consultation structure for effective relationship building.

area is imperative if oral nutritional interventions are to demonstrate efficacy.

Patients and their informal carers have high expectations of nutritional intervention and have on occasion chosen invasive options such as total parenteral nutrition, with no hope of effect (McCann et al., 1994; Plaisance, 1997). Thoughtful counselling acts to improve patient management and, by putting the patient at the centre of care, allows them to make choices and identify realistic goals. It should be remembered that the Internet is a source of dietary information accessed by many patients and their carers. This may result in alternative therapies being used such as macrobiotic diets, supra dosing of vitamins, and homeopathy. This should be explored in the consultation so that the clinician has a complete picture of what the patient is doing for himself.

Dietary counselling with particularly complex cases involving cachexia-anorexia is a resource-intensive management strategy relying on the knowledge and communication skills of the dietitian. A more effective and efficient strategy may be to promote self-supported management with the patient and carer (Davidson et al., 2012).

Nutritional supplements

Oral nutritional supplements normally provide 1.5 kcal/mL and 0.6 g/mL of protein presented in 200–250 mL cartons and are intended to supplement, not substitute, energy intake from food. Compliance with oral nutritional support regimens was often poor (Akner and Cederholm, 2003) but in recent years this seems to have improved markedly (Hubbard et al 2012). This improvement will result in increased energy intake which in turn may be associated with clinical benefit. Progress in the quality of dietetic consultations may account for this positive shift in compliance to oral nutritional supplements. The role of altered ingestive behaviour should also be taken into account in prescribing the timing of taking oral nutritional supplements.

Timing of consumption

It is well recognized that the control of ingestive behaviour in cachexia influences nutritional intake profoundly. Many patients may have amplification of the satiety cascade (neural and humoral), thereby prolonging the inter-meal interval and

Box 4.8.1 Effective dietary counselling: suggestions for constructing a patient interview

◆ What changes in your diet have there been over the last few months?
  • Quantity
  • Food aversion/taste changes
  • Consistency
  • Diet history.
◆ Do you think nutrition is an important part of your care?
◆ Any symptoms around mealtimes that are troublesome?
  • Pain
  • Respiratory distress
◆ How are you managing with nutritional supplemental drinks?
  • Compliance
  • Change prescription
  • Taste fatigue
◆ Is there any time of the day when you feel at your best?
  • Opportunity to optimize intake.
◆ How is your informal carer (if patient interviewed?)
  • Pressure for patient to eat
  • Anxiety of carer
  • Identify home enteral feeding problems
◆ Are you happy that your nutritional status is monitored?
  • Objectives.

If the patient cannot be interviewed then the carer becomes the source of dietary information.

---

reducing daily consumption. Indeed, early satiety is frequently reported in patients with a palliative diagnosis (Andrew et al., 2009) to a relatively low gastric volume. One strategy to address this would be to offer energy- and protein-dense supplements

before meals (1 hour) when feelings of hunger are strongest. In addition, patients should be discouraged from consuming low nutritive fluids at the beginning of meals such as soups. The rationale for this is to minimize the volumetric effect of fluids on satiety. While this approach is based on the translation of pathophysiology to practice, it remains to be evaluated in the clinical situation (Bell et al., 2003).

There are some concerns that consumption of supplements before meals would result in energy compensation at mealtimes, thus reducing overall daily intake. Interestingly, in a study (Rolls et al., 1991) that examined the effect of nutritive pre-loads (high fat, high carbohydrate) on meal consumption in elderly subjects and younger controls, the elderly subjects did not compensate for the pre-load. These results are encouraging, given that the majority of patients in palliative care are elderly; however, in this study no subject had metabolically active disease which influences both sides of the energy balance equation detrimentally.

Nutritional modulation

A characteristic feature of cachexia, despite its primary cause, is the presence of systemic inflammation. A consequence of this, in addition to loss of functional tissue, is reduced motivation to eat and the ineffective utilization of nutrients. Thus, in conditions where the inflammatory response is more profound, the associated anorexia may be more resistant to interventional strategies and the accretion of lean body mass becomes an impossible goal. In recent years there has been considerable interest in the use of nutrients with putative anti-inflammatory properties that attenuate cachexia and promote anabolism to improve body composition. The primary aim of this treatment modality is to improve survival and quality of life where functional ability is a key component.

Work in patients with advanced pancreatic cancer (Richardson et al., 2001) examining the effect of a fish oil-enriched supplement (eicosapentaenoic acid (EPA), energy and protein dense) on total dietary intake was initially very promising. Nutrient intake (meals and supplement) was significantly greater in those patients receiving the fish oil, than in the group randomized to energy and protein supplements alone. Results from 200 patients with pancreatic carcinoma supplemented with 2 g of EPA revealed net gain of weight and lean tissue. Despite these early successes, more recently a study (Fearon et al., 2006) of over 500 cachectic patients (gastrointestinal and lung cancer) supplemented with either 2 or 4 g/day of EPA indicated no significant treatment benefit in terms of weight or survival. This is supported by other work (Bruera et al., 2003) in a more heterogeneous cachectic group showing EPA had no significant benefits on energy intake and nutritional status. The literature continues to provide unequivocal results with respect to *n*-3 fatty acid supplementation. A recent double-blind, placebo controlled trial (Finocchiaro et al., 2012) intervening with both EPA and docosahexaenoic acid provided evidence of better preservation of body weight status and anti-inflammatory effects in lung cancer patients receiving chemotherapy.

There remains insufficient evidence to support a clear benefit to *n*-3 fatty acid supplementation in advanced disease (Ries et al., 2011). However, it may have a role in maintaining nutritional status and limiting the effects of active treatment in palliative therapy in specific homogeneous clinical populations.

Patient acceptance

Taste and smell

Physiological stimulation of gustation and olfaction by food in healthy individuals appears primarily to be a positive influence on intake, so long as the food itself is palatable. Hence chemosensory changes which accompany advanced disease have a significant impact on the quantity and quality of nutrients ingested (Hutton et al., 2007) and predict poorer functional status and quality of life.

Factors that contribute to aberrations in taste and smell are rooted in treatment modalities (drug treatment, radiotherapy), but are less understood in the disease process itself (Lennie et al., 2006; Vance and Burrage, 2006). Perceived changes in taste and smell reported by patients in palliative care, however, are not uniform which makes provision of general advice difficult. To improve compliance in taking supplements, patients should be offered a range of flavours and this also applies to 'normal' diet. This strategy may prevent the development of sensory specific satiety (Rolls and Rolls, 1996) and limits the negative impact of chemosensory changes on nutrient quality.

Promoting dietary intake

Maintaining dietary intake to meet requirements can be particularly difficult in the palliative stage for both practitioner and patient. Health-care professionals must appreciate that eating-related distress is evident in both patients and their family. Frequently food presented needs modification in consistency, attractiveness, and portion size. Symptoms such as pain can reduce dietary intake. In addition, the pressure that the informal carer can put on the patient to eat often goes unrecognized (Strasser et al., 2007).

> My husband is doing his best he cooks my favourite foods and brings it to me on a tray. It's too much, I just can't eat it so I scoop half of it into a bag. [Cancer patient]
> At first cooking was difficult; since developing Parkinson's we have radically changed what we eat. [Parkinson's patient]

These issues should be explored during dietary counselling.

Individual attention to detail is important in encouraging dietary intake and many issues are addressed in Table 4.8.1. It is important to make sure the patient is comfortable (e.g. correct positioning, toileting) and the environment is conducive to eating (e.g. catheter bag covered, table/tray attractively presented).

Dysphagia

Patients who may develop dysphagia include those with motor neuron disease, Alzheimer's disease, progressive multiple sclerosis, and Parkinson's disease and is particularly well documented in those with head and neck cancer (Roe et al., 2007). The severity of dysphagia varies considerably. Some patients may have mild swallowing problems requiring minor food modification (texture modification). The recently updated descriptors for texture modified diets (British Dietetic Association, 2009) provide guidelines for all modifications required for patients with swallowing impairment. It should be remembered that the liquid content of modified diets tends to be high and acts to dilute the nutrient content. Macronutrient and micronutrient fortification is often required. Whereas others with severe dysphagia may be unable to tolerate even very little oral intake. For those patients who are unable to

swallow enough to maintain hydration or nutrition, placement of a percutaneous endoscopic gastrostomy (PEG) tube may be considered, but long-term treatment goals must be identified.

Home artificial nutrition

The majority of palliative care patients on home feeding are prescribed enteral nutrition (nasogastric and PEG). Implementation of home artificial nutrition support requires significant education and training of the patient and/or their carer. Meticulous discharge planning, communication between the care team, and a structured monitoring process are key elements to making home enteral nutrition an acceptable treatment modality. In a recent survey, the primary reason for instituting home artificial nutrition was found to be to support patient well-being and not, as one might expect, to prolong life (Orreval et al., 2009). The informal carer is most likely to take responsibility for maintaining patency of the feeding tube, feed administration, and routine mentoring.

Prior to starting feeding or sending patients home on feeding, the patient's home should be visited to evaluate practical issues such as:

◆ What storage space is available to stock feed and related consumables (e.g. giving sets)?

◆ Can a drip stand be moved freely round the house? Steps and loose carpets may increase the patient's risk of tripping

◆ Communication support issues.

Nutritional assessment

A precursor to assessment is nutritional screening and the Malnutrition Universal Screening Tool (MUST) is a validated tool used widely in clinical practice (Elia and Stratton, 2012). This screening tool has been designed to identify adults who are underweight or at risk of malnutrition. Screened patients identified at risk of becoming malnourished may be referred to a dietitian who will undertake a full nutritional assessment.

This assessment not only involves determination of nutrient intake (dietary and/or artificial nutritional support), a procedure generally well accepted by the patient, but should also include sequential monitoring of the patient's nutritional status. The latter provides information relating to the progression or attenuation of loss of body mass. Sensitivity to the patient when undertaking the assessment is paramount. If a patient is in the terminal stage of their disease, is immobile, and/or severely demented, undertaking a nutritional assessment may be inappropriate. However, if the patient's stage of cachexia can be appropriately classified (Fearon et al., 2011) this may prove useful in identifying when dietetic interventions are likely to be of greatest benefit.

Body weight

An individual's body weight can be compared with tables (Metropolitan Life Foundation, 1983) which provide 'normal' values for individuals of the same sex, age, and height. However, consideration of recent weight loss (i.e. past 3 months) allows an insight into the magnitude and progression of weight loss. Sarcopenic obesity is now common. It is important to respect the patient's wishes, in that some might not wish their weight to be monitored, and these should be respected. However a recent UK-wide hospice study indicates that there is a clear reluctance of staff to instigate weighing for fear of upsetting patients (Watson et al., 2010). This

is despite 96% of patients reporting that this procedure had never upset them and 74% of patients weighing themselves at home.

Weight loss as % of 'used' body weight:

$$\% \text{ weight loss} = \frac{\text{used body weight (kg)} - \text{current weight}}{\text{usual body weight}} \times 100$$

This approach allows the patient to provide their own reference value. An unintentional weight loss of 10% in 3 months is indicative of significant weight loss and 20% of protein energy undernutrition (Kinney, 1988).

Body mass index

Another method of using weight as a nutritional parameter is to express height as a power index of weight:

$$\text{body mass index (BMI) units } \left(\text{kg/m}^2\right) = \frac{\text{Weight (kg)}}{\text{Height}^2 \text{(m)}}$$

◆ A BMI less than 20 is indicative of mild undernutrition

◆ A BMI less than 18 is indicative of moderate undernutrition

◆ A BMI less than 16 is indicative of severe undernutrition.

The assessor should be aware that the presence of oedema or ascites may mask the degree of undernutrition and care in interpretation of weight data is required. In addition, an overweight patient can be malnourished and may also have significant loss of muscle mass (sarcopenic obesity).

Arm anthropometry

Triceps skinfold thickness provides an indication of fat reserves. This measurement is taken using skinfold calipers at the mid-point between the acnomium process and the olecranon and results are compared with standard values (Jelliffe, 1996).

An indication of skeletal muscle mass may be obtained from subtracting the skinfold thickness from the mid-upper arm circumference. This technique assumes the upper arm is a perfect circle.

$$\begin{aligned}\text{Arm muscle circumference (AMC)} \\ = \text{mid-upper arm circumference (MUAC)} \\ - (\text{triceps skinfold} \times \pi)\end{aligned}$$

The upper arm is easily accessible and less prone to oedema. Information on arm anthropometry should be considered with weight data.

Handgrip dynamometry

Weakness, asthenia, and fatigue are common symptoms of palliative care patients. While weight and arm anthropometry provide quantitative information relating to body mass, handgrip dynamometry is a functional marker of mass and, in end-of-life patients, correlates with body weight (Fig. 4.8.1). If the aim of nutritional intervention is to improve lean body mass, it is important that both the quantity and quality of this tissue increases. This non-invasive technique involves determination of patients maximal grip strength (Windsor and Hill, 1988).

However, it should be remembered that in the presence of a systemic inflammatory response, improvements in body mass are generally not achievable. The overriding component of nutritional management in palliative care is ensuring the wishes of the patient and family are fulfilled. Today, patients and relatives are more informed than ever before and many actively seek information relating to disease and management. This means that the boundaries of practice for health-care professionals have shifted and this is a continuous dynamic process. Now more than ever there is a need for professionals to integrate their understanding of clinical science and current research to inform their practice. The science of cachexia treatment options and research are discussed in detail in Chapter 10.5.

4.9

Physiotherapy in palliative care

Anne M. English

Introduction to physiotherapy in palliative care

Palliative care and rehabilitation both focus on the concept of helping people to maximize their potential and live as well as they can, given their circumstances.

Physiotherapy is defined as a health-care profession concerned with human function and movement, thereby maximizing people's quality of life. It is a constantly evolving profession that strives towards excellence and consistency within clinical practice (Chartered Society of Physiotherapy (CSP), 2005). It is a science-based profession and takes a person-centred approach to health and well-being which includes the patient's general lifestyle and uses physical approaches to promote, maintain, and restore physical, psychological, and social well-being. It is committed to applying, evaluating, and reviewing the evidence that underpins and informs its practice and delivery (CSP, 2013).

Physiotherapists practise independently, as first-contact practitioners and as part of the multidisciplinary team (MDT). They help to encourage, develop, and facilitate independence, working with people to optimize their functional ability and potential (CSP, 2011). They address problems of impairment and manage recovering, stable, and deteriorating conditions, treating a wide range of physical conditions of people with varying health status (relating both to physical and mental health) (CSP, 2005).

The role of the physiotherapist in palliative care includes assessment, symptom management, function and rehabilitation, education and communication, prevention, and psychological aspects of care. The physiotherapist plays an important role in the MDT in cancer care. Effective MDT working should result in care being considered by professionals with specialist skills and knowledge in the relevant aspects of each cancer type (National Cancer Action Team, 2010). Evidence also supports a multiprofessional approach to patients with neurological conditions, suggesting that neurology, rehabilitation, and palliative care services should be closely linked in order to support patients from diagnosis to death, and physiotherapists are recognized as being involved at different stages of neurological illness trajectory (National End of Life Care Programme, 2010).

Working alongside the patient in a one-to-one relationship provides the opportunity for the physiotherapist to explore further the patient's misconceptions and hesitantly voiced fears. Understanding the physical processes involved can reduce the patient's anxiety and distress. The provision of management strategies empowers the patient to regain control over aspects of their condition, at a time when they are often experiencing helplessness and loss of independence. Carers and family members should also play an active part in caregiving.

Assessment and communication

Patient assessment identifies problems and enables the patient and physiotherapist to agree on realistic goals, formulate a treatment plan, and decide on appropriate outcome measures. Rehabilitation assessment in relation to cancer can be recognized in four stages—preventative, restorative, supportive, and palliative (Dietz, 1980)—and are recognized as essential components of the patient pathway (National Institute for Health and Care Excellence (NICE), 2004). A four-level model has been suggested, recognizing those professionals who should be involved at each level, their function, and their level of expertise (Rankin et al., 2008). Early referral is important to allow anticipation of problems and put coping strategies in place. All goals must be patient centred, measurable, and achievable. They may be simple or complex (e.g. 'to attend my grandson's wedding'). Reassessment and redefining of goals may be necessary on a daily basis as the patient's condition can fluctuate rapidly. Knowledge regarding evidence-based principles of falls management is essential in order to be aware of risks and plan appropriately. A proportion of falls in palliative settings may be preventable and avoidable with regular risk assessment (Help the Hospices, 2010).

The importance of good communication skills in cancer and palliative care is widely recognized and advanced communication skills training is now available (NICE, 2004). Physiotherapists work closely with patients and may be asked difficult questions about prognosis or disease progression. It is important that they have the knowledge and skills to cope in such situations.

Challenging and complex problems

Patients with palliative care needs present multifaceted problems associated with an increasing range of underlying pathologies in a wide range of care settings (Allied Health Professions Palliative Care Project Team, 2004).The physiotherapist is involved in the treatment of patients with active and progressive conditions which may include cancer, HIV/AIDS, neurological, cardiac, chronic respiratory, endocrine diseases, and dementia.

Patients with respiratory problems

Dyspnoea

Breathlessness is a devastating and common symptom in patients with cancer and other advanced progressive illnesses (Fallon and

Hanks, 2006). It is difficult to manage and physiotherapists need a clear understanding of the nature of breathlessness in order to support their patients. A breathlessness assessment must be patient centred, holistic, and an ongoing process. Outcome measures may be subjective, and reliable scales such as the visual analogue scale, numerical rating scale, and modified Borg scale (Borg 1978) may be used to measure the sensation of breathlessness in patients with cancer. Measurements may be taken at first contact with the patient and then at agreed times during and on completion of treatment. A holistic breathlessness assessment may look at timing and frequency of breathlessness, what makes it better or worse, and explores the feelings associated with it (Corner and O'Driscoll, 1999).

Restrictive disorders, for example, primary and secondary lung cancers, mesothelioma, pulmonary fibrosis, and neuromuscular diseases, are characterized by reduced lung volume, poor compliance, and increased work of breathing. Obstructive disorders, for example, chronic obstructive pulmonary disease (COPD), bronchiectasis, and cystic fibrosis, cause increased work of breathing and airflow resistance (Hough, 2001).

Breathlessness is a frightening and unpleasant sensation experienced by many patients with various diagnoses. The effectiveness of a breathlessness service for treatment of lung cancer is recommended by NICE (2011), and suggested by Hately et al. (2003). Management may include airway clearance, breathing control, positioning, cognitive behavioural therapy, fan therapy, pacing (controlling breathing while walking or climbing stairs), prioritizing (choosing the most important activities that need to be done), relaxation, energy conservation, provision of walking aids, and education. Auscultation, pulse oximetry, a thorough history of the patient's medication, including inhalers, nebulizers, and the use of oxygen, are all important (Hough, 2001). Breathless patients automatically adopt positions that ease their breathing. This reduces the work of breathing and sensation of breathlessness. Useful recovery positions are sitting forward while resting forearms on thighs, forward lean standing, and relaxed sitting. Resting positions include forward lean sitting (see Fig. 4.9.1) and high side lying (i.e. lying on the side, knees slightly bent, rolled slightly forward, using three or four pillows to raise the shoulders, one pillow

Fig. 4.9.1 Forward lean sitting.

to support the head and neck) (Leyshon, 2012). Breathing control involves the use of the lower chest and upper abdomen therefore encouraging better use of the diaphragm. As the patient becomes more proficient they should be able to control the rate and depth of breathing to suit their needs.

Anxiety and emotions are closely associated with breathlessness and impact negatively on a wide range of other symptoms. Bausewien et al. (2008) conclude there are moderate levels of evidence to support breathing training including ways of managing anxiety in breathless patients. There is also strong evidence to support chest wall vibration and neuroelectrical muscle stimulation to relieve breathlessness in people with COPD (Bausewien et al., 2008).

Relaxation has been shown to reduce heart rate, respiratory rate, oxygen consumption, and blood pressure in breathless patient (Gosslink, 2003). It can also be used to reduce anxiety and to aid control of negative thoughts. Regular practice enables the patient to recall the technique and recreate the feeling of relaxation (Payne, 2000).

A handheld fan directed to the face may also help to reduce the sensation of breathlessness in some breathless patients (Galbraith et al., 2010).

In patients with chronic obstructive airways disease, pulmonary rehabilitation programmes are recommended, with a view to improving exercise capacity, dyspnoea, health status, and psychological well-being (Bolton et al., 2013). There are high levels of evidence to support pulmonary rehabilitation in people with COPD (Bolton et al., 2013). Pulmonary rehabilitation is described as an interdisciplinary programme of care, individually designed to optimize physical and social performance and autonomy. It has been shown to relive dyspnoea and fatigue, improve emotional function, and enhance the patient's control over their condition (Lacasse et al., 2006). Following an exacerbation of their COPD, pulmonary rehabilitation appears to be a very effective and safe intervention (Puhan et al., 2011). Pulmonary rehabilitation programmes include individual exercise programmes and education delivered by the interdisciplinary team (NICE, 2011). Programmes lasting 6–12 weeks are recommended (Bolton et al., 2013).

Management of respiratory secretions

Traditional physiotherapy techniques (e.g. chest wall shakings and vibrations) are used with caution in palliative care and these interventions would be contraindicated for patients with osteoporosis, bone metastases, and haemoptysis (Hough, 2001). Active cycle of breathing, assisted cough, and positioning are used on a regular basis by physiotherapists. Active cycle of breathing is an airways clearance method used to loosen secretions. It includes a combination of breathing control, thoracic expansions, and forced expiratory technique, facilitating expectoration (Bott et al., 2009). Research evidence favours active cycle of breathing over most alternatives for short-term improvement of secretion clearance in patients with COPD, bronchiectasis, and cystic fibrosis (Lewis et al., 2012). Adequate humidification and hydration is essential to encourage secretion clearance and a nebulizer may be helpful.

The use of respiratory suction, especially at the end of life, is a controversial subject and is difficult to research. Noisy breathing is thought to be caused by accumulation of secretions in the upper airways; however, this remains unproven. Oropharyngeal suction, if applied, should always be carried out with extreme caution, as

it may be distressing for the patient. Evidence suggests that positional changes and regular mouth care are more appropriate (Wee and Hillier, 2010). Relatives at the bedside may find this stage distressing and good communication skills by the physiotherapist are essential.

Cough

Patients with neuromuscular disorders (e.g. motor neurone disease (MND)) experience a number of respiratory problems. Poor lung compliance and consequently reduced lung volumes hinder the ability to cough effectively. There is a direct link between maximal inspiratory pressure and cough flow, demonstrating the importance of inspiratory muscle strength (Kang et al., 2006). An efficient and inexpensive piece of equipment, the lung volume recruitment (LVR) bag can be used to develop a breath stacking system, resulting in increased cough effectiveness (Armstrong, 2009). The LVR bag can be used up to four times per day or as required (see Fig. 4.9.2). To increase the expiratory force of a cough, a combination of a manually assisted cough and a cough assist machine may be used. The cough assist or mechanical in-exsufflator assists sputum clearance by the use of both positive and negative pressure. Gradual application of positive pressure to the airways is quickly changed to a negative pressure. This pressure change produces a high expiratory flow rate and stimulates a cough (Anderson, 2005). Physiotherapy techniques combined with this, enable secretions to come into the mouth and be wiped or suctioned away.

Cardiac failure

Cardiac failure is becoming more prevalent as people live longer and breathlessness is one of the early symptoms patients experience (Nicholas, 2004). Palliative care plays an important role in improving the quality of life of patients with heart failure, and therefore presents a challenge for physiotherapists to develop future services for these patients; however, heart failure patients have limited access to palliative care services (Harrison et al., 2012). Non-pharmacological interventions to manage breathlessness may include breathing retraining, pacing and prioritizing,

Fig. 4.9.2 Lung volume recruitment bag.

relaxation, a handheld fan, exercise and provision of walking aids and equipment, and psychological interventions (Gadoud et al., 2013). Rehabilitation is focused on exercise programmes to address cardiorespiratory deconditioning and maintenance of muscle bulk (Rees et al., 2009).

Patients with neurological problems

Patients may present with a wide range of different conditions, such as spinal cord compression (SCC), peripheral neuropathies, and cerebral tumours. The disease trajectory of brain tumour patients can vary as symptoms change over a short period of time. The rehabilitation professional must consider the fluctuation in symptoms and patient ability, the ultimate goal is maintaining independence and improving quality of life (Carr et al., 2008). Patients with long-term neurological conditions also come under the palliative umbrella and the importance of controlling symptoms and offering social, psychological, and spiritual support is described (Department of Health, 2005). These patients may have similar symptoms to cancer patients but, due to longer illness trajectories, will experience these symptoms over a greater period of time. Such diseases include multiple sclerosis, Parkinson's disease, MND, and muscular dystrophies.

Physiotherapists have a wide knowledge base and expertise in movement analysis and functional assessment, enabling them to develop individual treatment plans and agree the most appropriate interventions with the patient.

Active assisted exercises and passive movements are helpful in maintaining joint range, preventing muscle shortening and contractures, and reducing spasticity and pain. Patients are encouraged to maintain good posture when sitting and mobilizing. The physiotherapist assists with normal movement patterns, balance, gait analysis, and movement control. Training is given in use of appropriate mobility aids and sometimes the use of a tilt-table is helpful to enable standing to aid ventilation, bladder and bowel function, and most importantly psychological well-being.

Introduction of a wheelchair may be difficult for the patient, as it represents changes in lifestyle and dependency. Advice should be given on transfers into, rising from, and sitting in the wheelchair, maintenance of cushions, and safety for both patient and carer when manoeuvring the chair.

Spinal cord compression

Patients with advanced cancer may develop metastatic cord compression and this often indicates advanced disease. For many patients it may represent the final stage of their illness, and they will need help and support in adapting to a drastic reduction in functional ability and in developing future coping strategies (Lee et al., 2012). The physiotherapist is often ideally placed to note the early signs of SCC and alert the team concerned with future management of this oncological emergency.

In the unstable spine, surgery may be indicated to decompress the tumour and maintain stability, and the physiotherapist will be a core member of the post-surgical team. If unfit for surgery, radiotherapy may be the treatment of choice (Al-Hakim et al., 2006). If SCC occurs, it results in loss of varying degrees of motor, sensory, and autonomic function below the level of compression.

Physiotherapy may consist of balance training, development of upper body strength, instruction in transfers, and use of a

wheelchair. Relatives and carers will also require instruction in appropriate techniques. Provision of braces, splints, and walking aids may enable the patient to be as independent and comfortable as possible.

Fatigue

Fatigue is described as a persistent, subjective feeling of tiredness, weakness, or lack of energy, which may be physical or psychological, and is related to cancer or advanced chronic illness (National Comprehensive Cancer Network, 2010).

The effects of cancer-related fatigue are well documented, affecting between 70% and 100% of patients. Fatigue is a common and stressful symptom experienced by patients, and will impact greatly on quality of life (Watson and Mock, 2004). Physical exercise seems to have some benefit in the reduction of fatigue associated with cancer (Cramp and Daniel, 2008). A systematic review (Cramp and Byron-Daniel, 2012) suggests that physical exercise, for example, aerobic walking and cycling, may help to reduce fatigue during and after cancer treatment. This evidence relates specifically to patients with prostate or breast cancer. Hayes et al. (2009) recommend aerobic exercise three to five times weekly for 20–30 minutes in active patients and daily exercise for deconditioned patients.

Exercise

Exercise is known to have many physiological and psychological benefits and is a well-established intervention in palliative care (Oldervoll et al., 2006). Inclusion of physiotherapy-led exercise within cancer pathways can reduce and help to prevent disability (Headley et al., 2004). Exercise may be individual or group, must be safe, have known benefits, and take into account the patient's age, present condition, past medical history, and nutritional status. Positive effects include improvement in muscle strength, balance, endurance, joint range, functional capacity, and reduction in anxiety and depression. Patients presenting with conditions such as anaemia, bone metastases, respiratory insufficiency, and musculoskeletal problems must be carefully assessed, as exercise may be contraindicated. Exercise at end of life should be little and often and goal focused, for example, transferring bed to chair.

Cancer cachexia guidelines and classification are discussed in Chapter 10.5. Fearon et al. (2013) suggest that the management of cachexia is limited and complex. The physiotherapist may become involved in cachexia management. Maddocks et al. (2012) suggest the use of therapeutic exercise as a sound rationale in patients in advanced disease, with a potential to maintain or slow the loss of physical function (see Chapter 10.5).

Pain

The experience of pain is multifactorial and encompasses physical, psychological, emotional, social, and spiritual components (Robb and Ewer-Smith, 2008). Physiotherapists play a major role in pain management and rehabilitation is now considered an essential component of care (NICE, 2004). It is important to involve the patient and carers in treatment planning and goal setting using a patient-centred approach. The aim is to relieve pain and improve function using the best available evidence. A common response to pain is developing pain behaviours, for example, avoiding activities. Pain avoidance is an important part of pain management. Inactivity leads to a cycle of deconditioning, increased muscular tension, joint stiffness, possible contractures, and muscle shortening leading to an increase in pain. Appropriate positioning of patients helps reduce stress on weakened joints and muscles and prevent development of pressure areas. Fracture sites, weakened muscles, and deformities may be immobilized and braced by provision of splints, collars, and various supports.

Physiotherapists may work as part of a MDT ensuring the delivery of high-quality, effective care for people with dementia (NICE, 2006). Physiotherapists may be involved in mobility, falls prevention, exercise, and pain management (Christofoletti et al., 2008). In the advanced stages of the disease, physiotherapists may be working passively, as the patient may not remember or understand the instructions given to them (Pace et al., 2011). In end-of-life care, physiotherapists may advise on positioning, seating, and managing painful contractures (Oddy, 2011).

Physiotherapy techniques to manage pain may include exercise, re-education of posture, relaxation, transcutaneous nerve stimulation (TENS), acupuncture, heat, ice, and massage. Touch is probably the oldest method of relieving pain and discomfort and massage may be used to reduce muscle spasm, relieve pain, and aid relaxation. Soft tissue mobilization is widely practised and includes myofascial techniques and connective tissue massage (British Pain Society, 2010) (see Chapter 9.12).

Nausea, loss of appetite, and constipation

TENS and acupuncture may be used to relieve nausea using the Neiguan antiemetic acupuncture point (Fønnebø, 2011) (see Chapter 9.12).

It has been demonstrated that patients receiving regular physiotherapy of more than 10 minutes daily, experience a significant reduction in appetite disturbance (Laakso, 2003).

Evidence also suggests that there is an increased risk of constipation in people walking less than 0.5 km daily and a squatting position has been shown to facilitate efficient funnelling of the pelvic floor favouring defecation (Kyle, 2007). This can be simulated by provision of a simple step on which to rest the feet, when the patient is seated on the toilet. Raising the knees above the level of the hips, combined with relaxed deep breathing and a gentle rocking motion, may help ease the process of bowel evacuation and relieve constipation.

Chronic oedema

Physiotherapy skills contribute to the team management of lymphoedema and palliative physiotherapists may choose to train to graduate diploma level in lymphoedema management. A swollen limb is a heavy limb, placing stresses on weakened muscles and joints, affecting both posture and mobility. Gravitational oedema may develop in an immobile, dependent limb. Failure of the muscle pump will reduce venous return and increase the load on a struggling, one-way, lymphatic drainage system.

Self-management, using the following four cornerstones of lymphoedema treatment, is taught to patients and/or carers (Mortimer and Todd, 2007):

◆ Meticulous skin care

◆ Graded exercise and movement

◆ Compression, in the form of hosiery, specialized garments, or bandaging

◆ A modified massage technique which encourages lymph drainage.

This may offer the patient some degree of control but they must be empowered to accept such control. In advanced disease, palliative bandaging is used to control lymphorrhoea and to support the affected tissues.

Lymphoedema management includes breathing exercises. Inspiration has a major effect on thoracic lymphatic drainage and sudden increases in intra-abdominal pressure, for example, coughing, sighing, and laughing, will greatly increase abdominal drainage and empty the cisterna chyli (Twycross et al., 2000).

Conclusion

Physiotherapy in the field of oncology and palliative care is a continuously evolving and developing speciality in cancer and other non-malignant disease (Association of Physiotherapists in Oncology and Palliative Care (ACPOPC), 2009). Rehabilitation is now considered a crucial aspect of the patient pathway in which the physiotherapist plays a pivotal role (NICE, 2004). Many physiotherapists work as sole practitioners and need peer support, clinical supervision, and opportunities for continuing professional development. Membership of ACPOPC is recommended to assist the development process. Physiotherapists working in this speciality may choose to extend their practice to include other skills such as communication training, acupuncture, and lymphoedema management. Physiotherapy students on palliative placements benefit because they experience a diverse range of life-limiting conditions and gain valuable experience. The need for further research remains, however there is already a significant body of evidence to support the importance of physiotherapy in palliative care and the physiotherapist's valuable contribution to the interdisciplinary team.

4.10

Speech and language therapy in palliative care

Tim Luckett and Katherine L.P. Reid

Introduction to speech and language therapy in palliative care

Palliative care is an emerging speciality area within the field of speech and language therapy (SLT), with only a small number of specialist positions appointed. Patients with palliative care needs are most often referred to SLTs on the basis of needs associated with their diagnosis (e.g. motor neurone disease (MND)/ amyotrophic lateral sclerosis (ALS)) rather than phase of illness. A search of electronic literature databases returns only a handful of articles on SLT in palliative care, most of which are commentaries rather than research reports (Frost, 2001; Pollens, 2004; Eckman and Roe, 2005; Myers, 2010; Javier and Montagnini, 2011). This belies the fact that many patients in the palliative phase suffer problems with swallowing (dysphagia) and communication, the core domains of SLT practice. The limited presence of SLTs in palliative care means it is likely that swallowing and communication problems go under-recognized and undertreated. Successful management of these problems can have significant impacts on quality of life (QOL) (Kulbersh et al., 2006; Hill, 2010), the ultimate goal of palliative care (World Health Organization, n.d.).

Communication diagnoses common in palliative care include:

◆ dysphasia/aphasia—a difficulty understanding and/or using spoken or written language

◆ dysarthria—impaired speech due to muscle weakness

◆ dyspraxia/apraxia of speech—a difficulty forming speech sounds and words due to impaired motor programming

◆ dysphonia—voice impairment (e.g. weak, hoarse).

It is important to recognize that these problems are distinct; any given person may present with one or a number of them.

In the swallowing domain, SLTs primarily focus on dysphagia in the oropharyngeal stage, with common symptoms including coughing or choking on solids and/or liquids, increased time to eat or drink, and discomfort/pain when swallowing.

This chapter will describe SLT needs commonly associated with a range of life-limiting conditions, together with the latest evidence for clinical practice and service delivery. We begin by summarizing overarching principles and considerations that are shared regardless of the underlying pathology.

A palliative approach to speech and language therapy assessment and management

Palliative goals

Goals of assessment and management in the palliative phase are generally to optimize and maintain communication and swallowing for as long as possible in the context of declining health. But the story is not always one of inexorable decline; there may sometimes be a need to rehabilitate functioning following a medical emergency (e.g. cerebrovascular accident) or treatment with adverse effects (e.g. radiotherapy). As a general rule, interventions aimed at maintaining or improving functioning in communication and swallowing should be undertaken only when there is a reasonable expectation that these domains will positively influence psychosocial well-being or QOL more generally. For example, while (as for any client group) management of dysphagia may be aimed at ensuring nutrition and preventing aspiration, a palliative approach would require that the burden of assessment and management be weighed against likely net benefits to QOL (see below and Chapter 10.1).

The UK's Royal College of Speech and Language Therapists (RCSLT) recommends that SLT in palliative care be guided by the following principles:

◆ Assess only as required to provide the answers to plan management

◆ Minimal intervention for maximum gain

◆ Maintain function where possible

◆ Improve function if appropriate and realistic

◆ Utilize compensatory strategies, diet modifications, and safe swallow strategies

◆ Work as member of a multidisciplinary team (MDT)

◆ Provide holistic, individual-centred care

◆ Facilitate communication between individual and team

◆ Provide education and information

◆ Advise on risk–benefit evaluation (RCSLT, 2006).

Ensuring a person-centred, multidisciplinary approach to client care

SLTs should seek to assess and manage functioning in a holistic manner that considers biobehavioural contributors and sequelae within the context of each client's cognitive and sensory functioning, symptom profile, broader health status, and personal preferences and needs. Complex care needs arising from multiple comorbidities are commonplace in the palliative setting and require a comprehensive, multidisciplinary approach. SLTs will typically contribute to case management either as a member of an MDT or via consultation (see Chapter 4.1 for a summary of other disciplines commonly involved in palliative care). Of these two models, membership of an MDT generally affords greater opportunity to contribute to care plan development. Care plans outline a given client's individualized goals of assessment and management together with the necessary interventions and multidisciplinary roles required to attain these. The prominence of communication and swallowing will vary according to the urgency of other needs as well as client and family priorities for care. Delivery of SLT should be integrated with other services as parsimoniously as possible to minimize client travel and other burdens. SLTs will need to work with the whole team to implement interventions and support decision-making. Members of the MDT with whom SLTs work especially closely include dieticians to ensure adequate and safe nutrition, physiotherapists to monitor chest conditions, and occupational therapists to access alternative communication devices and devise appropriate set-up for meals.

Assessment and management of problems in communication

Regardless of diagnosis, people in the palliative phase of illness often suffer communication problems due to general weakness, fatigue, and side effects from medication (MacDonald and Armstrong, 2010). Communication is important for advance care planning, decision-making, and psychosocial well-being of both the patient and family as they progress along the disease trajectory. Enabling clients to participate in decision-making about their care is one of the SLT's major roles in the palliative setting (Pollens, 2004).

Assessment and management of communication problems often takes place within the context of limitations in hearing and cognitive functioning, especially where patients are elderly. Optimizing the preconditions for effective communication (e.g. by means of a hearing aid) is essential before implementing interventions targeted at specific deficits.

Problems in speech and voice

Speech production relies on the coordinated processes of respiration, phonation, resonation, articulation, and neurological integration (Kantner and West, 1941): air from the lungs (respiration) passes through the vibrating vocal chords (phonation) to produce sound that is modified in the pharynx, mouth, and nose (resonation) and shaped by the tongue, teeth, and lips (articulation) to produce speech. Declining health status and deconditioning towards the end of life often impact breath control and speech musculature even when these are not directly impaired by underlying pathology.

Voice disorders are generally classified as dysphonia or dysarthria (Cohen et al., 2009). Dysphonia refers to impairment in phonation caused by a deficit in the larynx ('voice box'). It is common in the elderly regardless of health status, especially in the form of presbyphonia, which refers to weakness of voice, change in pitch, decreased projection, vocal fatigue, increased effort to speak, and altered quality of the voice arising from ageing of the larynx. Dysphonia is often worsened in these cases by compensatory strategies such as straining, the remediation of which forms the focus of SLT. Voice therapy aimed at improving efficiency of voicing has been shown to increase voice-related QOL in elderly clients (Berg et al., 2008), and the benefits are likely to be even greater for people with poor health status in whom compensatory strategies may be fatiguing. Conversely, surgical approaches that are sometimes used to treat dysphonia in other groups are less likely to be appropriate in the palliative population.

Dysarthria and apraxia of speech are more common in certain health conditions and will be considered in the next section.

Problems with language

Language refers to systems of symbols that give meaning to speech or other, non-verbal forms of communication (e.g. writing). Language disorders acquired through illness are collectively described as dysphasia/aphasia (terms often used synonymously). Language problems can rise separately or concurrently in the abilities to use or understand language, referred to as expressive and receptive dysphasia respectively.

Problems with communication

Where speech or language, or both, become inadequate for communication due to lack of intelligibility, loss of voice, or inadequate ability to retrieve and use words, SLT may focus on supplementing or replacing these with augmentative or alternative communication (AAC). AAC can take either a low-tech or a high-tech form. Examples of low-tech AAC include paper-based communication charts containing words or pictures that the person can point to. These can either be customized to the particular communication needs of the patient or rely on generic templates that include standard requests in the hospital or home setting. A number of high-tech computerized versions are now available including iPad applications (apps) that rely on input via picture/word selection or typing and produce auditory output (see Fig. 4.10.1). These are now available for loan and subsequent purchase in some service settings. The social acceptability of the iPad has done much to overcome the stigma of AAC; friends and family are often interested in the technology and keen to participate in communication attempts. While there are now a range of free AAC apps for both children and adults, those that are more expensive generally allow greater customization and chance of communication success.

Assessment and management of dysphagia

Assessment and management of dysphagia is alone among the SLT domains in having serious medical implications and should be undertaken only by SLTs who have undergone specialist training at either an undergraduate or postgraduate level.

Langmore et al. (2009) recommend that the following should be considered signs and symptoms for increased risk of dysphagia and aspiration that prompt assessment or re-assessment:

Fig. 4.10.1 A model of care for speech and language therapy.

◆ Persistent throat clearing or coughing during or after eating or drinking

◆ Symptoms such as general weakness and mental status changes

◆ Changes in medical diagnosis such as recent stroke or thyroid disease

◆ Introduction of new medications, particularly if these are likely to impact on level of consciousness or used to treat oropharyngeal symptoms (e.g. oral pain medication for throat cancer)

◆ Recurrent aspiration pneumonias

◆ Significant weight loss of greater than 5–10% or recurrent episodes of dehydration (Langmore et al., 2009).

Other signs to watch for include increased shortness of breath, taking longer than usual to eat or drink, pain/discomfort on swallowing, and difficulty initiating a swallow.

A palliative approach to SLT means that invasive instrumental assessments (endoscopy) and, to a lesser extent, radiological examination (videofluoroscopy/modified barium swallow) tend to be indicated less commonly than for non-palliative client groups. The American Speech-Language-Hearing Association (ASHA) recommends that instrumental assessment not be undertaken where:

1. the client is too medically unstable to tolerate a procedure

2. the client is unable to cooperate or participate (e.g. dementia), or

3. an instrumental examination would not change clinical management (ASHA, 2000).

Alongside other MDT members, SLTs are responsible for supporting clients and families to make shared decisions regarding their care in full knowledge of the burden, risks, and benefits of different approaches to assessment and management, including the option of taking no action at all. ASHA has published guidelines

for ethical decision-making relating to dysphagia (ASHA, 2002). Decisions regarding artificial nutrition and hydration in terminal illness are particularly controversial (Goodhall, 1997; Landes, 1999; Huang and Ahronheim, 2000; Wasson et al., 2001; Lipman, 2004; Bozzetti, 2008). Engaging the patient in advance care planning while (s)he still has cognitive capacity will make decision-making less onerous for families if such capacity is lost (Gillick, 2006). Where patients make an informed choice to risk dehydration, malnutrition, and/or aspiration rather than be fed by nasogastric or percutaneous endoscopic gastrostomy tube, management may be aimed primarily at maximizing eating enjoyment while making the best of suboptimal strategies for avoiding these risks to minimize negative impacts on QOL.

Strategies for reducing the risk of aspiration can be classified as compensatory, rehabilitative, or compensatory/rehabilitative (Langmore et al., 2009). Compensatory approaches include changes to the consistency of food and drink (e.g. thickened liquids), postural changes (e.g. sitting upright; 'chin tuck' (Hardy and Morton Robinson, 1999)), alterations in swallowing behaviour (e.g. repeated swallowing, coughing afterwards), or external manipulations (e.g. using a spoon for liquids) aimed at supporting the oropharyngeal stage of swallowing, protecting the airway, and/or ejecting aspirated material. Rehabilitative strategies are aimed at improving the speed, strength, and timeliness of swallowing, and include therapeutic exercises for the tongue, larynx, or pharynx.

Compensatory/rehabilitative strategies are those that are compensatory when introduced but may lead to improved swallowing without continuing intervention in the longer term. These include manoeuvres requiring effort from the client (e.g. super-supraglottic swallow) and increased sensory stimulation (e.g. using ice, sour taste, or electrical stimulation). Aspiration is also less likely where oral and pulmonary hygiene is of a high standard (Langmore et al., 1998).

Box 4.10.1 The Choking Prevention Program

The Choking Prevention Program is an afternoon workshop offered to palliative patients and their carers or nursing staff in Tasmania, Australia. It involves education about the mechanism for choking and risk factors. Then families/carers are trained on what action to take if someone chokes, how to mix thickened fluids and decrease food texture, and how best to position for eating/drinking. A recipe book is provided together with information handouts. Advance care planning is then discussed, with a focus on preferred action to be taken if a choking episode occurs and the benefits and disadvantages of enteral feeding. Often, patients elect to modify their diet and use postures but also continue taking small quantities of food or liquids in their usual consistencies (e.g. sips of tea in the afternoon). In the event of choking, the majority of patients and their families decide that they would like basic measures (i.e. postural adjustment, pressure to the back then chest) but that they do not wish to be resuscitated if they stop breathing. Feedback from families and patients suggest that the Choking Prevention Program alleviates anxiety related to swallowing problems at the end of life.

Over and above avoiding aspiration, aims of SLT intervention for dysphagia in palliative patients often include enhancing enjoyment of eating and drinking, improving nutrition, lessening fatigue, reducing the time spent on meals and taking medications, and reducing anxiety relating to choking. Recent studies also suggest that keeping patients hydrated may be helpful in managing delirium, a common and distressing problem in people at the palliative phase (Galanakis et al., 2011). A palliative patient recommended to take thickened liquids by one of the current authors described the benefits as follows: 'Thank goodness I can drink a glass of water with comfort now. Without that [the thickener], it takes your breath away and it hurts a bit and it (the thickener) doesn't taste of anything.' As well as being flavourless, new-generation thickeners are easy to mix (stir for 30 seconds) and give a smooth, even texture in any temperature or type of liquid that is stable for 24 hours. See Box 4.10.1 for an example of a programme aimed at reducing anxiety related to choking.

Disease-specific considerations in speech and language therapy assessment and management

In addition to the general principles introduced above, assessment and management of communication and swallowing will need to address issues that are specific to particular health conditions encountered in the palliative setting. These are summarized in the following sections, together with case studies from the authors' experience that have been formulated to protect patient identities.

Head and neck cancer

The potential for SLT to contribute to supportive care in cancer has been acknowledged in national guidelines (National Institute for Clinical Excellence, 2004). People with advanced cancer of any type may experience communication and swallowing problems, and dysphagia is predictive of survival (Vigano et al., 2001). Most commonly, however, SLT is indicated for cancers of the head and neck, where both disease and treatment may have profound impacts on the ability to speak and/or swallow (Logemann et al., 1997). A chart audit of hospice patients with head and neck cancer identified that 53% of patients had communication difficulties and 74% dysphagia (Forbes, 1997).

Assessment and management of patients with head and neck cancer often takes place within the context of particular psychosocial predictors and sequelae. It is more common in men, in whom it is associated with socioeconomic disadvantage and continuing heavy alcohol use (Deleyiannis et al., 1996; Conway et al., 2010). Psychosocial problems may become exacerbated in cases where either disease or treatment, or both, is disfiguring (Katz et al., 2003). Lack of management adherence is sometimes raised as a concern but seems to be less of a problem where SLT needs are assessed at a multidisciplinary clinic, at least in early-stage disease (Starmer et al., 2011).

Surgical removal of part or all of the tongue in the treatment of oral cancer is likely to reduce speech intelligibility, especially when the tip of the tongue is affected (Cohen et al., 2009). Where surgery is extensive, SLT may be needed to teach compensatory manoeuvres aimed at modifying intonation, pitch, vocal intensity, and rate of speech (Skelly et al., 1971). Where swallowing is compromised by surgical removal of part of the tongue, head tilting can be used to transit food via gravity (Newman, 2009). Sensory feedback may also be negatively impacted by surgery; in these cases, it may help to exaggerate stimuli by adjusting the size/temperature of the bolus or artificially increasing pressure on the tongue (e.g. using a spoon). SLTs may sometimes work with a prosthodontist to design and support use of a prosthesis.

Rehabilitation of voice and speech in clients who have undergone laryngectomy for laryngeal cancer may make use of oesophageal speech, artificial larynx, or tracheo-oesophageal voice restoration. A study by the United States Department of Veterans Affairs found artificial larynx to be the most frequently used option following laryngectomy, despite being judged the least intelligible (Hillman et al., 1998). The appropriate option for each client will vary according to personal choice, post-treatment tissue changes and complications, behavioural and psychosocial variables, and the availability of SLTs to support rehabilitation (Cohen et al., 2009). SLTs will need to work closely with the medical team and client both pre- and postoperatively to support decision-making and rehabilitation. Because treatment via radiotherapy or chemotherapy is more aggressive when aimed at cure, the most severe acute adverse effects may not be commonly encountered in the palliative setting. However, where curative treatment is unsuccessful or the cancer recurs, SLTs may need to assess and contribute to management of sequelae from long-term impacts of high-dose radiation, including dental decay, subcutaneous fibrosis, oesophageal stenosis, hoarseness, and damage to the middle or inner ear (Manikantan et al., 2009). Where radiotherapy is palliative, a balance is sought between benefits to functioning and QOL resulting from reduction in tumour versus adverse effects such as mucositis and xerostomia (Agarwal et al., 2008). Pre-assessment of swallowing prior to treatment is useful in identifying clients at risk of long-term dysfunction so that information and management can

be tailored accordingly (Patterson and Wilson, 2011). Prophylactic swallowing exercises prior to radiotherapy may also be helpful but require further evaluation, especially where radiotherapy is palliative (Roe and Ashforth, 2011).

Brain tumours

In brain tumours, assessment and management of communication and swallowing difficulties often occur within the context of changes in cognitive functioning and, sometimes, personality and social behaviour. Despite the poor prognosis associated with most brain tumours, evidence from a small-scale study suggests that swallowing difficulties may be as responsive to rehabilitation as in stroke (Wesling et al., 2003). Where dysphagia occurs in the weeks prior to death, decision-making about appropriate management will be more complicated (Pace et al., 2009; Sizoo et al., 2010). Communication impairment in brain tumours may include dysphasia, dysarthria, dyspraxia of speech, disfluency, and dysphonia. Intervention may take the form of rehabilitation, the teaching of compensatory strategies to the patient and carers, and education regarding the impairment. Acquired dyspraxia of speech is linked to either cortical or subcortical damage, or both, in the language-dominant hemisphere of the brain (McNeil et al., 2009). Approaches to rehabilitation of dyspraxia can be grouped into (a) articulatory-kinematic, (b) rate/rhythm control treatments, and (c) inter-systemic facilitation/reorganization treatments (Wambaugh et al., 2006a, 2006b). Most evidence for these approaches comes from studies with stroke patients and is most substantial for articulatory-kinematic treatment, which uses a combination of repeated motoric practice, modelling-repetition, integral stimulation, and articulatory cueing.

Brain tumours are among the few cancer types that occur in children and adolescents, with one study reporting an 81% prevalence of problems in SLT domains (Goncalves et al., 2008). Palliative care for children is distinguished by the unique psychosocial implications of life-limiting illness for clients and families in this group (Moody et al., 2011). See Box 4.10.2 for a case study of a client with a brain tumour.

Lung cancer and respiratory disease

Problems with dysphagia and communication are common where there is deterioration in lung function. A developing body of literature suggests a tight neural coupling between the central control of respiration and swallowing which may be disrupted by ageing, neurological disease, respiratory disease, or cancer (Martin-Harris, 2008).The normal breathing pattern during swallowing is inspiration, which aids propulsion of food/drink into the pharynx, a pause in breathing (apnoea) during the swallow, followed by expiration, which helps clear any residue in the airway. Poorly controlled pre-swallow inspiration can lead to material being breathed into the airway. Particularly if a patient is short of breath, it is not uncommon for the swallow to be followed by inspiration due to respiratory drive, increasing the risk of material being drawn into the airway.

Whilst not among the most common symptoms in lung cancer, dysphagia tends to worsen over time (Lovgren et al., 2008). In addition to the mechanism just outlined, dysphagia may also occur as a result of chemoradiation, where there is phase II evidence for efficacy of the human recombinant keratinocyte growth factor, palifermin (Schuette et al., 2012).

Box 4.10.2 Brain tumour case study

AB was a 62-year-old woman with a history of glioblastoma. She was living at home and referred to SLT due to word-finding difficulties and intermittent coughing on liquids. Assessment found mild oropharyngeal dysphagia and mild dysphasia with delayed processing, which progressed to moderate dysphasia over the next few weeks. The patient and family were given information regarding dysphagia signs, symptoms, and possible interventions both immediate and into the future. AB responded to the use of head flexion, which eliminated coughing on fluids, and began taking her medication with semi-solids (yoghurt) to increase ease of swallowing. For communication, AB and her family were trained in using an iPad with an AAC app, which she used in both the community and at hospital. The menu was customized to include pictures and phrases relating to her children/grandchildren and trips to the hairdresser.

Up to one-third of patients with advanced chronic obstructive pulmonary disease (COPD) experience dysphagia, often with silent aspiration; this is often a precursor to an exacerbation and hospital admission (Reid, 1998). SLT in COPD patients has demonstrated significant improvement in self-management and swallowing-related QOL, including decreased burden of dysphagia, physical problems of dysphagia, and managing diet options and food selections (McKinstry et al., 2010).

Hoarseness is a common symptom in patients with COPD secondary to gastro-oesophageal reflux disease (Rouev et al., 2005), xerostoma (Roh et al., 2006), or inhaled corticosteroids (Williamson et al., 1995). Disturbances in airflow volume and rate found in COPD also contribute to decreased vocal volume and shorter message length (Martin-Harris, 2000). These problems may also occur in patients with lung cancer, together with vocal cord paralysis (Benninger et al., 1998). Non-invasive interventions by the SLT for vocal paralysis include pushing exercises to improve vocal cord approximation, AAC, and education on how to most effectively manage the impairment. See Box 4.10.3 for a case study concerned with lung cancer.

Dementia

People with dementia present a particularly challenging client group for both practical and ethical reasons. By definition, assessment, management, and decision-making must take place within the context of decreased cognitive function. Problems with swallowing typically begin in the later stages of dementia, by which time patients have often become resistant to care (Feldman and Grundman, 1999). By the time end-stage dementia is reached, almost all intentional communication will have been lost, and assessment must rely on observation alone. Weight loss often persists despite receiving food and fluids. In frontotemporal lobe dementia, the risk of aspiration from neurological deficits may be exacerbated by compulsive eating and food gorging (Langmore et al., 2007).

Intervention for dysphagia in dementia may include diet and posture modification as well as changes in feeding technique and environmental factors. Quite apart from any physiological problems with swallowing, patients may have difficulty maintaining hydration and nutrition due to cognitive and behavioural factors (e.g. an inability to recognize food or liquid in the mouth; refusal to open

---

Box 4.10.3 Lung cancer case study

CD was a 47-year-old man with advanced lung cancer who presented with difficulty swallowing, weak breathy voice, and fatigue. He was referred to palliative care primarily for reconditioning and pain control. On initial assessment, CD was drowsy secondary to pain medication, and his voice was so weak the listener had to place his/her ear beside his mouth to hear. CD's swallow was moderately to severely impaired, with difficulty chewing textured solids, a moderate delay in initiating a swallow, and a weak cough. He was recommended to take moderately thickened fluids and a purée diet. CD received oxygen during meals to decrease his shortness of breath due to the swallowing apnoea and fatigue. The medical and nursing members of the team worked to find pain control that minimized drowsiness. On review, CD was alert and his swallowing had improved. He progressed to nectar-thickened fluids and a soft diet. CD was keen to improve his voice, so a number of pushing techniques were trialled to improve the approximation of the vocal cords. Pushing down on a chair was found to be particularly effective, which CD began practising during automatic speech (e.g. counting), words, and phrases. Over a 3-week period, CD progressed to being able to have a conversation with someone sitting across the room. After 20 minutes, he became fatigued and made use of a pen and paper to communicate. With a regime of rest periods, CD was able to use his voice throughout the day. His swallowing also improved to the extent he was able to manage a small volume of thin fluids when accompanied by head flexing. Prior to his discharge home, CD and his family were trained in the use of thickened fluids and texture modification as well as what action to take in the event of a choking episode.

Box 4.10.4 Dementia case study

EF was an 87-year-old man with advanced dementia (Alzheimer's disease) who presented with difficulty eating, drinking, and communicating with his family. A swallowing assessment revealed moderate oropharyngeal dysphagia, characterized by difficulty forming a bolus and moderate to severe delay initiating the swallow for food, and clinical signs of aspiration on thin fluids. Intervention included removing distractions when eating, pressing the tongue down with a spoon to cue to the presence of food in the mouth, a puree diet, and the use of 3 teaspoons of lemon juice (thick) before the meal to stimulate the swallow (Pelletier and Lawless, 2003). While the patient responded to requests to use neck flexion and small sips of fluid, he was unable to retain this information without supervision and was placed on mildly thickened fluids. EF was particularly fond of lemonade so, using new-generation thickeners, his family mixed a jug for him so he could have this through the day. This improved his fluid intake. An advance care directive was discussed with the family. When informed about the evidence that enteral feeding does not increase life expectancy or QOL in advanced dementia, the family elected to continue with hand oral feeding into the future.

EF's family were instructed on how to more effectively communicate with him using pictures from home, short sentences, gesture, and tone of voice for meaning and emphasis. To ease the frustrations of communicating, suggestions were made for alternative activities that the family could do with EF that did not require verbal communication in consultation with the occupational therapist (e.g. organizing a box of nuts and bolts).

---

mouth) (Wasson et al., 2001). Whilst there is evidence that artificial nutrition and hydration neither prevents aspiration nor improves survival or other clinical outcomes (Ganzini, 2006; Sorrell, 2010), tube feeding in advanced dementia remains widespread. Many health professionals, including SLTs, may lack awareness that a palliative approach is indicated in advanced dementia (Vitale et al., 2011). In residential aged care, economic and practical factors may also be influential, as the cost of hand-feeding often outweighs that of artificial nutrition (Lipman, 2004). Educating health professionals and families about the appropriateness of a palliative approach and supporting them in making the transition to comfort care may be the priority at this stage of the disease trajectory.

Speech and language deficits vary according to dementia type (Ross et al., 1990). Cortical dementias such as Alzheimer's disease and Pick's disease are associated with disturbances of language function whereas subcortical dementias such as progressive supranuclear palsy affect the motor aspects of speech. Patients with vascular dementias often have dysarthria with or without language difficulties, depending on the site of the infarcts. Language problems in early dementia are characterized by a difficulty in recalling names or words (anomia), which results in reduced speech fluency and use of circumlocution; these problems worsen as dementia progresses until even the names of immediate family are difficult to recall (Ashley et al., 2006). Therapy is aimed at supporting communication through the use of AAC, situational cues and routines, as well as encouraging family and other caregivers

to enhance verbal communication with gestures, visual cues, and slower speech. Memory books, consisting of autobiographical and daily schedule information, together with prompts to overcome barriers have been found to improve quality of communication between aged care residents with dementia and staff in a cluster randomized trial (Bourgeois et al., 2001). See Box 4.10.4 for a case study concerned with dementia.

Degenerative neurological conditions

A range of degenerative neurological conditions such as MND/ALS, multiple sclerosis, Huntington's disease, and Parkinson's disease can impact communication and swallowing. Dysarthria is the most common speech impairment but differs between conditions with regard to onset, type, and progression (Cohen et al., 2009). Acquired dyspraxia of speech may sometimes be the first sign of neurodegenerative disease (Duffy, 2006). Patients with Parkinson's disease and especially MND/ALS will be likely to require AAC as the disease progresses. For patients in the latter group, AAC may need to become progressively more high tech as physical capacity declines, starting with typing and touchscreens before moving to head-tracking and eye-tracking technologies. A limited, low-tech alternative in the final stages of illness is to use eye-gaze to signal 'yes' or 'no'. In the future, there is hope that people with no physical capacity at all will have recourse to computer-based solutions that make use of brain rather than muscle activity (Allison et al., 2007).

In addition to swallowing problems shared with other diagnoses discussed in this chapter, people with degenerative neurological conditions may present with problems with the oral phase of swallowing due to muscle weakness and excessive saliva, resulting in problems with chewing and social stigma associated with dribbling (Squires, 2006). The disproportionate energy required to eat and drink means that 'little and often' may be the best approach to intake of food and fluids.

Cerebrovascular accident (stroke)

The SLT domain most specifically implicated in stroke is language, with dysphasia occurring in between 22% and 38% of cases (Pedersen et al., 1995; Kyrozis et al., 2009; Dickey et al., 2010). With regard to speech, dysarthria is more common than dysphonia and is worse where the stroke is bilateral, resulting in slow speech, imprecise articulation, and strained voice quality similar to MND; loudness, pitch, and vocal intensity and stress patterns may also be affected (Cohen et al., 2009). Stroke is also the most common cause of acquired dyspraxia of speech, which (as in other conditions) occurs especially frequently in patients who also have dysphasia (Duffy, 2005).

Problems with dysphagia following stroke are predicted by aspiration within the first 72 hours (Ickenstein et al., 2012). Where stroke leads to hemiparesis, the client should be encouraged to turn his/her head to the weak side to divert food down the stronger side of the larynx (Newman, 2009).

Stroke is less commonly the reason for referral to palliative care than a comorbidity endured by people referred for other reasons. Patients referred as a result of stroke often have limited consciousness, and intervention may consist simply of mouth care or comfort feeding (West et al., 2005; Foley et al., 2008; Brady et al., 2012).

Advancing the field of speech and language therapy in palliative care

Addressing the paucity of rigorous research literature is a priority if SLT in palliative care is to become evidence based in order to justify funding and resources. Research in palliative care is undergoing a period of rapid growth (Kaasa and Radbruch, 2008), and SLTs would be well advised to participate in collaborative research groups and other capacity-building initiatives available within the sector more generally. The multidisciplinary nature of palliative care makes it essential that research aimed at answering clinical questions of interest to SLT involves researchers from other disciplines to optimize usefulness and enhance dissemination and translation into practice. As for other symptoms, there is a need to harmonize measurements of communication and swallowing to enhance comparability between studies. For example, a review of speech and voice outcomes following chemoradiation for head and neck cancer found 18 assessment tools had been used in 20 studies (Jacobi et al., 2010).

In practice, there is a need to increase accessibility and referral to SLT for people with life-limiting illness. In the United States, patients enrolled in the Medicare hospice benefit are eligible to receive SLT and other allied health services without additional cost (Centers for Medicare and Medicaid Services, 2010). But even in universal health-care systems, the availability of SLT in palliative care services is variable. Health-care insurers often cover SLT only when the patient has a specific diagnosis. This neglects the fact that patients with life-limiting illness of any kind may require support for communication and swallowing due to weakness, fatigue, and side effects from medication.

Finally, there is a need to develop understanding and capacity in the SLT workforce relating to the palliative approach. Specialist training programmes and SLT support networks are at present limited. In the United Kingdom, an SLT special interest group in palliative and supportive care works in partnership with the RCSLT to develop clinical guidelines and policies and provide opportunities for education (Eckman and Roe, 2005). In Australia, efforts have been made to introduce palliative care to the SLT curriculum at an undergraduate level (Mathisen et al., 2011). A personal communication from ASHA (3 October, 2012) identified no similar initiatives underway in the United States.

Conclusion

This chapter has summarized communication and swallowing problems commonly encountered in people with life-limiting illness, together with approaches to assessment and management. More research is needed to inform appropriately integrated, person-centred models of SLT provision that enable problems with communication and swallowing to be addressed alongside other symptoms and psychosocial and practical needs.

The contribution of art therapy to palliative medicine

Michèle J.M. Wood

Introduction: what is art therapy?

Art therapy is an umbrella term for a range of approaches that use visual art media within a psychotherapeutic relationship. Art therapy enables someone to explore personal issues by expressing thoughts, feelings, and other significant issues non-verbally, and thereby provides an alternative to spoken language, aiding better communication and symbolic representation. The art therapist's task is to facilitate the patient's expressive capacities, and help him or her reflect upon what they have produced, including their chosen media and style of working. Art therapy does not aim to distract or divert a person from their difficulties but through encouraging an experience of creativity these difficulties can be perceived and worked with in a new way. The purpose of art therapy is to empower the patient to develop and flourish on a personal level, even at the end of life.

The loss of control in many areas of patients' lives is an inevitable consequence of illness, and one that art therapy aims to address. The physicality of art therapy, where an individual must actively engage with the materials to produce a picture or object, provides an experience that reinforces the person's ability to make choices and their sense of their own vitality. The artwork represents not only something of the patient's mental state but also, by capturing in its marks and traces the movement and pressure of the patient's pencil, brush, or finger, it represents something of their physical condition too. This articulation through the artwork of the mind–body relationship is intrinsic to art therapy. It has been suggested that art therapy's potency resides in this link (Borgmann, 2002; Collie et al., 2006; Siegel, 2009; Stern, 2010), so that art therapy is ideally placed to respond to the psychological effects of physical trauma (Gantt and Tinnin, 2009).

An important aspect of art therapy is that it provides an opportunity to express emotions that may feel unacceptable to the patient. The patient may have stifled feelings of anger, envy, and sadness for fear of upsetting their family or staff. In art therapy, pounding clay, pouring paint, and scribbling violently on paper gives the patient permission to express strong feelings, and the presence of the therapist ensures the patient is not left alone with their distress. Art therapy also allows for the development and expression of more positive feelings such as tenderness, hope, or beauty. The breadth of emotional expression possible through art therapy demands a working environment that provides confidentiality and in which the patient can feel free to be vulnerable. A separate therapy or quiet room designated for art therapy sessions is ideal. There is growing discussion regarding the therapeutic importance of creative spaces within palliative care settings. For example, Glenister suggests a link between the creativity that can be facilitated within such environments and optimal spiritual care (Glenister, 2012).

Art therapy and creative art: similarities and differences

It is important to distinguish art therapy from creative arts activities (Pratt and Thomas, 2007; Hartley and Payne, 2008). Although there are some areas of overlap, art therapy and creative arts projects have different yet complementary functions within palliative care. Both engage the patient in actively using art media and provide a focus and sense of purpose. Both result in an increased sense of control, self-confidence, and make a positive contribution to patients' quality of life. Creative arts projects may aim to help the patient produce artwork for sale, or to bequeath to relatives. Although the artwork produced in art therapy may on occasion have a similar outcome, its focus is different. As patients strive to express and explore their inner emotional landscape through their art there is no expectation that work should be aesthetically 'good' in a conventional sense, or viewed outside the therapy space. Consequently, the artwork may have a rough undeveloped quality to it.

The manner in which the artwork is made offers additional expression for the patient, and deepens communication with the therapist. The need to witness the patient's art-making process is one reason for the therapist's presence in the sessions. Although an aim of art therapy is to facilitate psychological adjustment by the patient to their changed health through this multifaceted communication, the permanent nature of the artwork means that its significance can continue to be unpacked from session to session and outside of the therapeutic relationship. Patients have been known to use their pictures to communicate with friends, family (Luzzatto et al., 2003) other patients in similar situations (Connell, 1998; Wood, 2005), and their doctors and other members of the interdisciplinary team.

Art therapists, artists in residence, and art tutors can and do work alongside each other in many establishments; their combination of skills is particularly effective where their differences are understood. While both encourage the patients' creativity and improve the overall milieu of the health-care environment, art therapy works with the psychological and emotional needs of the

patient, which includes their barriers to creativity and their difficulties with self-expression. It can be hard for a patient or a professional to know whether art therapy or recreational art is more appropriate. Most art therapists provide assessment sessions in which the patients' needs may be discerned. Case 1 describes the dual functioning of art making in a palliative care setting showing the different roles played by art therapy and art activity for a woman with motor neurone disease.

Case 1: 'Rosemary' by Jackie Coote, art therapist

Whilst working in a large London hospice I was introduced to Rosemary, who had recently been diagnosed with motor neurone disease. Having become paralysed down one side of her body and rapidly losing the power of speech she had expressed a wish to 'paint her feelings'. She was, by the time I met her, using an electronic writer to communicate and only had the use of her right arm. Anything she 'said' was through the writer. Although unfamiliar with the use of art materials, she engaged in the process very quickly, allowing herself to paint freely. She began to look forward to 'the unexpected', which presented itself to her in each session, like the painting she referred to as her 'Devastated Woodland—half dead, struggling for survival' (Fig. 4.11.1). She was able to relate the image to her feelings about her own situation. Her 'fun' painting became a way to address serious issues around her encroaching illness. Through it she began to express her thoughts and feelings about the adjustments she had to make, not just physically, but psychologically. Through her images she was able to express her painful recognition of change and loss. With the loss of spontaneity and inflexion in speech, Rosemary's painting became her 'voice'. Her choice of materials would often indicate her tone and mood. On one occasion she chose bright, cheerful colours, but the black paper she used reflected her underlying melancholy, and the resulting picture helped her to recognize the tendency to 'put on a cheerful front' when all behind it was not well.

In the course of using art therapy to express difficult and painful feelings, Rosemary discovered another side to her image making. She began to paint alone in her room. This work took on a 'painterly' quality. She painted gardens resembling images from

Fig. 4.11.1 Rosemary's 'Devastated Woodland'.

the *Arabian Nights* that contained a sense of richness and fertility. Staff and other patients would come and see what she had been doing each day, and her self-esteem increased considerably. Her images enabled her to become empowered at a time of increasing powerlessness and dependency. With the increase in Rosemary's use of her newly found creative skills, it became important to differentiate between her 'public art' and her 'private art'. She needed reassurance that she still had a private and safe space in the art therapy sessions where she could pour out what she called her 'madness'. She seemed at this point to have moved into a third and what was to be the final phase of the art therapy sessions where, as her body deteriorated, the emotional floodgates opened. Fear, grief, anger, hatred, and despair appeared in the images before us. Her art therapy sessions provided the container necessary to hold the overwhelming grief she poured out in torrents. It was the coping strategy she needed in order to carry on throughout the rest of the day.

Who would benefit from art therapy?

Art therapists work in a range of settings: patients' own homes, prisons, day care units, specialist inpatient units, hospices, and private practice (Bell, 1998; Beaver, 1998; Wald, 2004; Waller and Sibbett, 2005; Oster et al., 2006; Agnese et al., 2012). People with a wide range of conditions including HIV/AIDS, rheumatoid illness, multiple sclerosis, cancer, dementia, and Niemann–Pick's disease have been reported as benefiting from art therapy (Wood, 2004). The range of conditions and variety of settings in which art therapy is offered indicate something of the multiple contributions art therapy can make to patients' care. Whilst recognizing this breadth of application, is it possible to discern which conditions or types of patients would benefit most? Since art therapy is a means of facilitating communication, it is particularly useful for patients, their family, or carers, who are having difficulty with usual modes of communication. Such difficulties can be physical, cognitive, emotional, or even spiritual in origin, and thus provide different starting points and ways of working for the therapist. Case 1 clearly illustrates how art therapy can extend a patient's capacity to manage their emotions, and communicate with others despite physical decline. Similarly, the person with AIDS dementia may no longer be able to coherently discuss their fears and anxieties but may be able to use the qualities available in art to express themselves and relieve their frustrations. In this case, the art therapist may not focus on discussion or interpretation (Wood, 2002). By contrast, where there are emotional difficulties the therapist may well explore in depth the patient's associations to their image and their behaviour. Coote illustrates this in her work with an attention-seeking patient where art therapy allowed the expression of bitterness and resentment, unrecognized aspects of the patient's inner self (Coote, 1998). Connell gives an example of how art therapy was used to address and work through a patient's spiritual struggles (Connell, 1998). The importance of spiritual aspects of art therapy is also discussed by Bell (2011). Trauger-Querry and Haghighi describe an approach using art therapy and music therapy in the reduction of pain (Trauger-Querry and Haghighi, 1999).

Young children, whose developing capacities for verbal expression limit their use of talking therapies, are an obvious group for art therapy, as art and drawing are more familiar means of

self-expression (Teufel, 1995). Farrell Fenton, an art therapist with children and young people who have cystic fibrosis, suggests that art therapy works on two levels simultaneously: by providing a means of emotional catharsis while at the same time harnessing the young person's coping strategies (Farrell Fenton, 2000).

Many factors including social status, educational levels, and ethnic backgrounds influence the patient's comfort in expressing and addressing their emotional responses to illness with health professionals. In my experience of serving an ethnically diverse population, art therapy can be a welcome tool for patients negotiating their experiences of illness and treatment in a language and cultural setting that is not their own. Art therapy can strengthen their 'voice' and validate their experiences. While it is important to offer people from all cultural backgrounds access to art therapy, staff should be mindful of the complexity of their patients' cultural values and the ways in which these may vary within groups. One example found in some orthodox branches of Judaism, Islam, and Christianity is the issue of aniconism, where making any representation of the human form is prohibited (Khan, 2012). While such beliefs do not preclude a person from participating in art therapy, understanding the religious and cultural underpinnings of their relationship with visual imagery is vital.

Art therapists as part of the palliative care team

Art therapists usually work under the auspices of the counselling or psychosocial teams and as part of the wider multiprofessional palliative care team (Jones and Browning, 2009; Jones et al., 2013). Referrals to art therapy arise from a close consideration of patients' needs by the team, and in cases where a patient requires emotional support but is unable or unwilling to access counselling, art therapy may be suggested. For example, I work as part of the patient and family support team in a specialist palliative care unit alongside counsellors, social workers, chaplains, and family therapists. Referrals can be made to anyone of us individually, or to our team itself for further assessment of the patients' psychosocial needs. How the different disciplines of the palliative team work together is a matter for consideration, and in particular art therapy's part in this. For example, should a patient have art therapy at the same time as counselling or other emotional/psychological therapies? Art therapy works at verbal and non-verbal levels and while it may be possible for an art therapist to work in conjunction with a counsellor or psychologist this must be based on careful assessment of the patient's needs. It may be that someone begins with art therapy and then moves on to work with another discipline such as music therapy or chaplaincy. Coordination and communication amongst the professionals is key to successful outcomes for the patient.

Art therapists are often employed on fractional or sessional contracts, with the result that they may not always be able to attend team meetings. However, their contributions to patients' care should be conveyed to colleagues in written form as patients' records, in case reports and summaries. Where staff time is limited, art therapists, counsellors, and social workers do represent each other in team discussions to convey the emotional aspects of their patients' care. In the United Kingdom, specific guidelines have been written to enhance an understanding of the role of sessional arts therapies staff (Pratt and Thomas, 2007).

Funding of art therapy is often a major problem. When there are constraints on funding for palliative care services these will often be felt by art therapists, whose contribution may be more readily considered disposable and 'value-added' rather than core to patient care. This issue of funding is probably the main challenge for art therapy in palliative care, since it can confine art therapists to fractional contracts which limit their work, and prevent access to the sorts of research and continuing professional development opportunities enjoyed by their medical, nursing, and allied health professional colleagues.

Are there any hazards of art therapy?

The hazards due to art therapy are minimal but the following pitfalls are worth mentioning. There can be a concern from some staff that the expression of feelings through image-making may unleash a flow of emotion that will overwhelm the patient and those around them. Usually, these concerns dissipate when it is realized that the processes and boundaries of art therapy prevent this from happening. The patient never fully relinquishes control, but through the manipulation of the art materials their usual defences can give way to more symbolic expressions of feeling states (see Case 2). The therapist's skill in working safely and effectively ensures that difficult feelings are contained, addressed, and resolved.

The therapeutic value of art therapy may be undermined if the position of the art therapist in relation to the interdisciplinary team is not respected or clearly understood. One example of this can be seen when art therapy sessions are interrupted for procedures or questions that could be done at another time. Another example is where communication between the art therapist and their colleagues is not valued and there is an unnecessary replication of work with the patient or family.

Another hazard of therapeutic work, and indeed of all work in palliative care, relates to the emotional well-being of staff (Hardy, 2001). Therapists need to ensure that they themselves are adequately supported through the use of supervision, supportive teamwork, and possibly their own personal therapy. All these strategies have proved to be beneficial in guarding against staff burnout and inappropriate behaviour. Art therapy itself is often used for staff support and can facilitate a valuable level of creativity, communication, and expression in tired staff teams (Belfiore, 1994; Nainis, 2005).

On a practical level, the hazard posed to patients by the art materials does need to be considered. Most materials used in art therapy are non-toxic, but where materials could pose a risk (e.g. fixative) therapists ensure that usual health and safety precautions are taken. In cases where cross-infection between patients may be an issue it is standard practice that separate sets of equipment are used.

Evaluating art therapy

The anecdotal literature consisting of accounts by practitioners and patients themselves on the value of art therapy for people with life-threatening, -limiting, or terminal conditions suggests potential benefits of art therapy, which are outlined in Box 4.11.1 (Hill, 1948; Teufel, 1995; Pratt and Wood, 1998; Jones, 2000; Waller and Sibbett, 2005; Stein, 2006; Solomons, 2007; Malchiodi, 2012). Systematic research into art therapy is only just emerging as

Box 4.11.1 Outcomes of art therapy

◆ Development of a creative attitude by the patient towards their circumstances

◆ An increased sense of control

◆ Better communication

◆ Wider range of expressive capabilities

◆ Increased insight into patient's own behaviour

◆ Body image issues addressed

◆ A cathartic release of emotive issues

◆ Increased self-esteem and self-efficacy

◆ Increased ability to confront existential questions and relieve spiritual distress

◆ Development of positive coping strategies and an increase in coping resources

◆ Reduction in experiences and reports of physical pain

◆ Increased quality of life

practitioners and academics begin to investigate its various interventions, outcomes, and therapeutic efficacy. A recent systematic review of studies on art therapy and the management of symptoms in adults with cancer took a close look at the research studies for this population (Wood et al., 2011). It found that most studies were small scale, had methodological limitations, and the disparities between definitions of art therapy and diversity of patient groups prevented evaluation. However, there was some evidence that art therapy might have a beneficial effect on reducing fatigue, tiredness, and psychological and spiritual distress, and in promoting coping. The authors concluded more work was warranted in exploring these benefits further. Since that review, newer studies have favourably evaluated the perceived helpfulness of art therapy to support those undergoing cancer treatment (Forzoni et al., 2010; Agnese et al., 2012) and the benefits of an art therapy intervention for terminally ill patients in hospital in Taiwan (Lin et al., 2012).

Adjusting to multiple losses (purpose, health, and social position), and facing one's own mortality, is equally central to care of the elderly. There has been much work done by art therapists with this population who are often cared for outside of palliative settings. One UK-based study (Rusted et al., 2006) evaluated art therapy with people suffering from dementia using a control group design where the control situation was a standard day centre, mixed activity social group. The researchers found that there was a significant difference between the patients participating in art therapy and those in the control group.

How quickly can the benefits of art therapy be seen?

Patients are referred to art therapy for a variety of reasons and at differing stages of their journey from diagnosis to terminal care. What is clear from many practitioners' reports is that patients with life-threatening and terminal illnesses are motivated to make the most of the time they have left. There is evidence (Balloqui, 2005; Nainis et al., 2006) that even a single session can be of value, as Case 2 shows.

Case 2: 'Robert'

Robert, a man in his early 30s, was diagnosed with AIDS and was in hospital for respite care and symptom control. He had a detached and objective approach to his diagnosis and liked to be informed of all medical facts. When we met, he had announced to staff he no longer wished to discuss his condition.

Robert began the art therapy session by being somewhat surprised by the range of art materials available, and that we had a whole hour together. He said he was unsure about what to do, and I invited him to experiment with the materials to see what marks they made, and what he liked using. Robert said he was anxious about making a fool of himself and of making a mess; he wanted to do things properly. We talked about this initially in relation to his life outside the hospital, and then how he felt about making an image with me watching. Once we had acknowledged these concerns Robert began to draw.

Robert worked with some skill and concentration. As he worked he began to cry. Initially he was embarrassed, but did not stop himself. In fact he was glad to cry. He said that he had not realized he could still feel the things the drawing had brought to mind. He allowed himself to cry freely as he continued with his picture (Fig. 4.11.2). His starting point had been to draw an image of the leaves on the tree outside his bedroom window. However, despite attempts to draw autumn leaves he found himself only able to make them green. He noticed that he concentrated on the veins of the leaves, and made a link with his constant examination of his own veins, which he did to monitor his health. We talked about his green leaves being separate from the tree in the background,

Fig. 4.11.2 Robert's picture.

and his feelings of being plucked from the tree of life before his autumn years.

The tree he had drawn was beginning to blossom, and Robert felt very positive about it. The scene in the background was one that he had drawn several times before when he was a schoolboy. He remembered growing up in the countryside and talked of the dreams he had then for his adult life. Aspirations he regretted that would never now be fulfilled. Robert noticed that he had omitted a fence, which meant that the gate was useless. There seemed to be nothing separating him from the unknown place that lay beyond this field.

At the end of the session Robert reported feeling exhausted but light inside as though a burden had been lifted. This session had enabled Robert to connect with the grief he felt about having AIDS. Although we talked about some of the issues raised in the picture, the main focus was allowing him to feel and to cry. His announcement to staff indicated that he had gone as far as he could with words. This one-off session prompted a positive change in Robert that was noticed by hospital staff and his partner.

Art therapy and support for the carers and those bereaved

Palliative care aims to support not only the patient but also those who are close to them. Support is often provided at hospices for partners, spouses, children, and other family members and friends while the patient is ill and after the patient has died. Case 3 illustrates this.

Case 3: 'Caroline'

'Caroline' attended the hospice's carers' support group during the final months of her older sister's life. She found it helpful to talk with other carers about the stresses of giving up her home and time to support her sister, and Caroline acknowledged how easily she lost sight of her own needs. The art therapy element of the group provided the means by which Caroline could represent, reflect upon, and validate her feelings. She often used different media, drawing with traditional materials, photographing these drawings, and developing them digitally using her iPad. When Caroline's sister died she continued to attend the group, on one occasion bringing with her a seedpod she had found when clearing out her sister's belongings. Caroline used this as the basis for a picture, working both digitally and traditionally, and created a short animation. The animation represented the transformation of the seedpod, which scattered its seeds while Caroline glued it to the paper. What had begun for Caroline as a simple idea to characterize her sister's love of natural objects became a powerful symbol, and part of her process of grieving. Caroline sang Gershwin's aria 'Summertime' as the musical track for her animation; a song the sisters had enjoyed together, which had remained significant for her sister, and one played at the funeral.

Art therapy with the bereaved has been well documented over the past 20 years and in some settings has become an integral part of bereavement services (Simon, 1981; McIntyre, 1990; Pratt, 1998).

Conclusion

Art therapy is being practised in many parts of the world with adults and children living with life-threatening and terminal illnesses. There is a continuing recognition that art therapy does positively benefit patients, their carers, and the professional team. The flexibility of art therapy to address a wide scope of issues ranging from pain to a patient's search for meaning makes it a valuable aspect of palliative care. To ensure that the benefits of art therapy are more clearly understood and that its efficacy is maximized there needs to be an increasing investment in research into this discipline.

Stoma therapy in palliative care

Jane Ellen Barr

Introduction to stoma therapy in palliative care

Patients with ostomies, wounds, or incontinence in the setting of a serious or life-threatening illness experience numerous challenges, including distress related to pain and other symptoms, psychological disturbances, and family concerns. Expert management of these conditions and their many complications is an essential part of a comprehensive palliative plan of care. In many countries, nurse specialists with advanced training in the management of ostomies, wounds, or incontinence are available as consultants or as members of a specialist palliative care team. These professionals—known variably as stoma nurse specialists; enterostomal therapists; ostomy specialists; wound, ostomy, and continence nurses; or other terms—can improve health care and quality of life for selected patients across venues of care that include hospital, home, long-term care, hospice, and specialized settings. If a stoma nurse specialist is available, he or she may have a key role in directing decision-making and care management related to these problems, evaluating and controlling symptoms that cause patients and families suffering, and providing psychosocial and spiritual support.

Caring for the patient with faecal or urinary diversion

The prevalence of faecal or urinary diversion in populations with advanced illness is unknown, and there is little information about how an ostomy affects care needed at the end of life. Disease progression may affect a patient's ability to continue to manage ostomy self-care. Most patients are encouraged to become independent in ostomy care from the time of their surgery. As health deteriorates, continued self-care may require simplifying pouching systems and accessories. Often, however, self-care activities become compromised and it is necessary to have caregivers assist with care. The stoma specialist may need to identify caregivers who are able and willing to assist and then provide critical training, such as that required to manage pouching systems or drain a continent diversion.

Advanced disease also may create new complications even in those whose course has been stable for a long time. Changes in the peristomal plane (the area under the solid skin barrier and tape of the pouching system, extending out approximately 4 inches (10 cm) from the base of the stoma (Rolstad and Boarini, 1996)) may evolve, requiring stoma care adjustment to prevent bleeding, leakage, and peristomal irritation. The development of constipation, diarrhoea, or bowel obstruction may require special attention. In a worst-case scenario, progression of disease may result in the need for emergent ostomy surgery near life's end.

Palliative ostomy surgery

Surgery to place an ostomy typically is necessitated by a serious complication affecting the intestine or colon. It is intended to decompress bowel obstruction or divert intraluminal contents proximal to an intestinal perforation or a rectovaginal, rectovesical, or enterocutaneous fistula. These complications may be related to the primary disease, usually cancer, to disease-modifying therapy such as pelvic radiation, or to an intestinal disorder unrelated to the terminal illness or its treatment.

The stoma specialist has a key role in palliative ostomy surgery, as with all ostomy surgery. He or she may be involved in stoma site selection, and both pre- and postoperative teaching and management, including pouch selection.

Autonomy, assistance, and dependence in ostomy care

With advanced disease, the person who has had an ostomy often experiences a conflict between the desire to maintain independence in self-care and the inability to face the physiological challenges of debilitating illness. The latter challenges may include motor, sensory, vision, and cognitive defects (Tilley, 2012). In some situations, independence can be maintained by simplifying ostomy care with use of drainable pouches with Velcro® closure or clips, pouches with pre-cut or mouldable skin barriers, closed-end disposable pouches, one-piece pouching systems, or newer two-piece pouching systems with adhesive systems rather than flanges which requires less manual dexterity and strength to apply. A professional specializing in ostomy management is best suited to evaluate the specific needs of the patient, make recommendations, and provide the training necessary to transition to a new system.

At times, it is necessary for a caregiver to assume total responsibility for ostomy care. Planning for this change should be discussed with the patient, if possible. Ideally, the caregiver who becomes responsible would be both the person preferred by the patient and the one most capable to learn and implement the care. Ostomy teaching of the caregiver should begin early, giving the caregiver enough time to adjust. The specific education and training provided to the caregiver generally includes stoma care or diversion intubation. The caregiver's ability to cope with this added burden of care should be assessed and support should be

provided. If a caregiver needs to assume full responsibility, specific approaches may simplify care and be preferable, such as the use of closed-end disposable drainable pouches (for faecal diversion) or the use of urostomy pouches or continent urinary diversions that attach to the bedside.

Principles of pouching

Obtaining a good ostomy seal against the peristomal plane, and thereby preventing leakage that could damage peristomal skin integrity, may become increasingly challenging as health deteriorates. The peristomal plane may be changed by weight loss or weight gain, which may result in new abdominal folds and creases, or by a change in the contour of the abdominal wall caused by ascites, tumour growth, varicosities related to portal hypertension, or other conditions. Selecting the right pouching system to obtain a good seal and prevent leakage requires expert assessment of the peristomal plane while the patient is in a lying, sitting, and standing position. In all positions, the stoma specialist assesses the skin for firmness, softness, or unevenness caused by scars, folds, or tumours. Further assessment of the abdominal contour is made, and the peristomal area is inspected to determine whether it is flat, recessed, or protruded. The stoma profile also is assessed.

There are several key principles to follow in pouching an ostomy:

◆ The pouching system should contain a skin barrier, to prevent the peristomal skin from effluent, and a pouch to contain the effluent.

◆ The stoma opening in the skin barrier should be the same size and shape as the stoma or equal to or no greater than 1/8 inch (0.3 cm) larger than stoma size.

◆ The skin barrier type should be chosen based on type of effluent. In faecal diversion, when effluent is liquid and with high amount of digestive enzymes, extended-wear barriers should be chosen. If stool output is formed, standard-wear barriers will provide adequate wear time. Urinary diversions will also get a better wear time with extended-wear skin barriers.

◆ Flat pouching systems are considered firm or flexible. Firm systems, which have flanges that cannot bend or mould to the contour of the peristomal area, will provide needed support if the peristomal skin is soft or flabby. Flexible systems, which have adhesive and no flange, can be one piece or two piece, and are useful if the peristomal plane is round, firm, or protrudes (e.g. from ascites or peristomal hernia) because it will contour to the shape.

◆ Convex skin barriers improve the seals when stomas have retracted below skin level and are another option when the peristomal plane is soft or flabby or when the convexity is needed to fill scarring, folds, or creases.

◆ The stoma profile also gives guidance in selecting a skin barrier and pouching system: a flat skin barrier can facilitate a seal in flush stomas. A convex barrier can be used with stomas that are flush, retracted, or retracted with peristalsis. A flexible skin barrier without flanges is safest for prolapsed stomas to prevent injury.

◆ The skin barrier should mirror the distinctiveness of the peristomal area. If the peristomal area has creases or scars, skin barrier pastes or washers can be used to fill in the defects and uneven areas.

◆ When changing the pouching system, the back of the skin barrier should be assessed for any 'hidden leaks' where effluent is on the wafer but has not extended from the skin barrier's adhesive (tape). This is to help establish the wear time of the pouching system and to help assess if any changes are needed to obtain a good seal.

Stoma and peristomal complications

As health status deteriorates, stoma and peristomal skin complications are more likely to occur. Patients with advanced disease who receive newly created stomas are at relatively higher risk for mucocutaneous separation or retraction. Those who have lived with an ostomy may develop long-term complications, such as caput medusa, hernia, or prolapse. These stoma complications can result in poorly fitting and leaking pouching systems, with resultant impaired peristomal skin integrity leading to disorders such as irritant dermatitis or candidiasis.

Stomal and peristomal impairments are important stressors, and may occur in parallel with numerous other problems related to progressive illness. They can augment mood disturbance and social isolation, and profoundly undermine quality of life.

In populations with cancer, palliative ostomy surgery may be required in an area that was previously irradiated. Both radiation injury and recurrent malignancy makes stoma construction difficult. As a result, a postoperative complication, stoma retraction, may occur. With retraction, the stoma is pulled below skin level. Pouching options and adjustments to obtain a good seal may include use of convexity, support belts, and binders.

Mucocutaneous separation is detachment of the stoma from the peristomal skin and can be partial or circumferential, superficial or deep. It often precedes stomal retraction. The risk of mucocutaneous separation after surgery is relatively higher in patients who are in less than optimal condition, such as may occur with immunocompromise or poor nutrition. In most cases, the management of mucocutaneous separation is conservative, focusing on measures to support wound healing when possible. The separation is filled with an appropriate dressing, either to maintain a moist environment or to absorb drainage. The goal is to facilitate granulation tissue formation and re-epithelization of the defect. The skin barrier of the pouching system fits over the filled area to provide protection from the effluent. When the separation heals, other potential complications, such as stenosis and retraction, may occur. Convex skin barriers are not recommended in the presence of mucocutaneous separation as they may increase separation at the stoma and skin junction. When separation is below fascia, surgery is indicated.

Peristomal hernia, a bulge around the stoma as a result of loops of bowel protruding through the fascial defect around the stoma and into the subcutaneous tissue, can result from any cause of increased intra-abdominal pressure. Pouching systems should be changed to flexible systems that mould to the shape of the peristomal plane. Hernia support belts may increase comfort and offer cosmetic benefits by decreasing bulge. Patients who have been irrigating a colostomy are instructed to stop this activity. Use of bulk laxatives and stool softeners often assist with bowel regulation as needed.

Stoma prolapse is a telescoping of the bowel through the abdominal stoma site. It can occur as a result of increase intra-abdominal pressure due to ascites, tumour, or other condition, and often is associated with stomal mucosa oedema. The enlarged stoma is at risk for trauma if a rigid pouching system with a flange is used. Therefore, especially at the end of life, management is often conservative, and involves the selection of a flexible, flangeless pouching system that can accommodate the width and length of the stoma without causing trauma to the stoma. The patient or caregiver can be taught how to reduce the prolapse by lying in a supine position to decrease intra-abdominal pressure, applying a cold pack to the pouch over the stoma to reduce the oedema, and then applying light pressure to the distal portion of the stoma, thereby returning the stoma to its intraperitoneal place. The patient can wear a binder specifically made to include a prolapse flap to keep the stoma reduced during normal activities of living. Should the prolapsed bowel become incarcerated, ischaemia can occur. If pain is severe or infarction occurs, surgical intervention may be necessary.

Patients with advanced liver disease (e.g. from malignancy, cirrhosis, or portal hypertension) may develop a stoma complication known as caput medusa. This condition presents as bluish-purple discoloration of the skin caused by dilatation of the cutaneous veins around the stoma (peristomal varices) (Lo et al., 1984). The varices are large portosystemic collateral veins that appear around the stoma and are related to portal hypertension from where the portal venous system communicates with the systemic circulatory system. Any trauma to the stoma may result in profuse bleeding, which may appear in the pouch itself or occur at the time of the pouch change. Management focuses on controlling the bleeding: direct pressure, cold cloth, topical haemostatic agents (silver nitrate, thrombin), or suture ligation. Patient should be taught measures to prevent bleeding episodes, such as gentle appliance care with removal and washing. Firm, rigid, or convex pouching systems should be avoided. In severe cases, sclerotherapy or surgical intervention to ligate the portosystemic channels or create a portosystemic shunt to lower pressure may be indicated.

Two of the most common peristomal skin complications, irritant dermatitis and candidiasis, are related to pouching problems. Peristomal irritant dermatitis is caused by exposure to stool or urine of peristomal skin under the skin barrier. This condition presents as erythema or a macular rash that progresses to moist, shallow, peristomal denudement and erosions if exposure to irritant continues. The patient may complain of pain, itching, or burning in the peristomal area beneath the skin barrier. Management focuses on correcting the cause by properly measuring and selecting a pouching system that takes into consideration the stoma profile, abdominal contours, and skin surface, by adjusting the frequency of change, and by teaching proper pouching procedures to patients and caregivers. The skin impairment is treated using the 'crusting technique': applying skin barrier powder which is then covered with liquid barrier film with each pouching system change until skin heals.

Peristomal candidiasis is caused by the proliferation of *Candida albicans* in the warm, moist, dry environment beneath the skin barrier. Risk factors for candidiasis are increased with treatments or side effects of treatment such as long-term antibiotic administration, cancer, chemotherapy, and immunosuppressive drug therapy. The primary lesion is a pustule on an erythematous base that evolves into sharply demarcated, eroded patches with small peripheral satellite papules and marginal scaling. The patient may complain of burning and itching, and often leaking pouching systems. Management includes applying topical antifungal therapy, such as miconazole (which treats *Candida* and tinea) or nystatin (which treats *Candida*). Liquid barrier film needs to be applied over antifungal powder to obtain a good skin barrier seal. The infection should be eliminated in about 1 week, but treatment should be continued for another 2 weeks to avert the potential for recurrence. If other sites are noted to be infected, such as the inguinal region or the anxilla, the patient should also be treated with systemic antifungal therapy (e.g. fluconazole).

Continent diversions

Selected patients with colon cancer, inflammatory bowel disease, familial polyposis, or bladder cancer may be able to benefit from more advance surgical techniques that eliminate the need for incontinent faecal or urinary diversions and the wearing of external pouching systems. Continent faecal and urinary diversions are managed by intubation of the pouch or reservoir created during the surgery. In a person with advanced disease who can no longer intubate their own continent diversion, the caregiver may need to learn the technique. Urinary reservoirs are often intubated every 4 hours during day and once at night; faecal reservoirs are intubated four times daily and before bedtime. If the caregiver cannot manage the technique or frequency of intubation, a catheter may be inserted into the reservoir and attached to bedside drainage. If leakage occurs from the continent diversion, it can be pouched in a manner similar to a conventional urinary or faecal diversion. Urinary reservoirs that have increased mucous production may need to be irrigated once or twice daily with water or normal saline, with or without acetylcysteine. In faecal reservoirs, lukewarm water can be instilled into the internal pouch to thin out the stool if necessary to empty the reservoir.

Management of gastrointestinal symptoms in a patient with a stoma

Whenever prescribing or administering medications to a patient with an ostomy, it is important to know the type of ostomy (colostomy, ileostomy) and what amount of bowel was removed or bypassed during the surgery. Patients with right-sided colostomy or an ileostomy with rapid transit time and high liquid output should avoid enteric-coated or sustained -release products.

Patients with a faecal stoma can experience bowel irregularities or complications such as constipation or diarrhoea. Ostomy patients who require opioid analgesics should be assessed for regular bowel functioning. When severe constipation is suspected, a digital assessment with a lubricated gloved finger into the stoma may be indicated to check for impaction. Preventing constipation is important, just as in patients without stomas. Patients and caregivers should be instructed on behavioural interventions, such as exercise as tolerated, and dietary interventions, such as maintaining hydration by drinking fluids or increasing bulk in the diet if appropriate. Laxatives should be prescribed as indicated. If a colostomy becomes impacted, an oil retention fleet enema (administered through a stoma cone), followed by a colostomy irrigation, may be tried. Ileostomy

patients do not usually have constipation problems, but bowel functioning should also be assessed. In advanced cancers, whether the patient has an ileostomy or colostomy, partial or complete intestinal obstruction must be considered with irregular bowel functioning.

Just as patients can experience constipation, the person living with a stoma may also have management difficulties related to diarrhoea. Diarrhoea can be a result of too many laxatives, faecal impaction, *Clostridium difficile* infection, or medications such as chemotherapeutic agents. Assessment to determine the cause is crucial since treatment is based on the aetiology. When diet management can have an impact on decreasing frequency of bowel movements, patients and caregivers can be taught about foods that thicken stool such as dried fruit, bananas, boiled rice and pastas, creamy peanut butter, and marshmallows.

Palliative wound care

Prevention of pressure ulcers

The risk of pressure ulcers increases in populations with advanced illness. Risk factors include malnourishment, cachexia, dehydration, chair-bound or bed-bound status, and multisystem failure with resultant poor tissue perfusion to skin. Pressure ulcers can decrease comfort, rest, and quality of life for the person and family. The patient and caregivers should be educated on basic measures to prevent pressure ulcers, such as use of appropriate support surfaces, need for turning and positioning, maintaining clean and dry skin, and use of skin and positioning products to protect high-risk areas. The patient and their family should be assured that pain medication will be provided as needed to keep the patient comfortable during care, such as position changes. Research is needed to clarify the extent to which pressure ulcers are preventable. The term skin failure has emerged in the literature related to impaired skin and tissue integrity near death. Skin failure is defined as death of the skin and underlying tissue resulting from hypoperfusion secondary to multisystem organ failure which occurs as part of the dying process (Langemo and Brown, 2006). Patient, caregivers, and health-care providers need to discuss and agree on the preventive and management plans for each individual person to prevent or treat skin failure. 'Palliative wound care', which follows the basic principles of wound management, such as cleansing, debridement, and creating an optimal moist environment, may lead to very positive results, decreasing the risk of pain and improving quality at life's end. Some patients are cured, a goal of curative wound care protocols (Ennis and Meneses, 2005), which can be viewed as a benefit in improving a patient's overall quality of life (Tippett, 2005). For others, wound healing is an unrealistic goal, either because of poor clinical conditions or local wound factors. Realistic goals may include creating a stable wound with relief of pain, eliminating odour, managing drainage, preventing infection, and maintaining the person's optimal level of function.

Malignant wounds

Malignant fungating wounds occur when an underlying tumour extends through the epithelium. The lesions might be the result of a primary cancer or a metastasis to the skin (O'Brien, 2012). As the tumour increases in size, vessels may rupture or become occluded, with resultant tissue necrosis, infection, and a high output of odorous drainage. Malodour results from bacteria, both aerobic and anaerobic, that reside in necrotic wound tissue.

Fungating lesions are physically and emotionally difficult for the patient and caregivers to manage. They can have a tremendous negative impact on the patient, deepening the sense of helplessness, poor self-image, and isolation from family and friends because of the malodour. Care is focused on symptom management. By decreasing bioburden and necrotic tissue on the fungating lesion, the amount of exudate and odour is often controlled. Topical management includes cleaning the lesion with antibacterial soap and water (often in a shower, if patient can tolerate this), applying topical antimicrobials such as metronidazole crushed tablets or metronidazole gel, and using dressings to facilitate autolytic debridement, exudate absorption, and pain management. When bleeding is a problem, calcium alginate dressing is applied for its haemostatic properties. Hydrofibres and foam dressing also are used to control exudate. Silicone-backed foam dressing may decrease pain and prevents added trauma on removal, in addition to its absorptive effects. Silver and medihoney dressings can also be used for their antimicrobial benefits. The therapeutic effects of honey-based dressings include anti-inflammatory properties that reduce pain and scarring, antibacterial properties that aid in reducing odour, and debridement properties that reduce necrotic tissue (which also helps to decrease odour) (Pieper, 2009).

Herpes zoster

Commonly known as shingles, herpes zoster results from the reactivation of the varicella-zoster virus in a patient who is often immunocompromised. The clinical presentation includes fluid-filled vesicular lesions in a unilateral dermatomal distribution (Wilson, 2007). Management includes use of antiviral medications (aciclovir, valaciclovir, or famciclovir) to decrease the duration of the herpes zoster rash and the severity of pain. The antiviral medications works best when administered to the patient while new lesions are being formed, and no later than 72 hours after the eruption of the rash. Initially, when lesions are moist and draining, topical dressings such as foams with silicone backings provide for absorption, and may decrease pain (Serena and Fry, 2006).

Conclusion

Palliative ostomy and wound care strives to meet the majority of patient's physical and mental health needs in an interdisciplinary team approach. Attention to the patient's and their family's unique needs, culture, values, and preferences are paramount. Focus is on improved quality of life and the provision of effective and efficient patient- and family-centred care. Emphasis is on pain and symptom management, communication, emotional and spiritual support, improved quality of life, and better patient and family satisfaction.

Clinical psychology in palliative care

Anja Mehnert

Introduction to clinical psychology in palliative care

Psychological interventions can address a wide spectrum of objectives in palliative care and together aim to reduce psychosocial distress and maintain quality of life in patients and their caregivers. Some of these interventions help the patient and family cope with the fear of death and dying, manage anxiety, and reduce feelings of isolation, sadness, despair, and depression. These affective states closely interact with the physical symptom burden and often track with the deterioration of the illness. Other psychological approaches address problems associated with changes in relations and social roles, increasing dependency, the need to adjust to often impaired functional status, and existential concerns such as the search for meaning in life, hope, sense of dignity, grief, and spirituality. For the practitioner, the provision of psychological care as part of the palliative care team approach is characterized by high time demands, the need for flexibility and cultural competence, the ability to assist with decision-making, and facility with a variety of psychotherapeutic skills including the ability to support non-verbal communication (Irwin and von Gunten, 2010).

Psychological distress and mental disorders in patients with advanced disease

Response to stressors

Recent clinical and research models of comprehensive patient care endorse the integration of palliative care early in the disease trajectory, during the period that disease-modifying and other life-prolonging therapies are actively pursued (Irwin and von Gunten, 2010). The palliative care continuum therefore includes acute illness, chronic illness, and end-of-life/hospice care, as well as bereavement care. This model subsumes the course of psychosocial distress in patients and caregivers, and underscores the significance of their supportive care needs.

The ability to cope with illness and adapt to the challenges it presents is influenced by the changing severity of stressors over time, psychological and psychosocial processes that mediate and modulate response, and the potential occurrence of comorbid disorders. During the trajectory of a life-threatening disease such as cancer, patients are confronted with a variety of biological and psychosocial stressors. Figure 4.13.1 illustrates a model of pathways of distress for cancer adapted from the work of Li et al.,

(2010). This model includes cancer and treatment-related stressors and psychosocial stressors, moderating individual and interpersonal factors, and a range of psychological and behavioural stress responses that have guided clinical psychological research in palliative care through recent years. According to the model, biological stressors arising from the disease and its multimodal treatments include pain and severe physical symptom distress, as well as neurobiological changes that are likely to influence psychological and behavioural stress responses and mental disorders (Li et al., 2010). Medical factors associated with psychological distress, particularly with increased anxiety, include metabolic conditions (e.g. hypo- and hypercalcaemia), neurological conditions (e.g. pain, central nervous system neoplasms), endocrine factors (e.g. hyper- and hypothyroidism), cardiovascular conditions (e.g. arrhythmia, cardiomyopathy), pulmonary conditions (e.g. hypoxia, pulmonary embolism, asthma), and medications (e.g. corticosteroids, bronchodilators, antibiotics, interferon, withdrawal states) (Breitbart et al., 1995; Pessin et al., 2008; Levin and Alici, 2010).

The psychosocial consequences of disease progression result in a range of challenges for both the patient and the caregiver. Advanced disease often is accompanied by functional impairments, dependency, and changes in appearance that can represent a threat to the sense of control, as well as the identity and the sense of dignity of a patient (Chochinov et al., 2009). Patients and caregivers also often face uncertainty and changes in relationships, attachment security, and social roles (Tan et al., 2005; Rodin et al., 2007). They simultaneously have to deal with the organization of care, difficult treatment decisions, changes in their life trajectory and life goals, and (anticipatory) loss and grief. Individual and interpersonal characteristics, such as age or education, life stage, personality patterns, coping strategies, family functioning, available and perceived social support, prior experience with illness and life crisis, and spiritual resources, can both influence and moderate the perception of stressors and the occurrence of psychosocial distress and mental disorders (Li et al., 2010).

In the context of advanced disease, physical symptom distress and psychological distress are closely interrelated. The continuum of psychological and behavioural stress responses consist of a wide range of emotional states experienced by patients and their caregivers. These include worry, anxiety, fear of death, feelings of helplessness, regret, shame, guilt or anger, sadness, demoralization, loss of meaning and hope, and (anticipatory) grief. A large
Fig. 4.13.1 Model of pathways to distress.

Adapted from Li, M. and Hales, S.R.G., 'Adjustment Disorders' in Holland, J et al. (Eds.), *Psycho-Oncology*, 2nd edition, pp. 303–310, Oxford University Press, New York, USA, Copyright © 2010, by permission of Oxford University Press USA.

body of evidence suggests that psychological distress can range from normal adaptive emotions through to higher levels of severe and clinically significant symptoms that fulfil standardized diagnostic criteria for an adjustment disorder, anxiety disorder, or depression (Ziegleret al. 2011). Some patients experience a loss of sense of dignity, suicidal thoughts and desire for hastened death, particularly during the end-of-life phase.

Common disorders and phenomena

Adjustment disorder

Adjustment disorder is defined as emotional and/or behavioural symptoms that are in excess of what would normally be expected from exposure to a given stressor (American Psychiatric Association, 2000). Adjustment disorders are characterized by a variety of clinically relevant emotional or behavioural symptoms arising from a specific stressful event such as the diagnosis or recurrence of a life-threatening illness. They are among the most common psychiatric diagnoses in oncology (Miovic and Block, 2007; Passik et al., 2008; Li et al., 2010). Frequent subtypes comprise adjustment disorder with depressed mood, anxiety or

mixed anxiety and depressed mood. Prevalence rates for adjustment disorders range from 11% to 35% (Kugaya et al., 2000; Akechi et al., 2004; Kirsh et al., 2004; Miovic and Block, 2007; Mitchell et al., 2011).

A specific form of non-specific distress, the *demoralization syndrome*, has been described by de Figueiredo and Frank (de Figueiredo and Frank, 1982; de Figueiredo, 1993). The demoralization syndrome is characterized as a person's inability to cope effectively with a stressful event and a loss of sense of mastery. Kissane et al. (2001) and Clarke and Kissane (2002) defined the demoralization syndrome as a clinically relevant syndrome of particular relevance for patients with severe and advanced physical illness, which is characterized by existential distress and despair, and could be diagnosed according to the following criteria: (a) affective symptoms of existential distress, including hopelessness or loss of meaning and purpose in life; (b) cognitive attitudes of pessimism, helplessness, sense of being trapped, personal failure; (c) absence of drive or motivation to cope differently; (d) associated features of social alienation or isolation and lack of support, and (e) allowing for fluctuation in emotional intensity,

these phenomena persist across more than 2 weeks. Furthermore, a major depressive or other psychiatric disorder is not present as the primary condition (Kissane et al., 2001). Severe physical illnesses are particularly demoralizing due to their threat to the integrity of the body and the mind, as well as a person's mastery and control (Clarke and Kissane, 2002). Given the frequency of illness-associated experiences of dependence, reduction of social roles and isolation in the face of an uncertain prognosis, populations with advanced illness are particularly vulnerable to stress responses generated from feelings of helplessness and hopelessness, despair and demoralization (Mullane et al., 2009; Mehnert et al., 2011; Vehling et al., 2012b).

Anxiety disorder

Anxiety disorder is characterized by specific cognitive, affective and behavioural/physiological symptoms, such as excessive anxiety and worry, difficulties controlling the worry, difficulty concentrating, irritability, and shortness of breath or chest pain. Subtypes include generalized anxiety disorder, panic disorder, and post-traumatic stress disorder. Using clinical psychiatric interviews, an anxiety disorder was found in 6% to 14% in patients with advanced disease (Miovic and Block, 2007; Mitchell et al., 2011; Vehling et al., 2012a). Using screening measures, much higher prevalence rates of anxiety and significant anxiety symptoms—up to 48%—have been noted (Roth and Massie, 2007; Teunissen et al., 2007; Roy-Byrne et al., 2008; Delgado-Guay et al., 2009; Kolva et al., 2011). With progressive disease, higher symptom burden (e.g. nausea, pain, and dyspnoea), and the physical deterioration, the prevalence of anxiety increases (Delgado-Guay et al., 2009; Kolva et al., 2011). Maladaptive cognitions are also associated with increased anxiety. Patients with advanced disease facing death may be plagued by recurrent unpleasant thoughts, including fears of toxic treatments, pain, further disease progression, social isolation, dependency on others, and death (Roth and Massie, 2007; Passik et al., 2008; Levin and Alici, 2010).

Depressive disorder

Depressive disorder is characterized by specific core symptoms, namely a persistent depressed mood or loss of pleasure. Other symptoms are related to psychomotor changes, and both cognitive and somatic complaints. Depression is a common disorder. Surveys reveal overall rates of depressive symptomatology that range from 14% to 37% in populations with advanced disease (Massie, 2004; Miovic and Block, 2007; Pessin et al., 2008; Delgado-Guay et al., 2009; Wasteson et al., 2009; Lo et al., 2010; O'Connor et al., 2010; Mitchell et al., 2011; Mellor et al., 2013). In severely and terminally ill patients, the prevalence is higher, especially when the illness is associated with limited functionality, insecure attachments, and additional disease burden such as pain (Chochinov et al., 1994; Breitbart et al., 1995; Rodin et al., 2009). For example, depressive symptomatology was found in up to 77% among cancer patients, up to 82% among patients with AIDS, up to 71% among patients with chronic obstructive pulmonary disease, and up to 36% among patients with heart disease (Solano et al., 2006). Other risk factors for depressed mood include younger age, a family and individual history of depression, low perceived social supports, low optimism and low self-esteem, poorer social functioning and a history of stressful or traumatic life events (Miller and Massie, 2010).

Sadness is common and appropriate as part of a human grief response when confronted with terminal illness and the approaching of the end of live (Pessin et al., 2008). In practice, this normal response must be distinguished from clinical depression, which is an adverse condition that causes additional physical and psychosocial burden for these patients (Mellor et al., 2013).

Suicidality and desire for hastened death

Uncontrollable pain, depression, feelings of helplessness and hopelessness, delirium, high unrelieved physical symptom burden, low family support, and being a burden to others are major factors in the desire for hastened death (Hudson et al., 2006; Rodin et al., 2009; Breitbart et al., 2010; Rosenstein, 2011). Occasional thoughts of suicide in patients with advanced disease often represent an attempt to regain a sense of control in a situation experienced primarily as uncontrollable. Studies show that suicidal thoughts occur on average in 15% of patients with advanced cancer, with a wide range between 1.5% and 51% (Henderson and Ord, 1997; Druss and Pincus, 2000; Akechi et al., 2001, 2002, 2010; Rasic et al., 2008). However, few patients experience persistent suicidal thoughts and express the desire for hastened death, particularly in the pre-terminal and terminal stage of the disease.

Khan and colleagues have pointed out that the loss of the will to live in patients with advanced disease may arise from diverse processes, such as the acceptance of death, the lowering of mood, demoralization, or changes in important relationships with caregivers and health-care professionals (Khan et al., 2010). Hudson and colleagues found that the reasons for desire for hastened death were often multiple and complex, and categorized the associated processes as (a) an expression of feelings and current reactions to their circumstances, such as the loss of autonomy and the sense of dignity; (b) a communication of distress and suffering and/or a communication to explore options for relieving their distress; (c) seeking of information about suicide or euthanasia; and (d) specifically seeking health professional assistance with hastened death or acknowledging an intent for suicide (Hudson et al., 2006).

When patients express a desire for death or suicidal intent, the assessment of the suicide risk and the early administration of appropriate treatments, including psychiatric interventions, are critical. Breitbart (1990) and Pessin et al. (2008) have emphasized the importance of a careful and comprehensive evaluation of suicidal thoughts, plans, and current intentions using an empathetic approach. They recommend evaluating the patient's understanding of his/her symptoms, and assessing the mental status, vulnerability, pain control, support system, recent losses, prior psychiatric history including alcohol and substance abuse, and prior suicide attempts and threats. The evaluation should clarify the need for observation and the formulation of a short-term and long-term treatment plan

It is important to pursue an integrated therapeutic approach when managing suicidal ideation in the palliative care setting. Given the associations between suicidal thoughts and emotional suffering from unrelieved pain and physical symptoms, feelings of being a burden to family and dependency on others, and the fear of impending death from advanced disease, one or more of these issues may require targeted interventions. The rapid and effective management of physical and psychological symptoms, for example, may quickly reduce distress and improve suicidal ideation in the majority of patients. Both pharmacological and psychosocial interventions may address depression, feelings of helplessness and

hopelessness, demoralization, and loss of meaning in life. Efforts to sustain supportive relationships with caregivers and health professionals also can help patients to regain quality of life.

Psychosocial distress in family caregivers

Psychosocial distress does not only affect patients. Interventions also may be needed to address the distress or disorders experienced by family, friends, and other caregivers. Patients with progressing disease and their caregivers both face the need to accept transition from an emphasis on disease-modifying therapy to an emphasis on palliative care alone. Particularly in the context of advanced illness or impending death, caregivers play an important and challenging role, providing emotional and social support for the patient, helping with medical needs, and meeting increasingly complex instrumental needs such as running the household and work. Furthermore, caregivers may be called upon to assist professionals in making difficult treatment decisions, and these occurrences may be experienced as highly stressful (Huang et al., 2012). When treatments have uncertain benefits and burdens, or the goals of care are ill-defined, conflict may erupt between the patient and caregivers, or between caregivers and health-care providers. Many studies have observed associations between high levels of emotional distress in caregivers, or anticipatory grief, and signs of clinical instability, sudden health changes, or end-stage disease in patients; distress also is magnified when patients experience depression or progressive cognitive impairment. During bereavement, support offers for caregivers include supportive counselling, psychodynamic and interpersonal psychotherapies, cognitive behavioural therapy (CBT), and family therapy (Lichtenthal et al., 2010).

Diagnosis and assessment of psychological distress and mental disorders

The assessment of psychological distress and diagnosis of mental disorders pose a range of clinical challenges in populations with serious or life-threatening illness. Given the complex medical issues and treatment interactions, the aetiology of both physical and psychological symptoms often remains unclear. In some patients, elevated levels of psychological distress or a mental disorder represent premorbid conditions that have continued or worsened with onset and progression of the medical illness. In the much larger proportion of patients, psychological distress represents a response to the life-threatening disease, the deterioration of their health, and the multimodal medical treatments (Kelly et al., 2006).

A relatively small proportion of patients with psychosocial distress or a mental disorder are identified by the health-care team early and referred to receive psychosocial support (Passik et al., 1998; Fallowfield et al., 2001; Kelly et al., 2006). Recommendations are needed to improve the opportunity for early intervention. To some extent these recommendations focus on the interpretation of selected symptoms in the context of advanced illness. It often remains unclear whether a particular symptom, such as difficulty concentrating or weight loss, is a consequence of a treatment such as chemotherapy, or a symptom of a mental disorder such as depression. Many authors recommend that the psychiatric and psychosocial assessment focus on cognitive and psychological symptoms, such as hopelessness or guilt, rather than on somatic symptoms (Passik et al., 2000; Pessin et al., 2005). This is echoed by diagnostic manuals, such as the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*. It is often

impossible, however, to differentiate the aetiology of symptoms in patients with advanced disease and multiple symptom burden, and excluding somatic symptoms in the diagnostic assessment risks further an underestimation of mental disorders such as depression (Pessin et al., 2005). In contrast, other diagnostic approaches include all symptoms regardless of their aetiology, and this probably leads to an over-identification of mental disorders (Cassem, 1990). Endicott has suggested a substitutive approach, in which somatic symptoms are replaced in the assessment of depression in patients with somatic diseases (Endicott, 1984). However, even this approach can lead to difficulties in distinguishing psychological symptoms that indicate elevated distress versus a normal adaptive emotional response to the end of life. For example, some catastrophizing thoughts or hopelessness may be present in patients with poor prognosis or in a terminal stage of the disease, yet not be associated with high distress.

During recent years, a range of brief and ultra-brief screening tools have been developed for the assessment of psychological distress in the medically ill. Kelly and colleagues have reviewed these tools and other approaches for measurement of psychological distress in palliative care (Kelly et al., 2006). Single-item screening instruments have been proposed as a useful approach in many conditions. Chochinov and colleagues suggested a single screening item approach ('Are you depressed?') for depression (Chochinov et al., 1997). The National Comprehensive Cancer Network (NCCN) in the United States has established the distress thermometer, a single-item measure to measure distress and associate it with one or more experiential domains (NCCN, 2003), and a single-item approach to identify spiritual distress at the end-of-life was published by Steinhauser et al. (2006).

A longer depression assessment has been developed by Pessin and colleagues (Pessin et al., 2005), based on the responses to the following questions:

- Anhedonia: *Have you lost interest or pleasure in the things you used to enjoy? Is there anything that you are still able to enjoy?*

- Depressed mood: *How has your mood been? Have you been feeling sad, depressed, or down? What are you feeling sad about?*

- Worthlessness and guilt: *Do you worry about being a burden to your family? Do you feel that your life is worthless right now?*

- Suicidal ideation: *Most patients have some thoughts about death; have you had any? Do you feel that life is not worth living? Do you find yourself thinking about death a lot or think you would be better off dead?*

- Suicidal plan: *Have you stopped taking care of yourself? Have things gotten so bad that you have thought about hurting yourself or ending your life sooner?*

- Hopelessness: *How are you feeling about the future right now? Are there things that you are looking forward to?*

- Insomnia or hypersomnia: *How is your sleep? Do you have trouble falling asleep? Staying asleep? Do you wake up frequently in the night? Do you find when you can't sleep that you are up feeling sad or worrying? Or do you find that the opposite happens, that you are sleeping too much?*

- Appetite: *How has your appetite been? Does food taste good to you? Would you eat more if you were physically able?*

- Concentration and indecision: *How has your thinking been? Do you have trouble thinking or remembering things? Do you have difficulty making decisions?*

◆ Fatigue and loss of energy: *How is your energy level? Do you notice that your mood affects your energy level?*

◆ Psychomotor retardation and agitation (clinicians should note behaviour): *Have you noticed you feel slowed down? Have you been moving more slowly than usual? Or do you find the opposite, that you feel fidgety, restless, or keyed-up inside?*

In populations with advanced illness, the time and burden associated with a comprehensive psychological or psychiatric assessment can be challenging for patients, and the assessment may yield information that is difficult to interpret. These negatives should be balanced against the potential positive outcomes that may follow identification and treatment of factors that contribute to distress for the patient and the caregiver. If a brief assessment, even a screening, provides sufficient information to act clinically, it can suffice; if not, additional efforts should be made to acquire information about the source of distress or mental disorder.

Psychological interventions for patients with advanced disease

Clinical psychological/psychotherapeutic care for patients with progressing disease and their caregivers comprises a variety of interventions and techniques, all of which can be integrated into a multidisciplinary care plan (Watson and Kissane, 2011). These include, among others, CBT, cognitive analytic therapy, narrative interventions, relaxation and guided imagery, mindfulness-based interventions, meaning-focused interventions, art therapy, and dignity therapy. Psychotropic medication often is combination with psychotherapeutic interventions for patients with severe distress and should be further clarified with the medical care team.

Psychotherapeutic requirements

The psychotherapeutic work and goals in palliative care settings differ in several respects from psychological interventions for patients with early or curative diseases or physically healthy individuals. First, the time frame for interventions may be limited. Usually, patients can be seen only a few times, depending on the physical condition, the course of the disease, and the inpatient or outpatient setting. The limited time has several implications for the development of a trustful and sustainable therapeutic relationship and psychotherapeutic treatment planning. Treatment planning often depends on the course of the disease and the sometimes quickly changing supportive care needs of patients and/or their caregivers. It requires medical knowledge pertinent to the patient's illness, and information about common medical treatments and their side effects. It also requires close contact and collaboration with the palliative care team, if involved. The often unpredictable course of the disease and changes in the supportive care needs may place high demands on the clinician with regard to flexibility, empathy, and understanding of the patient's situation.

Second, treatment planning for the patient with serious illness must consider that communication with the patient and the caregiver can be hampered not only by severe health conditions, such as delirium, but also by unclear or divergent perceptions about the goals of treatment and the curability of the disease. Temel and colleagues showed that despite having terminal cancer, about one-third of patients newly diagnosed with metastatic non-small cell lung cancer reported that their cancer was curable at baseline, and a majority endorsed getting rid of all of the cancer as a goal of therapy (Temel et al., 2011). In addition, patients experience hope and hopelessness often as closely linked constructs (Sachs et al., 2013). Rodin and Zimmermann used the term 'double awareness' to describe the situation of patients with advanced—yet not terminal—disease and the challenge in dealing with issues of death and dying while remaining engaged in life (e.g. dealing with complex treatment decisions, managing changing relationships) (Rodin and Zimmermann, 2008).

The clinical psychologist is often faced with the difficult task of encouraging patients and caregivers to cope adaptively while promoting acceptance. Support for coping may be focused on helping to maintain hope and quality of life, and reduce psychological stress. Acceptance may require that patients and caregivers face 'realistic' treatment goals and treatment decisions, which themselves have the potential to negatively affect the psychosocial well-being of the patient and the family. The psychologist must be prepared to manage the emotional responses of the patient and the caregiver, which can include frustration and anger, disappointment, despair, (anticipatory) grief, and high levels of distress. These emotions may lead to difficult therapeutic interactions. Finally, clinical psychologists working in palliative care settings must be prepared to deal with personal feelings generated by the closeness to death and dying, their own sense of helplessness, and existential or spiritual questions about the meaning of life and death.

Psychotherapeutic goals and approaches

Supportive psychotherapy

Psychotherapeutic interventions in palliative care usually have a foundation of supportive psychotherapy, on which is built a multimodal approach. Supportive psychotherapy is defined as a therapeutic intervention that aims to help patients and caregivers deal with distressing emotions, and to promote existing resources, strengths, and adaptive coping with the disease (Lederberg and Holland, 2011). In relation to these issues, the objectives of psychotherapeutic interventions include the following (MacLeod, 2008):

◆ Enhancement of adaptive coping efforts

◆ Clarification of misunderstandings and (mis-) expectations

◆ Clarification and/or strengthening of interpersonal relationships

◆ Mobilizing individual and family resources

◆ Reducing psychological symptom burden (e.g. anxiety, depression)

◆ Maintaining hope and life goals

◆ Promoting acceptance

◆ Maintaining a sense of dignity

◆ Finding meaning in life and a sense of peace

◆ Strengthening of self-esteem

◆ Acknowledgement of strengths and achievements in the life of the patient

◆ Reduce feelings of isolation and loneliness of the patients

◆ Acknowledgement of feelings of grief and sadness about loss/ saying good bye.

Cognitive behavioural therapy

CBT has been shown to be very effective in treating emotional distress and particularly depression in patients with chronic health

conditions (Horne and Watson, 2011). Nonetheless, the approach has been used less often in palliative care settings than in the management of patients with non-life-threatening conditions. However, cognitive techniques, such as cognitive restructuring/reframing, and behavioural techniques, such as activity scheduling and distraction, can help to relief distress from specific symptoms such as anxiety, depression, fatigue, and pain. Contraindications to CBT include organic mental syndromes, schizo-affective disorders, and delirium (Horne and Watson, 2011).

Relaxation and image-based interventions

Relaxation and image-based interventions comprise a wide range of techniques including guided imagery, visualization, and progressive muscle relaxation. These techniques are easy to learn and may help patients regain a sense of control and mastery, develop coping skills for side effects such as fatigue or nausea, and maintain or regain psychological well-being (Lewis and Sharp, 2011). In patients with severe health conditions, however, it should be considered that an intervention such as visualization of the body or body parts can also increase anxiety or even induce panic. Therefore, whether an intervention is appropriate or helpful for a patient should be carefully considered (Lewis and Sharp, 2011).

Mindfulness interventions

Mindfulness interventions, such as mindfulness-based stress reduction (MBSR), have been found useful in patients with life-threatening and advanced diseases (Payne, 2011). These treatments promote (a) self-regulating attention of immediate experience, allowing for greater awareness of mental events in the present moment; and (b) adoption of a curiosity, openness, and acceptance towards one's one experiences in the present moment (Payne, 2011). MBSR has been found to be effective in reducing a variety of unpleasant psychological states such as anxiety and depression, substance abuse, fatigue, insomnia, and fear of recurrence. It may further promote hope and quality of life.

Meaning-centred psychotherapy

Meaning-centred psychotherapy, which comprises specific approaches that promote a sense of meaning and purpose, have been receiving increasing attention in populations with life-threatening diseases. They may be realized as group therapy approaches or individual therapy, and are intended to reduce emotional and spiritual distress and promote hope, courage, and control; mobilize internal resources; and discuss future goals despite limited life expectancy (Breitbart et al., 2012; Nissim et al., 2012). Further aims include strengthening a patient's self-esteem and sense of dignity, to appreciate strengths and past achievements, reduce feelings of isolation, strengthen the relation with the partner and family members, and improve the communication with the professional health-care team (LeMay and Wilson, 2008).

Dignity-centred psychotherapy

Dignity and respect for the patient and his or her care needs represent an essential attitude in palliative care. A sense of dignity for patients encompasses feelings of respect and being worthy despite increasing physical and psychological symptoms; it is often mediated by both intrinsic and extrinsic factors, particularly social interactions (Chochinov and McKeen, 2011). Dignity-centred therapy is particularly designed for patients at the end of life (life expectancy at least 2 weeks). Based on the empirical dignity model by Chochinov et al. (2002), dignity therapy aims to reduce suffering

and promote emotional and spiritual well-being, quality of life, and a sense of meaning and purpose by encouraging patients to reflect on their memorable life events (Chochinov and McKeen, 2011). The intervention includes a dignity therapy interview (e.g. 'What are your hopes and dreams for your loved ones?'), and one or two therapy sessions. The interview sessions are transcribed, edited, and read to the patient again and (after corrections) the patient is given the document to share it with family members, friends, or others (Chochinov and McKeen, 2011). Dignity therapy was found to be effective in increasing sense of dignity, improving quality of life and spiritual well-being, and enhancing appreciation through the family based on self-report end-of-life experiences (Chochinov et al., 2011).

'Espero alegre la salida y espero no volver jamás' ['I hope the exit is joyful and I hope never to return'] wrote the Mexican-American painter Frida Kahlo on the last page of her diary next to a drawing, the black angel of death (Le Clézio, 2002)—distressing, touching and honest words which express bitterness, resignation, and perhaps relief and hope for a peaceful death at the end of an extraordinary but painful life. The painter, whose health increasingly deteriorated after life-long physical and mental suffering, needed nursing care and intensive pain management, stands as an example for many terminally ill patients whose lives are changed severely by a progressing disease, which affects all areas of life, including their self-determination. Clinical psychological/psychotherapeutic care for patients with progressing disease and their caregivers is an important part of multidisciplinary palliative care and can promote the acceptance of the life lived, quality of life, hope, well-being, and dignity.

The contribution of the clinical pharmacist in palliative care

Margaret Gibbs

Introduction to the contribution of the clinical pharmacist in palliative care

Medicines are an essential part of symptom control so it is logical for the palliative care team to include a pharmacist, whose particular expertise is in the safe and effective use of medicines. In the United Kingdom, the National Institute for Health and Care Excellence (NICE) in its guidance *Improving Supportive and Palliative Care for Adults with Cancer* (NICE, 2004) states that the expertise of pharmacists helps to provide the appropriate level of specialist palliative care to patients. Similar documents from the United States, Europe, and Wales have reached the same conclusion (NHS Wales, 2005; National Consensus Project for Quality Palliative Care, 2013) and the UK Palliative Care Funding Review report (Hughes-Hallett et al., 2011) acknowledged the importance of the continued funding for pharmacy services. This chapter reviews the role of clinical pharmacists in palliative care and is based mainly on the situation in the United Kingdom with additional information from other parts of the world.

All hospices with inpatients require a pharmacy supply service but not all include a clinical pharmacist as part of the multidisciplinary team. Clinical pharmacy has been defined as 'that area of pharmacy concerned with the science and practice of rational medication use' (National Consensus Project for Quality Palliative Care, 2013). The traditional training and role of pharmacists started to change in the United Kingdom back in the 1970s following the Noel Hall report (Working Party on the Hospital Pharmaceutical Service, 1970), which encouraged hospital pharmacists to step outside the dispensary and become more involved clinically in the decision-making processes for prescribing. Forty years on, the pharmacy degree, in the United Kingdom, is now a 4-year Master's degree and clinical training occupies the largest part of the curriculum (Wilson et al., 2005). Most hospital pharmacists spend the majority of their time in clinical areas, communicating with other health-care professionals and patients and in 2006, the first cohort of pharmacists qualified as independent prescribers. Many of these now run clinics in hospital and in general practice, seeing their own case load of patients. Pharmacists in the United Kingdom emerge from their training with a different set of skills to those of previous generations and many choose to specialize in a particular therapeutic area within the hospital, primary care, community, or industrial environment. Traditional supply roles associated with the practice of pharmacy have changed too, becoming more mechanized and delegated more to technical staff. These changes have, in many countries, enabled pharmacists to become more fully engaged members of clinical interdisciplinary teams.

Around 200 pharmacists work as part of palliative care teams in the United Kingdom. A 2002 study (Gilbar and Stefanuik, 2002) indicated that most Canadian teams included a pharmacist (59/69), whilst in Australia the proportion was lower at (42/76). The most recent survey in the United States, in 2012, showed that pharmacists carry out clinical, dispensing, and administrative work in hospice teams (Latuga et al., 2012). The job specification for a palliative care pharmacist can vary greatly with many spending only part of their working week within the speciality. Most UK hospices and hospital teams have a small number of beds, usually not enough to warrant the input of a full-time pharmacist. Community-based services may not have any regular clinical pharmacist input but are supported formally or informally by community or Clinical Commissioning Group (CCG) pharmacists. The 2002 study (Gilbar and Stefanuik, 2002) reported that most pharmacists worked fewer than 20 hours per week in the palliative care service and Canadian pharmacists were more involved clinically, while Australian pharmacists spent more time on administrative and supply functions. The American Society of Health-Systems Pharmacists' Statement outlines the role and responsibilities of a hospice and palliative care pharmacist (Box 4.14.1) and has broad similarities in practice with Canada, Australia, and the United Kingdom (Arter and Berry, 1993; American Society of Health-System Pharmacists, 2002; Gilbar and Stefanuik, 2002).

Several studies have evaluated the effectiveness of the interventions and recommendations of clinical pharmacists working in palliative care and an American study in 2011 (Lee and McPherson, 2006; Wilson et al., 2011) showed that almost 90% of the pharmacists' recommendations were accepted and 80% resulted in the desired clinical outcome.

Clinical pharmacy in the rest of Europe is in an earlier stage of development but a number of European pharmacists are establishing roles in palliative care teams. A palliative care team in Sweden has recently included pharmacists in the team with an improvement seen in stock management, logistics, and resolving pharmaceutical issues (Norrstrom et al., 2010). The value of pharmaceutical input in Japanese and Australian home-care services has been extensively evaluated. In one study from Japan, the value of the input from community pharmacists was marred in some

Box 4.14.1 The pharmacist's responsibilities

1. Assessing the appropriateness of medication orders and ensuring the timely provision of effective medications for symptom control.

2. Counselling and educating the hospice team about medication therapy.

3. Ensuring that patients and caregivers understand and follow the directions provided with medications.

4. Providing efficient mechanisms for extemporaneous compounding of non-standard dosage forms.

5. Addressing financial concerns.

6. Ensuring safe and legal disposal of all medications after death.

7. Establishing and maintaining effective communication with regulatory and licensing agencies.

8. Assessing the appropriateness of medication orders and ensuring the timely provision of effective medications for symptom control.

9. Counselling and educating the hospice team about medication therapy.

10. Ensuring that patients and caregivers understand and follow the directions provided with medications.

11. Providing efficient mechanisms for extemporaneous compounding of non-standard dosage forms.

12. Addressing financial concerns.

13. Ensuring safe and legal disposal of all medications after death.

14. Establishing and maintaining effective communication with regulatory and licensing agencies.

respect by the financial burden of providing this additional service, although this and another studies, including one carried out over 13 years, showed that pharmacy input was valued by patients (Hussainy et al., 2011; Kato et al., 2011).

The fundamentals of good pharmaceutical care

Pharmaceutical care has been defined as 'the responsible provision of drug therapy for the purpose of achieving defined outcomes that improve the patient's quality of life' (Hepler and Strand, 1990). When pharmacists review or advise on drug regimens, the patient is always at the focus. A traditional mantra for pharmacists is the provision of 'the right drug to the right patient at the right time'. Barber (1995) suggests that individual prescriptions are monitored to maximize effectiveness, minimize risks and costs, and

respect the patient's choices. This patient-centred approach is, of course, fundamental in palliative care so the clinical pharmacist's attention to detail on medication complements all other aspects of care. In order to provide the best care, the clinical pharmacist ensures that the following are provided:

- A reliable supply function and regular monitoring of prescribing, including economic reviews
- An appropriate medicines management system
- Advice and guidance on safe use of drugs of particular relevance to palliative care, for example, syringe driver compatibility
- The provision and dissemination of drug-related information both clinical and legislative, for example, involving controlled drugs (CDs).

The following sections will look at these areas in more detail and at how they can be executed most effectively in palliative care.

Supply and monitoring of medication

In the United Kingdom since 1995, hospices with inpatient units have been provided with a budget for their drugs and pharmaceutical services by the commissioners of health services in each locality. Changes are afoot in primary care but the Palliative Care Funding Review (Hughes-Hallett et al., 2011) recommended that current arrangements continue. A contract to provide pharmaceutical services may be set up with a local hospital pharmacy, a community pharmacy, or directly with a wholesaler for the supply function. If a contract is established with a hospital pharmacy, it is normally possible for the hospice to benefit from the advantageous contract prices for the drugs being used in an acute trust. The service should include the functions shown in Box 4.14.2.

An effective supply function is an essential part of the pharmaceutical service and this has, in most environments, become an almost mechanical process with 'original pack' dispensing of blister-packaged tablets or small volumes of liquid preparations. In the United Kingdom, once a pharmacist has screened a prescription for its clinical appropriateness the dispensing can be completed by suitably qualified pharmacy technicians and, in a few larger hospitals, by robotic systems. This means that a clinical pharmacist does not need to be involved directly with the supplies of drugs but needs to set up systems, be confident that they are working, and be made aware of any problems.

Economic issues

The economical use of drugs is important in all health-care settings but it is especially important in hospices, as most are registered charities, in many countries. The majority of drugs used for symptom management are older, relatively inexpensive generic drugs but there are some notable exceptions, such as the bisphosphonates and somatostatin analogues. In a small unit it is very easy for the symptom management for one or two patients who require expensive treatment to make a huge impact on the monthly budget figures. Regular pharmacy meetings to review prescribing patterns can highlight areas of concern, then audit and written guidelines can be constructive tools to ensure the appropriate use of high-cost drugs. The economic benefits of pharmacist involvement have been reported in Japan and Sweden (Lee and McPherson, 2006; Norrstrom et al., 2010).

Box 4.14.2 Functions of a pharmaceutical service to a hospice inpatient unit

Essential

1. A reliable and responsive delivery system with provision for a back-up to provide urgently needed medicines or pharmacist advice out of opening hours.

2. Regular visits from a clinical pharmacist for clinical checking of prescriptions and provision of medicines information.

3. Provision of stock drugs using a regular top-up system, ideally carried out by pharmacy technicians including a regular monitoring system for expiry checks of medicines.

4. Provision of individual patient supplies for the duration of inpatient stay and on discharge.

5. Provision of regular supply of controlled drugs using standard operating procedures.

6. A system for reviewing and updating agreed stock supply.

7. An effective communication system for ordering, managing queries, and supplying information where necessary when the pharmacist is not present.

Desirable

8. Inclusion of pharmacist on clinical governance, risk management, and drug and therapeutics committees within the hospice.

9. Availability of pharmacist to run teaching sessions for hospice staff.

Establishing an agreed stock list for an inpatient unit may evolve into compiling a core formulary. This has been shown to be an effective strategy for reducing cost and improving patient outcomes in one hospice in Kentucky, United States (Snapp et al., 2002). In another study from the United States, it was shown that newer, more expensive pharmacotherapy options were not necessarily more effective than traditional agents, if doses were monitored and titrated by clinical pharmacists (Weschules et al., 2006).

Ideally, any formulary should be evidence based, but the evidence for much of the drug therapy used in palliative care is of a lower level than for other therapeutic areas, at least partly because of the difficulties and perceived difficulties in carrying out randomized controlled trials in terminally ill patients (Steinhauser et al., 2006).

Definition of evidence-based practice

The judicious use of the best available evidence, moderated by patient circumstances and preferences to guide our practice to improve the quality of clinical judgements and facilitate effective health care.

Many sets of therapeutic guidelines now exist in the United Kingdom and on the whole, the list of drugs used for symptom control is broadly consistent. Guidance and core formularies have also been developed by palliative and supportive care networks, which were established as a model of integrated service provision alongside cancer networks, in response to *The NHS Cancer Plan* to improve coordination of cancer and palliative care (Department of Health, 2000b). Clinical pharmacists have been involved in many of the network subgroups, coordinating drug treatment and availability. In the United States, the introduction of standardized, evidence-based medication use guidelines is encouraged (Weschules, 2005).

As well as the choice of drugs, the clinical pharmacist can advise on the most appropriate formulation for individual patients. With some exceptions (such as strong opioids and drugs where the avoidance of peak effects in drug blood concentrations may lead to fewer side effects), prescribers are now encouraged to avoid the use of slow-release preparations on economic grounds. In palliative care, our patients' tablet 'burden' can often be a real problem and so use of a more expensive once- or twice-daily preparation, such as slow-release metoclopramide, may be justified.

Managing a drug regimen for a patient who has swallowing difficulties or is being tube fed has pharmaceutical implications. Crushing tablets is to be discouraged, as changing the form of a dose not only takes it outside the terms of its licence, but can also be hazardous as it may change its pharmacokinetics—especially dangerous with a slow-release formulation. Liquid or soluble tablets can be very expensive, so alternative drugs may need to be substituted. The decision to substitute any drug in a situation of stable symptom control has to be considered carefully.

The pharmacist may also alert colleagues to the sensitive issue of discontinuing medication. Effectiveness and tolerability of each medication will be reviewed regularly but decisions on whether a patient nearing the end of life needs to continue with such medication as statins or oral hormonal treatments normally need to be negotiated with the patient and possibly their carers. The goals of care and treatment should be considered in relation to prognosis and the patient's ability to manage their medicines. Initiating drugs with a long onset of action, such as the older antidepressants may not be appropriate if the time to benefit may exceed the patient's life expectancy. These are emotive issues but unfortunately their cost implications can be considerable (Holmes et al., 2006). Moreover, the burden of any side effects at initiation, will have been for no gain.

It is almost inevitable that we have a degree of wastage when drugs are dispensed for patients at the end of their life and although it is a difficult moral issue to destroy what seem to be perfectly sound drugs, we have a statutory responsibility not to re-supply any drugs that have been dispensed to a particular patient to others as we are unable to guarantee their integrity. The only practical way to counter this is to minimize waste by ensuring that appropriate quantities are ordered.

Nurses need also to be aware of the relative costs of dressings and skin and mouth-care preparations. Wound care and mouth care are often challenging areas of palliative care and there is a huge variety of products on the market. With pharmacist input, guidance or decision-making tools can encourage nurses to use the most appropriate and economical choices.

Palliative care in the community

The majority of dying people in the United Kingdom would prefer to die in their own home, although currently only about 20% do

so and many are admitted to hospices and more to hospitals in the last days of life (National Council for Palliative Care, 2010). This is a statistic that has rightly occupied a great deal of attention in recent years and strategies are being introduced to improve this. Good end-of-life care at home requires the input of a team of health-care professionals and the role of the pharmacist is expanding. The traditional medicine supply role is of paramount importance but more direct patient care is part of the pharmacist's role in some community teams in the United Kingdom and Australia. Pharmacists are members of the team visiting patients at home, where they can optimize medicines management and reduce medication-related problems (Hussainy et al., 2011). The opportunity to practise as an independent prescriber is a newer role in the United Kingdom and this can speed up access to medicine supply.

Although routine symptom control medicines are prescribed and supplied in the community, the provision of drugs for patients who deteriorate unexpectedly has always been complicated by legislative limits on the ability to hold 'stock' injectable drugs outside pharmacies and hospitals. In addition, many doctors no longer carry their own supply of opioids for security reasons. Medical and nursing cover varies from area to area but the simple lack of availability of the required drugs has led too often to an inappropriate hospital admission, and significant distress, especially during the out-of-hours (OOH) period, which is almost 70% of the week. OOH care in England and Wales underwent a substantial National Health Service (NHS) review in 2000 (Department of Health, 2000a) and other reviews of practice, such as those initiated by Macmillan Cancer Care resulting in the Gold Standards Framework (National Gold Standards Framework (GSF) Centre in End of Life Care, n.d.), have contributed to subsequent re-organization in recent years.

Systems for stocking small quantities of injectable drugs in designated community pharmacies have been set up in various localities. Whilst these schemes are an invaluable back-up, they have not always been a success. This may be because they are not always well publicized to the relevant professionals but, more importantly, there is an inevitable delay in getting the pharmacist and prescription to the pharmacy and back to the patient's house. Underuse of pharmacy schemes leads to expiry of stock. The system should be used in conjunction with immediate access to the necessary drugs by the on-call medical service. Commissioners are responsible for ensuring that there is a safe system in place for providing all the drugs on the national OOH formulary to providers of OOH medical care. A list of essential and desirable drugs is shown in Box 4.14.3. The details of the OOH arrangements need to be agreed locally to suit the geography and population. They should encompass the NICE guidance for improving supportive and palliative care (NICE, 2004), be supported by improved communications, facilitated by introducing the Gold Standards Framework after the publication of *Caring for the Dying at Home* (Thomas, 2003) for community care of the dying, and take into account the Preferred Place of Care (Cohen Fineberg and O'Connor, 2011) initiative.

Clinical pharmacists have been instrumental in establishing so-called just in case schemes where general practitioners (GPs) prescribe a small quantity of injectable drugs for individual patients identified as nearing the end of their life. These drugs can be kept safely in the patient's home in case of a sudden deterioration. In a pilot scheme in Hertfordshire, United Kingdom (Amass

---

Box 4.14.3 Emergency drugs for end-of-life symptom management
Essential (and now on the NHS OOH core formulary)
Strong opioid in injectable form—normally diamorphine or morphine.
Midazolam for sedation.
Cyclizine, haloperidol, levomepromazine for nausea and vomiting.
Glycopyrronium or *hyoscine* for retained secretions.
Desirable
Lorazepam tablets for anxiety and breathlessness.
Oral morphine liquid.

and Allen, 2005) over 6 months in 2004, 23 'just in case' boxes were issued, enabling 16 patients to have their symptoms managed and to die at home, which was their expressed preference. Each pack of drugs cost only £10 and the potential saving on an admission to hospital or hospice. Clearly, however, the satisfaction for the patient and their family resulting from good end-of-life care is immeasurable.

Medicines management

The UK Audit Commission introduced the concept of medicines management within its report *A Spoonful of Sugar* in 2001 (Audit Commission, 2001). It aimed to optimize the use of medicines in NHS hospitals, to improve the quality of patient care and rationalize expenditure. Although most hospices are independent of the NHS, the national strategies are normally adopted for the sake of congruity.

Definition of medicines management

Medicines management in hospitals encompasses the entire way that medicines are selected, procured, delivered, prescribed, administered and reviewed to optimize the contribution that medicines make to producing informed and desired outcomes of patient care.

Reproduced with permission from The Audit Commission, *A Spoonful of Sugar: Medicines Management in NHS Hospitals,* Audit Commission Publications, Wetherby, UK, Copyright © 2001, available from http://archive. audit-commission.gov.uk/auditcommission/sitecollectiondocuments/ AuditCommissionReports/NationalStudies/nrspoonfulsugar.pdf.

Patient-centred medicines management

When patients have a planned admission to an inpatient unit in the United Kingdom, they are encouraged to bring their current medicines in with them. This has several benefits; it is essential to establish a drug 'history', particularly if symptoms are out of control. It can also clarify whether the patient is actually taking the regimen as prescribed and note what has been used in the past and what the outcomes were. Patients may have a number of symptoms and coexistent pathologies, making it common for them to be taking a large number of medicines, so this is often a time-consuming job involving rummaging through bags full of dispensed medicines. Although the admitting doctor or specialist nurse will

normally do this as part of any admissions process, pilot studies have shown that a pharmacy-led medicines review process uncovers issues and is highly acceptable to the patient. Unfortunately, time limitations have not enabled these to become routine.

Bringing in their existing medication also ensures that patients have an ongoing supply, as most units will not have an exhaustive range of stock drugs. It also prevents duplication, reduces waste, and, ultimately, saves money. Not all patients' own drugs can be used so they must be screened for suitability using a checklist, ensuring they are suitably packed, identifiable, not time expired, and labelled correctly for the patient. This also forms part of an audit trail for medicines.

One of the main aims of the NHS medicines management programme is to encourage patients to keep charge of their medicines in a bedside locker and to continue to take them independently. Clearly not all patients admitted to a hospice are suited to self-administration, but those whose admission is for respite or symptom control should be encouraged to do so with multidisciplinary team agreement. Patients need to understand their regimen and manage practical issues such as their ability to open containers, read labels, and appreciate their responsibility for security of their medicines. An agreed assessment process needs to be part of the hospice medicines policy. Almost all patients who are given the chance to self-administer prefer it, because it gives them more control and promotes confidence in managing what may be a complex regimen (Ausburn, 1981). This confidence can be a major contribution to a successful discharge, as many admissions and re-admissions arise because of problems with managing medication. We know that low adherence to instructions with medication affects outcome so patients must be given sufficient information to make an informed choice on the benefits and risks of a therapeutic 'alliance' (Royal Pharmaceutical Society of Great Britain, 1997). Patient counselling by pharmacists promotes understanding of the purpose of each medicine and awareness of potential adverse effects (Al-Rashed et al., 2000). It can also provide an opportunity to discuss practical issues such as the provision of medicines in concordance aids ('dosette boxes'), which may be continued on discharge. Most GP surgeries and pharmacies have a delivery system for prescriptions from surgery to pharmacy and then on to the patient at home.

Community pharmacists establish relationships with their regular patients and their families and have a wider role to play than simply drug supply. In some countries, community pharmacists are responsible for preparing pre-filled syringes for syringe drivers. In the United Kingdom, groups of community pharmacists have undergone additional training in order to support palliative care patients, by setting up prescription monitoring and supply services.

Another important role for palliative care pharmacists is to provide 'seamless' pharmaceutical care for patients as they move from one care setting to another (Scally and Donaldson, 1998). A common NHS electronic patient record system has not been successful, so we rely on a number of different methods of transmitting medication information, some of which are less reliable than others. A medication list will normally be drawn up on discharge and sent to the GP or other doctor looking after a patient, but their community pharmacist can sometimes be left out of the loop and both may be faced with an urgent prescription for an unusual drug unless prior explanation has been provided. Where medicines

Box 4.14.4 Scenario 1

Susan is 47 years old and has breast cancer with brain and bone involvement. Pain has been the main problem for the past few months but now her increasing weakness is the most distressing part of her daily life. Her analgesic regimen has become very complicated by her being seen by a number of practitioners and more medications being added concurrently without detailed review. On admission to our service she was taking oxycodone modified release and immediate release, regular paracetamol, gabapentin, amitriptyline, diazepam, lidocaine plasters, and using fast-onset fentanyl for incident pain. She was starting to find it too difficult to swallow the oral medications and unsure any more about what was actually helping her pain. We decided to simplify the regimen by stopping the amitriptyline and reducing the diazepam. We changed her gabapentin to pregabalin, which can be taken twice daily instead of three times and advised that she could have the capsules opened and swallow the contents with a little liquid. After a few days, she agreed to a syringe driver so we were able to convert the doses and administer her opioid and a small dose of benzodiazepine via the subcutaneous route. She was able to go home for a few days before she died.

---

management systems exist, patients' discharge medication will often be dispensed well before the expected discharge. This can present last-minute problems if doses or drugs have been changed in the interim. The importance of timely prescribing and supply to patients, for whom time is limited, needs to be communicated to all health-care professionals providing services. Pharmacists have a major educational role in fulfilling this particular objective (see Box 4.14.4: scenario 1).

Advice and guidance on drugs in palliative care

The relatively new concept of clinical governance was introduced into the NHS with the aim of increasing accountability and quality of care. In common with many other NHS initiatives it has been extended into the voluntary sector and provides a framework for decisions made when considering new treatment options.

Definition of clinical governance

A framework through which [NHS] organizations are accountable for continually improving the quality of their services and safeguarding high standards of care by creating an environment in which excellence in clinical care will flourish.

Pharmacists have a major role in clinical governance issues involving medicines, with many sitting on their hospice Medicines Management or Drug and Therapeutics Groups. The terms of reference of these groups may vary but usually include the review of drugs coming on to the market or drugs being suggested elsewhere for symptom control as well as ensuring the correct application of new drug-related guidance or legislation.

Use of drugs outside their licence

Palliative care practice often involves using drugs outside the terms of their product licence. In order for any new drug to reach the market, the manufacturer must be able to prove that it is a safe and effective treatment. Once this has been proved in a drug development programme, it will be granted a licence for the conditions for which it has been tested. Licensing is both a commercial and medico-legal issue but a doctor may prescribe, a pharmacist may dispense, and a nurse may administer drugs outside the terms of their licence, as long as the drug was being used in accordance with a practice accepted at the time by a responsible body of medical opinion. There is encouragement from UK authorities to discuss the use of medicines outside licence with our patients and although we aim to involve patients in all prescribing decisions, terminology such as 'outside the terms of a drug's licence' may sound more worrying than it need be. Most of the drugs used in this way are long established with well-documented safety and adverse effect profiles, so the main issue is ensuring that there is sufficient evidence for this use, whilst the main issue for patients is to avoid any potential confusion arising from information they may read in the patient information leaflet (PIL), which must be supplied with their dispensed medicines. Hospice pharmacists have written PILs for their own establishment and are usually happy for such information sheets to be used by others. At a small hospice user group this was not an issue of great concern, with patients saying they trusted the health-care professionals to do what they could for them (User Forum, 2012).

Pharmacists regularly advise nurses on the correct methods of administration of drugs. With tube-fed patients or other patients who may find swallowing difficult, it is common practice to consider crushing a tablet or opening a capsule and sprinkling the resultant powder on food or mixing it with a drink. Any of these alterations to the original product renders it outside its licence. Pharmacists have written a number of reference sources to offer advice about the best method of administration of the drug in these circumstances. This may involve changing the drug to an alternative where a licensed liquid or soluble form is available. The use of medicines without any licence is a slightly different issue. It is unlikely that a palliative care unit would wish to use an unlicensed *drug* but we often wish to mix or compound known drugs in unlicensed *formulations* to suit individual patients. Some examples of this are the use of alfentanil injection made into a cutaneous solution that can be sprayed onto the nasal or buccal mucosa and the addition of lignocaine (lidocaine) to a thermoversible gel for the management of painful wounds. Both products are made in regional hospital pharmacies in the United Kingdom. Although US pharmacists are permitted to compound individual preparations for patients, this practice has become very limited in the United Kingdom and is now restricted to a few commercial 'specials' manufacturers and regional, licensed hospital pharmacy manufacturing units. Information on unlicensed medicines is limited, as products have not been subjected to the same regulatory processes as licensed medicines so as much evidence as possible is required that such products are being appropriately and with accountability. Prescribers and pharmacists must both be involved in the decision-making process, using a committee or the clinical governance team to approve and document the rationale for using

unlicensed products. Once sufficient experience has been gained in their use, specialists may start suggesting to generalists that these products be used. The production of referenced information leaflets is important in supporting this. The Brompton Hospitals and some hospices have produced their own leaflets either covering this subject in general or for specific drugs such as the use of haloperidol to treat nausea and vomiting.

Subcutaneous administration of drugs

The use of the subcutaneous route is outside the license for the majority of drugs used in symptom management. The major area of potential problems is where drugs are mixed together in the same syringe. Although the drugs used are familiar and well established, it is not necessarily in a company's financial interests to investigate the compatibility of its injections with those of others. Additionally, many of the drugs we use have lost their patent and are made by generic manufacturers who would be even less inclined to carry out such studies. Pharmacists have been largely responsible for gathering data on the mixing of drugs in syringes for subcutaneous infusions (Dickman and Schneider, 2011). Our knowledge in this area comes from a combination of clinical observation and laboratory tests and ongoing data collection continues to add to this (Palliativedrugs.com, 2014).

Complementary medicines

The use of complementary medicines needs to be considered as a safety issue. Understandably, many patients are concerned about the safety of conventional medicines but there is a perception, fuelled by marketing that if a product is herbal or marketed as 'natural', then it may be safer. There are countless products available

---

Box 4.14.5 Scenario 2

John is a 68-year-old ex-drug-user who has been on a methadone programme for 8 years. He has developed lung cancer with liver and bone secondaries and is finding it difficult to manage at home alone. He is very vague about his pain relief regimen and called into the hospice overnight to say he was in terrible pain and had just opened the bottle and drunk the whole 100 mL of his oral morphine solution (200 mg) with no effect—analgesic or otherwise. At that time he was prescribed modified-release morphine 100 mg twice daily with 40 mg stats. There is a discrepancy between him, his family doctor, and the drugs team with his reported daily methadone dose and an apparent duplication of prescribing. He has now been admitted to the hospice for symptom control of his pain and nausea. His son asked to speak to the doctor privately as he wants us to know that his dad has been buying street drugs too but feels he would have been unable to do this in the past week or two. We were able to explain to John that unless we were quite clear about what he was taking it would be much more difficult to judge what was helping his pain. He admitted to being very frightened by his pain. I contacted the drugs team to clarify his methadone dose and we decided to leave that as it was and manage his pain separately. After some days with us, he was converted to a fentanyl patch and high strength immediate-release morphine tablets which were easier to monitor when he went home. He managed to return home and although his life continued to be quite chaotic, once home, he reported feeling much better.

supported by testimonials and claims that they work wonders—from improving digestion to curing cancer. When taking a drug history, pharmacists will also make specific enquiries, as patients may not mention complementary therapies because they are not regarded as 'drugs'. The quality of information on complementary medicines is in general not required to be of the same standard as that of conventional medicines, as they are not subject to the same legal controls. This makes it difficult to unpick the evidence. Clinical pharmacists can review the information available critically and offer guidance on potential beneficial and adverse effects of complementary medicines, as well as advising on possible contraindications and drug interactions. Research and data collection on herbal medicines and supplements is enabling us to offer better guidance and the Medicines and Healthcare Regulatory Authority regularly releases bulletins warning of serious safety issues with these medicines. In offering guidance on these products, pharmacists need to carefully word their findings in order to indicate the level of evidence for their statements and to take into account the patient's individual choice to continue with such products.

Practical and pragmatic guidance from the pharmacist is also required for some drug–food interactions that may impact on patients. For example, the ingestion of excessive amounts of vitamin K-containing green vegetables can affect coagulation, but a normal portion of such vegetables on a regular basis presents very low risk. Similarly, the presence of a drinks trolley on hospice wards and day centres prompts pharmacists to alert staff involved in 'administration' to the possible interaction between alcohol and drugs.

Incidents and errors with drugs

Incidents involving drugs account for about 10% of all adverse events reported in NHS hospitals, although over 80% result in no apparent patient harm (National Reporting and Learning Service, 2009). These figures are not necessarily applicable to hospices but the need to review and take appropriate action following adverse drug events is no less important. The ethos of drug error reporting has changed in recent years with a 'no blame' reporting system instigated in many hospitals and the involvement of staff in reporting 'near misses'. The focus is now on *systems* rather than individuals and we are asked to review our practice by the NHS Commissioning Board Special Health Authority in the United Kingdom, which disseminates guidance and safety notices for areas of risk such as the alert on potential for confusion between strengths of opioids (unpublished data). Pharmacists are able to advise on systems for reporting errors and improving safety and are essential members of the group within a hospice that reviews incidents. Writing additional safety steps into policies and sending round awareness bulletins have had positive results in that incidents have not recurred (Anonymous, 2006). Sharing information with other hospice pharmacists has also highlighted common areas for concern and constructive changes, such as persuading a company to improve its packaging, have been achieved.

Provision and dissemination of information

Clinical pharmacy training includes time spent in medicines information centres where pharmacists learn to source and appraise information and research critically to produce unbiased drug reviews. As palliative care expands teams need to keep being updated on drug developments in therapeutic areas other than cancer. Pharmacists can tap into wide resources from regional medicines information services to share updates and reviews

The widespread use of CDs requires particular attention to legislation and regulations. Patients need to be enabled to make choices about their preferred place of care and also to be able to change their minds at short notice. To facilitate this, they need to be able to access their required medicines without delay, yet within the law.

Networking

Like many specialists, most palliative care pharmacists work alone so there is value in communicating with fellow pharmacists for advice and support. Regional and national groups for palliative care pharmacists exist in the United States, Canada, and the United Kingdom, with varying levels of activity. The Scottish Palliative Care Pharmacists Association has created a benchmarking tool for staffing levels of pharmacists, coordinates research, produces guidance, and has a strategic role within the Scottish Health Service. As most work some distance from colleagues, the Internet has become invaluable as a means of sharing information. Multidisciplinary web-based discussion groups have been set up with pharmacists being the third largest professional group participating (after doctors and nurses), and a UK palliative care pharmacists network has now been formed.

Conclusions

The role of a clinical pharmacist in a palliative care team is an especially rewarding and fulfilling one as it presents so many opportunities to utilize specific skills. One needs broad outlook, a flexible and pragmatic approach, and willingness to contribute to judgements based on what is best for any given patient, without always having the highest level of evidence to support some decisions. As palliative care opens up to more patients with non-malignant, life-limiting diseases, there is a need to be aware of a wider range of drug regimens and their implications and to educate as many colleagues as possible to the safe and effective use of drugs in patient-centred palliative care. It is difficult to imagine working in a more privileged environment than one where teams are dedicated to providing the best possible end-of-life care.

Medical rehabilitation and the palliative care patient

Deborah Julie Franklin and Andrea L. Cheville

Introduction to medical rehabilitation and the palliative care patient

Access to palliative care earlier in patients' disease trajectory has made the preservation of functional mobility and independence increasingly pertinent. This chapter focuses on the role that rehabilitation and rehabilitation medicine interventions play in comprehensive palliative treatment plans. Although this chapter concentrates on practices prevalent in the United States and United Kingdom, the issues it addresses are of global relevance.

Both disciplines place importance on the biopsychosocial model of patient care and employ interdisciplinary teams to develop care plans that respond not just to the physiological but also the psychological and social needs of patients and their caregivers. Both rehabilitation medicine and palliative medicine seek multidimensional outcomes that are not related specifically to disease state, such as the Functional Independence Measure (FIM) or quality of life (QOL) parameters.

Rehabilitation strategies contribute to palliative care by (a) maintaining and, if possible, promoting functional independence during a period of expected systemic decline and (b) providing strategies to prevent or slow deleterious complications such as generalized deconditioning, skin breakdown, and contractures.

The judicious selection of durable medical equipment (DME) is best done in collaboration with rehabilitation specialists who can combine extensive knowledge of available componentry with an understanding of the salient medical and prognostic characteristics of a given patient. Physiatrists, physiotherapists (PTs), and occupational therapists (OTs) will also often work closely with DME suppliers to select optimal adaptive equipment for patients developing progressive dependence at home. These can include automatic lifts, bathing, and toileting aides, and wheelchairs as well as smaller items that facilitate autonomy with self-care (e.g. reachers, buttonhole assists, and sock donners).

Delivery of rehabilitation services in palliative care

Many regional and international rehabilitation organizations have special interest groups that focus on palliative care populations. Among physicians, these include oncological rehabilitation groups, geriatric-focused groups, and pain management specialists. Many of these groups are now producing evidence-based care guidelines for treating patients with advanced disease (Sliwa and Marciniak, 1998) or participating in clinical trials assessing the efficacy of their techniques in this population (Dimeo et al., 1998).

Physical medicine and rehabilitation (PM&R), also called physiatry or rehabilitation medicine is the primary medical specialty responsible for the provision of rehabilitation services in the United States. The level of training and competency-based certification required for the delivery of rehabilitation team services varies between countries. In the United States, PTs complete a 2-year master's level degree programme or, more commonly in recent years, a 3-year professional doctorate but can delegate some of their active treatment to physiotherapy assistants or restorative aides.

PTs are asked to attend to issues of strength, endurance, and mobility requiring specialized training. This includes wheelchair skills and other adaptive mobility as well as gait training on increasingly challenging surfaces for ambulatory patients. Programmes should be tailored to reflect the environmental challenges of the home, such as stairs to enter, size of home, location of bed, and bathroom modifications. Transfers to car, van, or adapted vehicle should be reviewed. For patients with inexorably progressive disability, purchase or lease of a vehicle with full wheelchair carrying capacity may be appropriate but should be weighed against cost and limited prognoses. Easy transportation helps patients maintain an involvement in a wider variety of family and community activities.

OTs focus on essential functional activities such as dressing, bathing, toileting, and self-feeding. Many use validated cognitive assessment tools regularly, such as the Montreal Cognitive Assessment (MoCA[R]), a modified Token Test, the Wisconsin Card Sorting Test, or parts of the Wechsler Adult Intelligence Scale, during their initial patient assessment and, if indicated, at subsequent times (Zorowitz and Adamovich, 2000). Earlier in gradually progressing diseases, the input of quantitative neuropsychologists may be used by patients who want to learn strategies for limiting the effect of emerging cognitive deficits. In other situations, neuropsychologists may be asked to help differentiate the memory and attention deficits stemming from untreated depression or anxiety, from symptoms of progressive dementia, or other reversible and irreversible causes of cognitive decline. This information may help to initiate pharmacological management of anxiety, attentional, and arousal deficits as well as mood disorders. Neuropsychometric data may be needed to persuade patients to hand over financial or legal affairs to designated executors, or conversely, to persuade family members that the patient is still able to manage for themselves.

Supportive psychotherapists and counsellors are also core members of all but the sparsest rehabilitation teams. Rehabilitation psychologists have extensive experience in discussing loss of function, acceptance of disability, and illness experience with patients but may need to adjust to the impact of treating terminally ill and actively dying patients.

Social workers and case managers promote access to care by facilitating communication among patients, clinicians, and, where appropriate, funders. They often assist families in applying for financial support from charities to pay for home-care equipment needs or transportation to and from therapy centres.

Although there is an impressive overlap between members and goals of the palliative care and general rehabilitation teams, certain distinctions need to be appreciated when requesting rehabilitation specialists to treat palliative care patients. Most significantly, rehabilitation has traditionally been associated with the restoration of function, which may not be possible in the palliative population. In the palliative care setting, this goal is mostly replaced with the aim of maintaining functional independence for as long as possible. During the 1960s, John Dietz, MD, created one of the first cancer rehabilitation programmes through a collaboration between Memorial Sloan Kettering Hospital and the Rusk Institute of New York University. Dietz is best remembered for introducing a widely used, four-track model for the rehabilitation of patients with cancer:

1. Preventive

2. Restorative

3. Supportive

4. Palliative (Dietz, 1969).

Dietz's fourth track, palliative, produced a mandate to provide rehabilitation services tailored to patients with advanced disease. The efficacy of rehabilitation services at the end of life has been most studied among cancer patients, but rehabilitation care providers have also gained a wealth of experience in the treatment of patients with progressive disabilities such as end-stage organ failure or neurodegenerative diseases. The primary treating team may request a rehabilitation medicine consultation for a comprehensive approach, addressing all associated impairments and resulting disability, or they may choose to prescribe discreet therapeutic interventions administered by PTs, OTs, speech language and respiratory therapists, music therapists, and psychologists. While many of these treatments can be initiated directly by patients and their families in the community, they usually require medical staff to drive requests in a hospital setting.

Several large, well-organized cancer centres in the United States and Europe have established successful in-house rehabilitation programmes to meet the needs of their patients throughout the disease continuum. These centres have served as training programmes for more than two generations of rehabilitation specialists interested in end-of-life care (recognized examples in the United States include the M. D. Anderson Cancer in Texas, the Memorial Sloan Kettering Cancer Center in New York, and the Mayo Clinic in Minnesota). smaller cancer centres have sought to follow suit by funding part-time positions for rehabilitation medicine specialists, or paying for specialized training for therapy staff. The presence of rehabilitation specialists on palliative care teams is often reassuring to patients and their families at a time when they feel restorative services may be withdrawn prematurely. In some cases, palliative care patients may require separate admission to an inpatient rehabilitation programme. Short, targeted rehabilitation stays for palliative care patients may be entirely for family or caregiver training, with little expectation of independent functional gains by the patient. In other cases, a combination of functional gains and caregiver training are used to ensure safety, decrease burden of care, and maximize independence for patients returning home. Rehabilitation units associated with cancer centres have often accumulated decades of expertise in designing realistic and effective treatment plans for patients towards the end of life. Free-standing inpatient rehabilitation facilities that wish to begin treating palliative care patients may need to reinforce programme development with educational opportunities for staff who may not have as much experience in treating patients with advanced disease. The psychological demands of working with patients and their families towards the end of life need to be addressed, particularly for staff who may have chosen rehabilitation because of its focus on recovery.

Inpatient rehabilitation programmes can be offered at various levels of intensity and are designed to offer patients access to concentrated services that would otherwise be difficult to obtain and coordinate. Neuropsychologists, speech language therapists, rehabilitation certified nurses, and, in some cases, orthotists, prosthetists, and equipment vendors work with the treating rehabilitation medicine specialist to return patients to the community. Subacute programmes and skilled nursing facilities offer access to some rehabilitation services but at a lesser intensity. Rehabilitation services are provided routinely as part of home care for patients with many diagnoses. The goals of treatment in the home setting focus on the essentials of self-care, transfers, household ambulation, ascending and descending stairs, and perhaps some early community re-entry for patients, with reduced function, PTs and OTs can provide home assessments and direction for effective management. Lowe et al.'s systematic review provides an effective introduction to the emerging field of therapeutic exercise for cancer patients receiving palliative care (Lowe et al., 2009). Preliminary small studies consistently report functional gains in this population. Results have been replicated for aerobic as well as anaerobic and mixed exercise programmes using gentle bicycle ergometry and/or tailored resistance training. Bicycle ergometry regimens can be based on lower extremity pedalling or upper extremity pedalling. Implementing these interventions requires clearly articulated guidelines for common risks and complications that accompany active interventions in patients with advanced disease. Greater than average knowledge of the pathophysiology of advanced cardiovascular, pulmonary, and renal disease is needed for the selection of individualized interventions. Input from PM&R physicians or others trained in medical rehabilitation is strongly recommended at least at the programmatic planning stages.

Strength, endurance, and functional performance gains can be achieved or maintained through supervised home programmes (Cheville et al., 2012a). Therapists should encourage patients and caregivers to take opportunities for self-management once a programme has been designed. Skilled therapy involvement should be reserved for declines in function warranting reassessment and the introduction of new or altered programmes. For patients able to leave their homes, rehabilitation medicine outpatient visits every

4–8 weeks serve as opportunities for readjusting the overall rehabilitation treatment plan during disease progression. Symptom management including neurolytic procedures for excess spasticity, trigger point injections, advanced wound care, and pharmacological pain management are available through most outpatient rehabilitation medicine practices.

Patients with metastatic bone lesions, hemiparesis, or paraparesis may require customized wheelchairs. Improperly selected seating systems can result in skin breakdown as well as reduced performance. Most rehabilitation centres offer skilled medical equipment selection with medical justification for requested components. The introduction of new equipment often requires a period of supervised training for patients and caregivers. Rehabilitation centres should be able to coordinate delivery of these services through outpatient as well as home visits.

Patients able to seek rehabilitation services at an outpatient facility should be encouraged to do so as the capabilities of an outpatient setting far exceed what can be delivered in the home. Perhaps as importantly, patients may benefit from the social aspects of their visits and the inspiration they may experience from their own gains. However, as their disease progresses, patients may find that travel to the centre becomes too difficult. At such times of transition, outpatient therapists and treating rehabilitation medicine specialists should ensure that patients and their caregivers are equipped with a realistic, home-based maintenance programme.

In the final stages of end-of-life care, the role of rehabilitation services shifts towards preventing injury and the safe delivery of care. Positioning, maintenance of skin integrity, pain control, continence, and safe alimentation become priorities. Therapists may return briefly to teach a previously ambulatory patient and their caregivers wheelchair skills or proper use of mechanical lifts. The impact of rehabilitation services for patients at inpatient hospices has not been widely evaluated, however. However, Yoshioka's 1994 study showed functional gains and improved patient and family satisfaction associated with PT services in an inpatient hospice (Yoshioka, 1994).

Massage refers to the manipulation of superficial muscle groups and tissue. Certain techniques achieve deeper effects through specialized strokes or manoeuvres. Massage contributes to rehabilitation goals by direct mechanical effects as well as reflexive and psychological effects. The mechanical effects include the mobilization of oedema within soft tissue and improvements in vascular perfusion. The term reflexive effect is used to describe the influence of cutaneous stimulation on the autonomic nervous system and the spinal cord. The psychological benefits of massage therapy are reflected in the subjective sense of relaxation and well-being experienced during and after treatment.

More participatory forms of bodywork, such as Feldenkrais, Trager psychophysical integration, and the application of Alexander technique, help to address pain and functional deficits by treating underlying systemic dysfunction. The Feldenkrais method, for example, achieves its goals by increasing conscious awareness of bodily positioning and movement habits. This may be extremely important for patients seeking to limit painful and functional side effects of new hemiparesis or increased tone. Other techniques seek to relieve physical symptoms through a combination of bodily, emotional, and cognitive interventions. Trager psychophysical integration uses gentle mobilization via rhythmic oscillations and rocking with the intention of affecting the subconscious mind as well as the body.

While many types of bodywork require one-to-one patient sessions, several movement therapies can be delivered in a group or class setting. Qigong and t'ai chi can offer low-impact, minimal resistance programmes that improve balance, strength, and endurance (Lee et al., 2007). Modified yoga positions can make the benefits of this several thousand-year-old movement therapy available to even the most medically compromised patients (Farrel et al., 1999; Chen et al., 2007).

Many rehabilitation interventions that are used safely in other patient populations may carry increased risk of injury for patients with advanced disease. Pathological fractures, for instance, can occur without apparent trauma. Armed with this information, patients and givers may choose to proceed with interventions that will improve function and QOL, even if there is accompanying risk. Physicians caring for the patient should be able to provide guidelines and precautions for weight-bearing status, range of motion, cardiovascular parameters, and other limitations if indicated.

Assessment of needs, timing, and integration of interventions and goal setting

Assessment

A strong association between functional status and health-related quality of life (HRQOL) has been established for many disease states. This association is particularly well documented for patients with cancer. As a result, almost all QOL metrics used for cancer patients (e.g. EORTC-QLQ-C30, Functional Assessment of Cancer Treatment (FACT), Functional Living Index Cancer (FLIC), and Cancer Rehabilitation Evaluation System (CARES)) include items that assess functional domains (Heinrich et al., 1984; Schipper et al., 1984; Cella et al., 1993; Osoba et al., 1994). Patients wish to remain functionally autonomous for as long as possible. Eighty-eight per cent of the 301 hospice inpatients that participated in Yoshioka's study expressed a strong desire to recover independent mobility (Yoshioka, 1994). A survey of patients with late-stage disease revealed that the 'loss of ability to do what one wants' was rated highest among end-of-life concerns (Axelsson and Sjoden, 1998). Studies have shown that in some cultural settings, functional decline undermines cancer patients' QOL to the point that they may engage in passive suicidal ideation and ultimately express interest in physician-assisted suicide (Fairclough, 1998; O'Mahony et al., 2005; Mystakidou et al., 2006). In fact, functional status was among the strongest predictors of desire for hastened death and pursuit of euthanasia in several studies (van der Maas et al., 1996; O'Mahony et al., 2005).

As many as 70–80% of cancer patients with advanced disease express interest in receiving rehabilitation services and generally find them useful (Yoshioka, 1994; Cheville et al., 2008). Evidence indicates that substantial improvement can be achieved in multiple domains including mobility, self-care, vocational capacity, and communication (Harvey et al., 1982). Reports describe improved outcomes in both inpatient and outpatient settings among patients with central nervous system (CNS) involvement. In fact, their functional gains are comparable to those of patients with similar impairments of ischaemic and traumatic origin (O'Dell et al., 1998; McKinley et al., 1999, 2000). Hospice inpatients can also improve their mobility indices through standard rehabilitation therapies (Yoshioka, 1994). Mitigation of functional

decline through the proactive use of rehabilitation has been demonstrated in patients with inexorably progressive conditions, such as AIDS, progressive multiple sclerosis (MS), and other advanced disease states (Kraft and Alquist, 1996; Hicks, 1999; Yarasheske and Roubenoff, 2001). It is reasonable to generalize these findings and anticipate that functional and QOL maintenance should also be achievable for a proportion of cancer patients as well as those with less well-studied disease processes.

Timing

Joann Lynn and her colleagues have identified trajectories of functional decline in cancer and other illnesses over the last year of life (Lunney et al, 2003). Trajectories are generally characterized by an extended period during which functional capacity remains almost at baseline, with episodes of transient decline in response to disease progression, recurrence, or major disease-modifying therapies. The final phase in advanced disease is often characterized by a dramatic drop in function in the final year or months of life, with marked physical dependency especially in cancer (Cheville et al., 2012b). Many patients arrive at the terminal phase of their disease trajectory having already acquired neuropathies, cognitive deficits, degenerative arthropathies, and other physical impairments that place them at risk of abrupt decline. Determining when to intervene is not always self-evident. The timing of rehabilitation within the complex management of advanced disease is a particularly challenging and under-researched issue. Effective treatments must be delivered expeditiously to patients when they are able to derive the greatest benefits. A number of barriers make it difficult to achieve this goal:

1. Clinicians caring for patients with advanced disease are not necessarily familiar with either the substance or potential benefits of rehabilitation interventions. Consequently, reliable referral patterns are not always established (Beck et al., 2006).

2. Non-rehabilitation clinicians are less likely to screen patients routinely for functional decline. When functional evaluation is not a component of routine care, disability generally receives clinical attention only late in its course, when interventions tend to be less effective.

3. Clinicians may believe that at the stage of illness when disease-modifying therapies are of no further benefit, rehabilitation has similarly little to offer. Ultimately, many non-rehabilitation clinicians have difficulty determining accurately who, when, and why to refer for rehabilitation evaluation and services.

Patient-related barriers also impede the timely involvement of rehabilitation services. Function is not an issue that most patients are accustomed to discussing with their medical caregivers. In fact, they may consider functional decline an inevitable consequence of their condition and not even bring catastrophic declines in their mobility or activity of daily living (ADL) performance to their clinicians' attention (Detmar et al., 2001). Because most rehabilitation interventions require active and ongoing patient participation, patient and support system 'buy in' is essential. Patients must appreciate the need for rehabilitation, recognize future benefit in the process, and perceive meaning in its goals. This level of patient endorsement may occur only after significant functional decline when patients confront dependency.

As delivery of care shifts increasingly from the hospital to the clinic, the need for effective communication both between patients and caregivers as well as patients and their physician will be essential if disability is to be addressed effectively. Failure to address cumulative disability results in patients living at lower levels of function and experiencing more difficulty and distress than is necessary.

Characterizing the magnitude and rate of patients' decline is a challenge. Patients' baseline function, from which they subsequently decline, is also highly variable. Difficulty with an ADL such as dressing or bathing may reflect a drastic and precipitous decline for some patients and virtually no change for others.

It is usually neither fiscally nor logistically possible to have all palliative care patients evaluated by a rehabilitation physician. Elderly patients, or those with multiple co-morbidities and/or a disability at baseline, should be referred for more extensive assessment of their rehabilitation needs. At the very least, such referrals establish a relationship between patients and a rehabilitation team that can be developed in the future. The timing for referral of patients without these risk factors can be based on:

◆ any new or significant basic or instrumental activity of daily living (IADL) difficulty

◆ any new or significant decrease in household or community mobility

◆ frail, ill, or disabled caregiver

◆ recent hospitalization of significant change in medical status (e.g. a period of bed rest, pathological fracture)

◆ symptom (e.g. pain, dyspnoea) interference with function.

Goal setting: foundation, components, and barriers

Foundation

The link between physical impairment and disability has been studied in different populations with advanced disease. In stage IV breast cancer, for example, the most common physical impairments include paraplegia, steroid myopathy, and joint pains (Cheville et al., 2008). These impairments are generally related to disease progression and changes in treatment, and may be associated with abrupt functional decline in the absence of rehabilitation interventions. Pleural or pulmonary compromise can acutely undermine aerobic reserve leading to severe exertional intolerance. Malignant lesions, particularly bone metastases, can undermine the essential supporting structures of the musculoskeletal system. Non-surgical, anti-cancer treatments, including radiotherapy and chemotherapy, can produce disability by injuring muscles and nerves.

Cross-sectional studies in cohorts with advanced lung cancer have demonstrated correlations between fatigue, pain, and functional status (Fox and Lyon, 2006). Pain also correlates strongly with function in other cancer cohorts (Palmore and Cleveland, 1976; Beck et al., 2006). Breakthrough pain, defined as transient increases above baseline that warrant analgesic use, has been identified as an important cause of compromised functional status (Portenoy and Hagen, 1990; Portenoy et al., 1999). A recent longitudinal study established that pain and fatigue ratings, independent of disease progression or the presence of new bone or brain metastases, strongly associate with functional decline

(Cheville et al., 2012b). Therefore, proactive symptom control is an essential component of successful rehabilitation.

The degree to which pain and fatigue engender disability in advanced disease has immediate and practical implications. It has been shown that 75–95% of cancer pain can be controlled through non-invasive means but that these interventions continue to be under-utilized in the home-care setting (Foley, 1985; Levy, 1996; Ferrell et al., 1999; Miaskowski, 2005; McCarberg, 2007). Targeting pain not only addresses an important symptom and source of distress but has the additional documented benefit of limiting functional decline (Hanna et al., 2006).

Studies have determined that patients and their families strive to minimize discussion about caregiving preferences and other disability-related issues, partly because of reluctance to confront the patient's impending decline and partly, in a perhaps misguided effort, to protect one another from psychological stress (Edwards and Forster, 1999; Pecchioni, 2001; Zhang and Siminoff, 2003). Studies that have examined communication patterns between patients and physicians, and between caregiver and physicians, have shown that the needs and desires of patients and caregivers may conflict. Studies of caregivers, after patients' deaths suggest that caregivers would prefer more physician communication regarding the patient's illness (Hanson et al., 1997). These studies indicate that communication preferences cannot be summarized easily. Moreover, they reveal that patients and caregivers may, at times, have diametrically opposed communication needs which in turn can interfere with the selection and implementation of optimal rehabilitation strategies.

Components

Rehabilitation goals should reflect a patient's age, disease, co-morbidities, baseline fitness, and psychological, social, educational, and financial resources. Deitz described four complementary yet distinct function-oriented rehabilitation strategies—preventive, restorative, supportive, and palliative (Dietz, 1969):

1. Preventive rehabilitation seeks to avoid the expected impairments that accompany disease progression. Sitting protocols, for example, limit the physiological impact of prolonged bed rest. The positioning of paralysed limbs and pressure relief techniques are other examples of common preventive interventions. Caregiver education is often highly effective as empowering and informing caregivers can help reduce predictable complications, such as skin breakdown, that result from immobility or poorly managed urinary incontinence.

2. Restorative rehabilitation has as its goal the return of the patient to his or her premorbid level of function. Such approaches are often utilized following intensive oncological or other treatment. Pulmonary rehabilitation can be helpful after thoracotomy or on exacerbation of chronic obstructive pulmonary disease. Other restorative approaches are used to regain upper extremity strength and range of motion after mastectomy or radiation. Structured progressive aerobic conditioning represents a very effective restorative technique for patients undergoing bone marrow transplantation. It can be used judiciously to allow even patients with progressive disease to recover some portion of their premorbid fitness levels.

3. Supportive rehabilitation attempts to optimize functioning in patients with irreversible impairments. Supportive

programmes include the multi-modal techniques used to rehabilitate patients after limb salvage procedures such as internal hemi-pelvectomy. Combined interventions focusing on strength, endurance, proprioception, and balance can create functional ambulatory patterns that compensate for impaired limb and pelvic biomechanics.

4. Palliative rehabilitation includes supportive approaches designed to reduce patients' dependence in mobility and self-care activities. Emotional reinforcement and comfort should be provided concurrently. There are many opportunities for effective intervention. Preservation of bowel and bladder continence, for example, is an important goal for patients with advanced disease. Simple rehabilitation interventions can often extend patients' ability to toilet independently until the very terminal stages of cancer. Anasarca and progressive lymphoedema are common among end-stage cancer patients. Palliative rehabilitation approaches such as lymphatic drainage techniques and multi-layer compression bandaging can minimize oedema, thereby enhancing patient comfort and mobility. These measures also function preventatively to reduce the likelihood of local skin breakdown and associated infections.

Barriers

Uncontrolled pain remains one of the best understood components of functional decline in advanced disease. Integration of rehabilitation specialists in palliative care makes it more likely that incident pain precipitated by movement will be identified and managed with pharmacological as well as non-pharmacological interventions. The control of movement-related pain is essential for the maintenance of functional independence. Poor control contributes to a cycle of decreased activity, decreased autonomy, and deconditioning. Lost functional capacity is much harder to restore, particularly in patients with significant disease burden. A proactive approach to baseline and incident pain management thus preserves function as well as contributing to overall HRQOL in patients with advanced disease.

Palliative caregivers and rehabilitation specialists share an interest in achieving pain control in the home setting. Clinical teams often achieve excellent control of baseline pain but have inadequate opportunity to address movement-related, incident pain. Most patients' situations are in the home setting. Their activity profiles generally become more arduous and specific programmes are needed to manage pain induced by typical, at-home activities. Rehabilitation services can play a vital role in establishing an analgesic regimen that supports activity. Pharmacological approaches alone may not suffice. For this reason, an iterative process of refinement is required whereby interventional and pharmacological analgesic approaches coordinate with rehabilitative efforts in responding to the patient's feedback. Patients and their caregivers must be fully engaged in order to learn and practise compensatory strategies and therapeutic exercises. Sources of poor patient participation, such as depression and delirium, must actively be sought and definitely addressed whenever possible.

Rehabilitation's role in reducing incident pain can generally be fulfilled by using the following steps:

1. Ensure that all sources of pain potentially amenable to disease-modifying treatments (e.g. bone metastases, impingement) are addressed.

2. Confirm that baseline or 'at rest' pain is adequately controlled.

3. Establish that patients have recourse to 'as needed' or 'rescue' analgesic dosing for incident or movement-related pain.

4. Collect a realistic profile of the patient's activities following discharge.

5. Educate patients regarding the general approach and the need to attend carefully to incident- or movement-related pain.

6. Trial the full spectrum of activities with current analgesics, soliciting pain ratings for each activity.

7. If incident or movement-related pain intensity exceeds 5 on an 11-point numerical rating scale, retrial with proactive use of 'as needed' or 'rescue' analgesics. Depending on the agent's pharmacokinetics, a full hour may be required after ingestion to achieve maximal serum levels.

8. Retrial painful activities, soliciting pain ratings for each activity.

9. If incident or movement-related pain intensity remains unacceptable, deconstruct painful activities to identify evocative motions and positions.

10. Implement compensatory strategies and determine whether assistive devices and/or orthoses reduce incident pain.

11. Retrial painful activities, particularly when patients are fatigued, and solicit pain ratings for each activity.

12. If pain intensity remains unacceptable, increase 'as needed' medication dosing, change medication and/or add additional medications specifically targeting incident or movement-related pain. If the pain occurs with high frequency, adjustment of patients' baseline regimen may be indicated.

13. If incident or movement-related pain is severe and focal, interventional analgesic approaches may be indicated.

14. If incident or movement-related pain intensity remains unacceptable, continue to iteratively refine the 'as needed' analgesic regimen.

The analgesic principles governing management of incident pain have been detailed by several authors elsewhere and in chapters in Section 9. The main challenge is in achieving an adequate balance between analgesia and unwanted side effects, especially drowsiness when the patient is at rest. Patients and their caregivers should be educated to assess pain needs throughout the day and time breakthrough medication use appropriately. The negative impact of decreased activity that accompanies over-medication should be explained. All patients started on opioid analgesia should be educated about the need for a concomitant bowel programme and should be instructed in several pharmacological and non-pharmacological management strategies. Efficacy of the accompanying bowel programme should be assessed at each outpatient visit and frequently for patients receiving home care. Patients and their caregivers should be encouraged to bring inadequate pain control or troublesome side effects to their care team's attention so that adjustments can be made.

Symptoms other than pain such as dyspnoea, anxiety, nausea, and orthostatic hypotension may also undermine patients' function and autonomy. Using an iterative approach similar to that outlined earlier for pain management, the rehabilitation team can work with patients and their palliative caregivers to ensure that symptoms are controlled during activity. Rehabilitation techniques, compensatory strategies, assistive devices, and orthotics can be used. Activity-associated anxiety similarly can be managed with behavioural techniques and titration of anxiolytics coupled with rehabilitative strategies. Limiting the functional impact of symptoms requires ongoing assessment by therapists during treatment sessions, effective interdisciplinary communication when control is inadequate, and the coordinated efforts of palliative and rehabilitative clinicians.

Medical team leaders for palliative care patients are expected to coordinate with other medical specialties and to share changes in treatment plan or prognoses with rehabilitation clinicians, as these clearly impact on rehabilitation goals, the discharge disposition, and future equipment needs. The rehabilitation team can deploy its resources most effectively when equipped with current and accurate medical information concerning individual patient status.

Rehabilitation strategies for specific palliative care populations

Rehabilitation interventions in palliative care constitute an ongoing integration of rehabilitation services that may have begun with the initial diagnosis or treatment of the patient's underlying disease. Palliative care patients are able to benefit from carefully selected rehabilitation interventions designed to maintain or, in some cases, even restore key elements of independent function. Many of the rehabilitation strategies used to reduce the impairments and disabilities produced by acute and chronic illness offer significant benefit for patients with advanced disease. Rehabilitation units often develop treatment plans based on the six functional domains for FIM scores (Granger et al., 1990, 1993). These are mobility; self-care; sphincter control (bowel and bladder); communication; and social cognition including social interaction, problem-solving, and memory. Goals in these areas can be assigned by any member of the treatment team and discrepancies should be resolved in interdisciplinary team meetings and with input from the patient and their caregivers. Rehabilitation specialists working with patients who are still able to attend outpatient clinics may find themselves operating more independently, but should make every effort to share their treatment plans with all members of the extended treatment team. Although rehabilitation services can be obtained on an ad hoc basis, patients are best served when specific rehabilitation specialists are consistently part of a palliative care team. Medically trained rehabilitation specialists assist in the selection of appropriate goals for patients by combining knowledge of rehabilitation potential with an understanding of the underlying disease processes.

Rehabilitation of palliative care patients with motor deficits

Specific myopathies as well as neurologically mediated motor weakness occur in many patients with advanced disease. Progressive dystrophies, such as Duchenne muscular dystrophy or fascio-scapular-humeral dystrophy, create an increasing reliance on compensatory strategies and adaptive devices for many years prior to a final or more complete phase of dependence.

Patients with these diagnoses and their families have experienced a gradual loss of function over time and may have a wealth of knowledge and equipment that can be built on, as needs increase. Others, in contrast, may experience more abrupt and unexpected onset of motor deficits when vertebral metastases result in paraparesis or a metastatic brain lesion causes hemiplegia. Almost all people also experience a more generalized loss of motor function due to the complex interaction of cardiovascular, nutritional, and musculoskeletal changes associated with prolonged bed rest and frailty. Understanding the aetiology and physiology of impairments that contribute to motor deficits is essential to optimizing rehabilitation interventions.

Certain impairment groups have been the subject of more extensive clinical research. Paraparesis as a result of spinal cord compression (SCC) occurs relatively commonly in patients with metastatic cancer. Traumatic spinal cord injury (SCI) programmes may effectively address the functional needs of comparably impaired palliative care patients with a minimum of retraining. Palliative care populations with SCC require careful modification of SCI protocols as they have different life expectancies and co-morbidities. Common goals include enhancing the paralysed patient's ability to direct care, integrate compensatory strategies, utilize adaptive equipment, and accept realistic goals based on physiological as well as social and environmental constraints. The restoration of motor function in cancer-related SCC is possible in proportion to the duration of deficits prior to treatment usually with radiation or surgery (Guo et al., 2003).

Patients with intracranial processes resulting in motor weakness benefit greatly from the experience rehabilitation specialists have had with stroke and brain injury patients. Studies comparing the outcomes of patients with intracranial lesions who receive rehabilitation services with the outcomes achieved for stroke patients have consistently shown comparable performance in multiple domains (Marciniak et al., 1996). Patients with pure upper motor neuron or mixed upper and lower motor neuron involvement often have increased tone or spasticity that may benefit from neurolytic or pharmacological interventions. Local injections of phenol or botulinum toxin can be used to prevent contractures and joint deformities for patients with advanced disease states as can passive range of motion and splinting programmes.

Lower motor neuron impairments result in focal deficits producing a flaccid paralysis, although leptomeningeal disease can produce more diffuse patterns of lower motor neuron weakness. Lower motor neuron lesions require greater attention to bracing and positioning, to limit pain or further injury to the affected body parts. Understanding the aetiology and pathophysiology of the motor weakness again directs the selection of rehabilitation interventions. The functional benefits of increased tone that can be used to assist with transfers for patients with upper motor lesions is absent in lower motor injury. Earlier introduction of assistive devices rather than pure compensatory strategies may be required. A universal cuff (Fig. 4.15.1) for holding utensils, grooming, and hygiene aids can significantly improve autonomy for patients with hand weakness from a tumour-related compression of the C8 and T1 nerve roots. A balanced forearm orthosis (Fig. 4.15.2) enhances upper extremity function for patients with compromised proximal strength but preserved distal dexterity. Orthotics may be introduced to stabilize vulnerable joints, although their added weight can be counterproductive in the setting of significant weakness.

Isolated 'foot drop' or anterior tibialis weakness can be treated with dynamic or static ankle–foot orthoses (AFO) depending on clinical presentation. In some cases enhanced knee control can be achieved, despite quadriceps, or hamstring weakness, by altering the degree of dorsiflexion or plantarflexion specified in the orthotic prescription. Orthoses can be extended to encompass the knee (KAFO) but the added weight and cumbersome profile limits their utility. Unless a KAFO meaningfully improves a patient's mobility, limiting lower extremity orthoses to distal stabilization with a solid and supportive AFO sufficiently stabilizes and protects the joint to facilitates transfers, even in a patient with flaccid hemiplegia.

Instruction in compensatory strategies enables patients with motor deficits to remain mobile and accomplish self-care activities. Patients are taught to capitalize on the strength of preserved muscle groups and to modify posture and body mechanics to minimize the secondary complications that result from focal weakness. Appropriately selected assistive devices also facilitate mobility and self-care for patients with motor deficits. Reachers, for instance, permit partially paralysed patients to retrieve objects. Devices developed to assist with specific ADLs may reduce the amount of energy expended on specific tasks, such as dressing. Investment in more expensive DME, particularly power wheelchairs, presents a challenging dilemma for patients with advanced disease. Early, proactive identification of emerging deficits allows

for equipment to be prescribed for more extended periods. In these cases, prescribing physicians and suppliers should incorporate the expectation of further functional decline into the selection of components. Many amyotrophic lateral sclerosis (ALS)/motor neuron disease clinics, for instance, begin by providing power wheelchairs with patient-controlled toggle-steering initially, but with the ability to convert to a companion control, as many patients will lose the ability to operate the device safely.

Rehabilitation strategies for sensory deficits

Sensory deficits may be the result of progressive disease such as diabetes, peripheral nerve impingement by tumour, or neurotoxic treatment effects. Damage to proprioceptive and other sensory nerve fibres can have enormous functional impact on standing balance, ambulation, as well as the dexterity needed for many self-care activities. In some cases, sensory deficits can be expected to subside even in advanced disease, if neurotoxic treatments are stopped or there is tumour response to palliative radiotherapy. The devastating sensory and proprioceptive deficits accompanying advanced diabetes, however, are not reversible.

Protection becomes the primary principle in selection of rehabilitation goals and interventions for patients with sensory deficits. Injury to insensate skin must be avoided at all costs, particularly as healing is often impaired due to a number of factors including nutritional status. All patients with insensate skin and their caregivers should be taught a thorough approach to skin inspection and pressure relief through weight shifts and positioning. Exceptional care, including the provision of specialized ortheses, may be necessary as conventional devices may themselves produce non-healing wounds. Moulded AFOs (Fig. 4.15.3) can be trimmed or reshaped if wearing produces skin chafing and sustained irritation. Foam padding can also be added to enhance tolerance. Impaired hand or upper extremity sensation can also lead to non-healing wounds but the relative visibility of these body parts often results in better protection and more prompt treatment. Patients with impaired upper extremity sensation can benefit from consultation with an OT for an introduction to devices that restore some degree of fine motor function in the absence of sensory input. Enlarged utensil handles, buttoners, and even sock donners allow independent performance of ADLs despite impaired sensation, especially if visual function is spared.

Increased reliance on visual cues enables patients with proprioceptive deficits to achieve some degree of compensation. In addition, indirect positional information or proprioceptive feedback can be transmitted through assistive devices such as canes and walkers for patients with primarily lower extremity proprioceptive losses. In addition to proprioceptive feedback, broad-based devices such as walkers and Zimmer frames provide mechanical stabilization for people with impaired balance. The risk of injury from a fall requires careful assessment of when to limit ambulation or at least unsupervised ambulation altogether. Standard, in lieu of wheeled, walkers offer greater stability for frail patients. Many patients achieve greater autonomy and safety by propelling manual wheelchairs rather than walking shorter distances precariously. Nonetheless, the goal of 'walking again' often drives patients to select less safe and efficient forms of mobility. Assistive devices, particularly walkers/rollators/Zimmer frames and wheelchairs can be viewed as publicly embarrassing emblems of disease and declining function. As with the rehabilitation of

Fig. 4.15.3 Ankle–foot orthosis (AFO).

acute and chronic conditions, rehabilitation in palliative care requires skilful introduction of solutions that may be unpalatable. Interdisciplinary rehabilitation teams including rehabilitation psychologists have experience helping patients move from wishing for a cure to making the most of remaining abilities. Frequently, underlying depression needs to be addressed pharmacologically as well as psychotherapeutically before rehabilitation strategies can be integrated effectively. The importance of patient and family being integrated with professional management is central and is explored more extensively in our concluding remarks.

Rehabilitation for patients with cerebellar dysfunction or movement disorders

Profound mobility and self-care deficits are associated with the cerebellar injuries and movement disorders that occur as the result of metastatic brain tumours and the paraneoplastic syndromes often associated with ovarian and lung cancer (Clouston et al., 1992; Peterson et al., 1992). Patients with movement disorders such as parkinsonism or other causes of dysmetria, with or without tremor, may benefit from weighted utensils and assistive devices, particularly as motor strength is often preserved in these conditions. Safety awareness and fall prevention must be emphasized repeatedly as denial and other causes of diminished insight often cause patients with ataxia to underestimate the impact of their deficits. Therapists can build on patients' instinctive protective mechanisms, such as adoption of a widened base of support, to establish safe movement patterns. Home and environmental modification can improve safety and prevent falls for all patients with movement disorders, including the more diffuse bradykinesia and loss of protective reflexes seen in advanced dementias. Advanced alcohol-related encephalopathies, hereditary, and non-hereditary spinal cerebellar ataxias, and Huntington's chorea require a sophisticated approach to DME prescription. Wheelchair seating systems, for instance, must be selected to provide maximal postural support without compromising freedom of movement more than necessary. Patient ability to self-propel manually, as well as power mobility may need to be reassessed at intervals. Power mobility settings including speed and responsiveness often can be

adjusted to prolong the period of independent mobility in the face of decreasing motor coordination.

Rehabilitation for patients with cranial nerve and mechanical oral motor deficits

Cranial nerve involvement from neoplastic disease, ALS, or MS or other diagnoses can have severe medical and social consequences due to disruption of vision, speech, swallowing, and management of oral secretions. Collaboration with speech therapists, head and neck surgeons, and respiratory therapists may be needed to prevent aspiration pneumonia and ensure adequate oxygenation. Dysphagia and odynophagia can easily compromise nutrition, leading to the various functional and medical problems. Compensatory strategies are available for cognitively intact patients with focal swallowing deficits to help avoid tube feedings or restrictive food consistencies.

Dysarthria can be a devastating symptom for patients who experience a decreasing ability to make their needs known during a period of increasing dependence. In certain cases, intelligibility can be enhanced through compensatory strategies that increase respiratory support for vocalization, by introducing energy conservation techniques and the use of rest breaks. In other cases, augmentative communication devices from simple picture boards and artificial larynxes to computer interfaces that permit word or letter selection are more helpful. Family and caregiver education and training is also essential for diffusing the inevitable frustration of patients who lose the ability to communicate as part of a terminal illness.

Many, but not all, rehabilitation interventions for visual loss, field cuts, or oculomotor compromise remain effective in the palliative care setting. Few patients are going to learn to read Braille during the terminal phases of a disease but many of the other resources developed for the visually impaired in general, such as recorded books, textured organizational tools, and other adaptive equipment, can be used by people with diabetic retinopathy, optic chiasm tumours, or other diagnoses that impair visual function.

Rehabilitation opportunities for patients with cognitive dysfunction

Cognitive deficits increase caregiver burden, create safety concerns, and degrade interpersonal relations. Brain metastases can create deficits such as apraxia, alexia, and aphasia that have wide-reaching impact on numerous areas of independent function. Neurodegenerative processes often impair higher-level cognitive function, short-term memory, and attention, while also creating disturbances in executive function and emotional control. Treating clinicians need to be familiar with algorithms for distinguishing reversible from irreversible causes of cognitive dysfunction among palliative care patients. Urinary tract infections, medication effects, and other reversible causes of delirium are especially prevalent in medically compromised populations. Non-reversible deficits may resemble the more discrete aphasias associated with specific CNS lesions or present as more diffuse cognitive slowing and near-somnolence which can occur as a delayed effect of cranial irradiation.

Speech language therapy and cognitive interventions used for stroke and brain injury patients can result in modest but meaningful functional gains for terminally ill patients. Memory books and computerized prosthetics as well as pharmacological management of agitation or disrupted sleep–wake cycles can improve overall cognitive performance. Training of family, friends, and caregivers is often necessary to ensure continuity and the incorporation of compensatory strategies and other tools. Although time-consuming and only partially effective, these efforts engage patients and their support networks, often creating a sense of helping to make things better at a time that may otherwise be characterized by an overwhelming sense of helplessness and futility.

Rehabilitation strategies for patients with deconditioning

Deconditioning is one of the most widespread physical impairments to occur at the end of life. Many factors including anaemia, dyspnoea, pain, disrupted sleep, nausea, fatigue, orthostatic hypotension, and cachexia result in decreased activity tolerance and accelerate the downward spiral of progressive deconditioning. Rehabilitation interventions for patients with deconditioning in the setting of advanced disease can be divided into approaches that restore or preserve function and those that mitigate the effects of decreased endurance through compensatory strategies and environmental modification.

Therapeutic exercise, particularly for patients with advanced disease, should always be prescribed with careful attention to intensity, modality, and duration as well as the clear articulation of therapeutic goals and necessary precautions. Safe intensities are best understood for patients with advanced cardiac conditions but guidelines are emerging for other diagnoses (Bartels, 2000). Realistic goal selection will determine the choice of modalities although optimal programmes generally mix some proportion of flexibility, aerobic, and resistance or strengthening exercises tailored to the patient's current potential. Active and passive range of motion programmes are important for maintaining the ability to achieve comfortable positioning while also preventing pressure ulcers and limiting joint contractures that may impede hygiene, dressing, and other aspects of self-care. Therapeutic aerobic programmes in patients with advanced cancer have demonstrated the possibility of physiological as well as functional improvement provided that disease progression does not outstrip training effect. A graded conditioning programme can be prescribed for motivated patients. Studies of the efficacy of resistance training and strengthening programmes in androgen-deprived men with prostate cancer have proven the possibility of maintaining or even improving strength in the context of malignancy (Segal et al., 2003). Improved peripheral muscle efficiency often allows patients with pulmonary and cardiac compromise to accomplish more, despite fixed or worsening respiratory and cardiovascular function. Combining strength training with functional activities, such as sit-to-stand transfers is often an efficient way to design exercise programmes for compromised patients with little time or endurance for multi-modal protocols.

Patient safety and, at times, medical liability require careful delineation of exercise precautions. These should include limitations for patients with thrombocytopenia, weight-bearing restrictions for patients with bone metastases, or bracing requirements for patients with spinal instability.

Caregiver support

Palliative care has long recognized that effective interventions require attention to the larger context of patient, family, and social support networks. As disability accrues, these family and social networks may begin providing an increasing proportion of daily care. In their

Fig. 4.15.4 Bath chair.

recent analysis of the needs of family caregivers, Rabow and colleagues identified five burdens that can overwhelm giver resources:

1. Time and logistics

2. Physical tasks

3. Financial costs

4. Emotional and mental health risks

5. Other health risks (Rabow et al., 2004).

Short, focused inpatient rehabilitation stays or intensive teaching prior to discharge from an acute medical service can improve markedly patient safety and decrease caregiver burden. Caregivers should understand the biomechanics of patient transfers that protect both their own and the patient's body. Review of bowel and bladder programmes limits symptomatic and medical complications after discharge and is central to the protection of sacral skin, the prevention of sacral wounds, and minimization of the psychological distress accompanying adult incontinence. Rehabilitation nurses have experience in teaching complex wound care techniques as well as skin protection through pressure relief and positioning. Caregiver training by rehabilitation specialists reduces the risk of injury to patients or their assistants and can conserve time and energy for both by introducing labour-saving devices such as mechanical lifts, stair glides, ramps, wheelchairs, transfer boards, and bathing aides (Fig. 4.15.4). Follow-up training can be provided by home therapists as needs change. Caregiver training also alleviates some of the emotional and psychological stressors that burden patients.

Effective caregiver training includes the patient as much as possible given their current functional capacity. At a minimum, efforts must be made to explain techniques carefully to patients and to maximize their ability to direct their own self-care. Caregivers and, to some extent, patients should be trained to instruct others to allow for intervals of respite care.

Current barriers

All rehabilitation medicine's diagnostic and therapeutic effort is expended on enhancing or preserving patients' capacity for independent mobility, self-care, communication, and cognition. Diseases, their treatments, and their symptoms are only relevant to the rehabilitation paradigm in the manner in which they threaten or potentiate function.

Current clinical practices in palliative care rehabilitation are largely based on the consensus statements for specific disease types (e.g. National Comprehensive Cancer Network), evidence derived from the early or acute stages of disease (e.g. aerobic conditioning during adjuvant chemotherapy), isolated case reports, and common sense. In areas where literature exists, such as acute rehabilitation of cancer patients, study cohorts are generally defined by diagnoses rather than disease stage. Therefore uncertainty remains as to subjects' prospects for disease modification or cure and the proportion of their care delivered with palliative intent. As a result, limited inferences can be made as to the efficacy of rehabilitative interventions in far-advanced disease. At present, honest recognition of rehabilitation's incomplete evidence base in the palliative setting is the best means of preventing inappropriate adherence to therapies of equivocal benefit. The clinician must continuously ground him- or herself by asking, 'Will this improve or better maintain my patient's function?'

Burnout, compassion fatigue, and moral distress in palliative care

Nathan I. Cherny, Batsheva Werman, and Michael Kearney

Introduction to burnout, compassion fatigue, and moral distress

Work in palliative care and, in particular, end-of-life care is associated with inherent stressors that may impact on the well-being of clinicians working in the field. Work stressors may have diverse impacts on the emotional and professional lives of palliative care and hospice staff; not only to physicians and nurses but to all members of the professional staff and, in some cases, to volunteers as well. Through their impact on professional function, these stressors can adversely affect the effectiveness and quality of care and may compromise the ability to sustain a career in palliative care.

Clinicians involved in the provision of palliative care constantly confront professional, emotional, and organizational challenges. These challenges, especially when workplace support is limited, can make clinicians vulnerable to experiencing one or more of three well-described interrelated syndromes—burnout, compassion fatigue, and moral distress—each of which can lower the threshold for the development of the others (Sundin-Huard and Fahy, 1999; Keidel, 2002; Hamric et al., 2006; Pendry, 2007; Alkema et al., 2008; Newell and MacNeil, 2010; Maiden et al., 2011; Slocum-Gori et al., 2013) (Fig. 4.16.1).

Burnout results from stresses that arise from the clinician's interaction with the work environment (Maslach et al., 2001), compassion fatigue evolves specifically from the relationship between the clinician and the patient (Booth, 1991), and moral distress is related to situation in which clinicians are asked to carry our acts that run contrary to their moral compass. Clinicians who care for dying patients are at risk of all of these (Rohan, 2005) and they can be emotionally, personally, and professionally devastating. It is vital, therefore, that palliative care clinicians are aware of these potential problems and with strategies to mitigate risks and to manage them when they present either in their own individual lives or in the work environment.

Burnout

The burnout syndrome is characterized by losing enthusiasm for work (emotional exhaustion), treating people as if they were objects (depersonalization), and having a sense that work is no longer meaningful (low personal accomplishment). It relates to work (particularly human service work) and it is often present when individuals work under constant pressure. *Emotional exhaustion* refers to feelings of being overextended and depleted of one's emotional and physical resources. Exhaustion prompts efforts to cope by distancing oneself emotionally and cognitively from work (Maslach and Leiter, 2008). *Depersonalization* refers to negative, callous, cynical, or excessively detached responses to various aspects of the job and is another form of distancing (Maslach and Leiter, 2008). *Lack of personal accomplishment* refers to feelings of being ineffectual and underachieving at work.

These feelings may arise from a lack of resources (e.g. critical information, tools, or time) to get the work done, from overload, or from specific other stressors which may be directly related to emotional exhaustion and depersonalization or be independent of them (Maslach et al., 2001; Maslach and Leiter, 2008). Burnout tends to spread gradually and continuously over time unless circumstances alter or active steps are taken to address the factors contributing to work stress.

Better understanding of burnout can be gained by an understanding of its opposite: job engagement. Job engagement is characterized by energy, involvement, and efficacy in the workplace. Many clinicians working in palliative care express a sense of competence, pleasure, and control in their work (Vachon, 1995, 2008). Factors contributing to this desirable professional/emotional situation include feeling professionally competent and able to cope with challenges, having sustainable workload, feelings of choice and control, appropriate recognition and reward, having a supportive work environment, being treated fairly, and having a strong appreciation of the meaning and value of one's work.

Farber (Farber, 2000; Montero-Marin et al., 2009) proposed three different subtypes of burnout: 'frenetic', 'under-challenged',
Fig. 4.16.1 The relationship between moral distress, compassion fatigue, and burnout.

and 'worn-out'. The *frenetic type* is overinvested and works extremely hard (to the sacrifice of other personal needs) and is frustrated and distressed by the lack of proportionate satisfaction: success, reward, or appreciation. The *under-challenged type* is indifferent as a result of insufficient challenge, stimulation, or meaning from work. The *worn-out* type is neglectful as a result of having been overwhelmed by too much work stress and lack of proportionate satisfaction, success, reward, or appreciation for the stresses that are endured.

Symptoms and signs of burnout

Burnout ca-n effect individuals or, sometimes, whole teams. Some of the common presenting symptoms are described in Box 4.16.1.

Factors that contribute to burnout

The actors that contribute to burnout are complex and are often interrelated.

Box 4.16.1 Symptoms and signs of burnout

Individual

- Overwhelming physical and emotional exhaustion
- Feelings of cynicism and detachment from the job
- A sense of ineffectiveness and lack of accomplishment
- Avoidance of emotionally difficult clinical situations
- Irritability and hypervigilance
- Interpersonal conflicts: over-identification or over-involvement
- Perfectionism and rigidity
- Poor judgement: professional and personal boundary violations
- Social withdrawal
- Numbness and detachment
- Difficulty in concentrating
- Questioning the meaning of life
- Questioning prior religious beliefs: sleep problems, intrusive thoughts, and nightmares
- Addictive behaviours
- Frequent illness: headaches, gastrointestinal disturbances, immune system impairment.

Team

- Low morale
- High job turnover
- Impaired job performance (decreased empathy, increased absenteeism).

Source: data from Maslach, C., et al., Job burnout. *Annual Review of Psychology*, Volume 52, pp. 397–422, Copyright © 2002 and Vachon, M. L., Staff stress in hospice/palliative care: a review, *Palliative Medicine*, Volume 9, Number 2, pp. 91–122, Copyright © 1995.

Workload

Workload has been identified as a major stressor for palliative care clinicians (Newton and Waters, 2001; Payne, 2001; Rokach, 2005) especially in settings of staff shortages and financial restraint. Dealing with dying patients and their families, excessive caseload of challenging patients and families, inadequate supports, excessive bureaucracy, and lack of time to talk to patients have all been identified as workload stressors. The greater the mismatch between the person and the work environment, the greater is the likelihood of burnout (Maslach and Leiter, 2008). A clear relationship between nursing shortages, understaffing, and burnout among nurses has been demonstrated (Toh et al., 2012).

Control (and training)

A sense of personal control helps people maintain emotional stability and cope with challenges in life. Perceived lack of control and actual lack of control over aspects of one's professional life are both associated with burnout (Glass et al., 1993). Lack of control may be intrinsic, related to lack of competence to cope with the challenges of patient care, self-care, or professional team dynamics. Extrinsic lack of control may relate to organizational structure or style within the work environment.

When clinicians are expected to take responsibility with inadequate training they may experience extreme lack of control. Among palliative care clinicians this may occur if they lack knowledge in interpersonal or communication skills or specific management skills in palliative care. Clinicians with inadequate training in skilled communication (Shimizu et al., 2003; Travado et al., 2005; Bragard et al., 2010), stress management (Bragard et al., 2006), recognition and management of compassion fatigue (Slocum-Gori et al., 2013), conflict resolution (Montoro-Rodriguez and Small, 2006), and symptom control all have a higher risk of burnout (Keidel, 2002; Cherny and Catane, 2003; Bar-Sela et al., 2012; Caruso et al., 2012; Fang et al., 2012).

Extrinsic lack of control may relate to any one or a combination of the following factors: work conditions, scheduling of work hours, patient allocation, patient load, clinical decisions, or organization decisions. Nurses, social workers, and other para-medical staff often feel disempowered, especially in the setting of hierarchical (or vertical) team management styles and in particular by authoritarian decision-making by physician partners who ignore or minimize the significance of their input or judgements.

Interprofessional and team issues

Team conflict, particularly between doctors and nurses or among nurses or between other members of the care team all contribute to burnout (Payne, 2001; Garman et al., 2002; San Martin-Rodriguez et al., 2005; Estryn-Behar et al., 2007; Brinkert, 2010; Bowers et al., 2011; Lasebikan and Oyetunde, 2012). Characteristics commonly seen in poorly functioning interdisciplinary care teams include lack of collaborative practice among professionals, strong hierarchical characteristics, lack of a shared philosophy of care, stifled expression of concerns, and strong professional territoriality. Often conflicts are generated by lack of common understandings of the prevailing goals of care, role diffusion issues, or differences of opinion regarding the appropriate clinical management or issues related to management style (San Martin-Rodriguez et al., 2005; Brinkert, 2010).

Values

Attitudes of clinicians towards palliative care and communication impact how care is implemented (Cherny and Catane, 2003; Lloyd-Williams and Dogra, 2003; Schreiner et al., 2004; Addington-Hall and Karlsen, 2005; Cherny, 2010). There is evidence demonstrating that the degree of congruity between personal values and the values central to the work environment predict for feelings of energy, involvement, and efficacy which are essential for job engagement (Leiter, 2008; Leiter et al., 2009). For instance, oncologists who do not highly value the psychosocial aspects of care and investment in the relief of physical, psychological, and spiritual distress report greater burnout (Cherny and Catane, 2003) and describe a greater degree of burnout, a sense of failure at not being able to alter the course of the disease (Jackson et al., 2008) when working with palliative care patients.

Moral distress (see later section) arising from situations in which one is expected to perform duties that run contrary with one's moral compass may be a major stressor contributing to distress and burnout (Sundin-Huard and Fahy, 1999). Indeed, one of the factors contributing to moral distress derives from having difficulty getting up to one's own standards or to an idealized, and often unattainable, vision of palliative care for the provision of a 'good death'.

Reward

Limited or inadequate financial rewards for the extremely challenging work of palliative care can contribute to burnout. Lack of reward may also relate to the lack of institutional reward to support the development of palliative care services or to provide for the psychosocial and supervision requirements of the clinical staff.

Emotion-work variables

Caregivers dealing with patients who die, particularly those who have had long-term relationships with their clients may experience feelings of grief, loss, or chronic grief (Vachon, 1999; Merluzzi et al., 2011). Coping with grief reactions may be challenged when patients or their children are young, when the distress and symptoms of the patient were not well controlled, and when staff feel that they were unable to deliver the best possible care to the patient when the death was contextually inappropriate such as deaths arising from the side effects of treatment. Repeated intense involvement with the distress of patients and their families in the time leading up to and after the death can traumatize health-care providers and contribute to 'the compassion fatigue syndrome' (Keidel, 2002; Rourke, 2007; Slocum-Gori et al., 2013) (see later) with its consequences which may include avoiding contact with patients, a negative self-assessment of performance, and a host of other responses that may adversely impact on personal and professional well-being and function.

Intrinsic to the challenge of providing palliative care is a delicate balance of maintaining warm supportive contact to those facing death while at the same time finding ways of not being overwhelmed by the patient's suffering, and by the challenges and burden of trying to ease that suffering.

Extrinsic factors

Palliative care staff may also have personal sources of pressure outside of the work environment. These include family, financial

health, and societal pressures, limited supports, and problems with interpersonal relationships unrelated to their roles as carers (Keidel, 2002). Professional caregivers with more responsibility for their own children or elderly parents, report more stress (Kash et al., 2000). For both women and men, the greater the number of children at home, the more difficulty with work-life balance and emotional exhaustion (Keeton et al., 2007). Being single, however, is also an independent risk factor for burnout (Ramirez et al., 1996).

Personality factors

Overinvested, highly motivated health professionals with intense investment in their profession are at a greater risk for the development of burnout (Leiter and Maslach, 2005; Anewalt, 2009). They become overinvolved and are constantly exposed to experiences of loss, awareness of their own mortality, and the termination of intense relationships (Keidel, 2002). Clinicians with this trait often display diminished awareness of their own physical and emotional needs, thus contributing to a self-destructive pattern of overwork (Anewalt, 2009). This may express itself in a 'psychology of postponement', in which they repeatedly defer attending to their significant relationships and other sources of personal reward until all the work is done or the next professional challenge is achieved (Spickard et al., 2002). A compulsive triad of an exaggerated sense of responsibility, doubt, and guilt can have an enormous impact on clinicians' professional, personal, and family lives (Spickard et al., 2002; Shanafelt et al., 2006).

Demographic variables associated with burnout

Age

Younger caregivers report more stressors and exhibit more manifestations of stress and fewer coping strategies (Vachon, 1995); they are more prone to burnout and stress reactions (Graham et al., 1996; Ramirez et al., 1995, 1996; Kash et al., 2000; Taylor et al., 2005; Kuerer et al., 2007). In contrast, some studies have found that caregivers with more years of experience are less likely to report stress-related symptoms and burnout (Vachon, 1995; Whippen et al., 2004); this, however, has not been a consistent finding (Allegra et al., 2005).

Gender

The data on gender as a risk factor is conflicted and inconclusive. Although most studies show women to be at higher risk for burnout and mental health problems (Graham et al., 1996; Kash et al., 2000; Kuerer et al., 2007), two surveys on the mental health of UK National Health Service physicians (880 consultants in 1994 compared with 1308 in 2002) found male and middle-aged consultants to be particularly at elevated risk (Taylor et al., 2005).

Epidemiology of burnout in oncology and palliative care

There has been considerable research into the epidemiology of burnout in palliative care (Masterson-Allen et al., 1985; Bram and Katz, 1989; Nash, 1989; Mallett et al., 1991; Ramirez et al., 1995; Vachon, 1995, 1999; Keidel, 2002; Swetz et al., 2009; Ostacoli et al., 2010; Pereira et al., 2011; Huynh et al., 2012; Slocum-Gori et al., 2013) and in oncology (Costantini et al., 1997; Kash et al., 2000; Lyckholm, 2001; Whippen et al., 2004; Allegra et al., 2005; Asai et al., 2006; Sherman et al., 2006; Balch and Copeland, 2007;

Kuerer et al., 2007; Arigoni et al., 2008; Liakopoulou et al., 2008; Alacacioglu et al., 2009; Mukherjee et al., 2009; Ostacoli et al., 2010; Shanafelt and Dyrbye, 2012).

A number of studies have reported that clinicians involved in palliative care had neither more nor less stress and burnout than other health professionals (Vachon, 1995, 2008; Pereira et al., 2011). Some studies seem to indicate that palliative care clinicians have lower burnout levels (in all three dimensions), particularly when compared with physicians practising in other fields such as oncology (Ramirez et al., 1995; Schraub and Marx, 2004; Asai et al., 2006; Fanos, 2007). These results may derive, in part, from the self-selection of people with congruent personal and professional values who chose to work in palliative care and the support palliative care team members give to one another (Vachon, 1995; Pierce et al., 2007).

Consequences of burnout

Dissatisfaction and distress caused by burnout have significant costs for clinicians and their families, their patients, and the health-care settings in which they work. Burnout alters both the physician–patient relationship and the quality of care clinicians provide (West et al., 2006). High levels of burnout are associated with diminished empathy and compassion, lack of professionalism, and increased risk of making medical errors (West et al., 2006; Halbesleben et al., 2008; Sharp and Clancy, 2008; Ida et al., 2009). Clinicians who manifest burnout are more likely to endorse euthanasia or assisted suicide as appropriate end-of-life options (Portenoy et al., 1997). Given the potential human costs of medical mistakes, the emotional impact of actual or perceived errors can be devastating for clinicians. Burnout also appears to influence the degree of trust and confidence patients have in their treating clinicians and patients' satisfaction with their medical care (Halbesleben and Rathert, 2008).

In addition to these professional repercussions, burnout can have profound personal consequences for clinicians, including depression, substance abuse, intent to leave clinical practice, and even suicide (Vachon, 1995, 1999; Kuerer et al., 2007). Rates of psychiatric disturbances, including depressive symptoms, anxiety, and sleep disturbances (Grunfeld et al., 2000; Kash et al., 2000; Asai et al., 2006), in clinicians working in end-of-life care ranged from 12% in a study of palliative care physicians (Asai et al., 2006) to between one-quarter and one-third of oncologists in other studies (Grunfeld et al., 2000; Kash et al., 2000; Asai et al., 2006).

Factors mitigating burnout

Some researchers have focused on factors that promote a sense of well-being and which mitigate against the effects of stress. Among the factors identified were self-awareness, hardiness (resilience), promoting a sense of control, and good team function (Ablett and Jones, 2007).

Attitudes and values

Clinicians who strongly identify with the values central to palliative care are more likely to experience and to express feelings of energy, involvement, and efficacy which are essential for job engagement (Leiter, 2008; Leiter et al., 2009). Engaged palliative care clinicians often relate to their commitment to making the most out of life and out of relationships, they derive meaning from their contributions to the well-being of the patients and families they care for, they have realistic expectations as to what they can achieve, they are forgiving of themselves and of their colleagues when outcomes are less than optimal and they recognize that flexibility and compromise is often necessary in order to maintain coping.

Good team work

There is a substantial and growing body of evidence that well-functioning interdisciplinary team work characterized by shared philosophy of care, respectful interdisciplinary relationships, mutual trust and support, and strong culture of communication can mitigate the risk of burnout (Garman et al., 2002; Estryn-Behar et al., 2007; Bowers et al., 2011).

Resilience (hardiness) and coherence

The personality characteristic of hardiness or resilience is expressed as a sense of commitment, control, and readiness to meet and to cope with challenges (Sotile and Sotile, 2003; Nygren et al., 2005; Ablett and Jones, 2007; Swetz et al., 2009; Howe et al., 2012). Commitment refers to a sense of meaning and purpose in one's professional life; control refers not only to autonomy but to a feeling of empowerment to make a difference and to cope with challenges; and challenge relates to the ability to address new changes that, while not necessarily desired, are anticipated as an inevitable part of life. Resilience is related to a 'sense of coherence' which is a perception of one's life as being comprehensible (cognitively meaningful and predictable), manageable (personal resources sufficient to meet internal and external demands), and meaningful (life is emotionally meaningful and that problems are perceived as challenges rather than hindrances) (Antonovsky and Sagy, 1986; Nygren et al., 2005) (see Chapter 17.2).

Control (and training)

As described above, control is one of the elements contributing to resilience. A sense of competence, control, and pleasure in one's work were among the highest ranked coping mechanism of 584 caregivers to the critically ill, dying, and bereaved (Vachon, 1995). Competence and, more importantly, the perceived self-evaluation of competence of the clinician, are related to the adequacy of training. Training in palliative care, communication skills stress management, and conflict resolution reduces the likelihood of burnout (Fallowfield et al., 2002, 2003; Armstrong and Holland, 2004; Holland and Neimeyer, 2005; Jones, 2005; Bragard et al., 2006; Shanafelt and Dyrbye, 2012; Shanafelt et al., 2012).

A sense of control is also reflected in studies looking at sources of satisfaction from work in palliative care. Professional achievements such as successful engagement with patients and their relatives, helping dying people find meaning in suffering and death, and providing adequate comfort and support have all been identified as sources of personal reward derived from palliative care provision (Graham et al., 1996; DeLoach, 2003; Boston and Mount, 2006; Clark et al., 2007; Pierce et al., 2007; Slocum-Gori et al., 2013).

Use of wellness strategies

Multiple studies have demonstrated improved work satisfaction in clinicians who used wellness strategies in caring for themselves as they care for others (Shanafelt et al., 2005a, 2012; Balch and Copeland, 2007; Anewalt, 2009; Campbell, 2010) (see Box 4.16.2).

Box 4.16.2 Measures that may help prevent burnout and compassion fatigue

Personal wellness strategies

These include strategies that attend to personal, familial, emotional, and spiritual needs while attending to the needs and demands of patients. Suggestions for developing a good self-care plan that can minimize the impact of compassion fatigue include (Rourke, 2007):

1. Getting adequate sleep, good nutrition, and regular exercise (Jones, 2005; Wallace et al., 2009; Swetz et al., 2009; Newell and MacNeil, 2010).

2. Building relaxation into most daily activities including the regular use of tools such as meditation, deep breathing, visual imagery, and massage (Swetz et al., 2009; Wallace et al., 2009).

3. Engaging regularly in a non-work-related activity to rejuvenate and restore energy, commitment, and focus (Jones, 2005; Lovell et al., 2009; Swetz et al., 2009; Wallace et al., 2009).

4. Develop your supportive and enjoyable relationships with family and friends outside of work (Keidel, 2002).

5. Maintaining a good balance between work, family, and pleasurable activities to defuse work-related tensions (Lovell et al., 2009; Swetz et al., 2009; Wallace et al., 2009; Newell and MacNeil, 2010).

6. Monitor oneself for tendency to being over involved (Keidel, 2002).

7. Finding and allowing adequate personal time to grieve losses that come with losing a patient with whom one has a special bond (Wallace et al., 2009).

8. Self-awareness techniques including mindful communication (Jones, 2005; Shanafelt et al., 2005b; Harrison and Westwood, 2009; Rushton et al., 2009; Goodman and Schorling, 2012) and/or reflective writing (Bernardi et al., 2005, Fearon and Nicol, 2011, Meier et al., 2001, Coulehan and Granek, 2012, Wald et al., 2010).

9. Developing a specific set of coping skills, stress management, organization, time management, communication, and cognitive restructuring, to ease the challenges of day-to-day issues (Jones, 2005; Perry, 2008; Lovell et al., 2009; Newell and MacNeil, 2010).

10. Relying on psychotherapy or spiritual care, particularly for staff who are experiencing very strong emotional reactions to their work, staff who are strongly reminded of their own personal losses frequently, and those with no clear confidante in their daily lives (Holland and Neimeyer, 2005; Sinclair and Hamill, 2007; Newell and MacNeil, 2010).

11. Attending to one's spiritual needs and developing a philosophy of care that provides personal meaning and a sense of purpose in the delivery of palliative care (Holland and Neimeyer, 2005; Sinclair and Hamill, 2007; Swetz et al., 2009; Newell and MacNeil, 2010).

Professional development strategies

These approaches must recognize the realities of working in palliative care: many people die from their diseases and health-care providers are limited in their ability to relieve a patient's and family's suffering.

1. Remember who owns the problem: be interested in and challenged by your patient's physical, emotional and spiritual problems but don't make them your own.

2. Learning to handle conflict effectively (Jones, 2005).

3. Training in communication skills (Fallowfield et al., 2002; Fallowfield et al., 2003; Armstrong and Holland, 2004; Jones, 2005; Bragard et al., 2006; Shanafelt and Dyrbye, 2012; Shanafelt et al., 2012).

4. Maintaining a high level of clinical knowledge and familiarity with established clinical guidelines for management of common problems (Holland and Neimeyer, 2005; Rushton et al., 2009).

5. Engaging in peer consultation (most helpful if it occurs in a safe, confidential, and non-judgemental environment with conscious avoidance of catastrophization) (Perry, 2008; Swetz et al., 2009).

6. Developing assertiveness skills including learning to set limits, to say 'no', and to ask for what you need (Keidel, 2002).

7. Being clear and consistent with oneself and others about boundaries and personal limit-setting including taking vacations and limiting overtime and time on-call (Jones, 2005; Perry, 2008; Swetz et al., 2009; Newell and MacNeil, 2010) and maintaining a sustainable workload (Maslach et al., 2001; Jones, 2005; Kuerer et al., 2007; Maslach and Leiter, 2008).

8. Diversifying one's workload, so that not all professional time involves providing care to the most distressed patients. Examples include adding research, teaching, or other activities to round out clinical service (Quill and Williamson, 1990; Levine et al., 2005; Kuerer et al., 2007; Le Blanc et al., 2007).

9. Continuing educational activities (Robinson et al., 2004; Kuerer et al., 2007).

Box 4.16.2 Continued

10. Identifying the one or two scenarios that are most difficult and exhausting for a professional, and identifying and reviewing potential responses to use when these situations arise.

11. Finding and focusing on the positive features of one's own and one's patients' experiences (Jones, 2005; Perry, 2008; Swetz et al., 2009).

12. Connecting regularly with a respectful team of professionals that meets regularly and shares a common goal or mission (Jones, 2005; Sinclair and Hamill, 2007; Swetz et al., 2009).

13. Develop an approach/philosophy to dealing with death/end-of-life care (Jones, 2005; Shanafelt et al., 2005a).

Organizational strategies

The organization within which any palliative care provider works sets the stage for how stressful the work is, and for how effectively the provider is able to defuse that stress. It is essential that health-care organizations allocate adequate resources necessary to do the job well and provide structures for addressing compassion fatigue (Pisanti et al., 2011).

Organizations can be the focus for important interventions to prevent or reduce burnout and compassion fatigue. Some strategies that may move organizations closer to these goals include:

1. Providing adequate resources for the job, including regular and supportive supervision, continuing education opportunities, days off without undue hassle, appropriate benefits, and an overall positive work climate (Jones, 2005; Sinclair and Hamill, 2007; Newell and MacNeil, 2010; Pisanti et al., 2011).

2. Ensure schedules that accommodate work–life balance for providers as much as possible (Jones, 2005; Sinclair and Hamill, 2007; Perry, 2008; Swetz et al., 2009).

3. Providing clinical staff with physical settings that are comforting or soothing and offering meeting spaces that are appropriately furnished and private (Pisanti et al., 2011).

4. Encouraging and supporting choice and control (Shanafelt et al., 2006) and promoting fairness and justice in the workplace (Maslach et al., 2001; Maslach, 2003; Jones, 2005).

5. Appropriate recognition and reward (Maslach et al., 2001).

6. Developing a supportive work community (Maslach et al., 2001; Maslach and Leiter, 2008).

7. Adequate supervision and mentoring (Graham and Ramirez, 2002; Jones, 2005; Mackereth et al., 2005; Balch and Copeland, 2007).

8. Providing space for personal items that anchor clinicians to their lives outside of work (Pisanti et al., 2011).

9. Developing an atmosphere of respect for the work performed by palliative care clinicians (Jones, 2005; Pisanti et al., 2011).

10. Open acknowledgement, in routine and in education programmes, that compassion fatigue is an expected occupational hazard, not a weakness (Sinclair and Hamill, 2007; Newell and MacNeil, 2010).

11. Developing an interdisciplinary care team with an ethos of collaborative practice among professionals that values participation, fairness, freedom of expression, and interdependence (Jones, 2005; Sinclair and Hamill, 2007; Swetz et al., 2009).

12. Regular discussions of challenging cases, in which all team members, regardless of role, are encouraged to contribute, in an atmosphere that is safe supportive and which avoids catastrophization.

13. Mindfulness-based stress reduction for team (Cohen-Katz et al., 2004, 2005a, 2005b).

14. Meaning-centred intervention for team (Fillion et al., 2009).

Strategies particularly focused in improving self-awareness are discussed later in the section on 'Self-awareness (mindfulness) strategies'.

Spirituality and meaning

Studies of caregivers in end-of-life care have highlighted the importance of spirituality and meaning in preventing burnout (Holland and Neimeyer, 2005; Boston and Mount, 2006; Harrison and Westwood, 2009). Caregivers in oncology who rated themselves as being religious had a decreased risk of burnout (Kash et al., 2000). Huggard (2008) studied 230 New Zealand physicians and found an inverse correlation between burnout and spirituality.

Reducing burnout

Reducing burnout and promoting job engagement must include three dimensions: personal care, professional development, and infrastructural initiatives. Practical measures that may be used to reduce burnout and promote job engagement are outlined in Box 4.16.2. If distress persists despite use of these practices, and particularly if any objective impairment in functioning occurs, the clinician should seek psychiatric evaluation and treatment.

Administrators and clinical leaders have a major role in preventing or intervening in burnout (Medland et al., 2004; Estryn-Behar et al., 2007; Williams et al., 2007; Sprinks, 2012).

Clinical leaders have a responsibility to monitor staff conflicts and to promote positive staff relations through the use of support and discussion groups. Palliative care services must help prepare staff members to deal with the emotional needs of the patient and family through the development of counselling skills. Stress inoculation training may be useful for teaching appropriate coping skills (Admi, 1997; Medland et al., 2004). Workshops on job stress followed by small group discussions of concerned personnel may also be useful. One-to-one discussions to discuss mutual concerns between employees experiencing a conflict are sometimes necessary. If this is not comfortable for either party, an outside professional counsellor could be used (Keidel, 2002). These organizational interventions to reduce burnout can have additional flow-on benefits of increased staff retention and satisfaction, reduced absenteeism and staff conflicts, and improved patient and family satisfaction.

Compassion fatigue

Palliative care clinicians navigate situations of severe distress and they do this challenging work in the face of the intense emotions of the incurably ill patients and their families (Alkema et al., 2008). Many of the family members may demand time and attention that is simultaneously required to be directed towards helping the patient die peacefully and without pain or distress. Since most palliative care clinicians consider attentiveness to such distress to be part of their mandate, it is near impossible for them not be affected in some way by these interactions.

Compassion fatigue refers to the emotional impact of working with people involved in traumatic life events such as terminal illness; it has been referred to as the 'cost of caring', that comes from continuous compassion directed towards people in crisis (Booth, 1991). Some consider compassion fatigue to be a form of post-traumatic stress disorder (PTSD) in professional carers (Booth, 1991). Compassion fatigue is also known as secondary or vicarious traumatization (Tabor, 2011).

Clinicians may be more vulnerable to compassion fatigue in some situations than others. This is particularly true of the care of young people, be they patients or the children of patients (Robins et al., 2009), and when they are exhausted, stressed, or overworked. The intense relationships that often occur between palliative care providers and patients and their families can themselves be sources of compassion fatigue. Sometimes intense exposure to multiple deaths can lead to a feeling of 'grief overload' (Vachon, 1995).

The effects of compassion fatigue may endure or worsen over time, developing into serious reactions that compromise a health-care provider's ability to interact in positive and helpful ways with patients and families (Firth-Cozens, 2001)

Regarding the relationship between compassion fatigue and burnout, while compassion fatigue may be one of the factors contributing to burnout, it is important to appreciate one can have compassion fatigue whilst at the same time maintaining engagement and enthusiasm for one's work and with no sign of burnout (Booth, 1991; Keidel, 2002; Slocum-Gori et al., 2013).

Symptoms of compassion fatigue

Symptoms of compassion fatigue are similar to the three classic features of PTSD: hyperarousal, disturbed sleep, or outbursts of anger, and hypervigilance; avoidance, 'not wanting to go there again', and the desire to avoid thoughts, feelings, and conversations associated with the patient's pain and suffering (Wright, 2004). Compassion fatigue can have a profound impact on personal well-being and function and express itself across psychological, cognitive, and interpersonal domains (Box 4.16.3). Clinicians with compassion fatigue often have intrusive thoughts or dreams, and psychological or physiological distress in response

---

Box 4.16.3 Impact of compassion fatigue

Psychological

- Strong emotions (sadness, anger, guilt, worry)
- Intrusive thoughts or images/nightmares
- Feeling numb or frozen
- Avoiding the patient/family or situation
- Somatic complaints (gastrointestinal distress, headaches, fatigue)
- Anxiety or agitation
- Compulsive or addictive behaviours (drinking, smoking, shopping sprees)
- Feeling isolated or personally responsible, with no back-up
- Inability to make self-protective measures leading to maladaptive or harmful behaviours such as overworking, decision-making difficulties and a loss of sensitivity to one's own needs.

Cognitive

- Mistrust of others (family, patient, other staff)
- Increased personal vulnerability or lack of safety
- Belief that others aren't competent to handle the problem
- Increased or decreased sense of power or control
- Increased cynicism
- Increased sense of personal responsibility or blame
- Belief that others don't understand the work that you do.

Interpersonal

- Withdrawal from the larger treatment team
- Withdrawal from personal relationships (because people 'don't understand')
- Difficulty trusting others personally and professionally
- Over-identifying with the distress of others leading to skewed boundaries in relationships
- Detachment from emotional situations or experiences (including the patient/family)
- Becoming easily irritated with others.

to reminders of work with the dying (Valent, 2002; Showalter, 2010). They may manifest as either over-involvement or detachment and these can impact on clinicians' relationships with their patients, colleagues, and family members.

Among the complications of compassion fatigue are several syndromic behaviour patterns: splitting, the so-called saviour syndrome, and detachment.

Splitting

Splitting is form of good–bad polarization. It involves perceiving oneself or other members of the care team as entirely good and helpful, and others as entirely bad and extremely unhelpful. It produces intra-team conflicts and tensions that compromise team work and the cohesiveness of the care team. Additionally, caregivers may demonstrate splitting between their 'good patients' and their 'bad patients'.

The saviour (in contrast to helper) syndrome

The ultimate denial of the traumatic tragedy of terminal illness is to avoid the tragedy by rescuing the patient. Taking on the role of the saviour is one of the manifestations of compassion fatigue. It avoids the role of helping (which just feels too hard) by devoting energies to rescuing the situation. Among oncologists with compassion fatigue the saviour syndrome is often manifested as a 'counterphobic determination to treat'.

Becoming detached

Clinicians with compassion fatigue may gradually or abruptly withdraw as the emotional intensity increases. This occurs most commonly when clinicians are working alone or not being part of a supportive and collaborative team when providing end-of-life care.

Strategies to mitigate compassion fatigue

Empathic engagement between clinician and patient is at the heart of palliative care. It is hard to imagine a palliative care clinician who is not occasionally emotionally impacted by their work. The challenge is how to prevent these normal responses developing in strongly negative and destructive ways. The usual recommendation for mitigating compassion fatigue is 'good professional boundaries' (Anewalt, 2009; Hall, 2011). While professional boundaries are important, exclusive reliance on this as the main self-care strategy to prevent secondary traumatization may result in objectification, detachment, and reduced empathy. Hence, the need to consider other ways. As with burnout there has been increasing focus on factors that mitigate against the effects of compassion fatigue.

Exquisite empathy

Qualitative research on outstanding therapists who were thriving in their work with traumatized clients, including palliative care patients and their families, has identified a variety of protective practices that enhance caregivers' professional satisfaction and help prevent or mitigate compassion fatigue (Harrison and Westwood, 2009). In particular, trauma therapists who engaged in *exquisite empathy*, defined as 'highly present, sensitively attuned, well-boundaried, heartfelt empathic engagement', were 'invigorated rather than depleted by their intimate professional connections with traumatized clients' and protected against compassion fatigue and burnout (Harrison and Westwood, 2009).

This idea, which has also been referred to as bidirectionality (Katz, 2006), refutes the commonly held notion that being empathic to dying patients must lead to emotional depletion (Pearlman, 1995; Figley, 2002) and it challenges the characterization of empathy as 'emotional liability'.

The practice of exquisite empathy is facilitated by clinician self-awareness and mindful communication skills (discussed later) which were identified in another study as the most important factor in psychologists' functioning well in the face of personal and professional stressors (Coster and Schwebel, 1997).

Resilience (hardiness) and coherence

Personal and professional resilience predicate the capacity for positive outcomes from caring even in the most challenging of circumstances. These positive outcomes have been referred to as compassion satisfaction and post-traumatic growth.

Compassion satisfaction is pleasure derived from the work of helping others. Acknowledging the risks of work-related secondary exposure to trauma, Stamm (2002) identified compassion satisfaction as a possible factor that counterbalances the risks of compassion fatigue and suggested that this may partially account for the remarkable resiliency of the human spirit.

Post-traumatic growth (Tedeschi and Calhoun, 2004) is characterized by positive changes in interpersonal relationships, sense of self, and philosophy of life subsequent to direct experience of a traumatic event that shakes the foundation of an individual's worldview (Tedeschi and Calhoun, 2004). Post-traumatic growth is not uncommon and may occur concurrently with negative sequelae of trauma (Tedeschi and Calhoun, 2004). The term describes the phenomenon of clinician growth and inspiration that results from witnessing positive sequelae of other people's experiences of trauma. This may include the clinician's feelings that his or her own life has been enriched, deepened, or empowered by witnessing the patient's or family's post-traumatic growth (Harrison and Westwood, 2009; Splevins et al., 2010). When patients experience meaning and peacefulness in relation to their approaching death, this enriches the lives of the clinicians involved. This phenomenon appears similar to the 'healing connections' identified by Mount and colleagues (Mount et al., 2007).

Research has provided empirical evidence for the construct of vicarious post-traumatic growth (Linley et al., 2005; Harrison and Westwood, 2009). Exemplary therapists who were thriving in their work with traumatized clients experienced positive shifts in their sense of meaning or spirituality. Therapists enrolled in a study (Harrison and Westwood, 2009) described having gained an expanded worldview, even paradoxically feeling enriched, as a result of witnessing the sequelae of other people's experiences of trauma. Research on exemplary oncology nurses has focused on feelings of personal growth and development derived from moments of connection, making moments matter, and energizing moments with their patients and their families (Perry, 2008).

Grieving strategies

Approaches that facilitate grieving may be useful particularly for clinicians who are exposed to frequent and multiple deaths. Approaches that have been suggested include departmental memorial services, journaling, attending a funeral, or participating in a post-bereavement family visit (Vachon, 1998).

Use of mindfulness strategies

Mindfulness strategies, which will be described in greater detail later in the chapter, focus on enhancing intrapersonal

and interpersonal self-awareness and can assist practitioners in becoming more attentive to the presence of stress, to their relationship with the sources of stress, and to their own personal capacity to to self-monitor and be less emotionally reactive in stressful situations.

Use of wellness strategies

Wellness approaches have been strongly advocated as a means to mitigate against compassion fatigue (Mulligan, 2004; Benson and Magraith, 2005; Aycock and Boyle, 2009; Slatten et al., 2011) (see Box 4.16.2).

Moral distress

Clinicians working in palliative care are confronted with many ethically challenging situations. Sometimes the chosen course of clinical action runs contrary to what individual clinicians would see as the most ethically appropriate approach and yet they are expected to go along with the committed action plan that they ethically disagree with (Weissman, 2009). This is the scenario that creates moral distress.

Moral distress is a stress reaction characterized by feelings of frustration, anger, and anxiety. It occurs when an individual has a conviction of what is ethically correct but is constrained from acting in accordance with their convictions and often expected to act against their convictions (Andre, 2002; Rushton, 2006). External constraints that contribute to moral distress include power imbalances between members of the health-care team (the doctor has decided), patient or family preferences, poor communication between team members, pressure to reduce costs, fear of legal action, lack of administrative support, or hospital policies that may conflict with patient care needs. Although the phenomenon was initially described in nurses it has been identified among nearly all health-care professionals, including physicians.

Sources of moral distress in palliative care

While research has identified common sources of moral distress (Kalvemark et al., 2004; Cohen and Erickson, 2006; Ferrell, 2006; Rushton, 2006; Schluter et al., 2008), not every clinician will experience distress when faced with these situations, and some clinicians will experience distress from other circumstances.

- *Clinical decisions*: continued life support even though it is not in the best interest of the patient; inappropriate use of health-care resources, overaggressive care, nihilistic care, requests for cardiopulmonary resuscitation by terminally ill patients or their family members, inadequate pain relief, sedation at the end of life.

- *Communication issues*: inadequate communication about end-of-life care between providers and patients and families, false hope given to patients and families.

- *Resources*: when the interests of the organization override the interests of a particular patient because of limited resources or when working is situations in which appropriate medications, equipment, or staff are not available to provide optimal care.

- *Lack of staff time*: such as the distress of professional staff caused by the proportion of time devoted to administrative tasks rather than attending to the physical and psychological needs of patients and their families.

- *Rules and regulations*: this occurs when there is a conflict between the regulations and what the clinicians regard as the best for the patient. Moral distress can arise in situations in which clinicians break rules or when they are constrained by the rules against their better judgement.

Consequences of moral distress

Moral distress can commonly produce feelings of frustration, anger, and anxiety and of having been devalued and marginalized. Moral distress can be devastating, leading to nightmares, headaches, and depression (Schluter et al., 2008). Affected staff often feel disenfranchised and may be reluctant to divulge their distress and feelings of impotence. This can contribute to feelings of isolation, which is an additional threat to their self-worth. The issue of isolation is further confounded by the fact that in any given situation, not all of the involved clinicians will disagree with morality of the approach taken.

Moral distress can certainly be a factor contributing to burnout and, among nurses, it has been identified as a major risk factor for leaving either a department or the field of nursing entirely (Ferrell, 2006; Repenshek, 2009; Piers et al., 2011).

Moral distress, and the feeling that one has seriously compromised oneself or allowed oneself to be compromised tend to linger and, especially if repeated frequently, can impact adversely on self-worth. This has been called 'moral residue' (Hardingham, 2004; Epstein and Hamric, 2009).

Management of moral distress

Approaches to the management of moral distress should be developed at both an organizational level and at an individual level.

Organizational

Palliative care and hospice services must provide support resources and structures to decrease moral distress including a forum for discussing ethically troubling situations experienced in the daily practice. The development of an institutional and/or departmental culture of moral sensibility and commitment is probably the most important step that can be undertaken to relive the burden of moral distress. Development of a strong moral culture and the provision of support structures for ethical discussions can help reduce moral distress and moral residue (Kalvemark et al., 2004). An open and interactive approach to moral conflicts can assist care providers to cope better with ethical conflicts that will always occur in their day-to-day practice. Teamwork is important since interdisciplinary issues, particularly a lack of opportunity to discuss and achieve wide consensus regarding ethically sensitive clinical decisions, often contributes to moral distress. This work can be facilitated by the development of an ethics infrastructure including the availability of ethics consultations (Schneiderman et al., 2000; Schneiderman, 2006; Pfafflin et al., 2009; Romano et al., 2009).

When similar problems tend to recur in a work setting, this often signals that there are issues in the workplace or organizational dynamic that may be contributing. Consequently, remedial approaches should focus on the work environment and organizational issues. All involved parties must engage together to evaluate the work environment or team dynamic factors that may be generating these dilemmas. Generating factors need to be evaluated to distinguish between those which are amenable to change and

those which are not. Those which are amenable to change need to be targeted. The participation of a skilled ethics consultant in such situations has been shown to help resolve underlying structural issues that sometime contribute to moral distress (Schneiderman et al., 2000; Pfafflin et al., 2009).

Individual

Palliative care staff should be trained and encouraged to recognize moral distress in their professional lives and to discuss their concerns with their peers. Managing a situation of moral distress starts with a careful evaluation of one's own position and then of the constraining issues of the other involved stakeholders. A key question is whether the constraining factors are amenable to change.

Many sources of moral distress are caused by constraints that are potentially amenable to change; for instance, the orders of a doctor, the opinion of a consultant, a family member, or a religious advisor to a patient. When constraints are potentially amenable to change, clinicians are encouraged to articulate their concerns and to possibly relieve the constraints through discussion, negotiation of the issues, or persuasion. This approach requires moral courage (Gallagher, 2011). Situations when clinicians fail to act on their concerns in the face of potentially resolvable obstacles (moral cowardice) may contribute to reactive distress or feelings of guilt for not having spoken out (Jameton, 1993).

Some sources of moral distress are caused by constraints that are rigid and which are not amenable to change. Examples may include constraints caused by rationing of limited clinical resources, and patients who demand life-prolonging interventions on the basis of inflexible vitalist religious considerations. In these situations, the primary strategy relates to coping with the challenge of providing care and trying to understand the moral reasoning that has led other stakeholders to conclusion that vary with one's own. This requires personal flexibility and adaptability. Coping theory suggests that when the preferred ethical approach cannot be achieved, flexible people can maintain a sense of control by finding an alternative satisfying way to conceptualize the situation (Thompson, 2009). This is personally and ethically challenging and it requires a different form of moral courage that incorporates the ability to see the problem from the perspective of someone else rather than one's own to be able to function and care without feeling compromised or violated. There is indeed enhanced control in the 'capacity for choice', rather than reflex, as to how one sees the differing moral perspectives.

Clinicians need to develop an appreciation that there are different ways of reasoning in ethical dilemmas, a better understanding of their own process of ethical decision-making, and create a readiness to cope with situation when other critical stakeholders come to different conclusion to their own. Team and personal strategies need to be developed to cope with situations being generated by factors that cannot be changed. Coping and flexibility are vital skills and often there is more than one right way. Clinicians need to develop an understanding that circumstances may render their best moral option unworkable in prevailing circumstances and that sometimes the best we can do is a compromise. Learning to compromise, and the insight that compromise often comes from strength rather than weakness, is an important part of 'self-compassion'.

In the face of situations contributing to moral distress there is great healing wisdom in the Serenity Prayer: 'God grant me the serenity to accept the things I cannot change, the courage to change the things that I can, the wisdom to know the difference.' This approach, though soothing, can contribute to complacency. Betty Cherny (1932–2000) championed an inspirational version that challenges the reader to push the boundaries to render obstacles one considered fixed, as changeable: 'God grant me the serenity to accept the things I cannot change, the courage to change the things that I can, the wisdom to know the difference and the chutzpah [audacity in Yiddish] to push the boundaries.'

Self-awareness (mindfulness) strategies for prevention of burnout, compassion fatigue, and moral distress

Traditionally self-care strategies have emphasized the value of 'good professional boundaries' and 'effective self-care strategies outside the workplace.' These alone, however, can lead to emotional detachment by the clinician, leading to less job satisfaction, less patient-centred care, and less satisfied patients (Jackson et al., 2008).

Another approach to addressing loss of meaning and lack of control in life is developing greater self-awareness or mindfulness which includes four cardinal skills (Epstein et al., 2007):

1. The ability to notice and observe sensations, thoughts, and feelings even though they might be unpleasant

2. The ability to lower one's tendency to respond reactively to emotionally charged experiences

3. An enhanced ability to react with awareness and intention rather than being on reactive 'auto-pilot'

4. Focusing on experience, not the labels or judgements we apply to them (e.g. feeling an emotion rather than wondering if it is okay to feel that emotion).

It is proposed that by enhancing intrapersonal and interpersonal self-awareness practitioners can become more attentive to the presence of stress, to their relationship with the sources of stress, and to their own personal capacity to 'to self-monitor, to be less emotionally reactive in stressful situations, and to respond more skillfully to patient and family's needs' (Novack et al., 1999). This approach reduces burnout and compassion fatigue and it enhances the potential for job engagement and compassion satisfaction.

Kearney at al. have suggested that 'clinicians working in end of life care who are experiencing distress related to burnout, compassion fatigue or moral distress who use self-care strategies alone may feel as though they are drowning and barely able to come up for air, whereas self-care with self-awareness is like learning to breathe underwater' (Kearney et al., 2009).

There are a number of practical ways of enhancing self-awareness and mindfulness. These include initiatives such as participation in educational projects (Robinson et al., 2004; Le Blanc et al., 2007), and peer-support (Balint) groups (Rabinowitz et al., 1996; Benson and Magraith, 2005; Kjeldmand and Holmstrom, 2008; Bar-Sela et al., 2012). Two methods of enhancing self-awareness that have empirical data to support their effectiveness are mindful practice training (Epstein, 1999; Kabat-Zinn, 2003; Grossman et al., 2004; Shanafelt et al., 2005b; Krasner et al., 2009) and reflective writing (Frisina et al., 2004, Harris, 2006).

Mindful practice and mindful communication training

Mindful practice describes four qualities that are inherent in the behaviour of exemplary clinicians: *attentiveness* refers to the capacity to observe without making judgements that would otherwise distort or diminish one's capacity to understand. This involves monitoring one's own biases, thoughts, and emotions: observing the observer observing the observed. *Critical curiosity* refers to the ability to open up to possibilities, rather than premature closure and discarding new information or insights. *Informed flexibility* (sometimes referred to as having a 'beginner's mind') refers to the ability to be able to adopt a fresh perspective or to consider more than one perspective simultaneously rather than taking only a single fixed perspective on a problem. Finally *presence* which involves being there physically, mentally, and emotionally for patients, and accurately communicating an understanding of the patient's concerns and feelings back to the patient (empathy) (Epstein et al., 2007). This approach is predicated on the characteristics of mindfulness described earlier.

Mindful communication brings this approach to the situation of challenging communication encounters between clinicians and their patients (and family members of patients) and between professional colleagues in their professional deliberations and interdisciplinary discussions. The aim of mindful practice and communication training is to contribute to the ability of clinicians to respond to challenging situations with more flexibility, greater sensitivity, and less reactivity (Shapiro et al., 2007) and enhance their capacity to be more appreciative and forgiving of themselves (self-compassion) as well as to have greater empathy for others (Shapiro and Izett, 2008).

Researchers and educators from Rochester University School of Medicine, New York, United States, reported the results of an intensive course in 'mindful communication' which included a variety of self-awareness and body-awareness exercises, narratives about meaningful clinical experiences, appreciative interviews, didactic material, and discussion. The 70 participating physicians not only reported lower burnout and lower psychological distress, but also greater empathy and psychosocial orientation in care (Krasner et al., 2009; Beckman et al., 2012).

Strategies to teach mindful practice have been developed and initiated at a number of sites including the Stress Reduction

---

> **Box 4.16.4** Some suggested self-care and self-awareness practices in the workplace
>
> ◆ As you walk from your car to your workplace or through the corridors of your workplace, attend carefully to the sensation of contact between your feet and the ground.
>
> ◆ Set your watch or telephone alarm for midday each day. Use this as a prompt to perform some simple act of centring, for example, take four deep, slow breaths; think of a loved one; recite a favourite line of poetry or a prayer; imagine weights around your waist and the words 'ground, down'.
>
> ◆ Reward yourself after the completion of a task, for example, an early coffee break.
>
> ◆ Call a 'time out' (usually just a few minutes) as way of dealing with emotional flooding after a traumatic event; call a colleague saying, 'I need a walk' or take a break.
>
> ◆ Stop at a window in your workplace and notice something in nature; consciously give it your full attention for a few moments.
>
> ◆ Take half a minute of silence or take turns to choose and read a poem at the beginning of weekly interdisciplinary team meetings.
>
> ◆ Before going into the next patient's room, pause and bring your attention to the sensation of your breathing for two to five breaths.
>
> ◆ Take a snack before the end of clinic to prevent neuroglycopenia.
>
> ◆ Stay connected to the outside world during the day, for example, check in with loved ones.
>
> ◆ Multitask self-care, for example, dictate or meditate while using the treadmill in your office.
>
> ◆ Use the suggested 20 seconds of hand washing in creative ways, for example, pay attention to the sensation of the water on your skin and allow yourself to sink into this experience; make this an act of conscious receiving by acknowledging to yourself 'I am worthy of my own time'; or repeat a favourite line from a poem or prayer; or sing yourself 'Happy Birthday!'
>
> ◆ Don't be afraid to ask the question 'Is it time for a break?'
>
> ◆ Deliberately make connections during the day with colleagues and with patients, for example, use humour; look for something particular or unusual in the patient's room; or notice patient's birth date or age.
>
> ◆ Keep a notebook and write 'field notes' on traumatic or meaningful encounters and events; occasionally take time at interdisciplinary team meetings to share this material.
>
> ◆ Deliberately develop a 'role-shedding ritual' at the end of the day, for example, pay attention to putting away your stethoscope or hanging up your white coat; use the drive home from work deliberately, for example, take the longer, more interesting route; listen attentively to the news, music, or books-on-tape.

and Relaxation Program of the University of Massachusetts Medical Center (<http://www.umassmed.edu/cfm/index.aspx>) (Kabat-Zinn, 2003), the American Academy on Communication in Healthcare (<http://www.aachonline.org>), the Northwest Center for Physician Well Being (<http://www.tfme.org>), and the Mindful Practice Programs at the University of Rochester (Epstein et al., 2007). The Mindful Practice Program at the University of Rochester has published a curriculum which is also available online (Epstein et al., 2007).

Reflective writing

Writing in a reflective and emotionally expressive way is another form of self-care that enhances self-awareness. Physical and psychological benefits of expressive writing have been demonstrated in patients (Smyth et al., 1999; Stanton et al., 2002; Petrie et al., 2004; Cepeda et al., 2008; Morgan et al., 2008; O'Cleirigh et al., 2008) and this practice has been promoted as a tool to develop reflection and empathic engagement in clinicians (Charon, 2001; Brady et al., 2002).

In this approach, clinicians are encouraged to diarize challenging and/or rewarding clinical encounters, recording personal thoughts and along with the objective clinical data of the narrative (Pennebaker, 1997; DeSalvo, 1999; Charon, 2001; Spann, 2004). Narratives can be shared and explored in small group discussions or in one-on-one supervision or debriefing. The aims of the discussion are to facilitate a reflective/evaluative approach to understanding one's thoughts, thought processes, feelings, and responses. This approach aims to help foster better self-understanding, and the mindfulness skills described in the previous section.

Practising self-care

Although clinician self-care may happen through some of the formal practices and methods discussed earlier, it may also happen in countless informal ways as an everyday part of a physician's working life. Many experienced clinicians have evolved what are sometimes unique yet time-tested methods of self-care. A collection of suggested self-care and self-awareness practices in the workplace are listed in Box 4.16.4.

Conclusion: ongoing tasks

There remains abundant scope for research to address the prevention and management of burnout, compassion fatigue, and moral distress in palliative care. Specifically, there remains relatively little data on the frequency and specific nature and impact of compassion fatigue and moral distress among palliative care clinicians and the knowledge base regarding strategies for management remains largely anecdotal with only a very limited evidence base to inform practice beyond expert opinion. Researchers will be aided by the well-validated tools that are available to measure burnout (Maslach et al., 1996), compassion fatigue (Bride et al., 2007), and moral distress (Eizenberg et al., 2009). We look forward to being able to revise our next edition with additional knowledge you may have generated.

Integrative oncology in palliative medicine

Gary Deng and Barrie R. Cassileth

Introduction to integrative oncology in palliative medicine

Patients under palliative care, facing poor prognoses and a heavy symptom burden, often seek health-care practices and agents outside of mainstream medicine (Hyodo et al., 2005; Molassiotis et al., 2005). Collectively these modalities often are termed 'complementary and alternative medicine' (CAM), to describe a diverse group of therapies that range from unproved alternative 'cures' offering false hope, to adjunctive complementary therapies that provide legitimate supportive care and that comprise integrative oncology. Although complementary therapies and alternative approaches are sometimes discussed under the umbrella of CAM, it is clinically and conceptually necessary to distinguish between the two because they are profoundly different in approach. The acronym is an easy but incorrect and counterproductive conflation of two unrelated approaches.

In the cancer setting, 'alternative' therapies generally are promoted for use instead of standard treatment, despite the fact that there are no viable 'alternatives' to mainstream cancer treatment. Alternative purveyors cater to people who have lost confidence in or grown antagonistic to mainstream medicine. In palliative care, these may be patients aware of their poor prognosis and limited therapeutic options, but unready to give up the hope of cure. Alternative therapies by definition are not supported by evidence. If they were backed by solid data, they would not be 'alternative', but used instead as viable treatments. Alternative regimens typically are costly and potentially harmful, either directly through physiological activity, or indirectly when patients forego legitimate cancer treatment in favour of 'alternatives'. Patients in palliative care are especially vulnerable to these schemes, as they often promise a cure even in advanced or end-stage disease.

Complementary therapies, conversely, are used to control pain and other symptoms, enhance physical, mental, and spiritual well-being, and optimize quality of life for patients and their families. These goals are shared by the World Health Organization, the American Cancer Society, and the Society for Integrative Oncology (World Health Organization, 2006; Deng et al., 2009; American Cancer Society, 2012). Complementary or integrative therapies ease the symptoms associated with cancer and treatment side effects. Unlike 'alternative therapies', they are never offered as substitutes for mainstream treatment, but rather as adjuncts to proper care. Complementary therapies address physical and emotional symptoms. Thus, they are palliative and especially helpful for both patients and family members during end-stage disease. Complementary therapies are evidence-based and rational, and have a highly favourable risk/benefit ratio. Currently the terms 'integrative medicine', 'integrative oncology', and 'complementary therapies' denote incorporating adjunctive therapies that play a vital supporting role in optimal care (Cassileth et al., 2005; Remen, 2008). Some institutions use the term 'complementary and integrative medicine' (CIM) in another effort to distinguish their work from the 'alternative therapies' that fall under the 'complementary and alternative medicine/CAM' umbrella. The distinction is essential, and patients and oncologists should be aware of this unfortunate terminology issue.

Complementary/integrative therapies are increasingly available not only directly to patients on a private or in-home basis, but also in some hospitals and clinics. Health-care professionals should steer patients away from harmful or useless alternative therapies while making helpful complementary therapies available to patients and increasing patient awareness of those services.

This chapter summarizes the state of integrative medicine and medical oncology in the current health-care system. We discuss helpful complementary therapies applicable to palliative medicine and also describe the unproven alternatives that are widely proffered to patients and families internationally. When both approaches have been conflated for research purposes, we use the acronym CAM but, to the extent possible in terms of available information, discuss each separately.

Complementary therapies in the current health-care system

No longer a collection of covert practices (Cassileth et al., 1984), new approaches became increasingly visible in the 1990s, driven by public fascination with unconventional therapies, a growing acceptance of therapies from other cultures, legislative and regulatory changes propelled by various interest groups, and publications documenting the benefits of complementary modalities in symptom control. A 2012 Google search of 'alternative therapy' yielded 25.5 million hits. It is a multibillion dollar business in the United States (Nahin et al., 2009) and of equivalent impact and importance throughout the developed world. The popularity of both legitimate and unproven methods also has affected every component of the health-care system and all specialties of medicine, including palliative care. It has left its mark on the thinking and practice of physicians and other health professionals, and

has broadened patients' involvement and participation in their own care.

Prevalence

Prevalence rates concerning complementary and/or 'alternative' therapies ('CAM') internationally vary from less than 10% to more than 70% (Molassiotis et al., 2005; Barnes et al., 2008). The wide range is attributable primarily to variable interpretations and definitions of CAM. Some surveys use broad definitions that include lifestyle activities such as weight loss efforts, exercise, church attendance, and group counselling, while other surveys specify only the use of herbal products. Approximately 40% of adults use CAM therapies in the United States (Mao et al., 2011), with increasing use by cancer patients (Fouladbakhsh and Stommel, 2010) and a strong association among patients under palliative care (Hyodo et al., 2005; Molassiotis et al., 2005).

A consistent finding in cancer patient surveys is that users typically are younger, more educated, and more affluent, with the desire and ability to play an active role in their own care. Interestingly, however, some patients use products that lack sufficient information or fail to consult with their own health-care team (Hyodo et al., 2005). Many also tend to equate a lack of information about adverse effects with implied safety (Wood et al., 2003).

This dichotomy presents a key issue that must be recognized on the front lines of patient care: not only is the treatment of disease important, but so too are the myriad physical, emotional, psychosocial, and spiritual needs that arise as a result of serious illness. Patient and family attempts to 'do something more' reveal the unmet psychological and physical needs of these patients, which require attention and are not likely to resolve on their own.

The 1994 United States legislation known as the Dietary Supplement Health and Education Act allowed 'dietary supplements', including herbs, to be sold without US Food and Drug Administration review (US Food and Drug Administration, 2014). The sales of dietary and herbal supplements skyrocketed thereafter, despite media reports about safety concerns and questionable effectiveness and public confusion about the vast array of products. According to the Natural Products Association, annual sales of dietary supplements reached US$26.9 billion in 2009, including US$5 billion in sales and a 5% growth rate for herbs (Natural Products Association, 2012). The ever-expanding variety of both over-the-counter remedies and new age therapies, coupled with instant access to health-related information on the Internet are key contributors to this boom.

Public access to misinformation and quackery

CAM is an open and public issue today, discussed in the mass media and readily found on the Internet. Moreover, practitioners and product promoters widely advertise misinformation in all media. Product marketers produce infomercials, mass-mail newsletters and catalogues, and engage in multi-level marketing schemes, all with minimal to no regulatory oversight. Information available to the public varies widely in accuracy, and misinformation about health issues is widespread.

As early as 1999, the US Federal Trade Commission (FTC) announced that it had identified approximately 800 websites promoting and selling phony cures for cancer and other serious ailments in an estimated 15,000–17,000 health-related sites (FTC, 1999; Brann and Anderson, 2002). Because millions of such sites

exist today, it is likely that those selling bogus treatments have increased accordingly. More recently, the FTC launched a campaign to address bogus cancer cures directly with consumers in attempts to stem this trend (FTC, 2008a, 2008b).

Recognition of legitimate therapies by mainstream medicine

Legitimate complementary therapies have been increasingly recognized and integrated as important adjuncts to mainstream care at many medical institutions. The research landscape experienced several shifts from commentaries in the 1970s expressing concerns about quackery, to surveys of patients' knowledge and use of unproven methods in the 1980s and 1990s, to reports of actual research results in the mid 1990s. In 1996–1997, the National Library of Medicine added many new related search terms to its medical subject headings (MeSH), and began to cover alternative medicine journals previously not reviewed for inclusion in MEDLINE®.

Studies over the last two decades strongly support the use of rational, non-invasive, and inexpensive evidence-based modalities. These include acupuncture, massage therapy, music, fitness/physical activity, nutrition and mind–body techniques, which take advantage of the reciprocal relationship between the mind and body. In addition, the application and insistence of rigorous evidence within the field of integrative oncology is well established. Comprehensive evidence-based guidelines are available from both the Society for Integrative Oncology and the American College of Chest Physicians (Cassileth et al., 2007; Deng et al., 2009). Other organizations have also been established for the cause of integrating complementary therapies with mainstream care, for example, the Consortium of Academic Health Centers for Integrative Medicine (a group of 50 institutions) whose goal is to advance the principles and practice of legitimate integrative health care within academic institutions.

Increased research funding also has played an important part both by expanding the body of evidence for some complementary therapies, while debunking other approaches. The National Center of Complementary and Alternative Medicine (NCCAM) and the National Cancer Institute (NCI) Office of Cancer Complementary and Alternative Medicine (OCCAM), both divisions of the National Institutes of Health (NIH), each oversees approximately $120 million in annual support of complementary and alternative related research. More than 2500 projects funded by NCCAM in the last decade yielded over 3000 peer-reviewed scientific articles (NCCAM, 2012).

A health insurance programme in western Washington state covered 13.7% of its enrolees in 2002 for CAM claims, including acupuncture, naturopathy, massage, and chiropractic (Lafferty et al., 2006), and more than 30 major insurers in the United States cover more than one method. Coverage varies by state, with some carriers requiring a prescription or supervision by a physician. Acupuncture, massage therapy, and other complementary services are variably covered by insurers. Socialized medical programmes tend to focus on providing a small number of therapies. For example, the most commonly offered British National Health Service modalities were counselling (82% of 142 centres), although counselling is not a complementary or alternative modality, reflexology (62%), aromatherapy (59%), reiki (43%), and massage (42%) (Egan et al., 2012).

Expanding insurance coverage for these therapies reflects consumer demand along with managed care efforts to control costs. CAM users often have chronic conditions and use more health-care resources. If these patients are helped by complementary therapies or steered towards less expensive treatment regimens, overall health-care costs may be reduced. Interventions such as pre-surgical hypnotherapy have already been shown to reduce institutional costs associated with inpatient procedures (Montgomery et al., 2007). Acupuncture for the treatment of chronic headaches was found to be more cost-effective than other interventions (Wonderling et al., 2004). Future efficacy research that includes cost-effectiveness evaluations will be instrumental in the further expansion of coverage for services that also demonstrate reduced or controlled costs.

Unproven 'alternative' therapies

Alternative practices are unregulated, expensive, unsubstantiated, and often discredited, but they are aggressively promoted as curative treatments. Susceptible patients often embrace the promise of cancer cures without the toxic effects of mainstream treatment. In addition to creating unnecessary financial expenditures and false hopes, the use of these therapies delay receipt of mainstream care, enabling disease progression and even resulting in death. Some 'alternatives' seem especially aimed at reaching vulnerable cancer patients. These 'therapies' include metabolic therapies, herbal and dietary supplement regimens, and 'vibrational or 'energy healing'.

Unproven biological approaches

Protocols and regimens in this category can involve ingestion, or rarely, injection of substances claimed to induce physiological changes that prevent and treat disease. The regimen could be a specified dietary plan, herbs, vitamins, or other constituents extracted from natural sources. The rationale may be stated as based on laboratory findings such as anti-tumour activity *in vitro* or in animal models, or traditional use such as herbal preparations from Traditional Chinese Medicine, naturopathy, or homeopathy.

In palliative care, unproven biological approaches tend to be adopted for one of two reasons. First, patients may try them in a final effort to treat end-stage disease and, even in the absence of clinical data, to leave no stone unturned. Second, patients may use them as supportive measures to 'strengthen the body', 'boost the immune system', or 'improve nutrition'.

Metabolic therapies

So-called metabolic therapies are practitioner-specific combinations of diet plus vitamins, minerals, enzymes, and 'detoxification'. One of the best known sites for metabolic therapy is the Gerson Institute, which licenses clinics in Mexico and Hungary. Treatment is based on the belief that toxic by-products of cancer cells accumulate in the liver, leading to liver failure and death. The Gerson therapy aims to counteract liver damage with a low-salt, high-potassium diet, coffee enemas, and a gallon of fruit and vegetable juice daily (Green, 1992). The clinic's use of liquefied raw calf liver injections were suspended following sepsis in several patients and one death (Centers for Disease Control and Prevention, 1981). There are numerous such clinics, with many variations on the theme, in Mexico as well as in the United States and Europe.

Patients may also explore elaborate dietary plans, detoxification regimens, mega-dose vitamin therapy, laetrile, essiac tea, iscador (mistletoe extract), immuno-augmentative therapy, ozone oxygen therapy, and many others. Some alternative practitioners 'diagnose' disease, sell their remedies, and remain unaccountable for their actions. Several online sources provide reliable information for patients and health-care professionals about such products and regimens (Box 4.17.1).

Dietary supplements

Another common marketing tactic is to highlight a 'magic bullet' ingredient for its superlative anticancer properties. This approach also capitalizes on perceptions that herbs and other products of plant or animal origin are 'natural' and 'safe', as opposed to standard treatments, which are associated with undesirable side effects.

A prominent example is shark cartilage, which garnered attention with the 1992 book, *Sharks Don't Get Cancer*, and a television special that displayed apparent remissions in patients treated with shark cartilage in Cuba. These supposed outcomes were strongly disputed by US oncologists. Advocates based their therapy on its putative antiangiogenic properties. Although shark cartilage was found to contain a substance with antiangiogenic activity *in*

vitro (Lee and Langer, 1983), the active component appears to be a large molecule proteoglycan with a molecular weight of 10,000 Daltons (Liang and Wong 2000). Whether such large molecules can be absorbed in the digestive tract and reach the target tumour tissue at a sufficiently high local concentration is questionable. Clinical studies have yet to show survival benefit or improved quality of life in advanced cancer patients (Miller et al., 1998; Loprinzi et al., 2005) and the product was poorly tolerated due to its unpleasant taste.

Another example, 'caesium therapy', is based on the theory that an alkaline environment discourages tumour growth and that, by ingesting caesium chloride, one can alkalinize the body and kill cancer cells. In actuality, the activity of caesium chloride does not appear to be cancer-tissue specific. Excessive alkalization creates electrolyte and pH imbalances that disrupt normal cell functioning. Moreover, caesium therapy has resulted in life-threatening cardiac arrhythmia (Satoh and Zipes, 1998; Pinter et al., 2002).

Unscrupulous business practices colour many of these 'alternative offerings'. For example, a blanket promotion of 'coral calcium' as a cancer cure (Marcason 2003), was finally suspended by a governmental crackdown. Another popular and successful sales approach is multilevel marketing, with sales 'associates' motivated to sell the product while shielding the root promoter from liability arising from unsubstantiated claims. Often the results of the research on which 'alternative' therapies are based, if any, have not been evaluated for clinical relevance, or are exaggerated claims based on pseudoscience.

Herbs and other botanical products

Processed and marketed herbs may contain many different chemicals or even contaminants, most undocumented with unpredictable effects. The amount of purported active ingredients in botanical products also varies considerably across batches and manufacturers. Moreover, because these agents may have biological activity, their side effects and interactions with other drugs cannot be overlooked.

Even for reputable products, herbs and other botanicals for cancer patients may not be safe (Table 4.17.1). The harmful effects of the misuse of herbal remedies are documented (Lazarou et al., 1998), and herb–drug interactions may be underreported (Brulotte and Vohra, 2008). Moreover, botanicals can interfere with prescription medications through physiological mechanisms, including the induction or inhibition of drug-metabolizing enzymes such as cytochrome P450 (Frye et al., 2004) and transporters such as P-glycoprotein (Zhou et al., 2004). Herbs and supplements may increase bleeding when taken with anticoagulants, cause unwanted interactions with anaesthetics, enhance skin toxicity, and decrease the effects of radiation therapy. They also may stimulate the growth of hormone-sensitive cancers or decrease the effectiveness of chemotherapeutic agents.

More common adverse effects include allergic conditions such as hives, itchiness, swelling and bruising, and gastrointestinal symptoms such as nausea, vomiting, stomach upset, and constipation. Therefore, current opinion on the use of herbs and botanicals by cancer patients, especially before surgery or during chemotherapy and radiotherapy, is that such supplements should be avoided. The evidence regarding their safety is conflicting or absent (Wells et al., 1995; Prasad, 2004).

Biologically active natural substances have and will continue to serve as a rich resource for the development of legitimate therapeutic agents. Some of the most successful chemotherapeutic agents, including paclitaxel, topotecan, irinotecan, vincristine, and vinorelbine, were made from botanical compounds or their derivatives.

Other natural substances have shown promise in supportive care, such as carnitine for the treatment of cancer-related fatigue (Graziano et al., 2002; Cruciani et al., 2004) and glutamine to prevent taxane-induced neuropathy (Savarese et al., 2003; Stubblefield et al., 2005). Traumeel®, a proprietary blend, has been studied for chemotherapy-induced stomatitis (Oberbaum et al., 2001). Although promoted and sold as a homeopathic agent, it contains extracts from belladonna, arnica, St. John's wort, and echinacea, and should therefore be viewed as a botanical formulation. Other botanicals such as medicinal mushroom extracts are also under study for their potential to enhance immune function and reduce treatment toxicity (Lin et al., 2004; Deng et al., 2009). These agents should be used only under the supervision of oncology professionals who are familiar with their potential benefit and risks, taking into consideration the patient's medical condition and current medications. Any questionable agent should be used in a clinical trial setting with close monitoring of adverse events.

Vibrational medicine or energy field/healing therapies

Therapies in this category involve manipulation of a putative human energy field. This intervention may be provided by a 'healer', an individual believed to possess a special gift for energy healing. Popular over the centuries in less developed areas of the world (Cassileth et al., 1995), 'energy work' or 'vibrational medicine' has gained increasing public interest and acceptance in the United States, with some healers claiming the ability to cure cancer.

Purported energy field manipulation is also provided by devices that sell for hundreds of dollars, such as the 'BioResonance Therapy Device', which claims to detect electromagnetic emissions from a patient's cancer cells, modify them and send them back to the patient to correct cancer cell defects. Obviously, no one with a basic understanding of the pathogenesis and treatment of cancer would subscribe to such a theory (Ernst, 2004), but the manufacturers of these devices propagate the myth and sell the equipment internationally.

Although these practitioners may cause minor if any clinical difficulties when patients also receive mainstream care, many patients are firmly convinced of the healers' abilities, or of their effect on a patient's own ability to self-heal, and decline even to have tumours removed surgically in favour of the ministrations of energy therapy. Energy healing devices also tend to be costly.

Health literacy: the antidote for unproven 'alternatives'

A recent study estimated that 25% of adults have inadequate health literacy (Bains and Egede, 2011), without which patients cannot make correct choices. Health-care professionals must know how to obtain reliable information and to advise patients accordingly. Cancer patients and survivors especially should be alerted to the

Table 4.17.1 A sample of botanicals and supplements, their purported uses, and potentially serious adverse effects[a]

Botanical or supplement	Some common or purported uses	Potential adverse effects
Astragalus *Astragalus membranaceus*	Support/enhance immune system, colds and respiratory infections, chemotherapy side effects	◆ Decreased efficacy of immunosuppressants such as cyclophosphamide ◆ Increase risk of bone marrow or organ transplant rejection
DHEA Dehydroepiandrosterone	Alzheimer's disease, memory loss, osteoporosis, depression, cancer treatment	◆ Androgenic and oestrogenic effects ◆ Increased risk of some cancers ◆ May interfere with tamoxifen
Garlic *Allium sativum*	Cancer prevention or treatment, circulatory disorders, skin infections	◆ Interacts with CYP450 and P-gP substrates ◆ Antiplatelet effects, postoperative haemorrhage, increased bleeding risk with anticoagulants ◆ Unwanted interactions with anaesthetics ◆ May interfere with hypoglycaemic medications or ciclosporin with potential transplant rejection
Ginkgo *Ginkgo biloba*	Circulatory disorders, dementia, Alzheimer's disease, hearing loss, tinnitus	◆ Interacts with CYP450, MAOI, P-gP and UGT substrates ◆ Anticoagulant/antiplatelet effects; case reports of spontaneous bleeding ◆ Seizures in predisposed patients and when combined with antipsychotics including prochlorperazine (also an antiemetic)
Ginseng *Panax ginseng*	Cancer prevention/treatment, diabetes, immunostimulation, strength/stamina	◆ May stimulate the growth of hormone-sensitive cancers due to oestrogenic activity ◆ Interact with many drugs including imatinib (increased hepatotoxicity risk), insulin, and sulfonylureas (increased hypoglycaemic effects), anticoagulants (antagonizes effects), MAOIs (manic-like symptoms)
Green tea *Camellia sinensis*	Blood pressure and cholesterol; cancer prevention/treatment; heart disease; weight reduction	◆ Interacts with CYP450 and UGT substrates ◆ Inhibits bortezomib and irinotecan; may antagonize the effects of antiplatelets/anticoagulants ◆ Diuretic effects; nausea and GI upset
Maitake *Grifola frondosa*	Cancer prevention/treatment; diabetes, immunostimulation, weight loss	◆ May lower blood glucose level and have synergistic effects with hypoglycaemic medications ◆ May interact with warfarin
Saw palmetto *Serenoa repens*	BPH, prostate cancer, prostatitis	◆ Interacts with CYP450 and UGT substrates ◆ May have additive anticoagulant effects and prolong bleeding time; case reports of severe intraoperative haemorrhage, haematuria and coagulopathy, acute pancreatitis, and severe liver damage ◆ Self-treatment with saw palmetto for symptoms such as BPH could delay diagnosis and treatment of serious conditions including prostate cancer
Soy *Glycine max*	Menopausal symptoms, coughs, cancer prevention, cardiovascular disease	◆ May stimulate the growth of hormone-sensitive cancers due to oestrogenic activity ◆ May inhibit the actions of chemotherapy drugs including tamoxifen and aromatase inhibitors
St John's wort *Hypericum perforatum*	Depression, anxiety, mood and sleep disorders	◆ Can alter the metabolism of many drugs ◆ May cause photosensitivity or enhance skin toxicity of radiation therapy ◆ May reduce efficacy of chemotherapy ◆ Withdrawal symptoms have occurred with sudden stopping ◆ May cause serotonin syndrome with concomitant antidepressant use
Turmeric *Curcuma longa*	Cancer prevention, infections, inflammation	◆ Interacts with CYP450, P-gP and UGT substrates including cyclophosphamide, doxorubicin, and norfloxacin ◆ May increase risk of bleeding due to its antiplatelet properties

BPH, Benign prostatic hyperplasia; CYP450, cytochrome P450; GI, gastrointestinal; MAOI, monoamine oxidase inhibitors, P-gP, P-glycoprotein; UGT, uridine 5′-diphospho-glucuronosyltransferase.

Botanicals have many characteristics and therefore the potential for multiple effects. For example, immunostimulants or herbs with oestrogenic effects may also have antioxidant or blood-thinning properties.

fact that special dietary regimens, herbal supplements, and other remedies are not viable substitutes for mainstream cancer treatment, and that they are not necessarily 'safe' simply because they are not pharmaceuticals or by virtue of their lack of scrutiny in the medical literature.

Patients should be alerted to avoid concurrent use of these products with prescription medications or when undergoing surgery, chemotherapy, or radiation therapy, while being directed to complementary therapies that can support and enhance mainstream care and patient satisfaction. Appropriate patient education could help to avoid most interactions and delays in receiving appropriate mainstream treatment and beneficial integrative services.

Medical institutions must continue to expand their outreach in this area. Of 41 NCI-designated comprehensive cancer centres, 12 (29%) had no functional websites containing information about complementary therapies (Brauer et al., 2010). The International Collaboration on Complementary Therapy Resources, which includes national complementary and alternative medicine centres in Australia, Denmark, Norway, the United Kingdom, and the United States, aims to explore effective ways of presenting information to health professionals, patients, and the general public (Pilkington et al., 2011).

Complementary therapies in palliative care

Patients with late-stage cancer and other major illnesses experience a wide range of symptoms and treatment-related toxicities. Problems experienced during treatment such as lymphoedema, neuropathic and other pain, nausea and vomiting, depression, and anxiety often persist for years or even decades. Pharmaceuticals can relieve some of these problems but can produce their own undesirable and difficult-to-manage side effects.

Complementary therapies such as mind–body techniques, massage therapy, acupuncture treatment, music therapy, and physical activity/fitness can help ameliorate many symptoms without additional adverse effects. Some therapies are a blend of several modalities. For example, yoga is a physical practice with strong breath training and mind–body components. Some fitness therapies incorporate specific music genres to elevate the exercise experience by engaging the mind and emotions as well as the body.

Mind–body techniques

The very existence of placebo effect, in which suggestions and expectancy can induce biological change, demonstrates the connection between mind and body. The potential to influence health with our minds is an appealing concept and an underutilized opportunity. Mind–body therapies in palliative care are geared to decrease distress and promote relaxation. They can also satisfy the spiritual needs of dying patients.

Hypnotherapy can be integrated into the various stages of palliative care patients' reactions—identified as initial crisis, transition, acceptance, and preparation for death (Marcus et al., 2003a, 2003b). Visualization and progressive relaxation also decrease pain and promote well-being (Walker et al., 1999). Hypnotherapy has been shown to reduce nausea and vomiting, procedural anxiety, and acute or chronic pain in children as well as adults (Gellert et al., 1993; Ladas et al., 2006; Montgomery et al., 2010).

A meta-analysis of 37 clinical trials conducted between 1966 and 2010 highlights the value of psychosocial interventions in pain management for patients with cancer (Sheinfeld Gorin et al., 2012). The effectiveness of meditation, biofeedback, and yoga in stress reduction to control a variety of physiological reactions also is well documented (National Institutes of Health 1996; Carlson et al., 2004; Cohen et al., 2004; Deng and Cassileth, 2005; Kim et al., 2011). Conclusions from a meta-analysis of 116 studies indicate that mind–body practices decrease anxiety, depression, and mood disturbance in cancer patients, and improve coping skills (Devine and Westlake, 1995).

Attending to patients' psychological health is a fundamental component of good palliative care. Support groups, good physician–patient relationships, and the emotional and instrumental help of family and friends are vital. However, the incorrect idea that patients can influence the course of their cancer through mental or emotional work is not substantiated and typically evokes feelings of guilt and inadequacy when the disease continues to advance despite the patient's best spiritual or mental efforts (Cassileth 1989; Gellert et al., 1993; Cunningham et al., 1998).

An important feature of mind–body therapies is the use of regular practice to produce and sustain benefit (Shapiro et al., 2003). The adoption of realistic expectations with respect to mind–body therapies while recognizing their value and potential is key.

Massage therapy

Massage therapy is a popular and important component of palliative care for symptom management during all stages of cancer treatment and survivorship. An important type of massage that is standard practice for patients who suffer from lymphoedema is manual lymph drainage in combination with compression bandaging (Poage et al., 2008). Other types of massage therapy employ a variety of techniques on soft tissues and joints to improve circulation, reduce tension and pain, and encourage relaxation.

Massage therapy helps reduce anxiety, pain (Cassileth and Vickers, 2004), depression (Krohn et al., 2011), and physical discomfort, and improves mood (Listing et al., 2009). In a randomized controlled trial of 380 patients with advanced cancer, six 30-minute massage sessions and simple-touch sessions over 2 weeks reduced pain and elevated mood. Massage was significantly superior to simple touch in improving both immediate pain and mood, but not for sustained pain, quality of life or analgesic use (Kutner et al., 2008). Reflexology, which includes gentle manipulation of the palms and feet, is highly valued by patients and helpful for those who are frail or uncomfortable with body massage (Stephenson et al., 2000). According to a multicenter randomized controlled trial, aromatherapy massage improved clinical anxiety and/or depression in cancer patients for up to 2 weeks post-intervention (Wilkinson et al., 2007). Reiki, a practice from Japan that uses light touch, also may be helpful in both non-ambulatory and outpatient settings (Birocco et al., 2012; Coakley and Barron, 2012). Massage therapy is generally safe when offered by credentialed practitioners, and those specifically trained to work with cancer patients (MSKCC Integrative Medicine Service, n.d. c, n.d. d) are especially likely to avoid any negative side effects, such as tissue trauma from excessive pressure.

Acupuncture

Acupuncture, an enduring integral component of Traditional Chinese Medicine, involves the insertion and stimulation of

needles at selected points on the body to achieve a therapeutic effect (Fig. 4.17.1). Although based on the theory that needling regulates the flow of vital energy, neuroscience research suggests that acupuncture induces clinical response through modulation of the nervous system (Kaptchuk, 2002; Han, 2004). Acupuncture needles are filiform, sterile, single use, and very thin (32–40 gauge). They are regulated as medical devices in the United States. Acupuncture treatment is safe and causes minimal or no pain when performed by experienced, well-trained practitioners (MSKCC Integrative Medicine Service, n.d. a, n.d. b). Serious adverse events are extremely rare.

Acupuncture is well documented for the reduction of symptoms related to cancer and cancer treatment. Multiple well-designed studies also support its use to reduce chemotherapy-induced nausea and vomiting (Molassiotis et al., 2007), several types of pain (Pfister et al., 2010), and aromatase inhibitor-induced joint pain and stiffness (Crew et al., 2010). Acupuncture also was shown to be as effective as venlafaxine, the standard treatment for hot flushes in breast cancer patients (Walker et al., 2010). Early indications further suggest that acupuncture may decrease arm circumference in breast cancer patients with chronic lymphoedema (Cassileth et al., 2011) and alleviate dysphagia (Lu et al., 2010) in patients with head and neck cancer. Importantly, it has been shown effective for symptoms refractory to conventional care and often experienced by palliative care patients, including xerostomia (Pfister et al., 2010) and neuropathic pain (Alimi et al., 2003). Other concomitant conditions that may be experienced by patients with cancer have also been effectively improved with acupuncture, including osteoarthritis (Selfe and Taylor, 2008), migraine (Linde et al., 2009), and the relief of procedural anxiety (Wang et al., 2007, 2008).

Music therapy

Music can evoke deep-seated emotion and spiritual experience. A particular composition or genre may hold special meaning to an individual depending on his or her life experience. Music therapy can be receptive or participatory, and is provided by trained music therapists adept in dealing with the psychosocial as well as clinical issues faced by patients and family members. Music therapy is particularly effective in the palliative care setting. It offers a creative, lyrical, and symbolic means to address existential and spiritual needs, and is aesthetic and expressive. It brings form, order, comfort, and hope; transcends predicaments, space, and time; and affirms or re-establishes relationship with self, others, and the universe.

Many cancer centres in the United States and other countries offer music therapy programmes and studies have demonstrated its effectiveness in the oncology setting. A systematic review of 30 trials involving 1891 participants concluded that music therapy improves both psychological and physical outcomes in cancer patients by reducing anxiety and pain, and by improving mood and quality of life (Bradt et al., 2011). A randomized controlled trial of cancer patients undergoing autologous stem cell transplantation found that anxiety, depression, and total mood disturbance scores were significantly reduced in the music therapy group compared with standard-care controls (Cassileth et al., 2003). A perioperative music intervention suggests that music can reduce mean arterial pressure, anxiety, and pain among women undergoing mastectomy for breast cancer (Binns-Turner et al., 2011). In paediatric patients, music therapy-assisted procedures can reduce patient sedation, anxiety, and procedural time, and potentially prevent or reduce future negative associations (DeLoach Walworth, 2005).

Fitness/physical activity

An estimated 65% of all deaths worldwide currently are due to non-communicable chronic diseases such as cardiovascular disease, diabetes, and cancer. By 2030 that figure may exceed 75% (Blair et al., 2012). It is well known that physical inactivity affects mortality via risk factors such as obesity, diabetes, and hypertension. A growing body of literature also indicates that incorporating simple exercise regimens can improve survival in cancer patients.

In palliative care, fitness regimens can address many patient concerns including overall fitness, decreased mobility, breathing problems, difficulty relaxing, back and postural problems, and fear and anxiety (Selman et al., 2012). T'ai chi, a movement therapy derived from martial arts, can improve agility and reduce the risk of falls in frail and elderly patients (Faber et al., 2006; Lin et al., 2006). In a randomized controlled study of 256 elderly patients, a t'ai chi exercise programme resulted in significantly fewer falls, and fewer injurious falls when compared with a stretching control group. The risk for multiple falls in the t'ai chi group was 55% lower than that of the stretching control group. T'ai chi participants showed significant improvements in measures of functional balance, physical performance, and reduced fear of falling (Li et al., 2005). Yoga and yogic breathing also seem to improve persistent fatigue, sleep disturbance, anxiety, and mental quality of life (Dhruva et al., 2012; Bower et al., 2012), symptoms common among palliative care patients.

The issue of cancer cachexia is also of concern in the palliative phase (Fearon 2008). Multimodal approaches, including exercise, can stabilize and even improve nutritional status, function, and quality of life in patients with advanced cancer. A randomized controlled trial of physical exercise for 231 patients with advanced and progressive disease and a life expectancy of 3 months to 2 years found that physical exercise helped maintain physical functioning for at least a period of time (Oldervoll et al., 2011). For patients in palliative care, physical activity also can bring structure to everyday life and feelings of hope for the future (Gulde et al., 2011).

Fig. 4.17.1 Acupuncture.

Other therapies

Other complementary therapies, such as spiritual care, counselling, and group support have been part of supportive, rehabilitative, and palliative care for decades. Many of these behavioural interventions fall in the grey area between mainstream treatment and complementary medicine. Animal-assisted therapy (pet therapy) is a low-tech, low-cost modality that can improve mood and provide meaning to hospitalized patients (Marcus, 2012). A randomized clinical trial underway is examining how animal-assisted therapy affects pain in cancer patients receiving pain and palliative care at the NIH Clinical Center (2012).

Art therapy is a behavioural modality that uses creative expression to help develop coping skills. Many cancer centres provide access to artistic expression on a recreational basis or guided by professional art therapists. A few reports have shown an association between art therapy and higher comfort levels of children with leukaemia undergoing painful procedures. Art as well as music therapy can also reduce stress and decrease anxiety in family caregivers. Although scientific study of art therapy is minimal, it is clear that many patients enjoy creative activity. That enjoyment per se is an important end in and of itself.

Summary

The public in general and palliative care patients in particular are interested in complementary and alternative therapies, which are diverse and have variable risk–benefit ratios. Alternative therapies are often marketed to palliative care patients, but are unproven or disproved, potentially harmful, and often fraudulent. In the context of palliative care, this can also present specific and critical issues with respect to optimal delivery or interference with needed mainstream treatment.

Hospitals and other research institutions recognize the appropriate role that complementary therapies bring by supporting mainstream treatments. An increasing body of evidence over the last two decades supports the use of acupuncture, massage therapy, music, mind–body therapies, and other complementary modalities to reduce physical and emotional symptoms. Recommended and non-invasive therapies with favourable risk–benefit profiles should be applied to bring symptom relief particularly when conventional treatments produce negative side effects.

In palliative care, complementary therapies also may reduce the level of opioids required for pain control. In providing patient-centred medical care, complementary therapies must be tailored to the needs and preferences of each patient. Economic concerns, patients' belief systems, and cultural backgrounds also influence selection of therapies.

At the same time, educating patients about cancer cure marketing schemes, avoiding unproven methods, and the potential dangers of using natural products that seem 'safe' will assist optimal patient care. In light of product quality control issues and potential interactions with prescription medications, it is important to access or refer patients and families to sources of reliable information about common herbs and dietary supplements, such as those listed in Box 4.17.1.

This dual approach to complementary modalities can help alleviate troubling symptoms, promote family involvement and patient self-care, improve patients' well-being, and enhance the physician–patient relationship.

SECTION 5

Ethical issues

Human rights issues

Frank Brennan and Liz Gwyther

Introduction to human rights issues

The modern era has seen the articulation of a basic proposition: that palliative care should be viewed as a fundamental human right of all people. That proposition has been made in a context of, and in response to, clear inadequacies in the provision of palliative care around the world, absent or deficient national policies on pain and palliative care, restrictive opioid laws, and inadequate education of health professionals in all aspects of the care of people with life-limiting illnesses.

This chapter will examine:

1. the background of the concept

2. the fundamental argument and foundations of these rights in international human rights law

3. the content of the obligation

4. the response from the United Nations (UN) and the World Health Organization (WHO)

5. the counterarguments

6. current and future strategies in advancing palliative care by using a human rights discourse.

Background

Conscious of widespread deficits in the care of people throughout the world, the international pain and palliative care communities began, in recent years, to frame their advocacy in the language of rights. A series of declarations and statements emerged framing the provision of palliative care as a human right. These included the *Cape Town Declaration* (Mpanga-Sebuyira et al., 2003), the *Korea Declaration* (National Hospice and Palliative Care Associations, 2005), the *Joint Declaration of and Statement of Commitment to Pain Management and Palliative Care as Human Rights* (International Association for Hospice and Palliative Care (IAHPC) and the Worldwide Palliative Care Alliance (WPCA), 2008), the Panama Proclamation—*Proclamation of Pain Treatment and the Application of Palliative Care as Human Rights* (Latin American Federation of IASP Chapters and Foundation for the Treatment of Pain as a Human Right, 2008), the *Lisbon Challenge* (European Association of Palliative Care (EAPC), 2011) and the *Prague Charter* (EAPC, 2013).

These palliative care advocacy initiatives were concurrent to statements from within the international pain community. Indeed, as part of their response to the deficits around the world in pain management, clinicians, ethicists, and medical lawyers

began, in the 1980s, to argue that pain management was a universal human right. To Michael Cousins, a past President of the International Association for the Study of Pain (IASP), 'the relief of severe unrelenting pain would come at the top of a list of basic human rights' (Cousins, 1999). These assertions were eventually followed by authoritative statements by multiple national and international pain associations articulating a right to pain management. Finally, the inaugural Global Day Against Pain in 2004 had as its theme 'Pain Relief: A Universal Human Right'. Subsequent international declarations, including the *Joint Declaration of and Statement of Commitment to Pain Management and Palliative Care as Human Rights* (IAHPC and WPCA, 2008), the *Proclamation of Pain Treatment and the Application of Palliative Care as Human Rights* (Latin American Federation of IASP Chapters and Foundation for the Treatment of Pain as a Human Right, 2008), the *Declaration of Montréal* (International Pain Summit of the IASP, 2011), the *WMA Resolution on the Access to Adequate Pain Treatment* (World Medical Association, 2011), and *The Morphine Manifesto* (Pallium India et al., 2012) have all endorsed this approach.

A summary of these statements and declarations appears in Box 5.1.1.

The foundation of these rights in human rights law

While admirable in rhetoric and potentially strong tools of advocacy, do these statements have any foundation in human rights law? That foundation rests on two pillars: the international conventions on drug control and the international right to health.

The international drug control conventions were promulgated for a dual purpose: to monitor and control the use of both licit and illicit controlled substances. The International Narcotics Control Board (INCB), the body established to oversee compliance with the conventions, stated the importance of ensuring 'adequate availability of narcotic drugs . . . for medical and scientific purposes while ensuring such are not diverted for illicit purposes' (INCB, 2010, p. iii). The *Single Convention on Narcotic Drugs* (1961) expressly reminds and obliges signatory nations that the medical use of opioids is indispensable to the relief of pain and suffering (United Nations Conference for the Adoption of a Single Convention on Narcotic Drugs, 1961).

Several UN conventions articulate a right to the provision of health care. The central and most general statement of this is contained in the *International Covenant of Economic, Social and Cultural Rights* (ICESCR) (UN General Assembly, 1966,

Box 5.1.1 International statements articulating pain management and/or palliative care as human rights and their sponsoring organizations

Pain management

◆ Global Day Against Pain (2004)—IASP, EFIC, WHO.

◆ The Panama Proclamation—*Proclamation of Pain Treatment and the Application of Palliative Care as Human Rights* (2008)—Latin American Federation of IASP Chapters, Foundation for the Treatment of Pain as a Human Right.

◆ *Joint Declaration of and Statement of Commitment to Pain Management and Palliative Care as Human Rights* (2008)—IAHPC, WPCA.

◆ *Declaration of Montréal* (2011)—IASP.

◆ *WMA Resolution on the Access to Adequate Pain Treatment* (2011)—WMA.

◆ *The Morphine Manifesto* (2012)—Pallium India, IAHPC, PPSG, and 60 other organizations.

Palliative care

◆ *Cape Town Declaration* (2002)—African Palliative Care Educators.

◆ International Working Group (European School of Oncology) (2004).

◆ *Korea Declaration* (2005)—Second Global Summit of National Hospice and Palliative Care Associations.

◆ *Proclamation of Pain Treatment and the Application of Palliative Care as Human Rights* (2008)—Latin American Federation of IASP Chapters, Foundation for the Treatment of Pain as a Human Right.

◆ World Hospice Day (2008)—IAHPC.

◆ *Lisbon Challenge* (2011)—EAPC, IAHPC, HRW.

◆ *Prague Charter* (2013)—EAPC, IAHPC, WPCA, HRW.

EAPC, European Association of Palliative Care; EFIC, European Chapters of the IASP; HRW, Human Rights Watch; IAHPC, International Association of Hospice and Palliative Care; IASP, International Association for the Study of Pain; PPSG, Pain and Public Policy Studies Group, University of Wisconsin/WHO Collaborating Center for Pain Policy and Palliative Care; WPCA, Worldwide Palliative Care Alliance; WHO, World Health Organization.

sources of a human rights foundation to palliative care emerge from the international conventions:

1. Dignity. Each UN convention commences with a recognition of the 'the inherent dignity of the human person'. The attention to and the promotion of the dignity of individual patients is a central tenet of the practice of palliative care.

2. The right not to be subjected to inhuman or degrading treatment (UN General Assembly, 1976, Article 7). An example here would be a nation with laws prohibiting the availability of opioids for medical purposes.

3. The right to non-discrimination and equality (UN General Assembly, 1966, Preamble, Articles 2(2) and 3). The Committee overseeing the right to health in the ICESCR (UN General Assembly, 1966) stated that nations are obliged to respect the right to health and should not deny or limit equal access to all forms of health including palliative health services (Committee on Economic, Social and Cultural Rights (CESCR), 2000). An example would be a nation denying by law access to palliative care services to refugees or non-citizens. Arguably, an example of de facto discrimination would be a nation deliberately restricting the availability of opioids to a limited number of hospitals so that geographical distance and poverty means that only a small proportion of the population will realistically have access to these medications.

4. The right to seek, receive, and impart information (UN General Assembly, 1976, Article 19(2); CESCR, 2000, para. 12). An example would be a nation withholding information on analgesia or the nature and provision of palliative care.

5. Children. The *Convention on the Rights of the Child* contains a clear statement on the rights of all children and adolescents to the provision of health care (UN General Assembly, 1989). Significantly and expressly, the Committee overseeing the Convention identified States' responsibility to support the palliative care of children (Committee on the Rights of the Child, 2011). The Committee expressed concern that, in a particular country, most palliative care was provided by non-government organizations without sufficient financial support and recommended that the country establish adequate funding for these services (Committee on the Rights of the Child, 2011).

6. Older persons. The Committee overseeing the right to health in the ICESCR stated that State parties should uphold the right of elderly persons to the enjoyment of a satisfactory standard of physical and mental health (CESCR, 1995) and, in relation to older persons, to take a broad view of health including care of the terminally ill (CESCR, 1995).

The content of the obligation

Assuming that the right to pain management and palliative care exists under international human rights law, what obligations flow from that right? It is important to note that the rights articulated in the international conventions rest on individual nations, not on clinicians. Signatory countries are mandated to appear before that committee to outline their fulfilment of the rights enumerated in the covenant, including the right to health.

The content of the obligation on signatory countries in the provision of adequate pain management and palliative care can be

Article 12). The right to health is articulated in several other conventions: Article 12, *Convention on the Elimination of All Forms of Discrimination Against Women* (UN General Assembly, 1979), Article 24, *Convention on the Rights of the Child* (UN General Assembly, 1989), Article 5(e), *International Convention on the Elimination of All Forms of Racial Discrimination* (UN General Assembly, 1965), and Article 25, *Universal Declaration of Human Rights* (UN General Assembly, 1948).

Given that pain management and palliative care fall within health care, the international right to health is a source of obligation on signatory governments in these areas. Other potential

gleaned from the Committee that oversees the ICESCR. In 2000, it issued a General Comment on the right to health (CESCR, 2000). In essence it stated that this right contained the following 'interrelated and essential elements': availability of health goods and services, accessibility of health services to all citizens, acceptability in terms of culture and religious beliefs, and quality in terms of skills and expertise. These foundation stones—availability, accessibility, acceptability, and quality—are useful points of reference in assessing the adequacy of any nation in the fulfilment of its obligations in the provision of palliative care.

The Committee went on to describe the 'core obligations' of all signatory nations, irrespective of resources. They included obligations to ensure access to health facilities, goods, and services on a non-discriminatory basis, to provide essential drugs, as defined by the WHO, and to adopt and implement a national public health strategy. Interpreting this Comment in the context of palliative care, this would oblige nations to ensure a universal access to services, the provision of basic medications for symptom control and terminal care, including analgesics, and the adoption and implementation of national pain and palliative care policies. In addition to the 'core obligations' the Committee also enumerated obligations 'of comparable priority'. These included health education, access to information, and the provision of appropriate training for health professionals. In the context of palliative care, a 'main health problem' in all countries, this would obligate governments to ensure the education of health professionals in the principles and practice of palliative care and, further, provide access to the general community to information regarding it.

Towards a transdisciplinary consensus on the content of the obligation

Do the obligations that derive from human rights law accord with recommendations articulated from other sources? And if so, is there a synergy between them? The first source is the WHO; the second is the international palliative care community itself. The WHO laid down minimum standards of palliative care expected of countries. Those standards included the adoption of national palliative care policies, ensuring the availability of essential medications, including morphine across all health-care settings and ensuring the education and training of health professionals. Those standards are consistent with the WHO 'Public Health Strategy for Palliative Care' (Sjernsward et al., 2007) and have been consistently replicated in the multiple statements and declarations by the principal international pain and palliative care representative bodies. Synthesizing these sources—the Committee overseeing the right to health care, the WHO, and the international palliative care community—a consensus begins to emerge. Whether as an obligation under international human rights law or as recommendations through the WHO and international palliative care bodies the content of that consensus includes the following:

1. The creation and implementation of national palliative care policies.

2. Equity of access to services, without discrimination.

3. Availability and affordability of critical medications, including opioids.

4. The provision of palliative care at all levels of care.

5. The integration of palliative care education at all levels of the learning continuum from informal caregivers to health professionals.

The response of the United Nations

Irrespective of the strength of the argument that the provision of palliative care constitutes a human right, it could only truly gain hold if the UN itself acknowledged its merit. The first and vital steps in that acknowledgement came in statements made by two UN Special Rapporteurs on human rights. In a statement made to the UN Human Rights Council in 2008, the Special Rapporteur on the Right to Health placed palliative care firmly within the obligations that derive from the international right to health:

> Many other right-to-health issues need urgent attention, such as palliative care . . . Every year millions suffer horrific, avoidable pain . . . Palliative care needs greater attention. (Hunt, 2008)

Similarly, the UN Special Rapporteur on Torture in his report to the Human Rights Council in 2009 stated 'the de facto denial of access to pain relief, if it causes pain and suffering, constitutes cruel, inhuman or degrading treatment or punishment' (UN Human Rights Council, 2009) and that everything should be done to overcome all obstacles—regulatory, educational, and attitudinal—to the provision of palliative care and access to appropriate medications such as opioids. A similar statement was made by the Rapporteur in a report to the UN Human Rights Council in 2013 (UN Human Rights Council, 2013). In addition, the two Rapporteurs made a joint statement to the Chairperson of the Commission on Narcotic Drugs in 2008. After reviewing the inadequacies of pain management and palliative care around the world, they stated that under international human right to health governments should provide essential medicines and that the lack of access to such medication, including for pain management, was a global human rights issue (Nowak and Grover, 2009).

That statement then proceeded to make clear, practical recommendations for all nations that they:

- Ensure that national drug laws reflect the legitimate medical needs of the population for the management of pain and suffering.

- Ensure that national laws and regulations do not unnecessarily prevent access to these medications.

- Ensure that national authorities and health ministries, in consultation with health-care providers, work to establish health-care systems that are capable of ensuring wide availability of controlled medicines

- Ensure appropriate education to health professionals on the medical use of all controlled medicines listed on the WHO Model List of Essential Medicines and on the legal requirements for prescribing and dispensing controlled medicines.

- Allocate sufficient funds and personnel to implement all the above stated objectives (Nowak and Grover, 2009).

These statements were a major breakthrough. They not only represent the most explicit linkage of human rights UN, but they also provide clinicians and advocates a clear statement of recommendations to present to the health ministries of individual countries.

The response of the World Health Organization

From its foundation, the WHO has promoted the universal right to health care (WHO 1946). The WHO has stated that under its Access to Controlled Medicines Programme (ACMP), access to WHO Essential Medicines is part of a nation's human rights obligations (WHO, 2011). Subsequent to the *Montréal Statement on the Human Right to Essential Medicines* (University of Montreal, 2005), the WHO requested the IAHPC prepare a list of Essential Medicines for Palliative Care (De Lima and Doyle, 2007).

In the modern era, the WHO has expressly linked the overall right to health care with certain aspects of care, including pain management and access to analgesia. They did so expressly in a major document: *Ensuring Balance in National Policies on Controlled Substances: Guidance for Availability and Accessibility of Controlled Medicines* (WHO, 2011). That document was followed shortly thereafter by a landmark collaboration between the WHO, the INCB, and the UN. They jointly released recommendations for nations to ensure they accurately report their opioid requirements for medical purposes to the INCB and a guide for nations on estimating those requirements (INCB et al., 2012).

The counterarguments

There are several counterarguments to the proposition that pain management and palliative care are basic human rights. The first is the nature of human rights themselves. For some nations the concept of individual human rights is contrary to a view of a collective view of society whereby the paramount obligation of a government is the collective welfare of the people and society rather than necessarily meeting the needs of an individual. A response to that argument in the context of palliative care would be, given that mortality is universal and that the caring for individuals with serious illness will come to most members of society at some point, the provision of adequate palliative care services fulfils both an individual-based view of society *and* a collective one.

The second is the danger of arguing in isolation. Any discussion about access to palliative care services must be predicated upon the fulfilment of many other interrelated needs of a person with a serious life-limiting illness—water, sanitation, warmth, bedding, and a habitable environment. It would be artificial to separate 'a right to palliative care' from a general right to health, housing, water, and sanitation—social determinants of health that are inadequate in many communities living in low socioeconomic conditions. That interconnectedness was made express by the General Comment on the right to health (CESCR, 2000). The other perspective that needs broadening is the sense of palliative care itself. Rather than sitting in isolation, the discipline of palliative care articulates well with broader public health approaches of promotive, preventative, curative, and rehabilitative health.

The third is misunderstanding. *That these rights demand perfection.* They do not. They simply ask of governments to pursue the fulfilment of these rights progressively. *That these rights are Western ideals and are unattainable in nations of limited resources.* Studies have clearly shown that the provision of palliative care services including palliative care education, policy development, and legislative reform to ensure availability of essential palliative care medications are neither expensive nor unsustainable. Indeed, the growth of palliative care services in resource-poor environments demonstrates their feasibility and the application of basic strategies can provide much benefit.

The final contrary argument is that the above discussion is largely confined to the direct obligations on governments, not individual clinicians. That is true. To examine the obligations of clinicians in any society one must look at both the professional responsibility of a health professional to a patient and the legal framework of the country. In terms of professional responsibility one could argue that there is a universal obligation on doctors to manage the pain of their patients. Certainly, the *Declaration of Montréal* (International Pain Summit of the IASP, 2011) sponsored by the IASP, included this obligation on health professionals. Indeed, there is a direct connection between obligations on national governments and clinicians. The lack of fulfilment by the former makes it impossible for the fulfilment by the latter. If the infrastructure of pain management—availability, accessibility, education—is absent then it is extremely difficult for doctors to adequately respond to the pain management needs of their patients. Beyond ethical obligations, obligations that may arise from a legal right emerge from the domestic laws of that country.

Employing a human rights discourse to advance palliative care—current and future strategies

> There are few things more elemental than pain, they tell us of the fundamental equality, the fundamental dignity that all of us should enjoy. (Longstaff, 2012)

The basic argument linking pain management, palliative care, and human rights has moved from advocacy and assertion to action. In numerous discussions, workshops, and submissions on the subject of pain management and palliative care, a foundation argument has been the universality of these issues and the responsibility of governments, morally and legally, to do better in providing adequate access to these services. Those arguments can be made significantly more robust where there is a clear foundation not only in evidence-based practice but also in human rights law. In addition to strengthening the argument, an approach based on human rights carries with it a coherent structure upon which to assess the performance of any individual nation in its provision of palliative care.

How can this approach be used practically? There are multiple points of possible application. A human rights perspective may be incorporated in:

1. A national pain/palliative care assessment. This would involve examining five critical issues:

   a. Does the nation have pain and palliative care policies?

   b. The national opioid laws. To what extent do they restrict the availability and accessibility of opioids?

   c. Does the nation report their annual opioid requirements for medical purposes to the International Control Board? If not, that is a critical threshold issue. If they do, are these estimates realistic and commensurate with need?

   d. Education. To what extent is the management of patients with life-limiting illnesses and the safe and appropriate use of opioids incorporated into the education of health professionals?

e. To what extent are palliative care services integrated across all levels of health care?

Each aspect of this assessment reflects the human rights obligations of individual countries as signatories to international human rights conventions as outlined earlier. An example of a national assessment was the report by Human Rights Watch (HRW) on paediatric pain management in Kenya (HRW, 2010).

2. Once a national assessment has been made, to employ a human rights argument to strengthen advocacy to national governments. In essence that argument would be that, in addition to any other imperative for government engagement and action, there are clear human rights obligations on governments in this area. An example is the Lisbon Challenge launched at the EAPC Congress in 2011 with four clear objectives of palliative care for the nations of Europe based on a human rights approach. If a nation is struggling to report accurate estimations of annual opioid use, to refer departments of health to guidelines that can assist them (INCB et al., 2012).

3. Advocacy and support of citizens in countries where a right to health care is entrenched in the national constitution. A good example is the Republic of South Africa where, pursuant to a constitutional right to health care, the Department of Health proclaimed the *Patients' Rights Charter* (South African Department of Health, 2007). That Charter included a right of all citizens to access to affordable and effective palliative care.

4. A point of collaboration between clinicians and human rights lawyers and advocates. Examples include collaborative workshops held in South Africa (2008) and the Ukraine (2009) organized by the Open Society Institute and in the Netherlands (2011) organized by the International Federation of Health and Human Rights Organisations.

5. As a basis of opioid law reform. An example of legislative reform is seen in Romania where the government, on advice from the Romanian Palliative Care Commission, changed restrictive and burdensome opioid legislation to legislation in line with international recommendations (Mosoiu et al., 2007). A critical catalyst of this work was the Pain and Policy Study Group (PPSG) at the University of Wisconsin, United States, which has an international expertise in the promotion of, and practicalities around, opioid law reform. The African Palliative Care Association has also influenced governments in Africa to reform opioid legislation through workshops focusing on accessibility of essential pain medications (Ddungu and Mugula, 2007).

6. Submissions to agencies within the UN, including the Committees that oversee the relevant international covenants.

In the modern world, the universality of mortality has not been met by a universality of response. For patients with life-limiting illnesses, there remains widely divergent access to palliative care services, availability and accessibility of analgesic medication, and training of health professionals in this area. A study in 2011 by the WPCA reported that, out of the world's 234 countries, only 136 (58%) have one or more hospice or palliative care services available to seriously ill people and their families and carers (WPCA, 2011). Many nations are either poorly engaged or simply unresponsive to these needs. An approach based on human rights has emerged in the interrelated disciplines of pain management and palliative care. That approach has a clear foundation in international human rights law. It has been acknowledged by the WHO, the World Medical Association, and from within the structure of the UN itself and remains an important agent for advocacy, change, and development.

It is clear that palliative care services worldwide are inadequate to meet the needs of patients with life-threatening and life-limiting illness and there is much work to be done to ensure that palliative care is accessible, available, and affordable to people needing this care. A human rights approach to facilitate development of these services provides a strong foundation plan for the implementation of palliative care services within countries.

5.2

Confidentiality

Timothy W. Kirk

Introduction to confidentiality

This chapter offers an explanation of, and approach to, respecting confidentiality as an ethical obligation in the practice of hospice and palliative medicine. Understood in the context of coincident ethical obligations to maximize clinical benefit, avoid preventable harm, and restore moral agency, respecting confidentiality is embedded in the most basic philosophical precepts that define hospice and palliative care. *How* to respect confidentiality in everyday practice, however, can be a matter of unusual complexity. As such, following a brief conceptual framework, the chapter explores ways to employ the framework in the service of patients and families in clinical practice. While various regions and nationalities will have legal and regulatory requirements informing the definition and practice of respecting confidentiality, this chapter focuses instead on respecting confidentiality as an ethical value. Readers are encouraged to supplement the content of this chapter with the relevant requirements that apply in their practice location.

Agency, meaning, and interdisciplinary family-centred care: a brief philosophical context

Hospice and palliative care have a richly developed philosophical history, and it is only through that philosophy that the ethical significance of confidentiality can be fully articulated. Hospice care, in particular, is heavily informed by the clinical and philosophical work of Dame Cicely Saunders. Saunders was quite explicit in her writing that the defining feature of the hospice philosophy of care as she envisioned it was that it works with patients and families to restore and support the capacity of terminally ill persons to live meaningful lives. Indeed, while relief of symptom distress was an integral part of the hospice model Saunders established at St Christopher's Hospice in London, this relief was not an end in itself. Rather, it was a necessary condition employed, concomitantly with social and spiritual care, in the service of a more fundamental purpose: respecting the dignity of persons by allowing them to exercise their moral agency (Saunders, 1978; Kirk, 2014).

Restoring agency—the ability to intentionally express, live, and act upon the perception and creation of meaning—when possible, and respecting that agency in all cases, even when the capacity for restoration is minimal, are profoundly moral enterprises. By focusing on engaging patients at the level of their lived experience as persons, and not just their symptoms as bodies, hospice and palliative care clinicians acknowledge and affirm the value and dignity of patients and family members as human persons. It is

precisely this emphasis on restoring and respecting the agency of persons that led Saunders to construct hospice as a model of care that is interdisciplinary and family-centred.

Hospice and palliative care are interdisciplinary enterprises because assessing and addressing the multiple ways in which serious illness interrupts patients' lives require the coordinated intervention of multiple disciplines. Effective response to the vulnerability created by many serious illnesses requires a response more comprehensive and complex than can be delivered by a single discipline. And, because hospice and palliative care teams are restoring agency—and not just relieving symptom distress—the integrated work of expert medical and non-medical clinicians is necessary to mitigate the threats to personhood posed by serious and terminal illness.

Similarly, hospice and palliative care are family-centred care models because the professional care team recognizes that partnering with the support structures and meaningful relationships that patients have developed across their lifespans is often the most effective way to create and deliver a care plan that reduces levels of distress and suffering and empowers patients to recover and exercise their agency as moral persons.

Some (Randall and Downie, 1999) have argued that it is precisely this interdisciplinary, family-centred model of care that presents significant challenges to honouring ethical obligations related to maintaining confidentiality. However, this chapter presents an approach to understanding confidentiality as an instrumental value which gains its ethical significance through its connection to other, more fundamental ethical values of respecting persons, maximizing clinical benefit, and avoiding preventable harm.

Defining 'confidentiality'

Confidentiality is related to, but distinct from, privacy and secrecy. Privacy and secrecy focus on the phenomenon of disclosure. When we ask someone—whether a friend, colleague, or health-care provider—to keep a matter secret, we are asking them not to disclose the matter to others. Similarly, when we seek greater privacy in the form of closing window shades, closing doors, or planting trees along a property line, we are attempting to limit how much we disclose visually to others. *Why* we request secrecy or seek privacy is not germane to the nature of secrecy or privacy as phenomena.

Confidentiality, however, is more complex. While patients may be seeking privacy or secrecy when they request (or assume) confidentiality in health-care relationships, the very term itself points to the reason why: to establish or maintain confidence, or trust, in the relationship between patient and provider. In this way, confidentiality is primarily about the nature of therapeutic

relationships, not about specific bits of information. That is, confidentiality is a *relational* value: its meaning and ethical significance arise only in the context of specific relationships.

Given the above, respecting confidentiality can be defined as follows: those practices and behaviours that serve to strengthen the trust and confidence between patients and their health-care providers, with special attention paid to the use of any and all information disclosed by, or obtained from, patients during their care experience.

Justifying a duty to maintain confidentiality

As noted by Thompson (1979), the *why* behind respecting confidentiality is often neglected in the literature, despite much ink being spilled on the legal and regulatory nuances of *how* to do so. Asking why confidentiality is important, however, yields an instructive response quite relevant to clinical practice.

The ethical duty to respect confidentiality is valuable because it generates and reflects other phenomena that are valued by professionals, patients, and families. As such, confidentiality is an instrumental, rather than an intrinsic, ethical value (see Fig. 5.2.1). That is, rather than being something we seek in itself, its value is rooted in its association with more fundamental ethical values in health care: respect for persons, avoiding preventable harm, and optimizing clinical outcomes (see Fig. 5.2.1). Each of these three values will be addressed in turn.

Respecting confidentiality respects persons insofar as it honours patients' discretion, protects their integrity, and exercises fidelity to promises made to them in the care relationship (see Fig. 5.2.2). Part of what it means to be a full moral person is that we have the right to exercise discretion over what aspects of ourselves to make public and what aspects of ourselves to keep private (Yeo and Moorhouse, 2010). Whether it is revealing certain parts of our bodies, certain facts about our identities, or certain pieces of our histories, what makes such matters 'personal' is precisely the fact that persons have discretion over when, in what conditions, and to whom they are revealed or hidden. Indeed, Cassell's (1982) influential model of suffering claims that suffering occurs when there is a threat—actual or perceived—to integrity of one's personhood. He defines such integrity as the way in which the different pieces of one's life fit together to form a whole person. One of those parts, according to Cassell, is one's 'secret life', the thoughts, hopes, fears, and history that we choose not to reveal to (or, to only reveal to carefully selected) others. In this model, violating confidentiality constitutes an affront to the personhood of patients by interrupting the integrity of their lives. Finally, if patients reveal personal information to health-care providers in the course of seeking care, then agreeing upon the terms of use for that information, and honouring such an agreement, is a way of respecting their personhood. This is especially so given that patients who seek the care of palliative care practitioners may be subject to increased vulnerability that accompanies the symptom and psychosocial distress attendant to serious or terminal illness. As such vulnerability creates a power imbalance between clinicians and patients, clinicians incur a fiduciary duty to safeguard the personhood of their patients. Honouring promises made by maintaining confidentiality exhibits fidelity to those promises. As promises are inherently moral acts made by and to persons, acting with fidelity honours patients' personhood.
Fig. 5.2.1 The relationship between confidentiality and other core values in health care.
Fig. 5.2.2 Respecting confidentiality promotes three values essential for respecting a patient's personhood.

Respecting confidentiality facilitates beneficial clinical outcomes insofar as accurate diagnosis and treatment adherence are both linked to a patient's trust and confidence in her health-care providers (Hall et al., 2001; Graham et al., 2010). Simply stated, patients are more likely to adhere to the treatment recommendations of their health-care providers if they trust them. Respecting confidentiality generates trust. Similarly, as a successful diagnostic interview may require patients to disclose facts about their personal lives that they consider to be very private—facts about sexual behaviours, toileting patterns, illegal actions with health implications, etc.—the promise of confidentiality (and trust in the clinician to honour the promise) facilitates such disclosure. Failing to honour such a promise, or to adequately disclose the limits of confidentiality, constitutes a barrier to future disclosure. Whether via improved treatment adherence or truthful disclosure of relevant information, respecting confidentiality can improve outcomes (see Fig. 5.2.3).

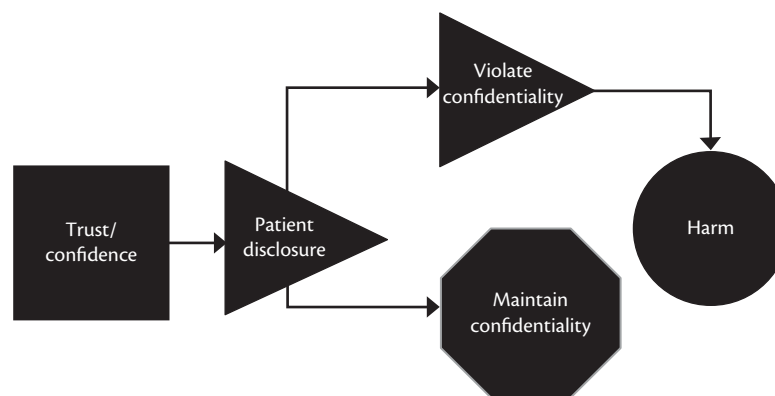
Finally, respecting confidentiality can prevent avoidable harm (see Fig 5.2.4). Patients may choose which information to disclose to whom in what circumstances based on the perception of harm or benefit that accompanies such disclosure/nondisclosure. The ability to discern the degree to which such perceptions are accurate is often outside the scope of practice of hospice and palliative care clinicians. Knowing only a small part of each patient's story and life situation, failing to respect confidentiality by violating patients' requests to keep certain information private risks incurring precisely the harm they may have been avoiding by keeping such information private.
Fig. 5.2.3 The ways in which respecting confidentiality can optimize patient outcomes.


Fig. 5.2.4 The relationship between trust, disclosure, confidentiality, and patient harm.

Respecting confidentiality: the basics

Clinicians in hospice and palliative care can respect confidentiality in their relationships with patients and families by ensuring that three basic elements are a part of their practice.

1. *Establish and follow organizational practices that effectively respect confidentiality.* Effectively respecting confidentiality requires effort at the level of organizational policy, and cannot be accomplished only through the efforts of individual clinicians. Policies and procedures addressing disclosure, record-keeping, email/fax/phone communication, and compliance with regional and national law should be established and implemented, practices monitored, and needs reviewed regularly. Procedures surrounding hiring and termination of employees should address confidentiality. All employees—from senior management, to senior clinicians, to trainee clinicians, to administrative and clerical staff, to operations and janitorial staff—have an important role to play in respecting confidentiality and should be educated and incentivized accordingly.

2. *Be clear and explicit with patients and families about the principles and practices related to confidentiality in your practice environment.* Patients and their families should understand the scope and limits of confidentiality as they relate to each aspect of their care. As it is the trusting relationship with clinicians that confidentiality fosters, explanation and discussion of the nature and limits of confidentiality in the clinical encounter

should be conducted by the primary clinicians involved in patients' care—not office staff or others outside of that relationship. This should connect the notion of confidentiality more directly with the clinical relationship in the minds of patients and families. Such discussions should address the following questions: who will have access to which information about patients? For what reasons? How will this be monitored? What information is considered 'confidential' and what is not considered so? How long does this confidentiality last? (Until the patient loses decision-making capacity? Until the patient's death? For a certain number of years following death?) What kind of information will need to be shared, under what conditions, regardless of a request for privacy, and with whom will it be shared?

3. *Immediately inform patients when breaches of confidentiality occur, and take action to mitigate the damages caused by such breaches.* Even in the presence of strong organizational policies and controls and in the practice of conscientious clinicians, breaches of confidentiality can occur. Quickly notifying patients of such breaches, and working with them to mitigate any short- and long-term harm arising from such breaches, fosters good will and is consistent with behaviours that maintain trust and confidence.

In sum, respecting confidentiality is intentionally engaging a set of behaviours that fosters the trust of patients and families in

clinical relationships in a manner that maximizes beneficial clinical outcomes, avoids preventable harm, and respects the personhood of all parties involved. The following three case studies make use of this framework to identify ethical questions and courses of action that seek to maintain confidentiality while being attentive to multiple ethical and clinical goals.

Case studies and analysis

Case 1

Mr Q is a 67-year-old African American husband and father of three who lives at home with his wife in a small city in the southern United States. Diagnosed 4 years ago with stage IV breast cancer, he has received several courses of chemotherapy with adjuvant hormone therapy that have slowed, but not stopped, disease progression. Mr Q's illness experience has been especially difficult because, in addition to the significant distress of a cancer diagnosis and treatment, he has found the type of cancer—breast cancer—to be emasculating and humiliating. Believing it to be 'a lady's disease', he has not revealed his precise diagnosis to friends or family, speaking only generically of 'the cancer'.

Following a meeting with his oncology team, with whom Mr Q has an open and trusting relationship, he agreed to talk with a nurse about receiving home hospice care. Attracted to the possibility of dying in his own home, he enrolled in a hospice programme 3 months ago. Throughout the course of his illness, Mr Q has been adamant about making decisions independently, preferring not to involve his wife or children in any care discussion that might reveal the fact that his cancer is breast cancer. Indeed, his primary concern in beginning hospice care was that he would have to tell his diagnosis to clinicians outside of his closely trusted oncology team. It was only with his oncologist's ongoing reassurance that the hospice team would maintain the confidentiality of his diagnosis that he finally agreed to receive care.

As Mr Q progresses toward death, his wife's distress is increasing significantly. While social workers and spiritual caregivers are offering her support, she is upset that 'the man she has shared a bed with for 40 years will not tell me what is killing him'. Mr Q's children are also growing upset about the lack of disclosure, wondering if they are at risk for 'getting whatever he has' when they are older, and telling him that he is 'harming our future health' by not telling them his diagnosis. Mr Q remains firm in not discussing his diagnosis with his family, and is increasingly worried that the hospice team will not honour his wishes.

In weekly team meetings, hospice clinicians are expressing confusion and concern about what, and to whom, their most important ethical obligations are in this case. On the one hand, Mr Q is the dying patient, and some team members stress the importance of respecting his wishes—including not disclosing his diagnosis to his family. On the other hand, hospice care is family-centred care, and some team members emphasize the obligations they have to the family, questioning whether maintaining confidentiality for Mr Q is increasing the suffering of his family and, in turn, violating their obligations to support and care for family members.

Analysis of Case 1

1. *Respecting personhood*. Mr Q has been unambiguous about his desire to keep his diagnosis a secret from family and friends. Honouring his discretion about revealing personal information,

the integrity of his secret life, and the promises made to him at the time of admission to hospice care all support maintaining confidentiality and not disclosing his diagnosis to his family.

2. *Maximizing beneficial clinical outcomes*. Mr Q's history with his oncology team clearly demonstrates that trust and confidence in his care providers is important to him. Similarly, his concern about the impact of his diagnosis on his masculinity raises the risk for stoic behaviour that may make him reluctant to disclose important information to his current hospice care team—information about symptom distress that, he may fear, would make him seem less 'manly' if he reported it or requested intervention for relief (Robinson et al., 2001.). As such, respecting confidentiality by honouring his request not to disclose his diagnosis is important if the team wants to partner with Mr Q in effectively managing his symptoms. Similarly, an accurate assessment of his symptom profile—a process greatly aided by timely and accurate patient disclosure of symptom burden—will aid the team projecting his time until death. This, in turn, will be quite helpful in supporting Mr Q and his family as death nears.

3. *Preventing harm*. Mr Q perceives the diagnosis of breast cancer to be a threat to his identity as a husband, father, and man. The team does not agree with this perception. There may be an opportunity for a member of the team to work with him to challenge this perception, to educate him about the prevalence of breast cancer in men, and to distinguish the concept of 'breast' as an object of sexual pleasure/beauty or maternal nourishment from the concept of 'breast' as a type of fatty tissue that, in his case, is the primary site of disease. They could also offer to work with his family towards a shared understanding of this information.

In addressing the family's frustration/anxiety over (a) the perception that Mr Q's lack of disclosure reflects a lack of trust and (b) that his lack of disclosure may be withholding important information relevant to his children's future health, the team could work with Mr Q to do a thorough family health history related to the cancer. If there are not first-degree relatives in Mr Q's family who have breast cancer, they could counsel the family that Mr Q's condition does not suggest an elevated risk for contracting his illness, and do so without disclosing the precise diagnosis. If the family history does reveal the presence of breast cancer in first-degree relatives, the team can present this information, along with his children's concerns, to Mr Q and pursue ongoing persuasive efforts with the goal of supporting him in making the decision to tell his loved ones the diagnosis himself.

In sum, the three primary values implicated in maintaining confidentiality—respecting personhood, maximizing beneficial clinical outcomes, and preventing harm—are all best supported in this case by respecting the patient's request to not disclose his diagnosis to family members.

Case 2

Ms S is an 86-year-old Caucasian woman in a large teaching hospital in Sweden. Diagnosed 2 years ago with congestive heart failure, Ms S has declined rapidly in recent months. She is unable to walk her dog, Ludde, to the corner without becoming dyspnoeic, and has developed significant oedema that is no longer adequately responding to diuresis. She was admitted to hospital 4 days ago in respiratory distress, and has been transferred to the palliative care

unit. Ms S's daughter, Marie, has been a constant presence at her side since hospitalization, leaving only once Ms S falls asleep in the evening and often arriving before she wakes in the morning.

On day five, Ms S encourages Marie to take some time away from the hospital to rest and check in on Ludde, who is being cared for by a neighbour. While her daughter is away, Ms S asks her primary nurse if she would be willing to witness a change in her last will and testament. In addition to Marie, Ms S has a son, Marc. Her current will leaves a modest estate split evenly between her two children. However, Marie has been so attentive during her hospitalization, and Marc so notably absent, Ms S now feels that an even split between the two may not be fair. 'After all,' she says, 'the end is near and I don't have much more time to make these changes. I may not even make it out of the hospital'. Ms S is adamant that no one, including Marie, be told of her desire to change the will.

The nurse is distraught. She has worked hard to establish a strong therapeutic relationship with Ms S and Marie. She is willing to be a witness for the document, but fears that not informing Marie (or, if he visits, Marc) might make them feel betrayed once they learn of the change. She does not want to be perceived by Marie or Marc as having colluded with Ms S behind their backs.

Analysis of Case 2

1. *Respecting personhood*. Ms S perceives, accurately, that the end of her life is very near. As such, her concern with the nature and content of her legacy with her family—in this case, her financial legacy—is an important expression of her personhood. Similarly, her desire to express her gratitude to her daughter, and express her feelings of loss and abandonment to her son, arise in the context of great vulnerability as she approaches the final transition of her life into death. Ms S surely has the right to discretion over to whom she leaves her estate, and how she does so. The role of a witness in this circumstance is simply to attest that Ms S had the decision-making capacity required to make an informed decision regarding her estate planning, and that she did so voluntarily. There are two distinct, though related, questions at play in this situation: (a) should the nurse serve as a signed witness to the document, and (b) should the nurse honour Ms S's request to not disclose the change in her estate plans?

   If the nurse agrees to witness the document, she should be very clear with Ms S about the terms of agreeing to do so. And, one of those terms should address whether or not, and for what reasons, the nurse also agrees to respect Ms S's request to not disclose that the document has been changed. In this case, the nurse would be agreeing or disagreeing to maintain confidentiality in her role as witness.

   Whether or not she agrees to witness the document, there is also the question of honouring Ms S's wishes to keep the fact that she is making changes to her estate planning confidential. If the nurse feels strongly that Ms S should discuss the changes with her family, she is free to explain that to the patient. However, as the patient waited until the daughter left the hospital to address the topic but openly discussed it with the nurse, this indicates that Ms S revealed her plan to the nurse under the implicit understanding that it would fall within the bounds of confidentiality. As such, maintaining that confidentiality also maintains fidelity to the nurse's professional relationship with the patient.

2. *Maximizing beneficial clinical outcomes*. As noted in the discussion of Mr Q, effective symptom management and psychosocial support at the end of life requires the honest and timely disclosure of new or heightened symptom distress by the patient to the team. Building trust increases the likelihood of such disclosure, and respecting confidentiality contributes to that trust. For that reason, maintaining confidentiality is likely to maximize beneficial clinical outcomes for Ms S.

3. *Preventing harm*. It is not clear for what reasons Ms S wishes to keep the change in her estate plans confidential. If, however, one of the reasons has to do with Ms S's perception that disclosing the changes may result in harm to herself or her family, then exploring that perception of harm with the patient may be helpful for Ms S. Given the very brief relationship between the nurse and patient (less than a week), and absent robust evidence that the perception is inaccurate, the nurse should assume that Ms S knows the situation best and honour confidentiality to prevent the perceived harm from occurring, and the ensuing anxiety/distress on the part of Ms S that it may occur.

Case 3

Mr L is a 62-year-old patient who has amyotrophic lateral sclerosis. He lives at home with his partner, Robert, and is wheelchair dependent. As his symptoms progress, Mr L begins receiving visits from a home care nurse. Mr L has participated thoughtfully in advance care planning for himself, carefully documenting his refusal of ventilator support and artificial nutrition and hydration when he becomes unable to eat, drink, or breath on his own. Robert is supportive of Mr L's wishes and is active in his care.

At the end of an afternoon nursing visit, Robert and Mr L invite the nurse to stay for a cup of tea. During conversation, Mr L reveals that a veterinarian friend of his has given him some pentobarbital and that he plans to take it during the weekend and die with Robert at his side. When the nurse asks why, Mr L explains that he does not wish to continue to live as his function progressively declines, and that he is telling the nurse because he and Robert are both grateful for her support and care and wanted to 'say a proper goodbye'. When writing up her visit notes that evening, the nurse wonders whether or not to document the conversation, and realizes she may have a legal obligation to tell her supervisor that Mr L is 'suicidal'.

Analysis of Case 3

1. *Respecting personhood*. The question of whether or not Mr L is suicidal, and what ethical obligations arise from the answer to that question, is a complicated one. In patients who are terminally ill, there is an increasingly accepted distinction between (a) suicidal ideation and (b) the desire for hastened death (Breitbart et al., 2000). The latter is a common phenomenon (Arnold et al., 2004), and does not necessarily constitute a psychiatric emergency. Primary distinguishing features between the two include if, and how, the patient's desire is rational and voluntary (Bostwick and Cohen, 2009). We are not given enough information in this vignette to assess either, but such an assessment is important. If the patient's desire is rational and voluntary, it may be an important expression of his

personhood and maintaining confidentiality may be justified as a way to respect that personhood. If the patient's desire is not fully rational and voluntary, the patient's decision-making capacity—a crucial component of how personhood can be expressed—may be compromised, and intervention may be warranted, even if such intervention compromises confidentiality. In this case I would recommend that the nurse return to the patient's home to further explore the decision and the extent to which it is rational and voluntary. Such assessment will inform the extent to which the nurse has ethical obligations to the patient to keep his plans confidential or share them with her supervisor. (Note: the obligations discussed herein may be supplemented by legal and regulatory requirements specific to the nurse's care region.)

2. *Maximizing beneficial clinical outcomes.* Mr L's plans, and the circumstances in which they arise, reveal the ambiguity that can surround determining which clinical outcomes are 'beneficial', and for what reasons. Mr L has decided that death is a more beneficial outcome for him than continuing to live with his declining functional status. If such a decision is a rational and voluntary one resulting from careful consideration, there may be reason to accept Mr L's analysis even if it conflicts with regional practice norms or the nurse's own analysis. One complicating factor is the plan itself: ingestion of pentobarbital obtained from a veterinarian. The nurse does not know if Mr L has an adequate plan to result in a peaceful death, and cannot really confirm this without asking more questions about the source and dose of medication—questions that will further complicate her role in the process and, depending on her practice jurisdiction, may increase her exposure to criminal liability. As such, while a peaceful death may be beneficial to the patient based on his own analysis, the extent to which his current plan will bring about a peaceful death is not known.

3. *Preventing harm.* As with the determination of 'benefit', the case of Mr L also highlights the extent to which the definition of 'harm', and the relative weight of harms and benefits in ethical reasoning, is highly patient specific. Knowing the extent to which documenting the nurse's conversation with Mr L, or informing her supervisor of the same, affects the risk of harm for this patient requires not only consideration of what constitutes 'harm', but also consideration of what the likely outcomes are of documenting/informing about the conversation. If, for example, it would trigger a mandatory and involuntary psychiatric assessment, the nurse would have to weigh the perceived harm of undergoing such an assessment against the possibility of allowing Mr L to hasten his death—a calculation that would have to be informed by the extent to which the nurse has reason to believe Mr L's decision is, or is not, rational and voluntary. If, on the other hand, failing to document the conversation would, in turn, fail to instigate a more thorough review of the patient's history in which the district nursing supervisor would discover a history of depression or compulsive harmful behaviour, the nurse would have to weigh the harm of violating Mr L's trust against the possible harm of missing information that could lead to a decision to intervene with more robust mental health support.

Conclusion

In each of the three cases discussed, the three-part model of an ethical duty to respect confidentiality—to respect personhood, to maximize beneficial clinical outcomes, and to avoid preventable harm—offers a useful framework to help guide clinicians in identifying questions and values to inform ethical decision-making about confidentiality. The framework does not change the reality that such ethical decision-making is fraught with difficulty and uncertainty. However, hospice and palliative care clinicians who use this framework will be well positioned to make clear and justified decisions on when and how to maintain confidentiality with their patients.

Neuro-palliative care and disorders of consciousness

Joseph J. Fins and Barbara Pohl

Introduction: why palliative care and brain injury?

Whether one dates the origins of the palliative care movement to the hospice of the medieval pilgrimage or the advent of St Christopher's Hospice under Dame Cicely Saunders, a constant theme has been the care of patients on the margins, near death, often in pain, and likely abandoned in their distress (Fins, 2006a). This laudable history now continues with the proposition that palliative medicine expand the scope of its care to patients with disorders of consciousness, individuals with severe brain injury in the vegetative and minimally conscious states. Like more conventional beneficiaries of palliative care, these patients are also on the periphery of the acute care system. Recipients of brilliant care that saves their lives, these patients are often abandoned to an ill-equipped chronic care system that generally neglects their needs and those of their families.

These challenges are amplified because patients with disorders of consciousness generally cannot articulate their feelings or preferences and are prone to misdiagnosis. Some patients can experience pain, and perhaps suffer, even as they are unable to voice their discomfort. Families watch and wait and experience a vigil of either anticipatory grief or the pain of a slow bereavement, all in a context of care which is unable to meet these biopsychosocial needs.

This can be a difficult time for surrogates who are suddenly compelled to become decision-makers about conditions they likely know little about (Fins and Hersh, 2011). This places a tremendous burden on families and is an opportunity for engagement by skilled professionals, but too often there is no one available to comfort and provide informed counsel.

We envision this role as one that might be fulfilled by those who now provide palliative care, not because these patients will imminently die—although some certainly will—but rather because the profound burdens experienced by patients and families touched by brain injury are, in many ways, reminiscent of what the dying patient and family may experience. Thus, the skills gained in developing competence in palliative medicine could be readily transferrable to this new target population. When patients do die, palliative interventions can take hold. And when patients and families struggle to survive and adapt to a new reality, a palliative approach can help them recast their goals of care (Fins, 2006a) and make sense of an inalterably different life, much as a patient might grapple with the new knowledge of a terminal diagnosis.

The engagement of these patients will need to be orchestrated with care, lest it be communicated that they are being seen by palliative care specialists because they are dying. That would be the wrong message. Instead, the objective is to blend the skill-set that resides in palliative medicine with expertise in brain injury medicine that resides primarily in neuropsychology, rehabilitation medicine, and some sectors of neurology, thereby establishing the norms of *neuro*-palliative care. All of this would be in the service of a population which has historically been underserved and relegated to custodial care through benign neglect (Fins, 2003).

To that end, this chapter will define and describe the neuroscience of disorders of consciousness. We will consider emerging methods of diagnosis and treatment, including neuroimaging and neuroprosthetics, and address how the palliative care needs of patients and their surrogates might be better met. We will address questions of pain and suffering as they related to this cohort of patients. In addition, we will explore the ethical challenges of surrogate decision-making in light of neuroprosthetics that lead to re-emergent patient communication from patients who had previously been 'silenced' by their injury. We will explore how this variation on surrogate decision-making both enhances and complicates the informed consent process for both routine medical care and decisions to withhold and withdraw life-sustaining therapies. Finally, we will conclude with a systematic discussion of how the palliative medicine and hospice communities can better meet the needs of this vulnerable population by fostering links with both acute care and rehabilitative sectors.

Disorders of consciousness
Nosology and prognostication

Disorders of consciousness refer to severe brain injuries, which result in disturbances in arousal and awareness. A number of descriptive categories, which have characteristic, but somewhat overlapping, behavioural and neuroimaging stigmata, subsume these conditions. Generally, coma, the persistent and permanent vegetative states, and the minimally conscious state (MCS) fall under this broad classification (Laureys et al., 2004).

There are two conditions, which are often included under the rubric of disorders of consciousness, which should be distinguished from these conditions, namely brain death and the locked-in state (LIS). Brain death refers to whole-brain death involving both the brainstem and higher cortical function. The LIS is a disorder of motor output, but is often conflated with disorders

of consciousness in error (Plum and Posner, 1972). Disorders of consciousness, in contrast, reflect composite disturbances of levels of arousal and awareness, that is, respectively, wakefulness or the 'readiness to respond to internal and external stimuli' (Bernat, 2009) and the ability to perceive aspects of the milieu and the self (Zemon et al., 1997).

In routine practice, and sometimes for polemical reasons (Fins and Plum 2004; Fins, 2006b) these categories are often conflated. When speaking with families of patients with disorders of consciousness, diagnostic clarity is important when invoking this nosology because each of these conditions has a particular time course and prognostic implications. Moreover, it is critical to appreciate that brain injury is dynamic and patients may start their disease trajectory in one state and evolve into another.

To track this trajectory, we will next define these brain states in more detail and suggest a means to convey prognostic information to expectant families as patients progress from initial stages of injury to later periods of recovery. Only as the course of the injury unfolds, can prognostic judgements reliably structure health-care decisions for patients with disorders of consciousness. As yet, no predictive model can fully account for the latent recovery of consciousness (Whyte et al., 2005; Katz et al., 2009). In the face of this knowledge deficit we suggest a method of *time de-limited prognostication* to structure clinical thinking and communication with surrogates (Banja and Fins, 2012). This method links clinical milestones, known to be associated with the process of recovery (The Multi-Society Task Force on PVS, 1994; Jennett 2002) with a longitudinal communication strategy to provide families with the information necessary to guide clinical care, both therapeutic and palliative (Fins 2007).

Coma

Coma may be the first clinical presentation of a severe brain injury or a complication or progression of an earlier insult. Patients do not exhibit wakefulness or respond to stimuli. It is an *eyes-closed* state of unresponsiveness, which represents dysfunction of the brainstem and higher cortical areas bihemispherically. Typically, they remain in this self-limited state for about 2 weeks, and can proceed in a variety of ways from brain death to full recovery (Schiff, 2009). If comatose patients do not devolve to brain death, or recover consciousness, they will progress to the vegetative state, either as a way station to higher levels of consciousness or to permanent unconsciousness as in the case of the permanent vegetative state.

Making a prediction regarding these variable outcomes depends on the history of the injury as well as the duration and time course of the comatose state. Comas from traumatic brain injury (TBI) have a far better prognosis than those following anoxia. Patients with a traumatic coma have a 50% chance of having an outcome at the level of the MCS or higher, while 77% of anoxic comas result in death or the vegetative state (Posner et al., 2007). The outcomes for anoxic coma with therapeutic hypothermia, as would follow cardiac arrest, is more favourable although precise data on outcomes are not yet available (Hypothermia after Cardiac Arrest Study Group, 2002; Scirica, 2013; Stevens and Sutter, 2013). Structural signs of herniation and loss of thalamic architecture are also associated with grave outcomes (Posner et al., 2007).

For the clinician, these distinctions in aetiology point to the importance of history taking in order to risk stratify outcomes. Overall the most important prognostic detail is how the patient was injured or became ill and distinguishing the aetiology as traumatic or anoxic, with vascular injuries being of intermediate severity. The exception to this general expectation is the emerging use of therapeutic hypothermia in the setting of cardiac arrest. This has a protective function that can be quite dramatic and cautions should be taken when prognosticating for recipients of this intervention.

Physicians may also be able to reliably formulate some expectations for recovery based on the length of time patients spend in the comatose state. Several studies indicate that while patients are in a coma, they exhibit neurological or electrophysiological signs that can reliably predict positive or negative moves to recovery (Posner et al., 2007). In most cases, an early versus late exit from coma portends a more favourable outcome, even if the patient only moves into the vegetative state, although a move to the vegetative state is less favourable than emergent consciousness. However, an early move to the vegetative state indicates recovery of brainstem function. The recovery of brainstem function defines the vegetative state.

Persistent and permanent vegetative states

Patients who do not recover consciousness after coma but recover brainstem activity, are vegetative, a state in which brainstem function is preserved but higher cortical functions are not. The vegetative state is a confounder for both clinicians and families alike. Unlike coma, it is an *eyes-open* state of unresponsiveness which can be both clinically confusing and ethically troubling. Clinically, the patient is in a state of what Jennet and Plum described as 'wakeful unresponsiveness', encapsulating both the physiological and ethical paradox of the condition (Jennett and Plum, 1972). Unlike comatose patients, patients in the *vegetative state* show signs of arousal but lack awareness. They will open their eyes in response to external stimuli, exhibit reflexive (but unintentional) movements and regain autonomic functions, such as respiratory or cardiac activity and sleep–wake cycles. None of these activities are purposeful and are basically autonomic functions.

This can be excruciatingly difficult for families. They become engaged with and generally ascribe awareness to individuals whose eyes are open. They can become optimistic about a patient's progress and think that their eyes-open state heralds a full recovery, only to become distressed when they are told that the patient is vegetative. Clinicians who consult with families need to appreciate how counter-intuitive the vegetative states can become for lay people and patiently help the surrogate understand this condition and its implication.

Most nosological schemes classify the vegetative state as *persistent* if it lasts for at least a month. It is considered *permanent* if it lasts for at least 3 months after an *anoxic* brain injury and for at least 12 months after a *traumatic* brain injury. Once the permanent vegetative state is reached, however, this neurological state is irreversible (Jennett, 2002). In addition, permanently vegetative patients have a mixed life expectancy. About 33% of patients in the permanent vegetative state die within a year of the injury (Jennett, 2002). Those patients who remain in the permanent vegetative state for more than a year typically do not die and can persist for many more years. Pulmonary and/ or urinary infections are frequent cause of death (Jennett 2002). In contrast, patients in the persistent vegetative state (PVS) have the potential to progress to the MCS (Giacino et al., 2009).

A patient's emergence from coma and move to the vegetative state does not necessarily mark a point where physicians can reliably make predictions of ultimate outcome. Most severely brain-injured patients will make this transition into the vegetative state, with it becoming the final outcome or a way-station to conscious recovery. The length of time that a patient remains in the vegetative state inversely correlates with the likelihood of further recovery. Based on a study done by the Multi Society Task Force for PVS, 52% of patients in the vegetative state for 1 month acquired consciousness a year after the initial injury while only 35% did so after being vegetative for 3 months. This contrasts with only 16% of patients regaining consciousness after 6 months in the vegetative state. A small number of cases move beyond the permanent vegetative state either to the MCS or to severe disability after these cut-offs, generally because they were misdiagnosed and had already reached the MCS by the 3-month or 1-year demarcations (The Multi-Society Task Force on PVS, 1994; Jennett, 2002).

Minimally conscious state and emergence from MCS

The MCS describes patients who have definitive evidence of consciousness demonstrating, by their behaviours, evidence of intention, attention, memory, and awareness of self, others or the environment. They may track objects in their visual field, say a word or phrase, or grasp a ball. But because of their state, they only do these actions intermittently and in an episodic fashion. If asked to perform the task, they will not reliably follow commands (Giacino et al., 2002). If a patient reaches the MCS, however, they have the potentiality to emerge and regain reliable functional communication (Giacino, 2005). At this juncture, we are unable to predict who in MCS will emerge and when or if it will happen. This is an area of active investigation (Schiff, 2010).

This prognostic uncertainty is highly problematic for surrogates who have to make decisions about quality of life and whether to maintain life-sustaining therapy. In the absence of prognostic clarity, care decisions can be difficult as possible trajectories are highly variable (Giacino, 2005). For some patients, MCS is a temporary bridge to further improvement and even emergence. For these patients, MCS is a transient state that will be overtaken by a higher functional status. However, other patients remain permanently in MCS, unable to reliably communicate but transiently exhibiting evidence of their consciousness. In the case of TBI, one study reported that 40% of MCS patients fully recovered 3 months after the initial insult and 50% a year after the initial insult (Lammi et al., 2005).

But it is even more confounding as the time spent in the MCS does not typically correspond to a positive or negative prognosis, as it does in the PVS (Schiff, 2005). In one highly publicized case, an MCS patient, regained functional communication after 19 years in what was thought at the time to have been the vegetative state. During that time, his parents observed behaviours that suggested he might have been aware, but their observations were ignored because they violated expectations and prevailing nosology. His emergence occurred in 2003, just 1 year after the Aspen Criteria describing MCS entered the lexicon (Fins and Schiff, 2003; Carey, 2006).

Once patients regain the ability to consistently and reliably communicate they are said to have emerged from MCS. This brain state is less ethically fraught than the MCS because the clinician has a direct resource to the thoughts and feelings of the patient, even as profound disability can persist. This vector of communication can help involve the patient in care decisions as we will discuss shortly.

Diagnostic assessment

As should be clear by now, the evaluation of patients with a disorder of consciousness is a dynamic process. Because brain states evolve over time, and sometimes do so with the assistance of drugs and devices, patients must be longitudinally evaluated (Fins, 2008b). Behavioural examinations, in skilled hands, are currently the standard way to diagnose patients and to track recovery. Most experts consider the Coma Recovery Scale-Revised (CRS-R) the most reliable way to make such assessments (Giacino et al., 2004). Unlike the more familiar Glasgow Coma and Outcome Scales (Teasdale and Jennett, 1974), CRS-R measures level of consciousness and is not wholly dependent on integrity of the motor system.

It is important to appreciate that behavioural signs do not always correlate with cognitive activity. Such misconstruals are an important source of error in assessing the related condition of the LIS where there is normal higher cortical function but absence of motor output through the brainstem. Although the LIS is technically not a disorder of consciousness, such patients can be mistaken as vegetative because of the paucity of behavioural signs offered by the LIS patient. These patients, however, are capable of communication using eye movements, and cranial nerves whose origins reside above the injured brainstem, as evocatively manifested in Bauby's memoir, *The Diving Bell and the Butterfly* (Bauby, 1997). Such patients can have misleadingly low scores on the conventional Glasgow scales because of their dependence on behavioural signs (Fins et al., 2007).

Increasingly, investigators are using functional neuroimaging to assess brain activity and delineate mechanisms of recovery (Laureys and Schiff, 2012). Methods like functional magnetic resonance imaging (fMRI) and positron emission tomography (PET) scans can provide information about metabolic activity and identify discordances between cognitive function and behavioural activity. Such results are most reliable when used in conjunction with the natural history and physical examination (Fins, 2008b) and need further validation within the research context (Laureys and Schiff, 2012).

At this juncture, the discordance between what physicians observe at the bedside and what they see using neuroimaging technology confounds the diagnostic process. Vegetative patients can have heterogeneous neuroimages (Schiff et al., 2002). A vegetative patient suffering an anoxic injury that impacts all parts of the brain will have significantly lower levels of metabolic activity as evinced by the PET scan. In contrast, in a vegetative patient with an injury to a particular structure like the thalamus, the fMRI will indicate the preservation of other portions of the cortex (Fins, 2011b).

Functional neuroimaging can lead to such provocative—and often confusing findings—but it can also help distinguish care needs by distinguishing the widely dispersed brain-wide neural networks of MCS from the non-integrated, even *dis*-integrated organization of the vegetative brain. This has clinical implications because the experience of pain, for example, requires an integrated pain network (Schnakers and Zasler, 2007). In a study done by Laureys et al., patients who were vegetative when given a noxious stimulus (nail-bed compression) only activated the

primary sensory area, not the wider pain network as occurred in MCS patients. It is postulated that in the absence of such integration pain perception does not occur. Such first-order activations are necessary but not sufficient without engagement with higher level somatosensory and associative areas (Laureys et al., 2002; Fins, 2011b). Another study demonstrated the higher-order activation in MCS patients necessary for pain perception (Boly et al., 2005, 2008).

Medical management

Patients with disorders of consciousness have a number of complications with which palliative care practitioners must become familiar. Primarily, their medical issues relate to prolonged periods of immobility. These conditions, which are briefly outlined here, can be mitigated by appropriate exercise and rehabilitative programmes. (For a comprehensive discussion of the medical needs of this population of patients, please see Bell and Shenouda (2013).)

Such interventions are important because immobility can lead to deconditioning, catabolism and muscle wasting, osteopenia, and contractures, which can be quite painful. These can further limit mobility and may require tendon release. These orthopaedic problems may further compound any neurological complications of brain injury which might also lead to impaired mobility such as hemiparesis or spasticity.

From an infectious disease point of view, these patients are at risk for bedsores, which can occur because of poor skin turgor related to malnutrition and catabolism as well as immobility. This risk is heightened as well by decreased sensory input—due to cognitive impairment and/or decreased arousal—which may allow ulcers to progress without subjective complaint.

Patients with severe brain injury are also at risk for aspiration pneumonias, especially if they have a tracheostomy or require a feeding tube. The usual precautions about feeding (bed elevation) and about pulmonary toilet pertain to these patients as to others who are bed bound, although special care needs to be taken because their lower level of arousal make them less able to control and maintain secretions.

Patients also suffer from gastrointestinal problems such as poor motility, gastro-oesophageal reflux, and constipation (sometimes due to hypercalcaemia due to bone resorption, especially in younger patients). They may have a need to be fed via percutaneous endoscopic gastroscopy tubes because they are neither alert enough to eat by mouth, control secretions, nor masticate. They are also prone to catabolic weight loss or obesity depending upon their context of care.

These patients also *age in time* (Colantonio et al., 2004), and young people who are victims of brain injury in their 20s become prone to the illnesses of advanced age, heart disease, and diabetes at an accelerated pace because of immobility and associated deconditioning. This mix of circumstances—plus associated fluid fluxes like dehydration due to decreased thirst mechanisms or diabetes insipidus—may also increase episodes of orthostasis and the risk of venous thrombosis. This may require filter placement or anticoagulation treatment or prophylaxis, an intervention that needs to be done prudentially given any associated central nervous system risks related to brain injury.

Finally, because surrogates have decided to continue to care for these individuals into adult life, decisions will need to be made about routine health preventive measures, such as screening mammography and assessment of cardiovascular risk. There are no existing guidelines to provide direction for these decisions and it is best to have screening and therapeutic interventions harmonize with goals of care. Throughout, it is important to be cognizant of the burdens and benefits of any intervention and the epidemiology of the cohort, who as survivors of brain injury have an independent increased risk for premature death as compared to the general public (Ratcliff et al., 2005).

Neuro-palliative care

Chronic disorders of consciousness not only pose diagnostic and management challenges, they also present complex clinical and palliative issues across the continuum of care. Physicians cannot easily determine how to manage any symptoms or suffering or establish the priorities of care for patients unable to express their feelings and preferences. Families involved in making these difficult decisions may face significant emotional distress, perhaps already grieving the loss of the patient or suffering a slow bereavement.

Pain

Minimally conscious patients require interventions to ease their pain and suffering in an effort to promote an optimal quality of life. This aim, which is the central tenet of palliative care, has long been missing in the context of severe brain injury. Until recently, very few empirical studies explored the quality of life for these patients and most discussions centred on the family members' interpretation of their loved ones' behaviours (Phipps et al., 1997; Phipps and Whyte, 1999; Bullinger et al., 2002). Objective knowledge of this information is scarce because patients with impaired consciousness are unable to communicate their physical and psychological needs and others cannot easily discern what they are feeling or whether they suffer (Laureys and Boly, 2007).

A variety of different factors may cause pain in patients with disorders of consciousness. In the acute stage of the injury, fractures, abdominal wounds, and invasive procedures can all cause pain. Other physical complications that accompany the severe injury may also produce pain. Blood clots can form in arms or legs. Bedsores commonly result from poor maintenance practices. Seizures, hindering functional outcomes, often recur. Muscular contractions leading to painful twitches and jerks are likely. Some vegetative patients may exhibit symptoms in response to nociceptive stimuli which also require attention (Schnakers and Zasler, 2007; Zasler et al., 2007).

Ongoing behavioural assessments include motor response tests which can inform providers about whether these patients consciously experience pain. The CRS-R gives a high score to patients who reach towards the site of noxious stimuli, and therefore exhibit a localized response to pain. The localized response to pain indicates that patients have the potential for conscious perception of pain (Giacino et al., 2002). In contrast, responses such as frowns or shouts independent of connections to specific stimuli may not signify pain. Clinicians have misinterpreted these signs in some vegetative state patients who exhibit these behaviours, thus the critical importance of making the initial distinction between vegetative state and MCS (Bernat, 2009) as the same behaviour in different diagnostic contexts would have a differential significance.

It is important to note that there are no dedicated pain scales to assess MCS patients and this should be an area of investigation. Despite general acceptance of the CRS-R as the most reliable way to assess conscious perception, it is not intended to collect data about the level of pain or suffering. Palliative care providers will require a new behavioural scale that can evaluate pain in patients with disorders of consciousness. It may be possible to revise existing scales used to assess pain in patients who lack the ability to communicate, such as those with advanced dementia, infants, or intubated/sedated individuals (Schnakers and Zasler, 2007).

Similarly, there are currently no guidelines for how to manage pain in MCS patients. A simple clinical pearl will need to suffice: be attentive to the diagnosis and the potentiality for distress. Interestingly, clinical guidelines currently do not recommend the use of analgesics for vegetative state patients. Since physicians may misdiagnose as many as 40% of MCS patients as being in the vegetative state (Childs et al., 1993; The Multi-Society Task Force on PVS, 1994; Andrews et al., 1996; Wilson et al., 2007; Schnakers et al., 2009), clinicians should cautiously interpret this guideline. Practitioners should remain cognizant of the possibility of diagnostic error and appreciate that its consequence is unremitted pain which could be controlled *in a patient who is likely unable to ask for relief.*

Another key issue is the under-treatment of pain in MCS patients. Many clinicians conservatively administer analgesic to patients with impaired consciousness, sometimes leading to patients' 'agitation' often observed in the acute or rehabilitative facility (Zasler et al., 2007). To adequately manage pain, physicians must use their clinical judgement and assess autonomic findings as an indicator of potential distress (Fins, 2000).

Suffering

Pain management is further complicated by the fact that MCS patients are often conflated with ones who are vegetative (Fins and Plum, 2004), who as we have seen, neither experience pain nor suffering. Thus, the most critical step towards pain management is a proper diagnosis in order to identify who should be the subject of dedicated pain management. Clinicians must distinguish patients with MCS from the vegetative state because MCS patients are conscious and able to perceive pain, and potentially even suffer in the forward-looking definition offered by Eric Cassell (Cassell, 1991). Cassell distinguished somatic pain from suffering which he consider a threat to the *Ich*, the 'I' or the self. Correspondingly, MCS patients may be able to suffer given the isolation and the frustration of being unable to communicate if their motor output deficit far exceeds their cognitive impairment. This remains an unknown for many patients but a prudential ethic would call for good pain management and psychosocial support for the patient. At a minimum, it would preclude discussions about the patient *in the patient's presence* that assumed that the patient was not there and could not understand. Such 'casual' remarks have the potential for iatrogenesis.

Thus, in the absence of sophisticated assessment, it is difficult to evaluate the potential discordance between bedside behavioural activity and neural correlates. The clinician should assume that the MCS patient can understand what is being said, and exercise discretion with bedside conversation. Moreover, the skilled and compassionate practitioner should attempt to engage MCS patients in what may appear to be a unilateral conversation so as to assuage potential fear and feelings of isolation.

Patients persisting in the MCS may also require some psychological assistance as they remain conscious and may have an understanding of their situation, which is greater than their ability to demonstrate behaviourally. Without the ability to functionally communicate, it is impossible to know. This potential sense of isolation is plausible given evidence suggesting that MCS patients retain the ability to process language. In one study, MCS patients displayed large-scale network activation, which was similar to healthy controls, in response to spoken narratives (Schiff et al., 2005). This contrasts with vegetative patients who do not.

For patients who recover more significantly, supportive and psychotherapeutic measures may be indicated to assist individuals in grappling with their altered selves and diminished capabilities. These isolated losses can prove complex with patients having a self-identity but, for example, a lost temporal sense. That is, one could know who one was but not appreciate one's age and temporal context (Fins, in preparation; Windslade, 1998). Alternately, patients who recover from severe brain injury may recall a former capability that they no longer possess, prompting a sense of loss and depression (Meili, 1998; Osborn, 1998; Banja and Fins, 2007).

Goals of care: restoration of functional communication

In response to the threat of isolation is the neuro-palliative (Fins, 2005) care goal of restoring functional communication. The ability of MCS patients to process language in the absence of functional communication suggests that such patients could have greater awareness than is manifested behaviourally and thus potentially experience distress. No one knows what MCS patients are 'thinking' and if they could express themselves they would be out of that diagnostic frame. But if we adopt a prudential ethic, a clear palliative goal would be to promote communication whenever possible, maximizing the residual or dormant cognitive abilities of patients.

Families who have been interviewed express the restoration of functional communication as a primary goal of care and it is obvious why that would be so. At the most basic level, it would enable families and patients to re-establish vital ties and meaningful interactions. Once patients can communicate, they can engage in their treatment course, indicate their ability to feel pain, express psychological fears, or guide their end-of-life care decisions (Schiff et al., 2009).

There is a range of interventions that can facilitate communication. At its most basic level, it would be with the provision of a simple letter board, augmented potentially by a small cadre of pharmacological agents which are being studied to increase arousal and awareness (amantadine, zolpidem, and selective serotonin reuptake inhibitors). Drugs falling into three categories—psychostimulants, dopamine agonists, and tricyclic antidepressants—improve awareness, facilitate speech, and encourage new behaviours (Giacino et al., 2007). Zolpidem, paradoxically, leads to improvements in patients with impairments of consciousness, arousing them and increasing their interactive behaviours (Schiff and Plum, 2007; Whyte and Myers, 2009). A recent randomized controlled study in *The New England Journal of Medicine* demonstrated that amantadine increased the *rate* of recovery in patients with disorders of consciousness (Giacino et al., 2012). These relatively low-cost interventions, becoming the standard of care in the rehabilitation and neuropsychology

communities (McNamee et al., 2012), should evolve as a standard neuro-palliative approach.

More involved interventions, also at the experimental level, include the use of what has been broadly termed neuroprosthetic devices (Fins, 2011a): deep brain stimulation (DBS) and neuro-imaging. In 2007, one of the authors was a co-investigator in a clinical trial describing the use of bilateral intralaminar nucleus thalamic DBS of a patient in MCS (Schiff et al., 2007). In *Nature*, we reported the case of 38-year-old man who had been in MCS for 6 years following an assault. Before DBS he could only inter-mittently respond to commands and was totally dependent upon tube feeds through his stomach. He was incapable of controlling his secretion and mastication. After the intervention, he was able to speak several words at a time and eat by mouth. Most criti-cally, the device restored a degree of personal agency (Schiff et al., 2009). With the intervention he was able to communicate with his family, express preferences and emotions, and tell his caregivers that he was in pain, if they asked. While this remains an area of investigation and is ready for dissemination, the use of such neu-romodulation technologies is likely to have a limited role for this population.

Neuroimaging methods are closer to clinical application and carry with them potential for neuro-palliative care. Over the past decade, functional neuroimaging has demonstrated the poten-tial to use neuroimaging as a window on the brain and a com-munication vector for those who lack behavioural output (Owen et al., 2006; Schiff, 2006; Fins, 2008b). These methods have enabled patients to communicate without repairing the structural dam-age to the brain (Fins, 2009). Recent notable examples using fMRI have the patient 'imagining' that they are playing tennis or swim-ming or walking about their house and toggling these activations to yes/no questions (Monti et al., 2010; Bardin et al., 2012; Fins, 2012). Although the results are still primitive and the bandwidth of the communication channel is narrow, this is a promising area of research. The one caveat is how we interpret these *forme fruste* communications in light of prior wishes (Fins and Schiff, 2010). We will address this question in the next section.

Surrogate decision-making

One of the central ethical considerations in this neuro-palliative framework is the place of the MCS patients in relationships and in decision-making. This is a complex interaction because it involves surrogates and the patient, both how he or she was and how they are in present when medical choices have to be made. A key ques-tion is the valence given to prior wishes as against current claims and desires. This becomes apparent in a hypothetical DBS exam-ple, where the intervention improved communication as in the aforementioned study. The dynamic between the patient's former uninjured self and his current state comes to a fore when one con-siders whether such a patient can direct his or her medical care, much less assert a right to withhold or withdraw life-sustaining therapy. This determination will fundamentally hinge on a deter-mination of decision-making capacity and awareness that the absence of communication via a prosthetic device may or may not preclude the presence of consciousness.

The re-entry of the patient's voice in the room, via assistive devices, presents a difficulty for surrogates who will need to weigh prior knowledge of the patient's choices, values, and expressed wishes against the cogency and reasonableness of what the patient is now saying. This mix of inputs from the past, the patient's pre-sent, and from the surrogate should be balanced together in the deliberative effort. Ultimately, a *mosaic* model of decision-making emerges which includes pieces from the patient and his past and the surrogate and her knowledge of the patient's values and cur-rent prospects.

Whatever the involvement of the patient, the burden of decision-making (for MCS patients) falls largely to families who must make choices amidst prognostic uncertainties. Clinicians should help families navigate the evolving trajectory of brain injury and help formulate temporally appropriate goals of care.

Right to care and right to die

Surrogates and clinicians must work together to respect the right to die and affirm the right to care (Fins, 2006b). Finding this balance amidst the general neglect of these patients, while advocating for care requires a balanced approach that recog-nizes the burdens associated with these conditions for patients and their families (Fins, 2003, 2010). Counselling about decisions to withhold or withdraw life-sustaining therapies can get overly focused on diagnostic and prognostic questions, often leading to an impasse.

In our view, it is better to identify goals of care and consider the feasibility of the patient reaching them. When articulated goals are elusive and likely not in reach, decisions to withhold or withdraw care may be more accepted. This functional approach to outcomes places the patient's condition into the context of a life narrative in a way that a simple diagnosis cannot (see Chapter 5.8).

Bereavement

Families caring for patients with disorders of consciousness face a significant burden; they must cope with severe emotional distress and be responsible for making health-care decisions amidst great prognostic uncertainty, and do so over the long haul. After their family member suffers a severe brain injury, they lose a psychological connection to their injured relative and often become socially isolated from family and friends. These losses may lead to what might be called a perpetual state of bereavement, heightening grief and distress when the patient actually passes. Some investigators liken their experience to caregivers of patients with dementia (Marwit and Kaye, 2006). Whether these factors lead to a complicated bereavement is a question for further study but our experience suggests that the mix of relief and sadness attending these loses make the recov-ery process for families more complex and nuanced and good candidates for follow-up support.

Expanding the mission of palliative care

Through our study of patients with disorders of consciousness and the experiences of their families we have come to appreciate that our systems of care neither accommodate the needs of this popu-lation vis-à-vis rehabilitation in the acute care setting, scientific advance in chronic care, nor palliation when it is most appropriate (Fins, 2003, 2005). All of this is in spite of the progress that has been made in this field (Fins, 2013). Curiously, this level of neglect has its origins in the evolution of the right to die in the vegeta-tive state, observed in cases like Quinlan, Cruzan, and Schiavo

(Annas, 1996; Fins, 2009). In day-to-day practice, practitioners acculturated to modern notions of palliative care and medical ethics erroneously equate patients with brain injury with a dying patient: they see the loss of consciousness in brain injury as akin to that which occurs as a consequence of end-stage disease (Fins, 2007). This prematurely truncates care and precludes the potential of recovery, all in a misplaced exertion of palliative care.

So another rationale for expanding the mission of palliative care to this population is to help ensure that the application of this area of practice is not merely in the exercise of negative rights but rather a positive entitlement that brings comfort and relief to those patients and families who sought fuller recoveries but were left with chronic morbidity and mortality. Palliative medicine, properly exercised, can pre-empt its reflexive application to unconscious patients and more laudably apply its ministrations to a population that truly is in need. The main institutional features of palliative medicine—the use of interdisciplinary teams, the provision of care in a variety of settings, and its blending of comfort and curative interventions—have the potential to successfully coordinate care from the acute to chronic phases of severe brain injury. Such dedicated efforts can promote the integration of special neurorehabilitation programmes, which provide a variety of services that respond to the psychological, physical, and social aspects of the pathology (Bernat, 2009).

The reservoir of compassion, caring, and expertise that exists in the palliative care sector—in hospitals, hospice, and the community—is a ready resource for patients and families who will grapple with medically and psychologically complex conditions for decades in a state, as we have noted, that is often equated with perpetual bereavement. These families need biopsychosocial support, respite care, and counselling, much like families that are anticipating a death. And families of severely brain-injured patients also face a heightened prospect of mortality because of their loved one's condition and co-morbidities.

Because the acute care system has been so inhospitable to brain-injured patients after the initial heroic measures have been provided, policy needs to turn to alternative venues for optimal care. Although it is beyond the scope of this chapter, one might envision a collaborative dialogue between clinicians and institutions providing chronic care, rehabilitation, and palliation. Combining the best that each of these realms offer could lead to a care system that comprehensively and longitudinally meets the long-term care needs of this vulnerable population.

Truth telling and consent

Linda L. Emanuel and Rebecca Johnson

Introduction to truth telling and consent

At the core of truth telling is a fairly new cultural value (Xue et al., 2011) that entails a revised role for 'healers' in society as well as care recipients (Cassell, 1985). Whereas in earlier times it was deemed helpful to shield people from the harsh reality of their conditions, clinicians practising palliative care in Western medicine today generally understand 'truth telling' as a legal and ethical professional responsibility. Persons with illness generally understand 'truth telling' as their right to information about their illness. This sea change in cultural values is reflected in the arts. Historically, cultural representations of the therapeutic relationship have emphasized physicians' dilemmas. For example, the tragic consequences of one-sided, professional honesty (Ibsen, 1984) and well-intentioned reticence (Narayan, 2006). More recently culture increasingly elects to profile individuals' illness dilemmas (Forster, 2010; Gurnah, 2011; Mankell, 2012).

This chapter focuses on the role of truth telling in the therapeutic relationship and the ways in which communications can maintain hopes and at the same time deliver information sufficient for informed consent. It outlines the evolution of standards for truth telling and consent and then presents practical approaches that can guide truth telling and informed consent. Finally, it concludes by considering these norms and some of their limitations from within a global cultural context.

History of truth telling

Truth telling in contemporary Western medicine has come to refer to the way in which information about the futility of treatment, a person's impending death, possible clinical pathways to death, and the possible impact of end-of-life decisions along those pathways should be communicated (Deschepper et al., 2008). Each person fears death in his or her own way (Yalom, 2008) and studies show that 'truth telling' around diagnosis or prognosis can be particularly difficult to communicate. For example, research shows that 'cancer' is a word which has the capacity to effect a blinding emotional reaction (Casarett et al., 2010; Nwankwo and Ezeome, 2011).

Research also suggests that communications which sustain hope along a disease trajectory are particularly effective in maintaining quality of life for individuals suffering from terminal or incurable diseases and their families (Clayton et al., 2008). However, these communications are sometimes difficult for clinicians. For example, some physicians are more comfortable talking about the disease or the technicalities of treatment than healing or choices that involve difficult decisions (Cassell, 1985; Deschepper et al., 2008). Importantly, many physicians and nurses are reluctant to communicate bad news (Gysels et al., 2004).

Approaches to medical truth telling in prognostic and diagnostic discussions differ around the globe. In Lebanon, China, Singapore, and Japan, for example, persons with cancer are often not told their diagnosis or their prognosis, whereas in the United States and United Kingdom, the American Medical Association and General Medical Council advocate truth telling and reject deception (Sokol, 2006). Studies in both these countries show that the gold standard is absolute truth about diagnosis and prognosis. Indeed, studies with families and persons with illness show that people appreciate honesty about their illness (Apatira et al., 2008). Preferred physician behaviours include being realistic, providing an opportunity for asking questions, and acknowledging the person as an individual while discussing the prognosis. However, it is less clear what each participant in the truth-telling interaction means by 'truth' and some studies show that preferences for information may change over time (Hagerty et al., 2004, 2005).

Hope is commonly equated with the potential for cure. Within the field of palliative care where cure is often a receding theme, hope still retains an important role. Observations in clinical practice suggest that when a future to hope for gets disturbed by difficult news, people move into a more fundamental emotional state in which dependence dominates and trust becomes more than usually essential. This response to disturbed hope underscores how powerful an emotional asset hope is (Hagerty et al., 2004, 2005; Eliott and Olver, 2006; Clayton et al., 2008; Kersten et al., 2012). In palliative care, the goal is to find something realistic to hope for and to tailor care towards that goal (Emanuel et al., 2007). For example, if a person says that he or she wants to attend a family life-cycle event, the care plan can focus on treatments which enable them to achieve this.

History of consent

Contemporary understandings of informed consent as a guiding ethical principle and practice within health-care settings have roots in the US and UK courts. Early English common law doctrine ensures that assault (the threat of bodily harm) and battery (the unlawful touching of another individual) are the key measures by which lawful behaviours are ascertained (Murray, 1990). Informed consent cases can be traced back to the early modern period of legal jurisdiction. Most cases present themselves in oppositional terms with the person with illness pitted against the physician, health-care team, and health-care provider. For example, a significant case in English medical law was *Slater v Baker and Stapleton* in 1767. Surgeons reset a femoral fracture without the person's consent and without giving sufficient prior warning. Custom dictated that physicians obtain consent to help patients

'take courage', and the judge ruled that failure to do so in this case was remiss (O'Shea, 2011).

Legal definitions of informed consent have evolved over the years. In the 1950s and 1960s, US courtroom debates focused on the question of medical judgement and how much a 'reasonable physician' might be expected to disclose. The normative assumption was that physicians knew how much to reveal about a medical procedure to patients and that professional bodies would provide guidelines. In the 1970s, a new formulation of person-orientated standards of care emerged, and the right to self-determined consent was enshrined in law (Bennett, 2000). Physicians were required to reveal as much information as a 'reasonable person' would wish to know. Informed consent was not just about protecting persons with illness from unwanted interference with their bodily integrity, it was also about enabling them to make informed choices about care (Appelbaum, et al., 1987).

The law of consent is now generally accepted as 'the vehicle by which the respect for personal autonomy' (MacLean, 1988) is translated into law. As a modern ethical formulation, informed consent can be seen as an attempt to codify and institutionalize a basic human right to self-determination of what happens to one's body (Bennett, 2000; Monagle, 1998). It has been argued that this is in part Western society's attempt to respond to some of the human rights violations which have occurred within medical practice and research. However, the relationship between consent and autonomy is not always as clear-cut as this implies. Autonomy can mean different things to different people in different contexts. For example, in geriatric palliative care autonomy for a person with illness may mean dignity in death. A person's definition of dignity may be strongly influenced by cultural or spiritual factors. For one person dignity in death may mean living for as long as possible and trying every curative treatment available (Johnson et al., 2005), to another it may mean relief from pain and suffering and no invasive end-of-life treatment (Deshpande et al., 2005).

Legal definitions of consent do not prescribe the type of interaction which should take place between a person, physician, health-care team, and families in order to ensure that consent is informed or articulate how it should be done. In fear of prosecution, many health-care providers have adopted a rigidly legalistic interpretation of informed consent, standardizing documentation and institutional review to deliver legal requirements. The danger of this approach is that communication about consent can become an 'empty ritual in which persons with illness are presented with complex information that they cannot readily understand and that has little impact on their decision making' (Grisso, 1998). Indeed, the legalistic approach seems a particularly poor match with the goals of palliative care where the person and his or her family is the 'unit of care' (McClement et al., 2007) within a complex and fluid system of health-care provision (Bowman et al., 2011).

Research has shown that single utilization of forms alone can result in limited person understanding of what they are consenting to (Tulksy, 2005). An alternative approach is the process model described by Appelbaum et al. (1987) where 'informed consent (is integrated) into the physician-person relationship as a facet of all stages of medical decision-making'. Constant communication around consent builds trust and services everyday norms of non-deception and non-coercion. Furthermore, persons and physicians build relationships of trust which can enable individuals to exercise consent as 'a waiver (to) legitimate actions that (taken out of context) might otherwise be seen as breaches of rights and obligations towards them' (O'Neill, 2002). Take, for example, a person with illness who decides he or she wishes to die at home. Nursing staff know that the family carers will not be able to turn the person and that they may develop pressure ulcers. The health-care team holds a family meeting which includes the patient to discuss the benefits and barriers to a good death at home. The group decides that it is best for the individual to go home (Eisenberger and Zeleznik, 2004). This example suggests that there are diverse interpretations of autonomy as well as arguments for a non-autonomy rationale when seeking consent. It also suggests that continuing and sustained communication between professionals and the person with illness/family as 'unit of care' is essential for effective and considered consent (Appelbaum, 1987, Heinemann, et al. 2002).

A psychological perspective on consent

Any experience of significant illness is identity changing (Miller, 2010; Bowman et al., 2011). The shift from health to illness and self-confidence to constant watchfulness can be transformative, particularly for persons with illness living through long disease trajectories. Several conceptual approaches have been developed to facilitate understanding of these identity changes. For example, the concept of 'pre-morbid personality' notes that acknowledging one's illness entails '[entering] another way of being'. It notes that illness can impair or change a person's 'standard currency' (Bowman et al., 2011).

Taking in frame-altering news: a cognitively refractory state

Other conceptual models have facilitated predictions about how an emotional context will vary over time as a person processes illness-related losses (Emanuel et al., 2007). A first encounter with frame-altering news often leaves a person 'numb' and unable to absorb information. A key lesson from these models is that the decision-making behaviour of, say, a woman who gives consent for aggressive radiation treatment of breast cancer is unlikely to mirror the decision-making behaviour of the same woman who gives consent for transfer to hospice (Bowman et al., 2011). A different dynamic of contradictory feelings, experiences, family and health-care personnel, and motivations is likely to be in play at each stage of the illness (Covinsky, 1994, Mezey, 1997). Although in purely legal terms these identity changes don't matter (unless they affect the person's capacity to give consent), in practice they will affect the choices the individual makes (Bowman et al., 2011).

Adjusting to a new reality: an emotional and cognitive experimentation phase/creative adaptation

Recent scholarship has seen the emergence of a number of concepts and interventions relevant to the way individuals adjust to end-of-life losses at different stages of their illness journey (Munn et al., 2008). These include 'preparative waiting' around diagnosis (Giske, 2007); life review and emotional disclosure for persons with less than 6 months to live (Steinhauser et al., 2009); dignity therapy for terminally ill persons (McClement et al., 2007); and stages of change modelling for social workers preparing persons for end-of-life care planning and decision-making (Rizzo et al., 2010). Knight and Emanuel's reintegration model (Knight and

Emanuel, 2007) posits the idea that adjustment to losses are linked to a broader biopsychosocial context than hitherto acknowledged. As a person adjusts to illness, several cycles occur: comprehension (i.e. recognition of what has occurred), creative adaptation (i.e. experimentation with alternatives for living in the new circumstance), and reintegration (i.e. consolidation of a revised way of being). For example, take two individuals who have each had a leg amputated because of serious illness. Person one grieves for the loss of their mobility but seeks outside help to cope, and thinks of ways to continue to be mobile. Person two on the other hand does not accept the loss of his/her leg and does not adapt to the change. He/she refuses to leave his/her bed and dislikes having bed sheets changed because the amputation can be seen. This comparison illustrates how the reintegration model can help to 'place' the person in the trajectory of adjustment, and possibly thence guide approaches to foster optimal adjustment and functioning.

Reaching equilibrium; a mature state capable of durable decisions

Loss of function, body image, relationships, control, independence, dignity, and anxiety about death can occur at any time (Yalom, 2008). The literature on loss and grief tells us that loss is the condition of being deprived of something or someone (Kübler-Ross, 1969, Worden, 1991). Loss may be anticipated, real or perceived, primary or secondary. Grief is a personal and normal response to loss. It can be physical, (e.g. physiological capabilities, functions), psychological (e.g. emotions, cognitions, behaviours), social (e.g. role in relationships), or spiritual (beliefs, existential experiences). Mostly it is a complex combination of all these. The intensity of the response will vary according to the meaning of the loss to the person experiencing it (Yalom, 2008). Since all persons with illness and their families experience multiple losses associated with those illnesses, grieving can form a significant part of the end-of-life experience. Competence in helping those in care to adjust to losses is therefore a high priority for health-care professionals.

Working in clinical settings with different stages of adjustment

To be effective in end-of-life care, health-care teams must be able to recognize and anticipate grief (Kübler-Ross, 1969; Worden, 1991). Team members need to recognize individuals stuck in states of incomplete adjustment. Successful transitioning from one state to another takes time, reflection, regular communication, and an environment that offers hopeful alternatives to the state that has been lost. Team members should aim to anticipate grief reactions, providing basic supportive care to persons with illness and families and referring individuals to bereavement experts quickly when grief reactions become complicated. Observation in clinical practice suggests that active listening and unconditional support whilst acknowledging the unwanted reality can offer the best approaches. It also suggests that sources of help can feel like two-edged swords to persons who are having a hard time accepting the situation they are in. Worden and Rando advocate a process-orientated understanding of how people resolve grief (Worden, 1991; Rando, 1993). Their model offers guidance for identifying where individuals may be having difficulty in their trajectories of mourning.

Types of shared decision-making

Shared decision-making

In the last decade, as the therapeutic relationship has become more of a partnership (Joosten et al., 2008), shared decision-making has become a core imperative of person-centred care (Stacey et al., 2010). Conceptualizations of the nature of this partnership have identified an important common hallmark: 'that persons and providers have different but equally valuable perspectives and roles in the medical encounter' (Makoul and Clayman, 2006) when it comes to making decisions about treatment. Key questions for effective practice include how best to communicate these perspectives (Mok et al., 2010), which decision aids to use (Feldman-Stewart et al., 2006), who takes the lead and when, and what constitutes 'decision quality' (Joseph-Williams et al., 2010).

Current models of shared decision-making typically include the person with illness and one other health-care professional (Stacey et al., 2010) and can be plotted along a spectrum with paternalism at one end (i.e. physicians making the decisions) and informed choice at the other (i.e. where individuals make the decisions) (Makoul and Clayman, 2006). Some researchers suggest competencies for both clinician and persons with illness, while others argue that clinicians have the responsibility to elicit or respond to the views of the person with illness (Chwening et al., 2012). Self-help books urge individuals to proactively ask questions about diagnosis and prognosis (Lynn et al., 2011). At the same time, the evidence points to large variations in decision-making role preferences among and between persons with different disease trajectories (Tariman et al., 2010). A mismatch often exists between persons' stated preferences for and actually chosen roles. For example, while the majority of persons with cancer interviewed by Gaston and Mitchell expressed a wish for full information, only two-thirds wished to participate in active decision-making (Gaston and Mitchell, 2005). The nature of the decision and the stage of the therapeutic relationship can also influence a person's decision-making role preference (Chewning, 2012). All of these are important considerations, especially given that involvement in shared decision-making can improve the quality of end of life (Steinhauser et al., 2009).

Interprofessional and family perspectives on shared decision-making

A theory analysis of shared-decision-making models shows that although existing models identify the ways in which health-care professionals can work with persons with illness to achieve shared decisions, few discuss how the decision-making occurs 'with others involved beyond the person–practitioner dyad (e.g. family members, other professionals)' (Stacey et al., 2010). The person–practitioner dyad remains paramount in the literature and a core 'ethical unit' of shared decision-making.

An exception to this is family caregiving research, also referred to as family systems in nursing research, where there is a growing body of literature showing how the involvement of family in health-care decision-making can strengthen collaboration and trust between families and health-care teams (Anderson, 2000; Rempel, 2006). Family engagement reduces the risk of providing care which persons with illness and families don't want (Fineberg, 2005) and unnecessary and distressing hospital admissions

among older persons (Ahearn, 2010). It can also impact positively on symptom management in non-verbal persons (Mentes et al., 2004), difficult invasive treatment choices (Deshpande et al., 2005), and the initiation of palliative care (Nolan, 2008). Wider dissemination of guidelines for palliative care in dementia, for example, has been linked to a decrease in the prescribing of antibiotics and increases in the use of analgesics with persons who are unable to verbally communicate their wishes and preferences (Volicer and Ganzini, 2003).

How to accomplish truth telling with good outcomes

In the determination to promote and improve communications around person-centred care, there is growing professional interest in matching different communication functions or behaviours to good outcomes (Back et al. 2009). The taxonomy illustrated in Fig. 5.4.1 suggests that six communication functions delivered at six stages along the cancer continuum can improve survival and health-related quality of life.

Epstein and Street suggest that a key task for researchers is to 'specify what [types of behaviours and interactions] will improve outcomes for a particular person at a given point in time on the continuum' (Epstein and Street, 2007). This is where many of the protocol-based guides designed for use by health-care professionals can be useful.

A stepwise guide

Stepwise protocols, for example, can help health-care teams to approach truth telling by structuring goals of care discussions with persons and their families. Protocols are essentially guidelines which can be adapted to local context and tailored for each individual transaction when required. SPIKES, the stepwise protocol recommended in the Education for Physicians in End-of-Life Care (EPEC) project and widely used in other countries (Swaminath, 2008), is based on Buckman's protocol for communicating bad news (Buckman, 1992). SPIKES is a tool which respects the autonomy of the person and enables the clinician to determine how much 'truth' or information the individual wants to know and how he or she wants to receive it. Fig. 5.4.2 illustrates how a six-step SPIKES approach might be adapted to help the clinician determine the appropriate presentation of information for a person who has received a diagnosis of cancer and wants to talk about prognosis. Research suggests that older persons in particular expect physicians to initiate discussions around prognosis and so do many members of health-care teams (Adelman et al., 2000; Gutierrez, 2012).

Although stepwise approaches are useful tools when it comes to structuring sensitive communications and linking practice to legal frameworks, it is important to remember that to be successful they need to reflect the values, practices, and assumptions of the setting they are used within. For example, what happens when the prescribed norm is not the cultural norm for the person and family in question? The one-to-one communication model that SPIKES represents may not be an appropriate approach for a person who has never previously accessed health care, or who is non-verbal. It may be not applicable in cultural settings where families have traditionally shielded the person from prognosis (Chan, 2011). Furthermore, research shows that effective information sharing in end-of-life care depends on continuous ongoing communications that take into account a person's hope, despair, and regret.

How to accomplish informed consent

Informed consent is shorthand for two distinct duties in Westernized medicine. Firstly, the clinician's duty to obtain consent before treatment, and secondly the duty to ensure that the

Bailea et al, SPIKES—A Six-Step Protocol for Delivering Bad News: Application to the Patient with Cancer, The Oncologist, Volume 5, Number 4, pp. 302-311, Copyright © 2000 by AlphaMed Press.

person has been properly informed about a treatment's risks and benefits (MacLean, 2013). A particular issue in end-of-life care is that many individuals are unable to make their own medical decisions and are increasingly being asked to elect proxy/surrogate decision-makers. One study showed that families made approximately 75% of medical decisions for hospitalized persons with life-threatening diseases (Hiltunen et al., 1999).

Advance care planning (ACP) is the process that has come to characterize true informed consent in the United States. A core outcome of ACP in the United States is a completed advance directive. Although advanced directives alone are insufficient to ensure successful ACP, research has shown that programmes of care that include ACP can make a difference to goals of care (Cantor et al., 2003). It is important to emphasize that ACP is a process. Informed consent is never achieved through a single act of communicating (Bowman et al., 2011). In addition, the systemized nature of health care means that as a person becomes sicker they are likely to meet more and more health-care professionals who may not have been privy to earlier consent discussions and who will introduce their own behaviours and attitudes into the consent process.

A stepwise guide

Analysis of the advanced care planning literature suggests five key elements to achieving informed consent. The steps are similar to those recommended for achieving truth telling: introduce the topic; engage in structured discussion; document the preferences

of the person with illness; review and update those preferences regularly; and apply the directives when needed. However, research has identified several deficiencies in ACP. Nursing home staff report that persons with illness do not understand the purpose of an advance directive with several thinking the directives appoint powers of attorney over their affairs (Moskop, 2004; Tulksy, 2005; Steiber-Roger, 2006). Other misunderstandings can arise around the scope of statutory document. For example, whether a living will applies if a persona has terminal conditions is in a coma or a persistent vegetative state (Gunter-Hunt, 2002).

Despite these drawbacks, ongoing ACP and discussion can prevent unnecessary admission to hospital and timely use of hospice. Persons with illness without ACPs or directives are more likely to be transferred to hospital for investigations and interventions that provide short-lived benefits (Moskop, 2004; Steiber-Roger, 2006).

Working with persons with illness, families, and team members

Continuous communication and information is essential for families to function and cope within what can be a bewildering health-care context. Most families have the capacity to share feelings of grief, open lines of communication, and eventually engage in collaborative decision-making. However, inconsistencies in information about a condition can fuel conflicts and disagreements between the person with illness and their family, between

family members, and between family and health-care team members. Research also suggests that health-care team member attitudes to death and caring for dying persons can also be a significant factor in the provision of long-term care. For example, health-care team members who have completed an advance directive are more comfortable about discussing end-of-life planning with their patients than those who have no advance plan (Horgas et al., 2007; Guthell and Heyman, 2011).

As a life-threatening illness progresses, a person's family will have an increasingly important role to play, particularly in decisions about goals of care and treatment preferences. Some of the emerging roles for family or kin include emotional support for illness, advocacy for appropriate treatment for the individual, trusted confidantes about health-care issues, and surrogate decision-makers. These are not roles family members or the health-care teams caring for their loved ones are necessarily familiar or comfortable with. For example, research studies suggest that the desire to remain one's own person without becoming dependent on kin or family (children in particular) is particularly evident among older people growing old in America (Lamb, 2009). Comprehensive end-of-life care therefore requires that health-care teams know how to respond to family concerns and conflicts and how to help families and persons with illness reach informed consent.

Family systems

Family conferencing is a particular useful and well-evidenced tool that can promote communication around goals of care and ACP between the health-care team, person with illness, and family in a variety of health-care settings. For example, regularly scheduled nurse and clinician family meetings in intensive care units have the potential to maintain family health during chronic and terminal illness and enhance the care of the person with illness (Nelms and Eggenberger, 2010). Family meetings can also allow health-care teams to effectively acknowledge the suffering and vulnerability of families when a loved one is undergoing long-term care and offer families an opportunity for honest sensitive communication with health-care team members.

Alternative tools which have been successfully used in clinical family nursing practice to facilitate discussion around a person's individual and social network are genograms and ecomaps. Both are graphic portrayals of family structure and cultural, social, and spiritual relationships (Rempel et al., 2007). Wright and Leahey outline how health-care teams can conduct a 15-minute family interview that includes completing a genogram and ecomap (Wright and Leahey, 2009).

Cultural considerations

Culture is a vital factor for the clinician aiming to deliver person-centred health care. As clinical populations become increasingly diverse there is a growing premium on understanding and respecting cross-cultural difference and thus avoiding cultural stereotyping (Lasch, 2000). Research shows that the cultural factors which influence truth telling and consent around health care are complex. Age, gender, and ethnicity can all combine with spiritual beliefs, traditional family roles, and assumptions about the causes of an illness or stigma associated with treatments (e.g. opioids). Consequently, culture can

have a powerful influence on what clinicians and persons with illness are prepared to talk about, how they interpret one another's communications, and how they and their families make decisions.

Culture and truth telling

As noted at the beginning of this chapter, current ethical debates about truth telling and consent in Western medicine can be traced back to English common law and case law. Countries that share this tradition look to each other's jurisdictions for examples and precedents (Edwin, 2008). The outcome of several medical legal cases in Australia, Canada, Ghana, South Africa, and India, for example, all illustrate arguments which show that individual autonomy is fundamental to the rule of law and the basis for disclosure to persons with illness (Edwin, 2008). Truth telling is therefore grounded in a shared cultural value—respect for a person's autonomy and the 'right to know' (Xue et al., 2011). One result of this norm, as illustrated by this chapter, is that the research focus of much medical literature around truth telling is on how to divulge sensitive information (Xue et al., 2011) rather than whether to tell the truth.

Despite the links between culture and truth telling, a patient's desire for truth telling cannot be redacted down to cultural origins: 'neither cultural origin nor affiliation accurately predicts patient preferences regarding information transfer or decision making' (Cherny, 2012). Patients in both Western and non-Western cultures will exhibit considerable variation in their preferred style of disclosure of bad news or information. No one model will fit all. Indeed, data suggests that there is substantial heterogeneity of preferences that are not individually predicated by geography, culture, age, race, sex, religion, or educational level (Cherny, 2012).

Cultural approaches to screening bad news as a care function: some examples

National or minority cultures which emphasize family collectivism or familism can generate powerful arguments against the person's 'right to know' and for the family's right to a predominant role in therapeutic care and decision-making. In China and Asian countries which share similar cultures, philosophies of life and death, and laws and regulations, person autonomy is not a cultural 'norm'. Despite a legal mandate that physicians should tell the truth about a person's disease, family beliefs and norms of medical practice mean that 'truth telling' is not straightforward. The negative impact of learning that one has cancer, for example, is culturally well understood by many groups (Lasch, 2000; Rozario and DeRienzis, 2008; Xue et al., 2011) where familism is predominant. A cancer diagnosis is devastating for the whole family. The person's main source of financial and emotional support and care, particularly palliative care, will be their family. As a result many families adopt responsibility for the individual's therapy, protecting them against 'maleficence' (Chan, 2011). In practice this can mean families insisting that the person not be told 'the truth' about their disease (Chan, 2011), that particular family members be included or excluded from translation of negative news (Lasch, 2000), and that family caregivers may not seek information about help that they think the family should be able to deliver (Rozario and DeRienzis, 2008).

A practical guide

Clinicians can become more culturally sensitive and more effective in delivering person-centred palliative care. One approach is to purposefully ask patients about their individual preferences and act in accordance with their wishes (Cherny, 2012). Cherny, for example, recommends offering patients a range of options. These include: 'explain the results to me, explain the results to me with my family members, explain them first to my family and then to me, or tell the family first and let then them decide what I should be told'. The value of this approach is that it avoids cultural stereotyping, ensures authentic patient preferences are obtained, and reduces possible physician/family collusion. Other strategies include consulting with community organizations and community health advocates (Lasch, 2000) or engaging in cross-cultural discussion about truth telling and consent in the international arena (Xue et al., 2011).

Approaches to substandard norms of practice

The rights ethos is now firmly embedded in medical practice as is a culture of quality improvement (<http://www.medqic.org>; <http://www.ihi.org>; <http://www.capc.org>; <http://www.medicaring.org>). There are multiple measures and tools for determining a person's capacity to consent to treatment (Sturman, 2005), the effectiveness of risk communication and treatment decision-making (Edwards, 2003), the effectiveness of decision-making aids (Feldman-Stewart et al., 2006), and a person's regrets about decisions (Joseph-Williams et al., 2010). Despite these safeguards, no framework can predict all the factors which may influence treatment decisions and care near the end of life. As Lynn et al. argue 'in the care of very sick people, the error is not that we never provide good care, it is that we do not always provide good care' (Lynn, 2008). Research suggests that having the right people on a team which reflects and revises practice can be an effective way to improve palliative care and maintain high standards (Lynn, 2008; Hewison et al., 2009).

Conclusion

In Western medicine today, clinicians understand truth telling as a legal and ethical responsibility. Persons with illness understand truth as their right to be given the information in order to make informed decisions about end-of-life treatments and care.

Studies of person, family clinician, and caregiver experiences show that truth telling is difficult and distressing at all stages of a terminal illness for all involved. Delivering bad news goes against the grain; it challenges social norms and expectations about the role of physicians as healers. Communicated badly, without intimate knowledge of a person and their family's hopes, expectations, and wishes, 'truth' can have a devastating impact on quality of life and care.

In response, a rapidly increasing body of clinical practice guidelines and generic templates for ways to communicate around difficult topics are being created to assist health-care professionals and improve consumer confidence in decision-making. Analysis and development of more complex conceptual and theoretical models of the biopsychosocial experience of terminal illness is enabling verbal and non-verbal communication tools and approaches to be tailored to different person group typologies.

However, it would be dangerous to think that a cultural hiatus has been reached. The global research shows how familism has to be considered alongside autonomy. Recent cases relating to truth telling and consent in the media have been focused on the right to die rather than the right to know, suggesting that this may be the next legally inspired ethical debate to require professional standardization in the decade to come as populations get older.

5.5

Ethics in paediatric palliative care

Richard D.W. Hain

Introduction: scope and function of medical ethics

A starting point for medical ethics is that there is potentially an imbalance of power between physician and patient that should be redressed by 'rules of engagement' setting out how a doctor should behave. That conception encompasses the idea of a moral obligation for persons to be fair to one another, and indicates that one requirement of fairness is that the strong should show special consideration to the weak. It is especially relevant to children needing palliative care, made multiply vulnerable by youth, small physical size, illness, and motor and cognitive impairment.

Ethical codes have elaborated on those basic ideas, through the Hippocratic Oath and principle of *primum non nocere* to the four-principles approach of Beauchamp and Childress (2009). The focus of medical ethics was how doctors should behave towards patients; the need for it also to account for a responsibility to society is recent.

The relationship between physician and child and family largely defines the *scope* of paediatric medical ethics. Its *function* can be expressed in several ways. From the perspective of child and family, it is an attempt to 'level the playing field' in relationship with the clinician. To society, it ensures doctors are not isolated from contemporary mores, including notions of how health-care money should be spent. From the perspective of the clinician, however, the task of medical ethics is analytical; to help resolve moral quandary and guide decision-making in patient management through an appeal to what is morally right, in clinical situations where rationality and medical competence alone do not provide a single clear answer.

This chapter sets out current approaches to ethics in paediatric palliative care, suggesting that none is completely satisfactory; a coherent, specifically paediatric account is needed.

Ethics in children: paradigms in practice

Two paradigms dominate contemporary ethical dialogue in children: rights-based arguments (United Nations General Assembly, 1989), and the 'four-principles' approach (Beauchamp and Childress, 2009). Rights-based claims are child specific (Goldhagen, 2003; Paul, 2007; Archard, 2010; Alderson, 2011; Streuli et al., 2011) but often not argued from an ethical premise. The four-principles approach flows from understandings of ethical theory, but is not designed for children. Each usefully informs

ethical discussions in children, though neither represents a complete account.

Rights

Rights-based dialogue provides a legalistic rather than ethical account of how a clinician should treat a child. Nevertheless, the idea that children have rights at all is a powerful and foundational ethical claim. Modern concepts of children's rights come largely from the United Nations (UN) Convention on the Rights of the Child (CRC) (UN General Assembly, 1989). The Convention is intended to give force to a child-focused legal agenda (Goldhagen, 2003); it does not provide any coherent ethical account of childhood or attempt a moral argument concerning the nature of rights. It invokes the earlier preamble of the UN Universal Declaration of Human Rights (UN General Assembly, 1948) in which rights were held to be self-evident, to apply to any human, and to be inherent in the individual. By applying this definition to children, the CRC insists there is no distinction between the moral values of child and adult. That is an important assertion. Children are often considered 'works in progress' whose moral value is as potential, rather than current, persons.

The CRC indicates that children are also distinct from adults in morally relevant ways. Their developmental nature imparts special value. It is their nature to be cared for in a family; society's responsibility to children is in supporting the family in caring for the child. These claims are in the preamble of the convention, identifying them as foundational.

As a matter of jural logic rights exist as the corollary of duties and must inevitably restrict the influence of states; even democracies (Hohfeld and Cook, 1978; Lazarev, 2005). That power concerns rights sceptics (Hafen and Hafen, 1995; Guggenheim, 2005). A lesser claim for rights (Alderson, 2011) as aspirational statements of moral intent, allows rights-based arguments more helpfully to inform an account of ethics in children.

Principlism

Thomas Beauchamp and James Childress (Beauchamp and Childress, 2009) famously articulated four principles: autonomy, beneficence, non-maleficence. and justice. Autonomy is the patient's own capacity to decide what medical treatment is done, beneficence is the responsibility of the clinician to do what is good for their patient, non-maleficence is the duty to avoid harm, and justice the responsibility of clinicians to participate in designing and maintaining a health-care system that is fair.

There may be no obvious way to resolve conflicts between the principles:

Following an uncomplicated pregnancy, a girl is born prematurely at 25 weeks' gestation. She weighs 695 g and is anatomically normal for post-conceptual age. She makes a respiratory gasp but clearly needs intubation and ventilation. Her parents request that 'everything' be done, but the neonatal paediatrician is reluctant to ventilate, knowing that majority of children born at this stage will suffer severe long-term cognitive and physical impairment, and that resuscitation of such children is expensive, not only in the immediately aftermath of the resuscitation, but in supporting the child medically and socially for decades afterwards.

Applying the four principles, it is possible to construct:

- An argument from respect for *autonomy* that the child should be resuscitated because her parents request it (either because they want it or because they think she would want it), or
- An argument from *beneficence* that she should be resuscitated because it will do her good, or
- An argument from *justice* that she should not be resuscitated because to do so would be unjustly consume resources in a world of finite health-care funding, or
- An argument from *non-maleficence* that she should not be resuscitated because to do so would do her harm.

This is not a shortcoming of the approach, but an illustration of the limitations of its scope. Principlism does not represent a single coherent ethical theory, but a practical heuristic for busy clinicians. The four principles represent a practical summary of complex philosophical deliberations, for use 'in the heat of battle', rather as a formulary summarizes practical prescribing but does not replace a sound knowledge of pharmacology.

In paediatric palliative care, however, there are important weaknesses in principlism as a result of the failure of some of the principles that lie behind it to account consistently for the nature of children. Autonomy is problematic in relation to children, accounts of beneficence and non-maleficence do not consistently distinguish between the interests of children and those of families, and establishing justice is complicated in a society composed mainly of adults. The status of the child in principlism is often unclear. Children ideally need a coherent ethical approach that is consistent with their nature as moral beings that are both distinct from, and have much in common with, adults.

The nature of children: special ethical considerations

Personhood and rationality

Personhood is often held to be a function of rationality, and the status of children in many ethical theories remains uncertain. Children probably rationalize differently from adults, but that is only determinative of rationality if the definition is limited to the way adults do it. Since even some non-human animals reason (Glackin, 2008), it seems unlikely that adult rationality is the only form of rationality there is among humans. In his book *Practical Ethics*, utilitarian philosopher Peter Singer (2011) asserts that infanticide is permissible. The infant, he says, lacks reason and therefore awareness of self over time. Being killed cannot rob the infant of anything she can truly be said to possess. Given modern understandings of infant neurodevelopment (Gopnik, 2007; Bauer, 2008), Singer's claim is improbable. The idea that infants cannot reason is perhaps a contemporary parallel to earlier ideas that they cannot experience pain; a convenient and widely held belief about children that simplifies decision-making for adults but is ultimately untrue. Nevertheless, the moral status of children who are genuinely non-rational (such as those with severe cognitive impairment) presents paediatric clinical ethicists with a challenge.

Dependence and autonomy

Autonomy is often taken to mean freedom, in the sense of having no restrictions on actuating one's will. In practice, a child is multiply restricted in the influence he or she can exert. Many limitations are inherent to the nature of the child; children are physically small, and often lack verbal skills simply by virtue of their age. The child given less influence because she is unimportant inevitably becomes increasingly unimportant because she cannot exert influence, and lack of autonomy is self-perpetuating.

Properly understood, however, autonomy describes the freedom to decide for oneself which set of restrictions to acknowledge. That more realistic definition does not exclude children so clearly since children often manifest autonomy by allowing parents to make decisions on their behalf, seeing themselves in a reciprocal and balanced caring relationship with family members (Carnevale et al., 2008). Ambiguities in the nature of children's autonomy are particularly significant in palliative care. Cognitive impairment and severely restricted physical mobility are usual. Expectations that parental autonomy will be respected, as well as that of the child, interpose a layer of ethical complexity. Even caring parents may, rationally or otherwise, choose what is less than ideal for their children (Brierley et al., 2013). Disentangling what parents feel their child would want from what parents want for their child is morally relevant, but not always possible.

Limitations on understanding autonomy are relevant in considering the ethics of euthanasia and physician-assisted suicide legislation that extends into childhood or young adulthood. Adolescents may appear more autonomous than they are. A perfectly competent and rational adolescent may request euthanasia for reasons that have little to do with a considered desire to end life. The high frequency of risk-taking behaviour and suicide during adolescence (Self and Findley, 2010) illustrates that an actual desire to die is only one among many influences. Even if it is conceded that people who ask for it should be killed, it is not clear that it is possible, in practice, to distinguish clearly between an adolescent's request for death and (for example) a request for more attention, or a protest against parental restrictions. The assumption that there is always a straightforward relationship between what people say, and what they actually mean, is even less reliable in adolescents than it is in adults.

The concept of autonomy, then, is foundationally problematic in children. Autonomy requires some degree of control over one's own life. For all children, it is more limited than it is for adults, for various reasons of which some have no moral relevance. It is over-simplistic to suggest a child inherently lacks autonomy,

and ethics therefore need account only for the wishes of parents. Nevertheless, a child is inherently in relationship with a family. To deny the importance of that relationship, and the authority it gives to parents to speak for their child, would be to deny something central to the ethical questions clinicians need to ask about children.

Interests: child versus family

Some sceptics of the concept of children's rights argue that it creates a separation between the interests of child and family that is spurious (Hafen and Hafen, 1995; Guggenheim, 2005). While that overstates the case, it is true that a child's moral deliberation normally occurs in a context in which family is extremely influential. The child will find it hard to articulate views of interests that differ from strongly expressed views of parents, potentially allowing coercion. Where differences are expressed, the medical team may need to arbitrate between them, or else privilege one over the other.

The concept of 'best interests' is especially problematic in children who are cognitively impaired. There are no objective measures of a good outcome. Survival probability is typically irrelevant, since death in childhood is expected. Other measures are subjective, requiring the child to be verbally and conceptually capable of articulating issues that relate to existential as well as physical components. In practice, this is difficult, and clinicians are often drawn instead to an account of ethics that allows us to regard a child's parents' interests as inseparable from those of the child. It is perhaps as a reaction to this problematic assumption that the modern children's rights movement has developed.

Relationality

It is important to individual families to know that a health-care system is fair, and to that extent, justice is appropriately considered one of the four medical ethical principles. In other respects, it appears out of place. Where autonomy, beneficence, and non-maleficence all relate primarily to decisions made in the context of a relationship between an individual child and an individual doctor, the principle of justice refers instead to 'states of affairs' (Smart and Williams, 1973). Typically, justice arguments are rooted in utilitarianism; that the ethically right decision depends on its impact on the whole community. While the other three principles focus on the needs of an individual patient, justice makes individuals subordinate to the needs of society.

A 3-year-old boy with an advanced metabolic degenerative condition was now felt by his paediatrician to be 'almost in a permanent vegetative state'. After a series of chest infections of increasing severity and frequency, his parents brought him to casualty with signs of another pneumonia, insisting that he should be ventilated again. The intensive care paediatrician saw the child in casualty and explained to the boy's parents that ventilation would not be offered, because it would mean their son occupying a bed that another child could use more effectively.

Few clinicians would disagree with the conclusion here that the child should not be ventilated. The ethical reasoning also appears sound. It is, however, cruel, unreasonable, and coercive to expect parents to sacrifice their child to the well-being of others

(American Academy of Pediatrics, 1996). Such an expectation flows from an ethical understanding that is hard to argue convincingly without ignoring the child's nature as a dependent being in the care of a family. Relationship has moral relevance in ethical deliberation around specific quandaries that is not easily accommodated by most forms of utilitarian consequentialism.

The relationship of physician and child is also of ethical relevance (Bartholome, 1985, 1996; Ramsey, 2002). In considering how to design a fair system of health care, it is a legitimate ethical starting point that all patients, real or hypothetical, are equally important. In the case described earlier, however, considering the impact on hypothetical 'other children' is outside the scope of this physician's relationship with this particular child.

Clinicians may need to make ethically relevant decisions in both modes. They will need to make some decisions in the context of their relationship with individual patients, and others in developing or maintaining fair systems. This is not inconsistent. It may even be ethically necessary; tension between the needs of the individual actual patient and those of hypothetical other patients is inevitable given limited health-care resources, and dialectic is integral to a consistent ethical approach, not antithetical to it.

Ethics in children: underlying theories
Deontology

Deontological arguments flow from an assumption that there is an absolute morality that is equally relevant to all people, in all situations, irrespective of the consequences. There at least three possible sources for an absolute moral code. One is the authority of God through religious scripture. Even in secular societies those codes are, it can be argued, authoritative at least to the extent that they are rational. Most scripture was, however, not designed primarily as an exposition of a consistent ethical code, and is often elliptical and/or subject to interpretation. Ethical accounts derived from religious understanding are rarely completely agreed, even among those who share that faith.

A second source of an absolute moral code might be the universe itself. Ancient and medieval understanding was that the universe was rationally ordered, and coherence with that rational order was the yardstick by which the rightness of behaviour should be measured. So, for example, the ethical rules by which children should live and by which parents should care for them both derive from the inherent nature of family.

A third authority might be that of pure reason. Kant (1785/2005) attempted to show that there were certain ethical premises that were beyond debate because for reasonable people they were logically inescapable. Some, he argued, were always true, irrespective of context (categorical imperatives) while others were contingent on the individual's prior beliefs about context (hypothetical imperative). Applying this to children is not straightforward; Kant considered the moral law to be co-extensive with rationality, and since he does not obviously consider children rational it is not clear in Kant whether a child has valid status as a moral being.

Consequentialism

In practice, the outcome of an ethical decision can be worse by obeying a rule than by breaking it. Consequentialists argue that this is an inherent weakness in 'rule-worship' itself, and that the only morally relevant aspect of an action is found in its

consequences (Smart and Williams, 1973). Consequentialists differ about what outcomes should be measured. Libertarian consequentialists judge the moral 'rightness' of an action by the extent to which it contributes to freedom. In medical ethics, utilitarianism is the best-known form, and the most widely recognized outcome measure is the effect on 'the sum total of human happiness'.

Some important ambiguities restrict the usefulness of utilitarianism in practice. The sum total of happiness could relate to a great deal of happiness on the part of a few people, or moderate happiness on the part of many. The nature of happiness itself is not agreed, and may not be measurable. Evaluating happiness is particularly problematic in children needing palliative care, who are often non- or pre-verbal and cannot articulate feelings or preferences. A close correlation between happiness and observable function or cognitive ability is sometimes assumed (Shaw, 1977) but there is little reason or evidence to indicate that life quality is influenced in any readily predictable way by physical condition, or closeness to death.

Utilitarianism does not concern itself with the happiness of the individual, except insofar as it contributes to the sum total of human experience. A central principle is that the happiness of each individual person is equally important—or, perhaps more accurately, equally unimportant—to the agent making the ethical decision. A paradox in most forms of utilitarianism is that utilitarians can be concerned for the total happiness of society, while remaining indifferent to the happiness of all its individual members.

Finally, utilitarian consequentialism does not acknowledge any ethical relevance for intention. This again makes it problematic for most quandaries in medical ethics. A doctor trying to decide on a particular course of clinical action has to decide whether to do a particular act or not to do it. The quandary defines, and is defined by, the agent's intention. Utilitarianism does not provide a mechanism for that decision, because it claims that ethical 'rightness' depends on something entirely isolated from intention; that is, outcome. The physician cannot know the outcome at the time the decision needs to be made. She can only make a judgement on the basis of knowledge and prior experience. That informed judgement is what constitutes intention in the context of medical decision-making. The fact that utilitarianism cannot accommodate intention—still less complex intentions as in double effect—illustrates an important limitation of its scope.

Virtue ethics

Although deontology and consequentialism might appear to be opposites, they have two important things in common. Both are 'absolutist' approaches—they claim unlimited scope to provide moral values that are always and everywhere right. Both also ultimately elevate something abstract over real individual human beings. In the case of deontology, it is a concept of duty. In the case of utilitarian consequentialism, it is a concept of happiness or some other descriptor of persons. Since neither duty nor happiness can have any meaning independently of individual persons, neither deontology nor consequentialism can, on its own, provide an adequate account of medical ethics, which relates primarily, though not exclusively, to decisions in the context of relationships between individual persons.

In contrast, virtue ethics (Macintyre, 2007) has its roots in Aristotle's understanding that an action is right if it is done by a virtuous person for the right reason. Aristotle locates the quality of

virtue, not only in the ethical rightness of an act, but in the character of the moral agent whose act it is. Virtuous people, and ethically correct acts, are mutually defining in the same way that force and acceleration are mutually defining in Newton's second law of motion. One cannot argue from virtuous act to virtuous person; it is simply impossible for either to exist independently of the other.

An understanding of the 'virtuous doctor' emerges from the Hippocratic oath and underlies professionalism; that is, what constitutes good medical practice (General Medical Council, 2006). To be professional is to behave in a certain way that is, as a corollary, the way in which a professional behaves. Virtue ethics provides a coherent and consistent account of ethical behaviour that most other theories cannot, but it does not provide an obvious decision mechanism for resolving individual ethical quandaries. Virtue ethics can therefore shape expectations of professional behaviour from doctors, but may not in its own replace an analytical approach to clinical ethics.

Double effect and withholding of life-sustaining treatment in paediatric palliative care
Principle of double effect

A 9-year-old boy with severe cerebral palsy is admitted to the paediatric intensive care unit (PICU) with the latest in a series of severe chest infections. Each infection has been worse than the last, and on each admission it has become more difficult to wean him off the ventilator. Despite adequate and appropriate interventions, including ventilation and intravenous antibiotics, it seems likely that on this occasion it will not be possible for him to breathe independently of the ventilator. In discussion with his parents, a decision is made for 'compassionate extubation' (that is, extubation in anticipation that he will die). The child has not seemed to be in pain and has never received opioids, but 2 hours before extubation, the PICU physician prescribes the equivalent of 2 mg per kilogram of oral morphine as a single intravenous bolus. She is aware as she does so that three possible outcomes are analgesia, anaphylaxis, and abolition of respiratory effort at the time of extubation.

The principle of double effect (PDE) is an acknowledgement of the possibility that a clinician can foresee a range of outcomes from a single act, but intend only a subset of them. It is logically inescapable, and the basis on which good clinical decision-making is made in many specialties, including palliative medicine (Fohr, 1998). Despite its apparently self-evident nature, the PDE is considered by some simply to be a 'fudge factor' that allows physicians to feel comfortable making decisions at the end of life that, in reality, hasten or cause death. There are several reasons for this, of which this chapter will consider only two: it is sometimes misunderstood, and its self-evident first premise requires certain further qualifications that are not agreed. Those include, in particular, conceptions of proportionality, and the extent to which a single act can be defined within, and reliably distinguished from, a series of acts.

A common misunderstanding of the PDE is that it legitimizes equally all outcomes that are foreseen. In the earlier example, relief of pain is ethically permissible, while inducing apnoea is

not.[1] It is sometimes thought that the PDE permits the overdose because the ethically problematic outcome is simply a secondary consequence of treating pain. The PDE does not allow this, however, for an important reason; the dose that is suggested is disproportionately high for the ethically permissible outcome. The dose required for pain in an opioid naïve child would be a tiny fraction of this (1 mg/24 hours). The dose suggested cannot be justified on the grounds of the permissible outcome.

The illustration shows that some element of proportionality must be shown between the act and its outcome in order to judge the intention. In palliative medicine, that proportionality can be considered in many ways. One is the reasonableness of the dose. Prescribing morphine analgesia is ethically justified only to the extent that the dose is appropriate for the degree of pain (Hain and Friedrichsdorf, 2012).

A second measure of proportionality is to consider 'directness' of the intention. Any action leads to a series of consequences that are increasingly remote from the agent's intention. It is not, as Glover humorously suggests (Glover, 1977, p. 89), a question of how long after the act its consequences manifest. The question of directness relates rather to the disposition of the agent; what result the physician expects from his or her action. Except to purist consequentialists, there is a morally relevant difference between intending A while recognizing that B is a consequence (that is, willing A but permitting B), and intending A and B equally. Temporal remoteness may be incidentally relevant, especially if it allows other agents to intervene to change the consequence as a result of their own intentions, but it is not of itself a measure of directness.

Proportionality can also be seen as a function of probability. Apnoea is likely at the dose suggested in the earlier example, but not inevitable. Pancuronium, however, guarantees it; a physician prescribing pancuronium during extubation intends apnoea and the PDE does not apply.[2] Conversely, anaphylaxis is a foreseen event for most drugs, but its rarity makes it obvious that a physician does not usually intend to cause death by prescribing it. Probability, as well as reasonableness and remoteness, are relevant to intention.

Problematically, the PDE demands that a single act can always be considered the sum of several smaller acts that are discrete. It is hard to find a valid basis for such analysis. The act of giving morphine could be said to begin with the injection, in choosing not to give naloxone to reverse it if apnoea occurs, or it could be considered inseparable from the overall act of caring for a dying child. According to utilitarian consequentialist understanding, the PDE is meaningless since it gives different ethical value to acts with the same outcome. Although utilitarians therefore dismiss the PDE as without moral meaning (Glover, 1977; Harris, 1985), it is equally rational to suggest that this is a further limitation of consequentialism in medical ethics.

The fact that application of the PDE in practice is not always straightforward does not, however, undermine its central thesis. It is a matter of everyday reality for paediatric palliative care physicians that it is possible to foresee consequences of an intervention that are not its aim. It is inconceivable, without re-evaluating the whole task of medical ethics, that the intention of the physician is not relevant. The ethical 'rightness' of an intervention with such multiple outcomes must rely on some concept of proportionality, measured as reasonableness of the dose, remoteness of the intention, or probability of a consequence.

Withholding and withdrawing life-sustaining treatment

The Royal College of Paediatrics and Child Health (RCPCH) (2004) in the United Kingdom recognizes several archetype situations in which medical treatment aimed at sustaining or saving life might be withheld. The guidelines represent a practical tool for considering the quandary, rather than a coherent ethical approach. Withholding and withdrawing are not the same decision, but if both serve the best interests of the child they are logically equivalent ethically.

Withholding or withdrawing treatment from *the child who is brain dead or in a permanent vegetative state* is permitted, not because the child is no longer of value, but because she no longer has interests and the residual interests are those of others, so that a beneficence argument need take only those into account. This situation therefore permits withdrawing or withholding, but it does not mandate it; for example, the family's interests may be best served by continuing. The justification for withdrawing in the *no chance situation* is not merely that the child cannot recover but, again, that the child's interests are best served by not prolonging treatment.

The same can be said of the *unbearable situation*. The term 'unbearable' is inherently subjective. There is an ethical duty on those caring for a child to explore with him what he feels about what is going on. That is not the same as securing the child's permission for treatment to be withdrawn. Although it is helpful if the child expresses a clear view, the *unbearable situation* does not preclude the possibility that carers will need to act as advocates, as well as proxies, for the child.

The *no purpose situation* appears to presuppose a provisional value for the child's life. What follows clarifies, however, that the purpose in question is that of treatment; that is, the benefit of that individual child. The *no purpose situation* is, again, a special example of beneficence, but unlike the *unbearable situation* it assumes the child cannot participate in the discussion. The responsibility of carers is therefore a little different; rather than giving a voice to his wishes, it is to make a wise and compassionate decision about what is best for the child.

Palliative care foundationally recognizes that death should sometimes be allowed to occur, even where it is technically possible to delay it. All the RCPCH 'situations' are best considered illustrations of the same principle of balancing burden and benefit, distinguished by what is at stake, whose interests are relevant, and the extent to which the child's own estimate of 'bearability' can be solicited. The only indisputably relevant ethical question in deciding whether treatment should be offered to or withheld from a child is whether the intervention is likely to do more good than it does harm to that individual child. That balance needs to take into account much more than the duration of life, including dimensions that are difficult to measure and/or are inherently subjective. A child's disability is relevant to the extent that it impacts on those dimensions.

Conclusion

This chapter has outlined some theories and paradigms in ethics of care at the end of life, and some special challenges of considering them in children's palliative care. Paediatric palliative care

clinicians face all the moral ambiguities of their colleagues working with dying adults, and often have to turn for ethical guidance to sources that were not intended for that purpose. Of those, the most important currently are the four principles approach, and the UN CRC. The first was developed for adults and is often unsuitable for children, particularly because of its emphasis on autonomy. The second is a series of axiomatic rights claims that, while they make some important fundamental ethical claims about the nature of children, are not obviously justified philosophically. Neither on its own provides the kind of coherent account needed by those working in children's palliative care.

Because it does not accommodate the moral relevance of the relationship of clinician and child, the scope of utilitarian consequentialism (in its purest sense) in paediatric palliative care should be limited to development of fair systems, rather than to specific clinical decisions about individuals. Children are vulnerable to the misapplication of utilitarian ethics to individual patient quandaries because they are typically unable to express clearly what they want and their removal from the world, particularly as infants, does little to detract from the sum total of human happiness.

Many of the specific ethical quandaries faced by clinicians working with dying children have their counterparts in the adult specialty. It seems likely that, as it becomes technically possible to resuscitate children at ever earlier stages in fetal development, and to keep children alive but suffering for ever longer periods of time, it will also become increasingly important to be able to address those quandaries in a way that is specifically paediatric. To do so requires that we do more than extrapolate from existing accounts such as rights or principlism; paediatricians and bioethicists must develop an ethical account of childhood itself that is consistent, coherent, and complete.

Acknowledgement

Notes

1. Unless killing (active euthanasia) is considered a permissible outcome.
2. I am setting aside, for the purposes of this illustration, ethical arguments that support intentionally killing the child. Any ethical justification for giving pancuronium at the time of extubation flows from those arguments, rather than from the PDE.

Dignity and palliative end-of-life care

Harvey Max Chochinov, Susan E. McClement, and Maia S. Kredentser

Introduction to dignity and palliative end-of-life care

In recent years, the concept of dignity has garnered increased attention by health-care researchers and practitioners working across various disciplines. Despite this attention (Higginson and Hall, 2007) and debate regarding the overall usefulness of the concept (Macklin, 2004; Schroeder, 2008), there continue to be calls for more in-depth understanding of dignity and its applications to end-of-life care (Billings, 2008). Discussions of dignity remain pervasive, perhaps because health-care providers and patients alike understand that loss of dignity is particularly relevant in the face of declining health or heightened vulnerability. Indeed, the fear of losing one's dignity towards the end of life, and the implications of this, are very real, despite tensions regarding the use of the term.

These tensions are embedded within a highly politicized environment surrounding the notion of dignity at the end-of-life. 'Death with dignity' is often the rallying cry of supporters of assisted suicide and euthanasia (Death with Dignity, 2012). The hospice and palliative care movement, on the other hand, invokes notions of dignity with entirely different goals (Carstairs, 2010): those consistent with alleviating suffering and optimizing comfort to the very end of life. Given the complexities of the topic, the purpose of this chapter is to review issues pertaining to dignity, which are often faced by health-care providers in the context of end-of-life care, including definitions of dignity, discussion as to why dignity is important, and how it applies to clinical practice.

Defining dignity

The challenges of defining dignity are complex. The *Oxford Dictionary of English* describes dignity as, 'the quality of being worthy or honourable' ('Dignity', 2013). This definition appears to reflect Schroeder's (2008) *meritorious dignity*, a conceptualization stemming from Aristotle's idea that dignity is associated with virtue. This definition implies that one must deserve dignity, and in acting honourably, it may be achieved (Killmister, 2010). By contrast, the Kantian notion of dignity—commonly espoused in the context of health care, ethics, and human rights—purports that dignity is 'inalienable and normatively inviolable', a quality that all rational beings possess (Killmister, 2010, p. 160). Notions of

dignity are often conflated with autonomy, and the seeming proximity of these two terms has led some to claim dignity as a 'useless concept' in medical ethics, no different from a basic respect for personhood and autonomy (Macklin, 2003). Yet, such claims are problematic in the sense that individuals who lack capacity for autonomous action or thought may consequently be seen as lacking dignity (McClement and Chochinov, 2006), which has particular implications in instances when illness and disability lay claim to personal or individual autonomy.

Efforts have been made to parse out the differences between dignity and autonomy. Pullman (2004) distinguishes between basic dignity and personal dignity. The former refers to the fundamental, intrinsic worth of all humans and is moralistic in nature, while the latter is a socially and individually referenced construction. This echoes work by Bechtel (2011), who distinguishes between inherent dignity—an irreducible and universal quality of all human beings—and non-inherent dignity—contingent on merit and social status. Inherent dignity, like Pullman's (2004) basic dignity and the concept invoked in documents such as the United Nations Universal Declaration of Human Rights (United Nations General Assembly, 1948), affirm dignity as inseparable from personhood and foundational to freedom and justice. Thus, in contrast to Macklin (2003) and others, inherent dignity is not synonymous with 'respect' but rather the justification for respect (Bechtel, 2011).

Self-respect, pride, poise, and self-esteem are all synonymous with dignity (Chapman, 1977). These multiple meanings and ambiguity led Levenson (2007) to describe dignity as a 'hurrah word—a term of general approval to which no one can object' (p. 8). *Dignity*, like the words *love* or *faith,* may seem intuitive, especially for professionals in health care who see helping as their primary goal (Chochinov, 2012). Others have suggested that they know dignity when they see it (Macklin, 2004). Perspectives such as these may contribute to the paucity of empirical work surrounding this topic, which has recently been placed under a more exacting, and in some instances empirical, lens.

Several organizations have formed to actively promote dignity in health care, and are beginning to offer helpful perspectives. In a comprehensive report by the UK organization Help the Aged, aimed at raising standards of care and behaviour in treating older people, Levenson (2007) describes dignity in a straightforward

fashion; it is about how people feel when they are receiving care. Levenson outlines six guiding principles that underlie dignity in care, providing shape for how dignity manifests in a health setting: dignity in care is inseparable from the wider context of dignity as a whole; dignity is about treating people as individuals; dignity is not just about physical care but also psychosocial and spiritual care; dignity thrives in the context of equal power relationships; dignity must actively be promoted; and dignity is more than the sum of its parts. Within health care, dignity has been connected with how people perceive themselves as reflected through the attitudes and behaviour of others towards them (Chochinov, 2004). Such an explanation implies that how patients are treated by health-care providers has a significant impact on how they feel about themselves, which can profoundly influence their experience and satisfaction with health care.

Still others take an ontological approach to the meaning of dignity. Parse (2010) suggests four tenets of human dignity that emerge from a 'human becoming' perspective, wherein 'human dignity is an august presence, a noble bearing of inherent uniqueness' (p. 259). These tenets include reverence in terms of a deep respect for what it means to be human, and awe in terms of appreciating the wonders of humanity. Both betrayal (a violation of human trust) and shame (humiliation with dishonouring human worth), erode human dignity in the sense that they violate the core being of another person (Parse, 2010).

Relevance of dignity in end-of-life care

Much of the debate and confusion in the literature regarding the importance or utility of the term dignity pertains to its lack of definitional specificity (deRave, 1996; Street and Kissane, 2001). Progress in the field of palliative care in the twentieth century has seen increased attention to understanding dying in terms of dignity and autonomy of the person (Graham and Clark, 2008). Dignity has been identified as one of the five basic requirements in caring for dying patients (Geyman, 1983). A basic tenet of palliative care is to relieve suffering and improve quality of life by addressing physical, spiritual, and psychosocial issues affecting the patient and family (World Health Organization, 2012). Such care can readily be conceived of as enhancing dignity (McClement and Chochinov, 2006). Several researchers and clinicians have suggested that dignity should, in fact, be the central goal of palliative care, given the breath of issues and considerations it subsumes (Coppens, 1998). Recent work has also given voice to patients regarding their conceptualizations and experiences of dignity within the health-care system (Chochinov, 2004; Chochinov et al., 2005, 2006, 2009; Hack et al., 2004; McClement et al., 2004).

Continued discussions and research into the meaning, relevance, and importance of dignity is particularly salient, given the current climate surrounding assisted suicide and euthanasia. While dignity is seen as a fundamental aspect in palliative care (Geyman, 1983; Chochinov, 2006, 2007; World Health Organization, 2012), it is also invoked as the justification for death hastening practices. Organizations such as Death with Dignity National Centre, which promotes and defends assisted suicide, equate dignity with autonomy. Legislation passed in the US states of Oregon and Washington legalizing assisted suicide is coined the Death with Dignity Act. From this perspective, dignity is enhanced by patients exercising personal control over the exact timing and circumstances of their death (Death with Dignity, 2012).

Loss of dignity is indeed a central concern of patients requesting assisted suicide or euthanasia. In a study examining end-of-life decisions amongst patients with amyotrophic lateral sclerosis (ALS) in the Netherlands, Maessen and colleagues found significant differences between those who chose euthanasia or physician-assisted suicide (EAS), continuous deep sedation (CDS), or neither of those options. When informal caregivers were asked why the patient hastened their death, they reported the reasons as 'no chance of improvement', 'loss of dignity', 'being dependent', and 'fatigue'. These experiences were all significantly higher in patients choosing EAS compared to those who chose CDS or neither (Maessen et al., 2009). When asked why their patients had selected EAS, the most common reason cited by 57% of Dutch physicians was 'loss of dignity' (Van der Mass et al., 1991). In Washington state, physicians reported that 72% of their patients requesting hastened death were concerned about loss of dignity (Back et al., 1996).

Notably absent from much of the research surrounding concepts of dignity, suffering, and end-of-life choices are the voices of dying patients themselves (McClement and Chochinov, 2006). Karlsson and colleagues interviewed 66 dying cancer patients, inquiring about the nature of suffering with respect to euthanasia, a good death, and dignity. In this qualitative study, the general attitude of study participants toward euthanasia varied. Twenty-nine per cent of the sample were in favour of euthanasia, 20% opposed euthanasia, and the majority (51%) were undecided on the issue. Patients who feared intolerable suffering and were inclined to euthanasia discussed the complex nature of suffering, including meaninglessness, whereas those who felt euthanasia was unwanted or unnecessary felt that suffering could be overcome in various ways, often linking to their own experiences of ameliorated pain or supportive contact with health-care professionals (Karlsson et al., 2012).

Wilson and colleagues (2000) explored the personal attitudes of 70 terminally ill cancer patients receiving palliative care toward euthanasia and physician-assisted suicide. The study also examined specific end-of-life concerns identified in previous research exploring euthanasia and assisted suicide, including loss of dignity, sense of being a burden to others, and hopelessness. The majority of participants (73%) believed that EAS should be legalized. Reasons for this position included one's right to choose and the presence of pain. Moral and religious concerns were raised by those individuals who opposed such legalization. Eight of the patients interviewed (12%) who would have made a request for euthanasia at the time of the interview had greater loss of interest or pleasure in activities, felt more hopeless, and had a higher prevalence of depressive disorders compared to the rest of the sample. These findings underscore the salience of accessing patients' perspectives surrounding end-of-life choices, and the importance clinicians must assign to the psychological domains of care (see Chapter 5.7).

Personal experience: what dignity means for patients and providers

Increasingly, researchers are attending to patient and health-care provider experiences of dignity, providing a meaningful context to academic discourse. Participants in a multi-country, World Health Organization survey indicated that next to receiving prompt attention for medical issues, dignity was the most important aspect of non-clinical care (Valentine et al., 2008). Qualitative

research by Jacobson has suggested that persons marginalized by poverty, illness, or both, are indeed very keen to discuss their views on and experiences with dignity in health care (Jacobson, 2009). Beach and colleagues found that the concept of autonomy (as gauged by involvement in treatment decisions) is culturally bound within Western ideologies. They reported that being treated with dignity, rather than only being involved in treatment decisions, resulted in greater treatment adherence for racial/ethnic minorities. Further, for patients from all backgrounds, being treated with dignity was significantly associated with receiving optimal preventative care, even when adjusted for involvement in treatment decisions (Beach et al., 2005).

Jacobson used grounded theory to describe patients' experiences of dignity violation within health care. In her interviews with experts in health and human rights and marginalized populations within the health-care system, several themes emerged. All participants reported experiences of rudeness, indifference, condescension, dismissal, disregard, dependence, objectification, restriction, labelling, contempt, discrimination, revulsion, deprivation, assault, and abjection as violations of dignity (Jacobson, 2009).

Explorations of how providers maintain patient dignity offers further insight into how dignity is constructed within health care. Lin and Tsai found that Taiwanese nurses ($N = 30$) maintain the dignity of their patients by showing them respect (100%), protecting privacy (93.3%), providing emotional support (40%), treating all patients in a similar fashion (13%), and maintaining patients' body image (13%) (Lin and Tsai, 2011). Dignity is seen as an essential component of nursing, suggesting that the nurse's role and how they experience the patient, often reveals more about what may be bothering them than a medical examination could (Castledine, 2006). In an observational study of nurse–patient interactions, Henderson and colleagues identified both physical and social environments that can enhance dignity, including maintenance of privacy during transfers and toileting, and treating patients in a courteous and age-appropriate manner (Henderson et al., 2009).

Chochinov and colleagues have been engaged in a programme of research seeking to better understand factors that enhance and erode dignity for terminally ill patients. In semi-structured interviews, they explored how patients with cancer perceived dignity. Using latent content analysis and constant comparative techniques, they identified three major categories that have a bearing on dignity-related issues, and generated an empirical model of dignity in the terminally ill (Chochinov et al., 2002b) (Table 5.6.1):

- *Illness-related concerns* that influence dignity derive, or are related to, the illness itself. These illness-mediated issues and their attendant themes and subthemes threaten or actually impinge a person's sense of dignity. For example, two themes within this category are 'level of independence' (the degree of reliance an individual has on others, influenced by cognitive acuity and functional capacity) and 'symptom distress' (the experience of discomfort or anguish related to the disease progression).

- *Dignity-conserving repertoire* includes a person's dignity-conserving perspectives, that is, a way of looking at one's situation that helps to promote dignity, and contains the subthemes of continuity of self, role preservation, generativity/legacy, maintenance of pride, hopefulness, autonomy/control,

Table 5.6.1 Model of dignity in the terminally ill. Summary of major categories, themes, and subthemes arising from qualitative work examining the construct of dignity from the perspective of the terminally ill

Illness-related concerns	Dignity-conserving repertoire	Social dignity inventory
Symptom distress	*Dignity-conserving perspectives*	*Social issues/ relationship dynamics affecting dignity*
Physical distress	Continuity of self	Privacy boundaries
Psychological distress	Role preservation	Social support
Medical uncertainty	Generativity/legacy	Burden to others
Death anxiety	Maintenance of pride	Aftermath concerns
	Hopefulness	
	Autonomy/control	
	Acceptance	
	Resilience/fighting spirit	
Level of independence	*Dignity-conserving practices*	
Cognitive acuity	Living in the moment	
Functional capacity	Maintaining normalcy	
	Seeking spiritual comfort	

Adapted from *The Lancet*, Volume 360, Issue 9350, Chochinov et al., Dignity in the terminally ill: a cross-sectional, cohort study, pp. 2026–2030, Copyright © 2002, with permission from Elsevier, http://www.sciencedirect.com/science/journal/01406736.

acceptance, and resilience/fighting spirit. Another facet of the dignity-conserving repertoire is dignity-conserving practices, that is, personal actions that can bolster or reinforce one's sense of dignity. These practices include living in the moment, maintaining normalcy, and seeking spiritual comfort.

- *Social dignity inventory* speaks to social concerns or relationship dynamics that enhance or detract from a patient's sense of dignity. Themes within this category include privacy boundaries, social support, care tenor, burden to others, and aftermath concerns.

The integration of these three categories forms the model of dignity in the terminally ill. Patients who experience difficulties with aspects of the social dignity inventory and/or illness-related concerns may experience an eroded sense of dignity. Yet, this can be moderated by their dignity-conserving repertoire. By invoking or utilizing resources contained within the dignity-conserving repertoire (i.e. feeling hopeful, maintaining normalcy, spiritual care), patients may be able to buffer dignity-associated challenges. The strength or integrity of those resources will determine the degree to which these assaults will erode or undermine individual sense of dignity. In this sense, the model is dynamic in that it incorporates aspects of dignity that are internal and external to the individual, and provides a framework for health-care providers to mitigate dignity-related distress (Chochinov et al., 2002b).

From patienthood to personhood: practical applications to enhance dignity

In an effort to better assess patients' distress at the end-of-life, Chochinov and colleagues created the Patient Dignity Inventory (PDI). Developed using the themes and subthemes of the model of dignity in the terminally ill, the PDI is a 25-item self-report

Table 5.6.2 The Patient Dignity Inventory

For each item, please indicate how much of a problem or concern these have been for you within the last few days	Not a problem	A slight problem	A problem	A major problem	An overwhelming problem
1. Not being able to carry out tasks associated with daily living (e.g. washing myself, getting dressed)	1	2	3	4	5
2. Not being able to attend to my bodily functions independently (e.g. needing assistance with toileting-related activities)	1	2	3	4	5
3. Experiencing physically distressing symptoms (such as pain, shortness of breath, nausea)	1	2	3	4	5
4. Feeling that how I look to others has changed significantly	1	2	3	4	5
5. Feeling depressed	1	2	3	4	5
6. Feeling anxious	1	2	3	4	5
7. Feeling uncertain about my health and health care	1	2	3	4	5
8. Worrying about my future	1	2	3	4	5
9. Not being able to think clearly	1	2	3	4	5
10. Not being able to continue with my usual routines	1	2	3	4	5
11. Feeling like I am no longer who I was	1	2	3	4	5
12. Not feeling worthwhile or valued	1	2	3	4	5
13. Not being able to carry out important roles (e.g. spouse, parent)	1	2	3	4	5
14. Feeling that life no longer has meaning or purpose	1	2	3	4	5
15. Feeling that I have not made a meaningful and/or lasting contribution in my life	1	2	3	4	5
16. Feeling that I have 'unfinished business' (e.g. things that I have yet to say or do, or that feel incomplete)	1	2	3	4	5
17. Concern that my spiritual life is not meaningful	1	2	3	4	5
18. Feeling that I am a burden to others	1	2	3	4	5
19. Feeling that I don't have control over my life	1	2	3	4	5
20. Feeling that my health and care needs have reduced my privacy	1	2	3	4	5
21. Not feeling supported by my community of friends and family	1	2	3	4	5
22. Not feeling supported by my health-care providers	1	2	3	4	5
23. Feeling like I am no longer able to mentally cope with challenges to my health	1	2	3	4	5
24. Not being able to accept the way things are	1	2	3	4	5
25. Not being treated with respect or understanding by others	1	2	3	4	5

measure (Table 5.6.2) that can be implemented to better understand the spectrum of patient dignity-related distress. The psychometric properties of the PDI have been examined, demonstrating robust internal consistency (α = 0.93) and test–retest reliability (r = 0.85). Factor analysis revealed five factors, labelled *symptom distress, existential distress, dependency, peace of mind*, and *social support*. Concurrent validity was established with each factor showing significant correlations with other common measures of distress (Chochinov et al., 2008). This measure provides one way that dignity-related distress can be identified, measured, and possibly tracked in a range of care settings. Administration of the PDI to 253 patients receiving palliative care found that patients identified nearly six problems each. The most highly endorsed items included a combination of distressing physical symptoms,

functional limitations (not able to continue usual routines, not able to perform tasks of daily living, not able to carry out important roles), and existential concerns (no longer feeling like who I was) (Chochinov et al., 2009). These findings speak to the importance of conducting patient assessments that encompass more than physical symptom distress. The PDI may help clinicians identify and track the complex and diverse nature of distress in the terminally ill, hence paving the way toward effective, dignity-conserving, end-of-life care.

A recently completed study examined how psychosocial oncology professionals (N = 90) utilized the PDI as a clinical tool within their practice. In almost 80% of instances, the PDI was able to uncover one or more areas of distress previously unknown to the clinician. Thus, the PDI may enable more efficient and targeted

psychosocial care amongst clients experiencing distress in the context of cancer (Chochinov et al., 2012b).

Dignity is profoundly influenced by the tone and texture of communication between the care provider and the patient; with acknowledgement of the patient as a whole person being paramount (Finset, 2010). Chochinov proposed an ABCD acronym for dignity-conserving care, rooted in the idea that how a patient views themselves is reflected in how they perceive they are seen by those providing care (Chochinov, 2002). This framework serves as a reminder to practitioners that their *Attitude, Behaviour, Compassion*, and *Dialogue* will markedly influence patient experience of dignity in care. Practical suggestions for implementing the ABCD framework are outlined in Table 5.6.3 (Chochinov, 2007).

Recognition for the importance of meaning and spiritual issues in palliative medicine (Puchalski et al., 2009) has seen the emergence of therapeutic interventions aimed at improving spiritual and psychological well-being at the end of life. Meaning-centred group psychotherapy has been shown to provide terminally ill patients with significant improvement in spiritual well-being and meaning, compared to patients participating in general supportive therapy (Breitbart et al., 2010). Breitbart and colleagues recently conducted a randomized controlled trial of individual meaning-centered psychotherapy (IMCP) with 120 patients who had stage III or IV cancer. Patients were assigned to receive either IMCP or a control treatment of therapeutic massage for 7 weeks, and were assessed on measures of spiritual well-being, quality of life, depression, anxiety, hopelessness, symptom burden, and symptom distress at baseline and 2 months post intervention. Patients in the ICMP condition showed significant improvement over the control group on measures of spiritual well-being (both sense of meaning and faith), quality of life, and symptom burden and distress (Breitbart et al., 2012).

Another approach coined dignity therapy consists of a brief psychotherapeutic intervention aimed at improving quality of life and reducing suffering for terminally ill patients and their families. The questions guiding dignity therapy are based on key themes and issues embedded within the model of dignity in the terminally ill. A trained professional guides the therapeutic encounter, helping the patient to elicit memories, hopes, and wishes for family members; life lessons they might wish to share; and legacy-related content they want to leave behind (Chochinov et al., 2011). Engagement in this process, along with affirmation from the dignity therapist, is meant to enhance a sense of meaning and purpose, sense of self, and overall sense of dignity. These sessions are recorded, transcribed verbatim, and then carefully edited into a readable narrative or *generativity document*. This document is returned to the patient, for any final editing and approval, for them to bequeath to friends and family of their choosing.

The effectiveness of dignity therapy has been demonstrated in various clinical trials. Chochinov and colleagues conducted a feasibility study of dignity therapy with terminally ill patients in Winnipeg, Canada and Perth, Australia. All patients who enrolled in palliative care in these cities and met eligibility requirements (less than 6 months to live, over age 18, English speaking, commitment to three to four contacts, no cognitive impairments, willing and able to provide verbal and written consent) were invited to participate. Over a 2-year timeframe, 100 patients—50 from each site—completed the study. Participants completed a broad range of tests to assess depression, anxiety, hopelessness, sense of dignity, suicidality, and sense of meaning and purpose, before and after completing the dignity therapy protocol. Ninety-one per cent of participants reported that they were satisfied or very satisfied with the intervention and 86% said it was helpful or very helpful. Patients also reported that the intervention helped their sense of purpose (68%) and meaning (67%). Just under half of participants indicated that dignity therapy increased their will to live (Chochinov et al., 2005).

A randomized controlled trial of dignity therapy provides further evidence for its application within palliative care. Data was collected between 2005 and 2011 at three study sites (Winnipeg, Canada; New York, United States; and Perth, Australia). Four hundred and forty-four participants aged 18 years and older with a life expectancy of less than 6 months who were receiving palliative care in a hospital or community setting were randomized to one of three study conditions: dignity therapy plus standard palliative care, client-centred care plus standard palliative care, and standard palliative care only. Participants in the dignity therapy condition received this intervention as described above. For client-centred care, participants engaged in supportive psychotherapy focused on present, rather than generativity-related, issues. Patients randomized to standard palliative care had access to all support services available within their site. The primary outcomes of the study were reductions in measures of distress, as measured by mean changes between baseline and post intervention. Standardized measures of psychosocial well-being, symptom distress, depression, anxiety, and hopelessness were used to assess these outcomes. The secondary outcomes were based on a post-intervention questionnaire capturing patient experiences regarding their participation in the study and the ways in which it was meaningful for them and their family.

Floor effects of initial distress resulted in non-significant differences between the study groups for the primary measures, such as depression, desire for death, and suicidality. However, dignity therapy outperformed the other study arms on the post-intervention questionnaire. Compared to client-centred therapy and standard palliative care, patients receiving dignity therapy were significantly more likely to report that the intervention was helpful, that it enhanced their sense of dignity, that it changed how their family saw or appreciated them, and that it would be helpful to their families (Chochinov et al., 2011).

Family members whose loved ones participated in dignity therapy have also been evaluated, to determine their perceptions of its impact on their deceased loved one, along with its influence on their bereavement experience. In a study of 100 patients who completed dignity therapy, 60 family members provided feedback on the experience approximately 1 year after the patient's death. Ninety-five per cent of family members whose loved ones received dignity therapy reporting it had helped the patient, and just over three-quarters indicated that the generativity document helped them during their grief and would be a source of comfort to them in the future (McClement et al., 2007).

Dignity therapy has been successfully delivered in various countries and languages, with minor adaptations for cultural differences (e.g. the notion of 'pride' did not resonate with Danish participants) (Houmann et al., 2010). It has also been implemented with geographically isolated patients using telemedicine (Passik

Table 5.6.3 Application of the dignity model to practice

Illness-related concerns	Directions for practice
Symptom distress	
Physical distress Psychological distress	Baseline and ongoing assessment of physical and psychological symptoms
Medical uncertainty	Provision of timely, relevant information about the illness and plan of care
Death anxiety	Exploration of concerns associated with illness progression
Level of independence	
Cognitive acuity	Baseline and ongoing assessment of cognitive functioning
	Vigilance in detection and treatment of delirium
Functional capacity	Baseline and ongoing assessment of ability to carry out activities of daily living
	Referrals to occupational and physiotherapy as appropriate
	Provision of supports needed to maintain independence (e.g. walker, raised toilet seat)
	Involvement in decision-making regarding plan of care, as desired by patient

Dignity-conserving repertoire	Directions for practice
Dignity-conserving perspectives	
Continuity of self	Communication with patient about those facets of life not affected by their disease
	Learn about the patient's biography, attending to those aspect of life that he or she values most
Role preservation	Exploration of roles important to the patient
	Facilitation of role enactment within limitations of patient's illness
Maintenance of pride	Discussion with patient about those aspects of their life that they are most proud of
	Professional demeanour in provision of care
Hopefulness	Talk with the patient about what is still possible, despite illness limitations
	Encourage redefining of goals and expectations
Autonomy/control	Assess patient's perceived level of control, and explore preference regarding level of involvement in care decisions and planning
	Where possible, provide choices
Generativity/legacy	Facilitate life review, or other activities that foster the sharing of memories that are meaningful to patient
Acceptance	Explore the impact of the illness for the patient
	Appreciate the dynamism of the process of responding to a life-threatening illness
Resilience/fighting spirit	Identify and promote patient participation in those interactions/activities that are most meaningful, given limited life expectancy
Dignity-conserving practices	
Living in the moment	Allow patient to participate in normal routines or take comfort in momentary distractions
	Identify things that can take the patient's mind off illness and provide comfort
Maintaining normalcy	Identify activities the patient still enjoys doing on a regular basis and enable them to participate in such activities where possible
Finding spiritual comfort	Inquire as to whether the patient is connected or would like to be connected with a spiritual or religious community
	Refer to a chaplain or spiritual leader and enable the patient to participate in the cultural/spiritual practices that are important to them

Social dignity inventory	Directions for practice
Privacy boundaries	Ask permission to examine a patient, use proper draping to respect modesty
Social support	Ask the patient who they are closest to and confide in
	Have liberal policies about visitation, rooming, and involve a wide support network
Care tenor	Ask the patient if any aspect of their care is undermining their dignity
	Treat the patient as worthy of honour, esteem, and respect
Burden to others	Inquire about whether the patient feels that they are a burden to others and encourage explicit discussions about these concerns with those they fear they are burdening
Aftermath concerns	Ask about the patient's concerns and encourage the settling of affairs, advance directives, making a will and funeral planning

et al., 2004). In addressing the floor effects of distress found in Chochinov et al.'s (2011) study, Julião and colleagues conducted a randomized controlled trial of dignity therapy with a Portuguese population experiencing high baseline levels of distress. Recruited from an inpatient palliative care unit, 29 patients received dignity therapy plus standard palliative care, while 31 control group patients received standard palliative care alone. Depression and anxiety, as measured by the Hospital Anxiety and Depression Scale (HADS—Portuguese version) (Pais-Ribeiro et al., 2007), were assessed at baseline (T1), day 4 (T2), day 15 (T3), and day 30 (T4). At baseline, compared to participants in the Chochinov et al. (2011) study, these participants had higher HADS-depression scores (12.9 versus 5.86) and HADS-anxiety scores (8.83 versus 5.22). For those in the dignity therapy condition, the intervention was conducted between baseline and T2.

Within the dignity therapy group, participants showed significant reductions from baseline in depression at T2 and T3, which plateaued by day T4; and significant reductions in anxiety at all three follow-ups. Within the standard palliative care group, depression ratings increased significantly between baseline and all three follow-up assessments, while no significant changes in anxiety were found. Compared to the standard palliative care group, patients in the dignity therapy group had significantly lower depression ratings at T2 and T3, and significantly lower anxiety ratings at T2, T3, and T4 (Julião et al., 2013).

The application of dignity therapy in community settings has also been explored, providing insights into the practical and logistical issues of offering this intervention. Montross and colleagues delivered dignity therapy to patients in a community-based hospice, with a psychologist trained in the protocol providing information about the service to members of the hospice team at meetings and rounds. This resulted in just over 100 referrals for dignity therapy, with 27 patients completing the full dignity therapy protocol (reasons for non-completion included cognitive/physical impairments impeding speech or comprehension, death before completion, patient declining participation, and patients lost to follow-up).

In terms of the logistics of providing the service, nearly three-quarters of referrals were from social workers. The average cost of a patients' transcript was US$55.94, and an average of 2993 words in length, with the therapist spending an average of 6.3 hours per patient in order to complete the dignity therapy document. Qualitative analysis of the themes of patients' documents revealed similarities to previous studies (Hack et al., 2010), including discussions of family, pride in their children/accomplishments, pleasure, and life experiences (Montross et al., 2011).

Dignity therapy has also been applied to participants who are not imminently dying. Avery and Baez recently published a case report in which a 61-year-old woman hospitalized for major depressive disorder participated in dignity therapy. She reported that dignity therapy had helped her feel more hopeful and improved her mood. That it can aid in improving depressive symptoms when distress is high (Julião et al., 2013), suggests that dignity therapy may facilitate feelings of increased purpose, meaning, and hopefulness in people with depression, and may also help their families (Avery and Baez, 2012). A recent feasibility study by Chochinov and colleagues has shown the benefits of dignity therapy for the frail elderly living in residential care. Dignity therapy was conducted with both cognitively intact residents and cognitively impaired residents by way of engaging family proxies.

While differing narrative themes emerged between the two groups, the majority of residents' family members and healthcare providers reported the intervention to be helpful to the patient. Further, family members felt the dignity therapy document would provide them comfort, and the majority of healthcare providers reported that the intervention changed how they saw and appreciated the resident and would be helpful in terms of how they provide care (Chochinov et al., 2012a). It thus appears that dignity therapy may have applications across a range of settings and a variety of patient populations. Moreover, the research on dignity therapy underscores the notion that knowing the patient as a person can improve care.

Future directions

Although more attention is being paid to notions of dignity, spirituality, and meaning at the end of life, further research is needed. While the term dignity is multifaceted and complex, its prominence in patient-centred care should spur inquiry across diverse context wherein notions of dignity are particularly salient, that is, the frail elderly, the chronically ill or disabled, those with major mental disorders, and patients encountering cognitively deterioration or impairment.

The notion of dignity in care and ways of affirming personhood also require further examination. These studies may broach cross-cultural comparisons of engaging dignity (Lee, 2010), and how cultural diversity impacts decision-making and experiences at the end-of-life for patients, families, and care providers. Longitudinal research, examining how patients experience dignity over the trajectory of their illness, would help inform dignity-based approaches that are sensitive to the needs and capacities based on disease imposed variables.

A central theme in palliative care is that the patient and the family constitute the unit of care; with the quality of life of family members directly impacted by the care the patient receives (McClement et al., 2007). Poor palliative care can complicate the grieving process and can leave family members with feelings of regret (Shiozaki et al., 2005; McClement et al., 2007), increasing bereavement-related health risks (Prigerson et al., 2009). Thus, researched aimed at better understanding family members' perspectives of dignity and how this impacts their experience of their loved one's illness would be beneficial.

Conclusion

The very nature of being a patient makes one vulnerable, wherein personal dignity may be in jeopardy (Jacobson, 2009). The violation of dignity at the end of life is a significant issue for patients and their families. Consistent with the goals of palliative medicine, dignity should be recognized as a key element of comprehensive care, with access to services—including optimal pain control, psychosocial, and spiritual support—posited as a fundamental human right (Breitbart, 2008). Understanding the multiple dimensions of dignity and how it is experienced in proximity to death, will contribute to a comprehensive and effective approach, which will improve care at the end of life.

5.7

Euthanasia and palliative care

Lars Johan Materstvedt and Georg Bosshard

Introduction: definition of 'euthanasia'

The word euthanasia is a combination of the Greek *eu* = good, and *thanatos* = death. Literally and etymologically it therefore means 'good death'. In the modern setting, its meaning is much narrower; essentially how it is understood in the Netherlands.

The Netherlands is the only country in the world with a long history of practising euthanasia. Here, euthanasia dates back more than 40 years, to the court ruling in the Postma case in 1973, with subsequent de facto legalization through case law over the years, eventually followed by a law on euthanasia which entered into force in 2002 (Griffiths et al., 1998, 2008; Netherlands: Law on Euthanasia, 2002). In a scholarly article on the Dutch practice published in 2012, the authors observed that 'In the Netherlands, euthanasia is defined as the administering of lethal drugs by a physician with the explicit intention to end a patient's life on the patient's explicit request' (Onwuteaka-Philipsen et al., 2012). Dutch-American professor of sociology of law John Griffiths and colleagues shed the following light on the topic:

> 'Euthanasia' in the strict—and in the Dutch context the only proper—sense refers to the situation in which a doctor kills a person who is suffering 'unbearably' and 'hopelessly' at the latter's explicit request (usually by administering a lethal injection). . . . 'euthanasia' is in the Netherlands reserved for killing on request. (Griffiths et al., 1998, p. 17)

The Dutch medical association Koninklijke Nederlandsche Maatschappij tot bevordering der Geneeskunst, the KNMG, which is in favour of euthanasia, states that it takes place 'when a physician ends the life of a patient at his express request due to unbearable and lasting suffering. Euthanasia means that the physician administers a lethal substance to the patient' (KNMG, 2011).

A similar law to the Dutch one which took effect in 2002 was introduced in Belgium in the same year (Belgium: Law on Euthanasia, 2002). Here, euthanasia is 'defined as medical administration of life-ending drugs at the patient's explicit request' (Chambaere et al., 2011a). Subsequently, Luxembourg legalized euthanasia, in 2009 (Luxembourg: Law on Euthanasia, 2009), as did Québec, Canada, in 2014 (Québec: Law on Euthanasia, 2014).

The European Association for Palliative Care (EAPC; see <http://www.eapcnet.eu>), which is opposed to euthanasia, defines it in a way that is congruent with the conception in the BeNeLux countries; namely as 'a doctor intentionally killing a person by the administration of drugs, at that person's voluntary and competent request' (Materstvedt et al., 2003).

In concrete terms, euthanasia involves injecting the patient with two types of substances: barbiturates to induce coma, followed by neuromuscular blockers which cause respiratory muscle paralysis. The consequent anoxia and cardiac arrest bring on immediate death.

Physician-assisted suicide (PAS): in contrast to in euthanasia, the doctor is not the final actor in PAS but instead provides medication for the patient to self-administer an overdose of barbiturates that suppresses respiration.

PAS is legal according to statute in the BeNeLux countries. It is also legal in four US states: Oregon, Washington, Montana, and Vermont (Oregon: Law on Physician-Assisted Suicide, 1997; Washington: Law on Physician-Assisted Suicide, 2009; Answers. USA.gov, 2013; CBSNEWS, 2013), and in Québec, Canada (Québec: Law on Euthanasia, 2014).

Assisted suicide: an act in which a lay person (i.e. someone who is not a *medical* professional) gives the drugs to the patient for self-administration. This practice is legally condoned in the penal code of Switzerland (Bosshard, 2008).

However, in all other jurisdictions that allow PAS (see earlier in this section), such *non*-physician assisted suicide is illegal.

Together, euthanasia, PAS, and assisted suicide comprise what is known as drug-induced 'assisted dying' (Bosshard and Materstvedt, 2011). Voluntary patient request is a key concept in the definition of all three.

Medicalized killing without request

Drugs are also used in the execution of what has been described as 'a life ending act without explicit patient request (LAWER)' (Chambaere et al., 2012).

Some regard such acts as falling within the category of assisted dying (Seale, 2009; Rady and Verheijde, 2010). It is our view that such non-requested ending of someone's life is by no means 'assistance'; it amounts to murder (Griffiths et al., 2008; Bosshard and Materstvedt, 2011; Materstvedt, 2012). There are two kinds of LAWER:

◆ *Non-voluntary medicalized killing*: this is a term used to describe induction of death in patients who lack decision-making competence—such as newborns and the senile demented, who concretely have no free will (Latin *voluntas*).

◆ *Involuntary medicalized killing*: such acts took place during and prior to the Second World War in what are often known as (the German) 'euthanasia clinics'. The name is misleading; in order to appropriately capture the true content of the practices in these institutions, they ought to be described as 'murder clinics' since the patient's life was taken against his or her will, regardless of the motivation for doing so—whether it be compassion, economic considerations, or other rationales (Materstvedt, 2003).

In a more recent example of involuntary medicalized killing, physician Wilfred van Oijen was convicted by the Dutch Supreme Court in 2002 of murdering one of his patients. Not only had this patient not requested a lethal injection, she had even made it clear that she did not want to die (Griffiths et al., 2008).

Assisted dying in practice

There exists a considerable amount of research data on legal assisted dying; however, we focus on selected findings pertinent to palliative care. We first and foremost report on the Netherlands, which has the most comprehensive evidence base on assisted dying by far (Youngner and Kimsma, 2012).

Frequency

Euthanasia is a much more common occurrence than PAS in the Netherlands. In 2005, for example, there were 2297 cases of euthanasia, compared to 113 cases of PAS (van der Heide et al., 2007). This yields a ratio of 20 to 1.

Age groups

Thirty-one per cent of the Dutch cases of assisted dying are found in the age group 40–59 years, while the majority (53%) are found in the 60–79 age bracket. In Belgium, the corresponding figures are 26% and 52%, respectively (Rurup et al., 2012).

Cancer predominant

The data on reported cases of assisted death in the Netherlands in 2010 show that general practitioners were involved in 92.5% of the cases, and that 83.1% of the diseased suffered from cancer, making it the predominant illness among those who were registered in the assisted dying statistics (Onwuteaka-Philipsen et al., 2012).

Relevance for palliative care

The fact that most patients who receive palliative care suffer from terminal cancer suggests that there is considerable overlap between this group and those who opt for assisted death. Hence, even if measured only by the numbers of patients involved, the issue of assisted dying is indeed relevant for palliative care.

Why patients request assisted death

The following findings can be listed:

◆ Over a 25-year period, pain became a significantly less important factor in patients' request for euthanasia in the Netherlands, whereas deterioration became more important (Marquet et al., 2003).

◆ Social, cultural, and existential issues such as loss of dignity and autonomy play a role in requests for assisted suicide in Switzerland (Fischer et al., 2009), and for PAS in Oregon. The 2013 annual report on Oregon's practice states that 'As in previous years, the three most frequently mentioned end-of-life concerns were: loss of autonomy (93.0%), decreasing ability to participate in activities that made life enjoyable (88.7%), and loss of dignity (73.2%)' (Oregon Public Health Division, 2014).

◆ Depression is another factor in these requests, according to a finding among terminally ill cancer patients in the Netherlands (van der Lee et al., 2005).

◆ Research in Oregon has similarly documented the impact of depression on decisions to request death (Ganzini et al., 2008).

◆ So-called tiredness of life has also been found to play a role, for example, in Switzerland. Weariness of life rather than a fatal or hopeless medical condition seems to be a more common reason among older members of the right-to-die organization Exit Deutsche Schweiz to request assisted suicide (Fischer et al., 2008).

What is a 'request'?

While much research has focused on requests for assisted dying, in clinical reality most patients' expression of a wish to die is not literally a plea for help to put an end to their life via drugs, but an expression of something else (Gudat et al., 2015). In particular, palliative care physicians and oncologists are familiar with this phenomenon from their clinical experience.

◆ This clinical knowledge has recently been scientifically confirmed in qualitative, semi-structured interviews with terminally ill inpatients at a palliative medicine unit in Norway about their attitudes and wishes regarding assisted dying (Johansen et al., 2005).

◆ It may be noted in this context that less than half of requests for assisted dying are granted by Dutch physicians (Onwuteaka-Philipsen et al., 2012).

Additionally, requests for euthanasia raise hugely difficult issues regarding patient autonomy and, at a deeper level, whether or not a person can know what are his or her best interests (Materstvedt, 2015).

How should palliative care deal with requests for assisted dying?

Various strategies for dealing with patients who request assisted dying are available. These include measures connected to all sorts of symptom treatment and psychosocial support.

The negative approach

Since all of these measures attempt to prevent premature death, they can be described as 'negative' responses. By contrast, the 'positive' or affirmative response is to comply with the request (Materstvedt, 2013a).

Because assisted dying is more or less universally prohibited, from the juridical point of view most palliative care providers are left with the option of pursuing the negative approach.

Where it *is* legal, however, or where it might be legalized in the foreseeable future, a real dilemma emerges. Should palliative care providers opt out of assisted dying, or should they be a part of the practice?

The World Health Organization stance

The World Health Organization (WHO) can offer guidance on this issue. According to its *Definition of Palliative Care*, such care 'affirms life and . . . intends neither to hasten or [sic] postpone death' and 'regards dying as a normal process' (WHO, 2014).

Death occurs as the culmination of a normal process when, for example, life-sustaining treatment (e.g. antibiotics) is withheld or withdrawn because contraindicated; that is, death is a normal

occurrence when it is not artificially postponed or delayed in fatally ill patients. The patient is allowed to die of his underlying disease—of natural causes: the 'normal' way.

Accordingly, within palliative care a so-called non-treatment decision (NTD) (Griffiths et al., 2008; Chambaere et al., 2012), which is always combined with continued *palliative* treatment until death, is a matter of letting the patient die naturally. It does not hasten death (Materstvedt, 2013a).

By contrast, assisted dying does precisely that: it hastens death. It therefore follows from the WHO's palliative care ethics that palliative care providers should *not* participate in such procedures.

Belgium: offering euthanasia in a palliative care setting

Nevertheless, there is fundamental disagreement on this issue. In 2003, the Belgian Federatie Palliatieve Zorg Vlaanderen vzw (FPZV; see <http://www.palliatief.be>), published a statement, according to which there is no conflict between palliative care and euthanasia:

> Palliative care and euthanasia are neither alternatives nor opposites. When a doctor is prepared to accede to the euthanasia request of a patient who continues to find life unbearable despite the best treatment, then there is no gap between the palliative care given previously by the doctor and the euthanasia he applies now; on the contrary. In such a case, euthanasia forms part of the palliative care with which the doctor and the care team surround the patient and his or her nearest. (FPZV, 2003)

'Palliative care and euthanasia are neither alternatives nor opposites'

Findings on attitudes among Dutch doctors contradict on both accounts this claim. About one-third believed that euthanasia could be avoided by providing high-quality end-of-life care to terminally ill patients. Furthermore, this proportion remained relatively stable over the measured 11-year period (1990, 1995, and 2001) (Onwuteaka-Philipsen et al., 2003).

In another study, two-thirds of Dutch physicians disagree with the suggestion that adequate treatment of pain and terminal care make euthanasia redundant (Georges et al., 2006). But this position, too, reveals dualistic thinking: 'Palliative care is not the answer; euthanasia is.'

By moving from caring to killing, one abandons the dual commitment to treating symptoms and letting someone die of the disease. Euthanasia is therefore a totally different undertaking from palliative care. Accordingly, the claim that there is 'no gap' between the two is incorrect.

The FPZV continues:

> In view of the delicate, irreversible and radical nature of euthanasia, it is vitally important that euthanasia only be performed in cases where there is evidence of suffering 'which cannot be alleviated' (Art. 3, §1 Euthanasia Act), and a situation 'for which there is no other reasonable solution' (Art. 3, §2, 1° Euthanasia Act). (FPZV, 2003)

Suffering that 'cannot be alleviated'

This phrase is ambiguous; it is open to several interpretations. It might allude to the fact that palliative care does not always function optimally, and sometimes cannot be made to do so. Accordingly it is not always good enough in a very strict sense.

But it is wholly unrealistic to expect palliative care to make all patients completely free of all symptoms at all times, including pain, fatigue, cachexia, nausea, vomiting, dyspnoea, anxiety, depression, and delirium.

Additionally, how patients experience and cope with these symptoms is to a large extent a subjective matter.

Refractory symptoms

If, by contrast, symptoms have become *refractory*, 'despite the best treatment', as the FPZV puts it (see earlier quotation), the suffering can perhaps be said to be *objectively* unbearable. However, in a palliative care setting where patients are approaching the end of life, various degrees of palliative sedation can be offered to address such suffering, with terminal sedation as a last resort (Materstvedt and Bosshard, 2009). So even refractory suffering can be alleviated—or, perhaps more properly formulated in the case of terminal sedation, *erased* (Materstvedt, 2012, 2013b)—through reduction or complete removal of the ability to perceive symptoms.

Scope of suffering

Does the word 'suffering' in the above FPZV quotation refer exclusively to *medical* symptoms (be they somatic or psychiatric) of the kind mentioned earlier? Or does it also include broader issues such as loss of autonomy, loss of dignity, or tiredness of life?

As we have seen, these issues can be on a par with medical symptoms in terms of contributing to a patient's suffering. If this is indeed the case, it is even more unrealistic to expect palliative care to alleviate all suffering; especially suffering of such a very personal and subjective kind.

In this context, the findings of a qualitative study carried out in southern Switzerland are remarkable. The study involved 11 relatives of eight patients, looked after by a palliative care team, who had died by means of assisted suicide. It revealed that pain and symptom burden did not constitute the patients' key reasons for seeking assisted suicide. Instead, existential distress and fear of loss of control were the key determinants. The patients did not regard the provision of palliative care as an influential factor in their decision, according to the relatives (Gamondi et al., 2013).

No 'reasonable' alternative to euthanasia

Where does this leave the idea that euthanasia is a solution to a problem that cannot be solved in any other way? The FPZV refers to situations when there is 'no other reasonable solution' than euthanasia. The Belgian law in English translation uses the wording 'reasonable alternative' (Belgium: Law on Euthanasia, 2002); as does the Dutch law, stipulating that 'the attending physician must . . . have come to the conclusion, together with the patient, that there is no reasonable alternative in the light of the patient's situation' (Netherlands: Law on Euthanasia, 2002).

That there is no reasonable alternative to euthanasia, whatever the meaning of 'reasonable', does not imply that no alternative is available; it entails that the available alternative, namely treatment and/or psychosocial support, is rejected by the patient. Again, we can only conclude that palliative care and euthanasia are indeed alternatives.

'Medical futility' and the legal requirements of assisted dying

The Belgian law states in Chapter II, sect. 3, §1, that the patient must be: 'in a medically futile condition of constant and unbearable physical or mental suffering that can not be alleviated, resulting from a serious and incurable disorder caused by illness or accident' (Belgium: Law on Euthanasia, 2002).

Concept of futility

This concept is subject to much discussion and there are many interpretations of it. Non-resuscitation in the case of an old and severely demented patient when the likelihood of treatment having any effect on survival is less than 1% might be taken as an example of a decision based on a 'medically futile condition'.

Nevertheless, the fact remains that the 'inner life' of this patient is non-accessible to outsiders. For all we (can) know, he might be happy to go on living—despite the fact that to us his existence may look utterly miserable. Presuming that staying alive is a benefit or good in this and corresponding cases, one may ask if there ought to be such a thing as a right to futile treatment (Ackroyd, 2005).

It happens from time to time, although extremely rarely, that patients who have been judged to be beyond rescue in intensive care units—that is, whose chance of survival has been assessed as 0% (which makes them paradigmatic examples of medical futility)—do indeed recover and leave the hospital premises on their own two feet.

Another interpretation of futility is that it is present when treatment is of very limited usefulness weighed against the risks and/or side effects associated with it. For example, a terminally ill patient diagnosed with advanced pancreatic cancer can be given somewhat life-prolonging treatment. However, he may perceive the treatment as overly distressing, thus feeling that its limited advantages are outweighed by the disadvantages. Hence, the patient may decline further chemotherapy and accept only palliative care.

Criterion of medically 'futile' or 'hopeless' condition

What, then, is 'a medically futile condition' according to the Belgian euthanasia law: which interpretation would apply? The law contains no information that might help us answer this question. Also, we saw that the law's criterion of suffering that 'can not be alleviated' is a debatable premise.

Furthermore, why the law prescribes that the suffering must be 'constant' (a second translation is 'persistent' (Griffiths et al., 2008)) is not easy to understand. Does it mean that a patient whose suffering fluctuates may have his euthanasia request denied based on this fluctuation?

Another translation uses, in place of 'futile condition', the wording 'medically *hopeless situation* of persistent and unbearable . . . ' (Griffiths et al., 2008; italics added by authors). In the Netherlands, the law stipulates that 'the attending physician must . . . be satisfied that the patient's suffering was unbearable, and that there was no prospect of improvement' (Netherlands: Law on Euthanasia, 2002).

'No prospect of improvement'

This formulation corresponds to the 'medically hopeless situation' wording of the Belgian law. Presuming that the translation 'medically futile condition' covers the same meaning, futility may then be understood as treatment that is unlikely to have any positive impact whatsoever.

However, both the treating physician and the second opinion physician (both laws require that a second doctor is consulted) might be wrong in their conclusion on this crucial issue.

What is more, beyond the strictly medical interpretation of 'improvement', even when there would be a standstill in this particular respect, the conception could be read in terms of *mental* improvement, for example, psychological or existential improvement. Thus it is not totally clear what the requirement actually entails.

'Unbearable' suffering

We noted above that perhaps some conditions are objectively in this category. But the laws quoted appear to be referring to suffering that is 'unbearable' according to the patient's subjective perspective. The physician needs, however, to comply.

This raises the question of how he, an 'outsider' who is not himself ill, can possibly be in a position to assess or vouch for the severity of the patient's subjectively perceived suffering.

No requirement of limited life expectancy

The Belgian law contains no restriction with regard to time left to live, and so chronic illness as well as psychiatric illness may provide legitimate grounds for assisted dying. In the Netherlands this has been the reality for many years (Griffiths et al. 1998, 2008).

And the Belgian law even includes suffering resulting from an 'accident' among the qualifying factors. Thus, a person who is paralysed from the neck down due to a car crash would in principle qualify for assisted dying.

Requirement of 'terminal' illness

The US states of Oregon and Washington, for example, are stricter on this point: the law requires that the patient be so-called terminally ill.

It should be noted, however, that 'terminally ill' is far from being a clear-cut concept. Nevertheless, it is defined in the following way in the Oregon Death with Dignity Act (the Washington act uses the exact same formulation): '"Terminal disease" means an incurable and irreversible disease that has been medically confirmed and will, within reasonable medical judgment, produce death within six months' (Oregon: Law on Physician-Assisted Suicide, 1997). (It will be objected that it is impossible to accurately predict death within such a long time span.)

One may conclude from this that the two US laws, in contradistinction to the Dutch and Belgian ones, are discriminatory in that they 'reserve' assisted dying for particular patient groups and diseases. The same is true of the Québec law, which uses the expression 'an end-of-life patient' both with regard to PAS and euthanasia (Québec: Law on Euthanasia, 2014). How can this be legitimated?

PAS versus euthanasia

In explicitly prohibiting euthanasia, the two US laws also effectively ensure that any granted right to die does not apply to people who physically cannot, or who (for some reason or other) will not, or who psychologically cannot bring themselves to, commit suicide by swallowing or otherwise self-administering drugs.

The law in Oregon states that 'Nothing in ORS 127.800 to 127.897 shall be construed to authorize a physician or any other person to end a patient's life by lethal injection, mercy killing or active euthanasia' (Oregon: Law on Physician-Assisted Suicide, 1997). The wording of the Washington law is almost identical: 'Nothing in this chapter authorizes a physician or any other person to end a patient's life by lethal injection, mercy killing, or active euthanasia' (Washington: Law on Physician-Assisted Suicide, 2009).

The idea of 'palliative futility'

Regardless of what might be the meaning of 'medical futility', it has been claimed that similarly, 'there is also such a thing as palliative futility', implying 'the right of patients to decide that further conventional palliative care is futile and to request and obtain physician assisted death' within the palliative care unit (Bernheim et al., 2008).

It is true that palliative care may vary in quality and effectiveness, ranging from optimal across good and acceptable to poor. But it is never futile. Even in extreme cases of refractory suffering in the dying, palliative care can offer relief, as we pointed out above, through the option of terminal sedation.

The idea of palliative futility is therefore both clinically misplaced and conceptually incoherent (Materstvedt, 2013a). Accordingly, it should be discarded, and palliative care personnel should ignore it altogether.

A basic challenge for palliative care, and the model of 'integral' palliative care

Palliative care 'will enhance quality of life', states the WHO (2014). Obviously, if assisted dying is performed, it rules out such enhancement beyond the point of completing this procedure. But the task of enhancing the quality of life for terminally ill patients can be very demanding on the personnel involved in palliative care. According to Professor Franz Josef Illhardt, a fundamental challenge facing palliative caregivers is that they 'must know answers to the question: What makes a terminal and perhaps miserable life important and worth living for the dying person?' (Illhardt, 2001).

Faced with requests for assisted dying, finding answers to this question can be an even more difficult undertaking. And if assisted dying is practised within the walls of palliative care institutions, it might well prove a 'mission impossible' at times—for the very reason that the reality of the existing option may in itself cause particular patients to lose the will to live. This concern is sufficiently serious for many doctors and nurses to question or downright reject so-called integral palliative care.

Others think differently, believing this model to be a step in the right direction as practices evolve within palliative care, and as palliative care is increasingly institutionalized. Indeed, some even believe it to be *the* humane way to move forward in a civilized society.

In 2011, the EAPC published a report on palliative care development in countries with a euthanasia law (Chambaere et al., 2011b). The report highlighted that there has been substantial development in palliative care services in these countries, and that it was not possible to conclude that the development of palliative care had either been hindered or promoted by the legalization of elective death options.

By way of example, in Belgium, euthanasia or PAS seem not to be related to a lower use of palliative care, and often occur within the context of multidisciplinary care (van den Block et al., 2009). Some even claim that the domestic palliative care and euthanasia movements have reinforced one another in this country (Bernheim et al., 2008; Bernheim, 2011). However, that has been disputed (Gamester and van den Eynden, 2009). Whatever the truth of the matter, it is interesting to note that a Palliative care Act (as well as a Patients Rights Act) was passed simultaneously with the euthanasia law in 2002 (Bernheim and Mullie, 2010).

Table 5.7.1 lists some of the crucial arguments on either side of the important debate on the relationship between euthanasia and palliative care. A similar compilation appears in Materstvedt (2013a; see this article for an exposition of the various viewpoints).

The Swiss model of assisted suicide

Switzerland is known for its unique practice of assisted suicide involving lay people affiliated with right-to-die organizations. At first glance, this practice resembles the model of 'a suicide service outside clinical care' suggested by professor of palliative medicine Ilora Finlay and her colleagues (Finlay et al., 2005).

Role of the doctor

In the Swiss model, however, a medical doctor is involved in all cases of assisted suicide. He writes the lethal prescription—note that lethal injection upon request, that is, euthanasia, is prohibited in the penal code—and Swiss case law established in 1999 that a doctor can write such a prescription only on the basis of a clear diagnosis and indication, after personally having examined the patient, having checked his decisional capacity, and providing information on his prognosis and any existing treatment options (Bosshard, 2008).

Role of right-to-die organizations

Nevertheless, right-to-die organizations take responsibility for an important part of the assisted suicide process. The first step is often that the individual seeking to die contacts one of these organizations. If an applicant seems eligible in principle but his treating doctor is unwilling to participate, these organizations help the patient find a doctor who might be willing to assist.

Most importantly, right-to-die organization volunteers are present and provide counselling during the patient's self-administration of the lethal drug, that is, during the actual execution of the assisted suicide. They also give general support to the patient and his family (Ziegler and Bosshard, 2007).

Since Switzerland has no law on assisted suicide, there are no legal criteria for determining what patient groups may legitimately ask for such assistance. Hence the various right-to-die organizations operate according to their own rules. The common denominator for all of the organizations is that the patient must be competent. Beyond this basic requirement, their criteria for accepting an applicant for assisted suicide are as follows (Bosshard, 2008): 'hopeless prognosis or unbearable symptoms or unacceptable disabilities' (Exit; see also <http://www.exit.ch/en>); 'fatal disease or unendurable disability or uncontrollable pain' (Dignitas; see also <http://www.dignitas.ch>); or 'incurable disease with fatal prognosis or important disability or, and intolerable physical suffering, or incapacitating multimorbidity due to old age' (Exit A.D.M.D.; see also <http://www.exit-geneve.ch>).

Table 5.7.1 Combining palliative care and assisted dying

Arguments for	Arguments against
Assisted dying may be a part of palliative care	Assisted dying is not *palliative* care and by implication cannot be a part of it
The Belgian model of 'integral' palliative care has already been realized	That something is realizable does not necessarily make it desirable
Integral palliative care respects patient autonomy	The patient may not be capable of autonomous action
Assisted dying stops intolerable suffering at the end of life	Terminal sedation is an alternative procedure for stopping intolerable suffering
Patients may feel abandoned if they are denied access to assisted dying in palliative care institutions	Patients in wards offering 'integral' palliative care may lose the will to live and may also come to think that it is their duty to request assisted dying
Assisted dying and palliative care are neither alternatives nor antagonistic	Empirical research on the attitudes of Dutch doctors contradicts both claims
Palliative care needs a new ethical foundation that allows for assisted dying	The current, widely accepted WHO palliative care ethics rejects assisted dying
There is such a thing as 'palliative futility', which necessitates assisted dying	Palliative care is never futile, and the concept of 'palliative futility' is therefore both incoherent and clinically misplaced
In Belgium, the palliative care and assisted dying movements have reinforced one another	There is a danger that palliative care may become a neglected area in times of economic crises, with emphasis shifting to the less costly alternative of assisted dying
Doctors within palliative care are faced with decisions on life and death on a regular basis in the context of withholding or withdrawing life-sustaining treatment. Thus they are also the obvious and natural experts to carry out assisted dying	Withholding and withdrawing life-sustaining treatment (non-treatment decisions; NTDs) is not a matter of hastening death, but rather of not artificially prolonging life or postponing death. Such decisions are therefore fundamentally different from any decisions to hasten death through lethal injection or provision of lethal drugs for the patient to self-administer

'Suicide tourism'

Also peculiar to the Swiss context is the phenomenon of 'suicide tourism', which means that patients travel from countries such as the United Kingdom and Germany to die (Bosshard 2008).

De-medicalizing assisted suicide

The Swiss practice is an instructive model in terms of showing what tasks and responsibilities can be dealt with without necessarily having to involve medical professionals. This division of tasks allows a certain distance between clinical practice and assisted suicide that may be perceived as helpful by many doctors.

The vast majority of cases of assisted suicide are carried out in the privacy of the patient's home. However, in recent years a number of nursing homes all over Switzerland, and a few hospitals in the French-speaking part of the country, have allowed assisted suicide to be performed on their premises (Pereira et al., 2008).

Statements on assisted dying by some palliative care organizations

Across the world, various palliative care organizations have published position statements on assisted dying.

We have seen that the Belgian FPZV is overtly supportive of elective death, however most such organizations oppose it, whereas some are neutral. The following is a selection that illustrates the spectre.

◆ *EAPC:* the EAPC's official position is that 'the provision of euthanasia and physician-assisted suicide should not be part of the responsibility of palliative care' (Materstvedt et al., 2003; Materstvedt, 2006, 2014; Payne, 2014).

◆ *The Australian and New Zealand Society of Palliative Medicine (ANZSPM)*: the ANZSPM is of a similar view, believing 'that the discipline of Palliative Medicine does not include the practice of euthanasia or assisted suicide' (ANZSPM, 2010).

◆ *The International Association for Hospice & Palliative Care (IAHPC)*: the IAHPC rejects assisted dying altogether in the short message that it 'believes that a plea for euthanasia is a plea for better care. There is no need or place for euthanasia in any form. The answer is the world-wide promotion and promulgation of the practice of Palliative Care' (IAHPC, 2012). They also stated 4 years earlier, in 2008, that 'assisted suicide and euthanasia should not be practiced in palliative care units' (IAHPC, 2008).

◆ *The Canadian Hospice Palliative Care Association (CHPCA)*: the CHPCA defends the right of those involved in palliative care not to contribute towards any hastening of death, stating that 'despite access to high quality end-of-life care, a small number of Canadians may still choose to have control over their own death . . . but we . . . have a choice not to participate or to be expected to assist in any efforts that intentionally hasten death' (CHPCA, 2010).

◆ *Canadian Society of Palliative Care Physicians (CSPCP)*: the position of the CSPCP is more conciliatory and is founded in membership opinion rather than ethical evaluation. They state: 'Based upon a membership survey, the Canadian Society of Palliative

Care Physicians strongly opposes the legalization of euthanasia and assisted suicide *at this time*, and most CSPCP members will not participate in euthanasia or assisted suicide' (CSPCP, 2012; italics added by authors). This position may be coined 'temporarily against', since by logical implication this means leaving the door open to legalizing assisted dying in the future.

- ◆ *The American Academy of Hospice and Palliative Medicine (AAHPM)*: the AAHPM 'takes a position of 'studied neutrality' on the subject of whether Physician-assisted Death should be legally regulated or prohibited, believing its members should instead continue to strive to find the proper response to those patients whose suffering becomes intolerable despite the best possible palliative care. Whether or not legalization occurs, AAHPM supports intense efforts to alleviate suffering and to reduce any perceived need for Physician-assisted Death' (AAHPM, 2007).

The future: palliative care on the 'slippery slope' towards euthanasia?

Against this background it is not easy to tell what the future holds for the relationship between assisted dying and palliative care. The picture is diverse. Will any of the organizations that have a somewhat unresolved attitude towards the topic today adopt a more accepting attitude towards combining palliative care and assisted dying?

Impact of new legislation

How will new legislation on assisted dying, if adopted by a particular country or state, impact on these views? Will some palliative care organizations abandon their long-standing resistance to assisted dying as a result of such legislation? And will we, as a consequence, be witnessing the realization, and hence the normalization, of the combination of palliative care and assisted dying?

Are we, in sum, going to see 'Palliative care on the "slippery slope" towards euthanasia?'—as asked in the title of a previous article by one of the present authors (Materstvedt, 2003). This issue has become all the more relevant with the very recent legalization of euthanasia in Québec, Canada, where the law requires that 'Every institution must adopt a policy with respect to end-of-life care', and that its annual 'report must also state, where applicable, the number of times . . . medical aid in dying were administered . . . *in the premises of a palliative care hospice* by a physician' (Québec: Law on Euthanasia, 2014; italics added by authors). In other words, the law explicitly paves the way for a practice akin to the Belgian 'integral' model (Bernheim et al., 2008; Materstvedt, 2013a). Accordingly, the Canadian organizations CHPCA and CSPCP, whose statements on assisted dying we quoted earlier, now face this reality.

Concluding remarks

For very many practitioners of palliative care the issue of assisted death is a potentially pressing one. They should therefore identify their own attitude towards it, and carefully think through the implications of this attitude. How do they justify their viewpoint? Would they or would they not be willing to participate in the practice?

Doctors' reluctance to participate in assisted dying: for clinicians, participating in assisted dying may prove to be a harder choice than abstaining. In a Dutch qualitative study of 22 primary care physicians, doctors described the emotional difficulties of performing euthanasia. One called euthanasia 'a rotten job'; another went as far as to depict himself as an 'executioner' (van Marwijk et al., 2007).

At the same time, doctors are becoming increasingly wary of being enlisted as experts in a field that extends far beyond medicine. There is often a presupposition in existing legislation and proposed bills that doctors' exclusive medical expertise can be utilized in the assisted dying process (Bosshard et al., 2008).

Doctors caught in the middle: doctors may also find themselves caught between society at large and professional concerns. On the one hand, a significant and growing proportion of the population in many Western countries seem to want assisted dying to be available as an option (Cohen et al., 2006). On the other hand, the overwhelming majority of medical organizations continue to view assisted dying as incompatible with the ethical codes of their profession (Bosshard et al., 2008).

From caring to killing?: but above all, the fact remains that moving from caring to killing is a big and fundamental step for palliative care personnel to take.

And for their patients, it is a matter of life and death—quite literally speaking.

Withholding and withdrawing life-sustaining treatment (including artificial nutrition and hydration)

Danielle N. Ko and Craig D. Blinderman

Introduction to withholding and withdrawing life-sustaining treatment

Although withholding medical treatment from the seriously ill is not new (Hippocrates et al., 1923), public debate over the appropriate use of life-sustaining treatment (LST) in seriously ill patients is at unprecedented levels, driven by multiple factors including advances in medical technology, an ageing population, ballooning health-care costs, the increased prevalence of life-threatening chronic disease, and more patients dying within health-care institutions.

LST is 'any treatment that serves to prolong life without reversing the underlying medical condition and includes but is not limited to cardiopulmonary resuscitation (CPR), mechanical ventilation, hemodialysis, left ventricular assist devices, antibiotics, as well as artificial nutrition and hydration' (Anonymous, 1992). *Withholding* LST is a deliberate decision not to initiate treatment aimed at prolonging life. *Withdrawing* LST involves removing a medical intervention without which life is not expected to continue due to the patient's underlying health status. Withholding/withdrawing LST is therefore performed with the expectation that the patient will die due to the natural progression of their underlying illness. This is in contrast to physician-assisted dying and euthanasia (see Chapter 5.6) which are acts intended to hasten death to prevent or alleviate patient suffering.

The primary goal of this chapter is to present a practical guide for clinicians who are faced with the prospect of withholding/withdrawing LST (as outlined in Box 5.8.1).

Consider the legal and ethical framework

Is withholding/withdrawing LST legal?

The legality of withholding/withdrawing LST differs between countries. In many countries (e.g. United States, United Kingdom, Germany, Japan, Netherlands, Taiwan, and Australia) withholding/withdrawing LST is legal, although each country tends to have different approaches for withholding/withdrawing LST

(Mendelson and Jost, 2003). In contrast, within the developing world, withholding/withdrawing LST is either of uncertain legal status (e.g. China and Brazil) or illegal (e.g. Kenya, Turkey, and India) (Blank, 2011).

Even in those countries where withholding/withdrawing LST is legal, it has been shown that poor clinician knowledge of the law is associated with higher levels of legal defensiveness and consequently more aggressive and unjustified treatment at the end of life (McCrary et al., 1992; McCrary and Swanson, 1999; Meisel et al., 2000). It is therefore important that clinicians have a basic understanding of the relevant laws. Since a thorough review of the relevant laws around the world is beyond the scope of this chapter, readers are advised to familiarize themselves with the laws governing this clinical practice in their own jurisdiction. Nevertheless, we highlight here some of the general legal principles that one might need to consider, using the US legal framework as an example.

While there is no absolute right to die (*Vacco v Quill*, 1997; *Washington v Glucksberg*, 1997), US case and statutory law generally support the right of a person to refuse life-sustaining medical treatment. Prior to 1976, however, US courts were reluctant to allow patients to refuse treatment if this would result in their death. *In Re Quinlan* (1976), the first reported US 'end-of-life' case, the New Jersey Supreme Court recognized that the existing right to determine one's medical care included the right to refuse LST. Karen Quinlan had been in a persistent vegetative state (PVS) as a complication of drug and alcohol intoxication, and required respiratory support and artificial nutrition and hydration (ANH) to keep her alive. Quinlan's father, her legal guardian, requested that the ventilator be withdrawn. The Court ruled that there was a right to refuse medical care based on one's constitutional right to privacy—a right that is not expressly mentioned in the US constitution but is implied in a number of its amendments—and that this right could be exercised on behalf of a patient without decision-making capacity by her guardian.

In 1990, the US Supreme Court made its first decision on withdrawing LST in *Cruzan v Director, Missouri Department of Health* (1990). Nancy Cruzan was a young woman in a PVS following a

Box 5.8.1 Withdrawing and withholding life sustaining treatment—a practical approach to decision-making

We find that a systematic approach to withholding and withdrawing LST is important to ensure best clinical practice and optimal patient outcomes. When faced with a decision as to whether to withhold or withdraw LST from a seriously ill patient, the following approach is suggested:

1. Consider the legal and ethical framework for withholding/withdrawing LST

Is withholding/withdrawing LST legal in my jurisdiction?
What are the ethical principles/considerations relevant to a decision to withhold/withdraw LST?

2. Assess the consequences of utilizing or forgoing LST in this particular instance

What is the patient's current prognosis?
What are the current goals of care of the patient?
What are the likely outcomes of utilizing LST in this patient?

- What is the clinical evidence for utilizing LST in this context?
- Will it extend the patient's life? If so, for how long?
- How will the LST impact upon the patient's quality of life?
- What are the physical risks or complications likely to result from LST? How likely are these to occur?
- What are the emotional consequences of utilizing LST here?
- How will the LST impact upon specific goals of the patient? For example, LST may allow the patient to share a significant life event (e.g. seeing a child get married or a grandchild born) or to say goodbye to family.
- Will the LST facilitate other treatment aims? For instance, will it enable adequate time to treat a patient's underlying depression.
- How do these outcomes accord with the patient's known end-of-life values?

What are the likely outcomes of withholding/withdrawing LST in this patient?

- What is the expected clinical course if LST is withheld/withdrawn?
- How will withholding/withdrawing LST affect patient survival?
- What physical symptoms may occur? How can these be managed?
- What is the likely emotional impact of withholding/withdrawing LST on the patient? The caregiver(s)? The family?
- Will forgoing LST alleviate existing physical, emotional or existential distress?
- How do these outcomes accord with the patient's known end-of-life values?

3. Assess patient's decision-making capacity

Does the patient have capacity to make this particular decision at this particular time?

4. Make a decision regarding LST

We advocate using a shared decision-making model, in which the patient provides the expertise regarding his/her values and goals and the clinicians provide the expertise to determine whether utilizing LST will accord with the patient's values and help them to achieve their goals. In practice, we adopt the following approach:

(a) *If the patient has capacity, what is his preference regarding LST?* For patients who have not formed an opinion regarding LST, we should consider their health-care values and goals and make a recommendation as to whether the use of LST will honour those values and meet those goals.

(b) *If the patient lacks capacity, does the patient have an advance directive specifying his preference for LST? If not, is there a surrogate decision-maker who knows the patient's wishes or can use substituted judgement to decide on the patient's behalf?*

Taking this approach, we find that a consensus decision to utilize or forgo LST can be readily achieved in the vast majority of cases. However, sometimes disagreement/uncertainty regarding the best approach will remain. In this event, we suggest attempting to address the following questions:

Is the disagreement/uncertainty arising out of clinical uncertainty (e.g. uncertain prognosis, uncertain benefit?), an ethical dilemma (is this the right thing to do?), a legal issue (is what I am doing prohibited by law?) or a combination thereof?

- For clinical uncertainty, medical evidence, clinical experience and consultation with colleagues should be utilized.

- For ethical problems, consider the ethical principles of beneficence, non-maleficence, autonomy, justice, and the concepts of proportionality and quality of life as well as seeking the opinion of an ethics committee (if available).

> *Is the conflict within the team, between the team and the patient/family, or between the patient/family?*
>
> ◆ For intra-team conflict, consider seeking advice from other senior physicians.
>
> ◆ For conflict between the team and the family/patient, is there a role for an ethics committee or is there a hospital policy that can provide guidance?
>
> ◆ For conflict between the family/patient, maintain focus on patient's goals. If the patient is competent, follow the patient's requests. Refer to social work/psychologists/chaplaincy if available for additional support.
>
> **5. If the decision to withhold/withdraw LST is made, make a treatment plan to actively manage resulting symptoms and provide support to patients/families and health-care providers**
>
> ◆ A clear plan for the treatment of the patient's underlying symptoms should be in place given the expectation that the patient will become more symptomatic and die once LST is withheld/withdrawn.
>
> ◆ For patients, families and health-care providers, the decision to withhold or withdraw LST is emotionally charged. Good communication will significantly aid in alleviating some of the distress. Existential and spiritual issues may become more prominent as death is expected. Referrals to psychology, social work, and chaplaincy should be considered.

car accident. The hospital applied for a court order sanctioning the family's request to remove the feeding tube. The Missouri Supreme Court declined because of a lack of 'clear and convincing' evidence that this is what she would have wanted. On appeal, the US Supreme Court affirmed Missouri's right to require 'clear and convincing' evidence, but otherwise left it to individual states to set the evidentiary burden. The Court confirmed that both patients with and without decision-making capacity have a constitutional right to refuse medical care under the 14th amendment's Due Process Clause (that no person shall be deprived of life, liberty, or property, without due process of law). Shortly after the Cruzan case and its focus on patient preferences, the Patient Self Determination Act of 1990 was passed by the US Congress (Patient Self-Determination Act, 1990). This legislation requires that federally funded health-care institutions provide patients with information about their right to direct future medical care via written advance directives (ADs), which can be applied in the event of future incapacitation. By doing so, the Act forced health-care institutions to develop and outline policies regarding withholding/withdrawing of LST.

Withholding/withdrawing LST is *not* the same as physician-assisted suicide

Withholding/withdrawing LST is declining treatment that is artificially sustaining a person's life. In contrast, physician-assisted suicide (PAS) is the provision of means to end a life prematurely. In most countries where withholding/withdrawing LST is allowed, PAS is illegal. In *Washington v Glucksberg* (1997), the US Supreme Court held that while patients have the constitutional right to refuse medical treatment, individuals do not have a constitutional right to PAS (*Washington v Glucksberg*, 1997).

Withholding versus withdrawing LST

From a Western bioethical perspective, there is no moral reason to differentiate between withholding and withdrawing LST (President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research, 1983;

Brock, 1997; Beauchamp and Childress, 2009). Notwithstanding this, withdrawing LST is an act of commission (as opposed to withholding LST which is an act of omission), and death usually follows more quickly than for withholding LST (Sprung et al., 2003). Consequently, withdrawing LST is frequently perceived to have direct causation in a patient's death. As a result, for many patients, family members, and clinicians withdrawal of LST carries a greater psychological burden (Solomon et al., 1993; Melltorp and Nilstun, 1997; Vincent, 1999; Dickenson, 2000). Moreover, for some orthodox religions, a distinction between withdrawal and withholding LST remains (Loike et al., 2010).

The common perception that withholding LST is morally more acceptable than withdrawing LST is further contributed to by the differential treatment the two acts are afforded in some legal jurisdictions. At a practical level, if only withholding treatment was allowed, time-limited trials of LST would not be acceptable and patients who chose LST would need to remain on those treatments until death.

What are the ethical considerations?

The ethical considerations around withholding/withdrawing LST have been the subject of considerable discussion. A summary of the important ethical principles that are relevant to withholding/withdrawing LST is outlined in the following sections. Since culture creates the context within which individuals comprehend the meaning of illness, suffering, and death, the moral considerations and the weight they carry are culturally determined (Vincent, 2001; Sprung et al., 2007b) and for any given patient, the most ethical option will depend on the individual circumstances of the case, and can only be determined by weighing all of the different principles.

General principles of modern bioethics

Beneficence, nonmaleficence, autonomy, and justice are the four guiding principles of modern bioethics (Beauchamp and Childress, 2009), and any decision to withhold/withdraw LST should carefully consider each of these.

Beneficence/non-maleficence

Dating back to the time of Hippocrates 2500 years ago, physicians have primarily acted to benefit their patients (beneficence) and refrained from causing harm (non-maleficence) (Will, 2011a). In modern medicine, where the ability to cure illness and extend life is widely celebrated, withholding/withdrawing LST can superficially be seen as running counter to the principle of beneficence. However, in those with serious advanced illness, clinicians need to be mindful that utilizing LST may not only be associated with significant physical harm (e.g. rib fractures frequently occur following chest compressions during resuscitation) but also be in violation of a patient's values and goals.

Autonomy

Autonomy is broadly defined as the human capacity for self-determination, that is, each person has the right to choose among the best alternatives according to a self-chosen plan (Kant and Gregor, 1998) and is derived from the basic moral obligation-respect for persons. Patient autonomy has a narrower definition, being the right of patients to make medical decisions and exert control over their medical care. Patient autonomy serves as the basis not only for informed consent to treatment but also for the right to refuse treatment (President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research, 1982; Will, 2011b).

When considering withdrawing or withholding LST, the desire to uphold autonomy (or more aptly, patient preferences) may come into direct conflict with other ethical principles. For instance, patients and/or their families may request interventions that the physician considers harmful. In this regard, it is generally accepted that, while patients have the right to refuse medical treatments, they do not have the right to demand harmful and non-beneficial treatments (Luce, 1995; Brett and McCullough, 2012). Moreover, some authors have noted that an overemphasis and/or uncritical acceptance of patient autonomy risks putting unrealistic responsibility on patients and their families and may in fact compromise their ability for self-determination by forcing them to make decisions for which they lack the prerequisite knowledge and experience (Quill and Brody, 1996; Billings and Krakauer, 2011).

Justice

Given the finite nature of health-care resources, justice requires these resources be fairly allocated. Despite this, many clinicians feel that they should not have to bear in mind such considerations when determining whether to withhold/withdraw LST, since their duty of care is to the individual patient and not to society at large. In reality, however, resource allocation does limit the options one considers for seriously ill patients. For example, while there are often hospital policies regarding allocation of limited intensive care unit (ICU) beds, it is clinicians who make the final determination regarding who is allocated an ICU bed. This decision is inevitably made up of judgements regarding benefits and burdens to the individual patient but also must have regard for competing demands for a bed by other patients in the hospital at any given time.

Other ethical considerations

In addition to the general bioethical principles just outlined, an understanding of several other concepts is important when considering withdrawing/withholding LST.

Proportionality

Proportionality, a concept originating from the Catholic Church, supports the idea that LST should be forgone if it would cause more harm than benefit, and requires one to weigh the burdens and benefits of a particular treatment relative to the clinical situation and prognosis of a particular patient (Pence, 1995; Quill et al., 1997; Jansen and Sulmasy, 2002). For example, mechanical ventilation may be considered proportionate for a young, otherwise healthy adult, with a severe but reversible lung pathology/injury, but the same therapy may be disproportionate in a patient dying of metastatic cancer.

In a patient at the end of life there is a risk that LST may prolong the dying process and/or subject the patient to a quality of life that is unacceptable. In such cases where the burdens of the treatment outweigh any benefits, it has been argued that there is no ethical obligation to provide disproportionate treatment and that it is morally permissible to remove such treatments and focus exclusively on the patient's comfort even if this results in an earlier death (Shannon and Walter, 1993).

Extraordinary versus ordinary treatments

Previously, some ethicists and theologians advocated for a distinction between 'extraordinary' versus 'ordinary' treatments as a way to decide whether to withhold/withdraw LST, with foregoing of extraordinary treatment being more ethically justified. The extraordinary/ordinary distinction is no longer considered useful given it is unclear what aspect of a treatment (usualness, complexity, artificiality, availability, cost, etc.) would make it extraordinary or ordinary, and the concept has largely been replaced by considering proportionality, that is, benefits versus burdens instead (Beauchamp and Childress, 2009).

Futility

In everyday practice, futility is a concept that is frequently used as a justification to withhold/withdraw LST (Wilkinson and Savulescu, 2011). Indeed, some have argued that physicians should use futility to *unilaterally* decide to withhold/withdraw LST if such treatment will not change the patient's outcome (e.g. survival to discharge) (Schneiderman et al., 1990). Consistent with this notion, the Texas state legislature in 1999 passed legislation allowing health-care facilities to discontinue LST over patient and family objections, so long as the continuation of LST is deemed to be futile by the treating physicians and appropriate provisions are met (including an ethics committee review of the case) (Fine, 2009).

Despite this, we do not advocate the use of futility as a justification for withholding/withdrawing LST for the following reasons. First, there is no accepted definition of 'futile' treatment (Burns and Truog, 2007). Thus it is often unclear to a clinician what this actually means in practice (Solomon, 1993). For example, mechanical ventilation of a patient with multiorgan failure and end-stage cancer may enhance their respiratory function (and is therefore not futile from a physiological standpoint), but it is unlikely to have any significant impact on recovery (and is therefore futile in terms of achieving any improvement). Second, on a related note, what a clinician judges to be futile is inherently subjective and influenced by his own values (Truog et al., 1992; Ashby, 2011). For example, while a clinician may feel it is 'futile' to provide ongoing life support to a patient in a PVS, the family might feel quite differently, and there is no objective way to determine which of these

value judgements is correct. Third, using futility as the basis for a unilateral decision to withhold/withdraw treatment enables clinicians to avoid having the difficult yet beneficial conversations that are frequently needed to bridge the gap between unrealistic family expectations and clinicians' prognosis.

Non-abandonment

Abandonment is when a physician withdraws from a therapeutic relationship without providing notice or reasonable alternative options for care. Withdrawing of LST is not a form of abandonment since the withdrawal of LST should always include a plan to continue care and provide intensive symptom management for the remainder of the patient's life. Especially around decisions to withhold LST, physicians should stress that the patient will not be abandoned and that every attempt will be made to ensure the patient's comfort. We should discourage clinicians from using the phrase 'withdrawing care' for the withdrawal of LST, as this gives an implicit message that we are no longer caring for the patient once we discontinue LST.

Double effect

The doctrine of double effect, originally formulated by Thomas Aquinas, applies to moral dilemmas in which it is impossible for a person to avoid all harmful actions and requires that (1) the nature of the act must be good or at least morally neutral; (2) the harmful effect must be foreseen but not intended; (3) the harmful effect must not be a way of producing the good effect; and (4) the good effect must outweigh the harmful effect (i.e. be proportionate). Thus, in the context of withdrawing LST, the doctrine of double effect has been used to justify the administration of high-dose opioids and sedatives for the purposes of pain and symptom relief during the withdrawal of mechanical ventilation, notwithstanding the unintended but foreseen risk of hastening the patient's death (Sulmasy and Pellegrino, 1999). The doctrine of double effect and its applicability to withholding/withdrawing LST was confirmed in the US Supreme Court decision of *Vacco v Quill* (1997).

Protection of vulnerable patients

Those at the end of life who often cannot speak for themselves require additional protections to make sure that their rights are not violated. The need to focus on patient values and protect the patient's best interests, when values cannot be discerned, is never stronger than when caring for the most vulnerable in society (children, elders, disabled, mentally incapacitated, minorities, prisoners, etc.). Members of cultural minorities with differing value structures and deep vitalist convictions also represent a group at significant risk of having their convictions dismissed by health care providers who do not ascribe the same value to survival (Burns and Truog, 2007).

Assess the consequences of utilizing or forgoing life-sustaining treatment

For any given clinical case, one of the primary tasks of a clinician is to consider the consequences (benefits and burdens) of either utilizing or forgoing LST. At the end of this chapter, we consider specific information pertaining to several common LSTs, including cardiopulmonary resuscitation (CPR), cardiac/circulatory support devices, haemodialysis, antibiotics, and ANH. In general,

however, we find the following questions helpful in determining the utility of any given LST.

What is the patient's current prognosis?

◆ How long are they likely to live?

◆ What is their expected quality of life?

What are the current goals of care of the patient?

What are the likely outcomes of utilizing LST in this patient?

◆ What is the clinical evidence for utilizing LST in this context?

◆ Will it extend the patient's life? If so, for how long?

◆ How will the LST impact upon the patient's quality of life?

◆ What are the physical risks or complications likely to result from LST? How likely are these to occur?

◆ What are the emotional consequences of utilizing LST here?

◆ How will the LST impact upon specific goals of the patient? For example, if it extends life, it might enable a patient to share a significant life event (e.g. seeing a child get married or a grandchild born) or to say goodbye to family.

◆ Will the LST facilitate other treatment aims? For instance, if it extends life, it might enable adequate time to treat a patient's underlying depression.

◆ How do these outcomes accord with the patient's known end-of-life values?

What are the likely outcomes of withholding/withdrawing LST in this patient?

◆ What is the expected clinical course if LST is withheld/withdrawn?

◆ How will withholding/withdrawing LST affect patient survival?

◆ What physical symptoms may occur? How can these be managed?

◆ What is the likely emotional impact of withholding/withdrawing LST on the patient? Their family? The caregivers?

◆ Will forgoing LST alleviate existing physical, emotional or existential distress?

◆ How do these outcomes accord with the patient's known end-of-life values?

Assess decision-making capacity

Decision-making capacity is defined as the cognitive ability to participate in making medical decisions. Strictly speaking, capacity is different from 'competence'. Competence is a legal determination made by the courts and relates to the presence or absence of global decision-making capacity. In contrast, health-care professionals determine capacity, which exists on a spectrum, or a sliding scale, rather than being strictly present or absent (President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research, 1982; Drane, 1985). For example, a patient may have the capacity to make decisions about whether to have stitches for a wound, but may lack the sophisticated understanding to make decisions around withdrawing LST. In practice, the consequences that follow when a physician judges

a person to lack capacity are often the same as a legal determination of incompetence. Indeed, in recent decades, competence and capacity have increasingly been used interchangeably in the legal, medical, and policy arenas.

At the end of life, cognitive failure and an associated lack of decision-making capacity is exceedingly common (due either to the disease itself, the treatments, or a combination thereof). In a recent study of almost 4000 adults who died, 42% were required to make important clinical decisions in their final days of life, but only 30% of those patients had sufficient capacity to do so (Silveira et al., 2010). Despite this, capacity assessments are frequently omitted under the mistaken assumption that sufficient capacity exists (Raymont et al., 2004; Sessums et al., 2011). And, even when an assessment is performed, clinicians repeatedly overestimate a patient's decision-making capacity (Fitten and Waite, 1990; Etchells et al., 1997; Marson et al., 1997; Sessums et al., 2011).

To help avoid such pitfalls, we advocate that a systematic capacity assessment be performed and documented in the medical record, whenever a decision to withhold/withdraw LST is being considered. To this end, we suggest a three-step approach. First, objective testing of cognition and reasoning should be performed (for instance, via the MacArthur Competence Assessment Tool (Dunn et al., 2006) or Aid to Capacity Evaluation (Etchells et al., 1999)). Second, clinicians should assess for the presence of depression, which will not only impair cognitive function but may also significantly bias patient preferences against LST (Ganzini et al., 1994; Hooper et al., 1996; Blank et al., 2001). If depression is suspected, discussion with family members regarding the patient's pre-morbid values and goals should be undertaken, and relevant treatment initiated if possible. Third, the following questions should be specifically addressed (Appelbaum, 2007):

1. Does the patient understand the relevant information? (e.g. *Can you tell me what you understand about your health problem and the treatments being offered?*)

2. Does the patient appreciate the medical consequences of the various treatment options? (e.g. *What do you believe will happen if you undergo this treatment and how will this likely impact your health?*)

3. Can the patient manipulate the information in a rational manner and state the reasons for making a particular decision? (e.g. *What makes treatment X better than treatment Y? Or why is not starting treatment Z better than starting treatment Z?*)

4. Can the patient communicate that choice? (e.g. *Can you tell me what your decision is?*)

Thus, the overarching question that a clinician should seek to address is not 'Does the patient have general decision-making capacity?' but rather 'Does the patient have capacity to make this particular decision at this particular time?' (Grisso and Appelbaum, 1998).

Make a decision regarding life-sustaining treatment

Up to this point, the necessary groundwork for making a decision regarding LST has been laid by assessing the legal and ethical context, the likely consequences of utilizing or forgoing LST, and the decision-making capacity of the patient. To proceed, we strongly advocate the adoption of a shared decision-making model where patients or their surrogates are encouraged to participate in selecting appropriate treatment options in accordance with the patient's values (Marshall and Bibby, 2011).

Shared decision-making: an introduction and some practical considerations

A shared decision-making model involves active dialogue and discussion between the clinician and the patient (and/or their families and surrogate), with specific roles for each (Charles et al., 1997; Frosch and Kaplan, 1999). The clinician (1) provides patients, their families and/or surrogates with information about the likely consequences of either utilizing or forgoing LST; (2) gains an understanding of the patient's values and goals; and (3) makes a recommendation, based not only on their own medical expertise and clinical experience but also their knowledge of the patient's values and goals and their assessment of whether utilizing LST will achieve those goals. Patients, families, and/or surrogates—with appropriate information regarding the likely consequences of LST and the clinician's recommendation—then make educated decisions that accord with the underlying values and goals of the patient. In this way, the shared decision-making model draws upon not only the clinician's expertise in LST but also the patient's, family's, and/or surrogate's expertise regarding the patient's values and goals (Elwyn et al., 2010; Health Foundation, 2010).

Ideally, clinicians will gain a good understanding of a patient's values and goals in the context of a long-term therapeutic relationship. However, in many areas the delivery of health care is often fragmented, such that patients are often cared for by providers who have no prior experience with them. In such instances, questions that may be helpful in eliciting a patient's values and health-care goals may include: *What is most important to you when you think about your health? What are you hoping for? What are your most important goals? What are your biggest fears about the future? Are there specific health states you would find unacceptable (for example, being a ventilator, dependent on others)?*

A shared decision-making model is a significant departure from how medicine is often practiced (Carlet et al., 2004; Cohen et al., 2005). Indeed, in some countries/cultures, it may be unacceptable to even discuss withholding or withdrawing of LST with a patient or base decisions on the patient's preferences and/or assessment of his/her quality of life (Thompson et al., 2004; Searight and Gafford, 2005). Nevertheless, we feel that a shared decision-making model is ideally suited to end-of-life care for several reasons. First, in the context of end-of-life decisions, data have shown that physicians are not only inaccurate in predicting what treatments their patients would want if they were seriously ill (Uhlmann et al., 1988) but also consistently underestimate a patient's quality of life (Uhlmann and Pearlman, 1991). The latter is exacerbated by the finding that ICU physicians and nurses place higher value on quality of life as opposed to quantity of life compared to patients and families (Sprung et al., 2007a). As a result, physicians are frequently biased toward withholding and withdrawing LST compared to their patients (Uhlmann and Pearlman, 1991). Second, a 2009 systematic review of 55 randomized controlled trials conducted over a 25-year period showed that patients involved in shared decision-making made clearer treatment decisions, were more likely to decline discretionary surgical intervention when compared to their doctors, and were no worse off in

terms of health outcomes (O'Connor et al., 2009; Stacey et al., 2011). Third, what constitutes an acceptable quality of life for any given patient and how to weigh the benefits and burdens of treatment in this regard can only be truly known by that individual. It is therefore imperative that clinicians do not allow their own views on quality of life to unduly influence their assessment of whether it is appropriate to withhold/withdraw LST. Finally, on a related note, a decision regarding withholding/withdrawing LST will almost inevitably involve a judgement based upon values and goals and, while the physician remains the expert on the medical treatments, the patient is the only true expert on his/her values and goals. Understanding the patient's values and goals is therefore a crucial step in making an ethically sound recommendation and enabling patient autonomy.

It is important to note that we are not advocating leaving patients to make decisions on their own, which is a misunderstanding of patient autonomy and respect for persons. We have noticed that many practising physicians in the United States are less likely to make specific treatment recommendations. Instead they opt to present a range of treatment options without identifying which is best, ostensibly as a means of promoting patient choice and autonomy. However, such an approach actually withholds the expert opinion of the physician and not only risks causing harm to the patient but also places unreasonable and unwanted responsibility on patients and their families, especially in the context of end-of-life decision-making (Billings and Krakauer, 2011).

If a patient has decision-making capacity, determining their preference for LST is usually straightforward, although this may require extended discussion regarding the patient's health-care values and goals and how utilizing or forgoing LST will achieve those goals. Occasionally, even if a person has capacity, they may not wish to be involved in the decision-making process, due either to their personality, coping style, and/or cultural background (Azoulay et al., 2004; Searight and Gafford, 2005; Kelley et al., 2010). For instance, patients of some religious and cultural backgrounds will usually defer decision-making to family members or a religious authority (Kelley et al., 2010). Thus, it is important to ascertain the desire of each patient to participate in the decision-making process. Notwithstanding that, most patients still prefer to be informed that their condition is life threatening (Yun et al., 2010). Thus, even in cases where the patient does not want to play a major role in decision-making, it is essential to keep the person well informed of the basic information.

If a patient lacks capacity, determining their preference for LST is more complicated, but can usually be achieved via ADs and/or surrogate decision-makers as described next.

Advance directives

ADs are legal documents outlining preferences for end-of-life care and can take the form either of a document outlining one's goals, values, and preferences regarding end-of-life treatments (including a living will, instructional directive, and values history) or of a health-care proxy form (where one appoints a proxy to make health-care decisions if capacity is lost) (Gillick, 2004).

The clinical utility of ADs has been widely debated. On the one hand, ADs promote early discussion about death and dying, help to alleviate patients' anxiety about future decisions, guide decision-making when capacity is lost, and reduce stress, depression, and anxiety in surviving relatives (Detering et al., 2010).

On the other hand, ADs have major limitations. First, individuals find it very difficult to predict what they will want when they are seriously ill (Danis et al., 1994; Loewenstein, 2005; Ubel et al., 2005). Second, only a minority of patients have completed ADs (only 29% of US adults had ADs according to a 2005 survey) (Pew Research Center for the People and the Press, 2006). Third, even when an AD exists, they are often difficult to locate or too vague to be of any use (Gillick, 2010).

Allowing for these caveats, clinicians should at the very least inquire about the existence of an AD and follow the AD if it is applicable to the situation at hand. In many US states, patients' treatment preferences have been converted into medical orders (e.g. MOLST (Medical Orders for Life-Sustaining Treatment) and POLST (Physician Orders for Life-Sustaining Treatment)) that are portable and legally upheld throughout the state's health-care system, whether the patient is in hospital, a nursing home, or at home.

Surrogate decision-making

In the event of incapacity, current bioethical thinking favours the idea that in order to protect autonomy, physicians should liaise with a surrogate decision-maker who, ideally aided by ADs, can assist in determining the patient's goals, values, and preferences (Buchanan and Brock, 1989). At a practical level, this raises two questions.

First, who should be the surrogate? Ideally, the patient will have specified a proxy decision-maker via an AD. However, usually this is not the case, and it falls to the next of kin or else the person with the strongest genetic and/or emotional ties to the patient. Interestingly, studies of patients in the ICU have found that family members are frequently too emotionally distressed to make decisions regarding their loved ones (Pochard et al., 2001). Despite this, there is general academic agreement and support from many court decisions that close family members are in the best position to make decisions because they are most likely to know the patient's values and goals (President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research, 1983).

Second, how should a surrogate decision-maker decide whether or not to forgo LST? In principle, surrogate decision-makers are supposed to use 'substituted judgement', that is, what the patient would have chosen. In some cases, this will be indicated in an AD or have been discussed previously with the patient. In the remaining cases, surrogate decision-makers should base the decision to withhold/withdraw LST on the patient's known values and goals or, if these are unknown, on what would generally be considered best for the patient (Pope, 2012). In reality however, achieving accurate substituted judgement is challenging (Emanuel and Emanuel, 1992). This was exemplified by one study which found that more than 30% of approximately 2600 surrogates incorrectly predicted patients' end-of-life treatment preferences, and that prior discussion regarding preferences between patients and their surrogates failed to improve the accuracy rate (Shalowitz et al., 2006).

Resolving conflict

Not surprisingly, there can be significant disagreement as to whether or not to withhold/withdraw LST. In such cases, trying to better understand the nature of the conflict can be very helpful. In particular, we usually try to address two key areas.

First, what is the nature of the conflict? For example, is there an ethical dilemma (e.g. is this the right thing to do)? Is there legal uncertainty (e.g. is what I am doing prohibited by law)? Or perhaps there is still clinical uncertainty (e.g. uncertain prognosis, uncertain benefit)? Or a combination thereof? In answering the questions, clinicians will often be able to identify suitable strategies for moving forwards and obtaining resolution. For instance, where there are ethical problems, re-evaluating the relevant bioethical principles and/or consulting ethics committees can provide additional clarity. Where there are legal uncertainties, seeking proper legal counsel is important. And where there is clinical uncertainty, obtaining additional evidence from the literature and consulting with other colleagues can be helpful.

Second, where is the conflict arising? Is it within the treating team? Between the team and the patient/family? Or among the patient and their family? For conflicts within the treating team, an independent mediator can be helpful to draw out the relevant clinical issues and re-direct focus to achieving an outcome in best accordance with the patient's values and goals.

For conflict between the team and the patient/family, the role of good communication cannot be overstated. For example, studies in the ICU suggest that many families lack even a basic understanding of a patient's diagnosis, prognosis, and treatment options (Azoulay et al., 2000), and that better and more frequent communication is associated with greater consensus between families and medical teams regarding ICU treatment (Prendergast, 1997; Garros et al., 2003). Along similar lines, remembering that the emotional distress of families in ICU impairs their ability to make decisions on a patient's behalf (Pochard et al., 2001), addressing this distress either directly or with the support of social workers, psychologists, and/or nursing staff, can assist the therapeutic relationship and may also aid in resolving or avoiding conflict (McDonagh et al., 2004; Stapleton et al., 2006) as well as improve the mental health of surviving relatives (Lautrette et al., 2007). Adoption of mediation techniques such as the 'principled negotiation' approach (Fisher et al., 2011) can help to focus attention on common interests rather than individuals and emotions and may be a useful tool for resolving end-of-life conflicts (Burns and Truog, 2007). In addition, hospital ethics committees—if available—can be an invaluable resource to not only provide an opinion on valid ethical options but also help with conflict resolution (Schneiderman et al., 2003).

There sometimes remain cases that cannot be resolved despite good communication. For instance, some patients and families will want to 'do everything' to maintain life regardless of the quality of life or the chances of 'success', leaving clinicians in moral distress about providing inappropriate LST. If clinicians truly believe surrogates are making decisions that are harmful to a patient, an application to appoint a different surrogate decision-maker can be made to the courts. In the rare cases where there is in fact no real harm to the patient, one option that has been suggested is that care be continued and that the focus should be on finding additional ways to support the medical staff to minimize the damage to the morale of the treating team (Burns and Truog, 2007).

Finally, for conflicts between the patient and their families, it is important to maintain focus on the patient's goals and, again, support from colleagues in social work, psychology, and chaplaincy can be of tremendous assistance.

Withdrawing/withholding life-sustaining treatment

Once a decision to withhold/withdraw LST is made, it is important to make a clear treatment plan to manage the likelihood that the patient will become more symptomatic following the withdrawal/withholding of LST (Truog et al., 2008). The presence of interdisciplinary palliative care teams may help alleviate patient, family, and staff distress around the time of withholding or withdrawing LST. It is also important to carefully document the decision-making process, the consent of families and patients, the withdrawal process (if applicable), and the treatment of symptoms until death.

Before LST is withdrawn, clinicians should inform families of the expected signs of the dying process, including Cheyne–Stokes respiration, skin mottling, and increased secretions. Families should be given an approximation of how long the patient is expected to live but also advised of the possibility that death may not be as soon as expected. In the event there is prolonged time between withdrawal and death, opioids, sedatives and all medications should be administered in doses necessary for the patient's comfort. Attempts should also be made to avoid unnecessary interventions during this time, including monitoring devices, alarms, blood tests, intravenous fluids, and so on (Truog et al., 2008).

At the same time, it is important to provide psychosocial support not only to patients and their families but also clinicians. The decision to withhold or withdraw LST is emotionally charged for all involved, and existential and spiritual issues may become more prominent as death nears. Referrals to psychology, social work, and chaplaincy can be helpful where available and appropriate. Families should also be allowed adequate time with the patient to say their goodbyes. Ongoing support via bereavement services is valuable in aiding families after death and a forum or other professional services for clinicians to debrief may help to decrease burnout and distress amongst professional staff (Felton, 1998; Bar-Sela et al., 2012).

Notes on specific life-sustaining treatments

Here, we consider specific information pertaining to several common LSTs.

Cardiopulmonary resuscitation
Background

In 1960, Kouwenhoven and colleagues first described CPR as a medical intervention for cardiac arrest (Kouwenhoven et al., 1960). The success of this simple technique, originally used in the perioperative setting and in newly established coronary care units, was subsequently applied to anyone who suffered a cardiopulmonary arrest both in and outside the hospital. In 1973, the National Conference on Standards for CPR and Emergency Cardiac Care in the United States recommended universal use of CPR for sudden death. Today, presumed consent for CPR is still the norm in US hospitals and CPR is generally attempted whenever the heart stops.

Outcomes of CPR

The outcomes of CPR are generally quite poor. Unlike on TV where 67% of TV hospital patients who undergo CPR survive to discharge (Diem et al., 1996), in reality the success rate is

considerably lower (15–18%) (Saklayen et al., 1995; Ehlenbach et al., 2009). Moreover, among high-risk patients, the prognosis is even more discouraging with survival to discharge rates of only 6–8% in those with hepatic insufficiency, haematological malignancy, metastatic cancer, or septicaemia (Larkin et al., 2010). Similarly, both advanced age and low pre-existing functioning are predictors of poor survival following CPR. For example, cancer patients with poor performance status at the time of admission (e.g. spending > 50% of time in bed) had only a 2.3% chance of surviving to discharge after receiving CPR (Vitelli et al., 1991). Indeed, the only cancer patients likely to survive to hospital discharge after CPR are those with good functional status who suffer an acute insult such as medication-induced cardiac toxicity (Faber-Langendoen, 1991). Thus, when cardiac arrest results directly or indirectly from advanced life-threatening illness, CPR is very unlikely to enable a patient to be discharged home.

Discussing code status

As clinicians and the public have become more aware of the poor outcomes associated with CPR—not to mention the likelihood of secondary chest pain and rib fractures—decisions not to attempt resuscitation using DNR (do not resuscitate) or AND (allow natural death) orders have become commonplace. Discussion of a patient's so-called 'code status' (i.e. whether or not to attempt CPR in the event of cardiac arrest) is therefore now quite common in places such as the United States, although most physicians lack adequate training in how to conduct such conversations (Anderson et al., 2011).

Like any LST, CPR is a medical intervention that requires a clinician to make a recommendation based on its likely outcomes and the patient's values and goals. We would therefore advise adopting the general approach we described earlier using a shared decision-making model to determine whether or not to utilize CPR. In actively dying patients or patients with significant co-morbid disease (e.g. multiorgan failure, metastatic cancer, advanced dementia), CPR is unlikely to prolong survival and should not be recommended (Blinderman et al., 2012).

Patient with a do not resuscitate/do not intubate (DNR/DNI) order requiring operative or sedative procedures

In some cases, suspension of DNR/DNI orders is appropriate. Ultimately, a decision will be made in light of a patient's values and health-care goals. For example, if a patient is planning to undergo a palliative procedure that would deliver good symptom relief, and expects post-operatively to have a reasonable quality of life and whose goal is prolongation of life and comfort, a suspension of the DNR/DNI order may be appropriate. In other cases, the patient or proxy decision-maker may prefer that no attempts to prolong life be made, even if the patient were to likely recover from an intraoperative cardiopulmonary arrest. In any case, the risks and benefits of the procedure should be made explicit with the patient or proxy decision-maker (American College of Surgeons, 1994) and a clear plan should be made with the responsible physician and the consulting interventionalist for the perioperative period.

Mechanical ventilation

Stopping mechanical ventilation is one of the most commonly performed withdrawals of LST. This issue is addressed in detail in Chapter 10.7.

Cardiac and circulatory support

Both continuous and intermittent inotrope therapy can provide symptomatic relief in patients at the end of life and may form part of a patient's hospice care plan (Stevenson, 2003; Lopez-Candales et al., 2004). Similar to other LSTs, the discontinuation or limitation of inotrope therapy should be considered when the therapy is no longer consistent with the values and goals of the patient, especially when continuation of inotropes seems only to be prolonging the dying process.

The deactivation or removal of cardiac and circulatory support devices, such as pacemakers, ventricular assist devices (VADs) and extracorporeal membrane oxygenation (ECMO), should be considered when such devices are no longer meeting the patient's goals, prolonging the dying process against the wishes of the patient, or when the benefits are outweighed by the burdens. The withdrawal of these devices is emotionally charged, since patients typically die shortly after the device is discontinued. Indeed, some describe these acts of withdrawal as 'justified killing' (Brock, 1992).

One scenario that is becoming increasingly common is the alert patient with a VAD or ECMO that has become a 'bridge to nowhere'. In such cases, the patient will usually have had a VAD or ECMO placed, as a bridge to future transplantation or to enable more time for clinicians to assess the patient's condition and prognosis and suitable treatment options, but subsequently become unsuitable candidates for either long-term device therapy (e.g. CentriMag®) or transplantation. Such patients thereby become confined to the critical care environment for the remainder of their lives and—although death will inevitably result from comorbid illness, an acquired nosocomial infection, or complications related to the device—discomfort about withdrawal of the device is inevitable as some of these patients appear 'well' and are not actively dying. Ultimately, the decision to discontinue the device rests with the patient and family, and withdrawal against patient or family objections should not be done (Abrams, et al., 2014). Ethical dilemmas encountered with the use of extracorporeal membrane oxygenation in adults. *Chest*. 145(4), 876–882). However, a disaster setting or serious epidemic that requires the availability of LST such as ECMO may change the ethical calculus in patients maintained on such therapies, but are not believed to survive to hospital discharge (Powell et al., 2008).

Haemodialysis

Interestingly, the withholding and withdrawing of haemodialysis frequently appears more acceptable to many people, since the patient is perceived to die more 'naturally'. Contrary to popular belief, death from uraemia is not symptom free but is often associated with symptoms such as pain, agitation, myoclonus/muscle twitching, dyspnoea, pruritis, and nausea, particularly in the last 24 hours of life (Cohen et al., 2000; Murtagh et al., 2007a, 2007b; Kane et al., 2013). Appropriate symptom assessment and management must therefore be incorporated into the care plan in patients who decline or discontinue haemodialysis (Moss, 2000), and collaboration with renal specialists to ensure appropriate selection and dosing of medications is desirable. If severe agitation or delirium develops, neuroleptics and sedatives may be necessary. Discussions with the patients and their families

regarding expected survival times post withdrawal of dialysis should occur: in patients with no renal function, average survival is 8–12 days (Sekkarie and Moss, 1998; Murtagh et al., 2007b).

Artificial nutrition and hydration

Patients with advanced disease (including dementia) often lose interest in food and drink, which frequently prompts the use of ANH. However, although effective in providing short-term support for acutely ill patients, ANH is unlikely to increase life expectancy in patients with advanced disease (Borum et al., 2000). In fact, ANH may actually add to suffering or even decrease life expectancy due to various complications such as line sepsis, aspiration pneumonia, diarrhoea, hypervolemia, as well as pressure ulcers, pain and local infection at the feeding tube site (Quill, 1989; Finucane et al., 1999; McClave and Chang, 2003; Casarett et al., 2005).

Despite the lack of strong evidence to support the use of ANH at the end of life, religious and cultural beliefs frequently support its use and oppose its withdrawal (Geppert et al., 2010). For example, according to Catholic, orthodox Jewish, and Islamic authorities, ANH has a special status and may not simply be removed in the same way. For example, ANH is considered basic humane care rather than medical treatment for devout Catholics (Pope John Paul II, 2004). That being said, one may be allowed to withhold or withdraw ANH if it is adjudged likely to cause more harm than benefit (Alsolamy, 2014). Similarly, for many cultures, food is believed to be necessary for the comfort of the patient, eliciting concerns that patients may be 'starving'. This issue needs to be approached with great care and sensitivity, and families can be reassured that once the patient no longer has the desire to eat the mechanism by which they feel hunger is no longer present and that the alleviation of thirst can be achieved by stopping anticholinergic medications, and providing good mouth care, ice chips, and sips of water (Burge, 1993; McCann et al., 1994).

Legally, US appellate courts have consistently found not only that ANH is a medical procedure that can be forgone in the same manner as other treatments but also that the cause of death is the disease that causes the inability to eat rather than the lack of nutrition itself (*Cruzan v. Director, Missouri Department of Health*, 1990). For example, in the highly publicized case of 'Terri' Schiavo, a woman who had been in a PVS for 8 years, her husband (and guardian) requested that ANH be withdrawn against the objections of her parents, and the Florida Supreme Court subsequently affirmed that her husband could exercise her right to discontinue treatments. After successive court appeals, the US Supreme Court refused to hear the case but reaffirmed the right to refuse medical treatments including ANH. Similarly, federal regulations and judiciary precedence in the US recognize that residents in long-term care facilities have the right to refuse all medical treatments including ANH (*Bouvia v Superior Court*, 1986; Department of Health and Human Services, 1989).

Antibiotics

Patients have a right to discontinue any and all medical treatments, including those that may be effective, like antibiotics for specific infections. The continuation or discontinuation of antibiotics is a highly contextualized medical decision at the end of life and antibiotics should not be withheld as a matter of policy from patients on hospice or those who wish to focus exclusively on comfort. In some cases, when the goal of care is to focus exclusively on comfort, starting or continuing antibiotics may assist in symptom relief (e.g. reduction of fevers from a bacterial infection) (White et al., 2003). On the other hand, discontinuation of antibiotics may be reasonable if the goal is no longer life prolongation, as antibiotics may prolong the dying process in patients with a terminal condition and acute infection.

Withdrawal/withholding of LST in the setting of severe neurological impairment

Patients with severe neurological injury may present a diagnostic dilemma that must be resolved if the withdrawal/withholding of LST is being considered. Specifically, clinicians should discriminate between patients in a PVS and those in a minimally conscious state (MCS), since management of the two is quite different. A patient in a PVS by definition lacks consciousness and therefore does not experience pain or dyspnoea and has no awareness of suffering. A MCS in contrast shows intermittent evidence of consciousness and offers the chance of further recovery. Despite these important differences, up to 40% of patients have been wrongly diagnosed as being in a PVS when in fact they have been in a MCS (Schnakers et al., 2009), highlighting the need to more accurately differentiate the two conditions (see Chapter 5.3).

In managing a patient in a PVS, the lack of consciousness is an important clinical factor that influences management. For example, if families perceive some behaviours as being signs of distress (e.g. reflexive coughing, posturing, secretions, tremors, respiratory patterns, and other physical signs), clinicians can gently and compassionately provide reassurance that the patient does not perceive these signs as distressful. Some have argued that for patients in a PVS, the focus of the clinician should turn to serving the best interests of the family rather than the patient who no longer has any true interests (Arras, 1991). In such cases, clinicians may therefore choose to treat upsetting physical signs not to alleviate suffering in the patient but to contain the family's distress.

In managing a patient in a MCS, it is important to optimize the conditions for neurological recovery and to attempt to communicate with them given the potential for awareness. Clinicians should also familiarize themselves with any special rules governing those in MCS. For example, in England and Wales, all decisions relating to the withdrawal or withholding of ANH in patients in MCS must be referred to the Court for a judicial ruling (*Airedale Hospital Trustees v Bland*, 1993; Mental Capacity Act 2005, 2005).

In patients where there is uncertainty about the neurological status of the patient, or the patient is found to have MCS, the same approach for non-neurologically injured patients should be employed when mechanical ventilation is withdrawn.

Conclusion

The appropriate use of LSTs in seriously ill patients is a controversial topic that continues to generate intense debate amongst private citizens as well as health-care professionals, bioethicists, lawyers, government, and religious institutions. Decisions to withhold/withdraw LST are difficult and will remain so. Ultimately, a clinician's approach to the issue of withdrawing and withholding LST will be influenced by many factors that shape the relationship between the patient and the physician/health-care system,

and include the individual culture of the hospital/clinic in which a clinician works, the broader health-care system of a country and the historical developmental of that system, the availability of health-care resources, the ethical values and cultural norms dominant in that society, religious practices/beliefs, the legal system, as well as government policies.

SECTION 6

Communication and palliative medicine

6.1

Communication with the patient and family

Thomas W. LeBlanc and James A. Tulsky

Introduction to communication with the patient and family

High-quality palliative medicine depends upon good communication, which can enhance the quality of care we provide while also improving patient and family satisfaction (Kaplan et al., 1989; Roter et al., 1995; Bertakis et al., 1991). Good communication fosters informed decision-making by improving the likelihood that patient choices remain consistent with individuals' stated goals, values, and preferences. This is particularly true at moments when patients and families face gut-wrenching dilemmas which require relatively sudden and difficult decisions to be made, often without sufficient certainty about the likely outcomes. Finally, by guiding terminally ill patients away from ineffective treatments towards care that is more likely to help them achieve realistic goals, good communication may also increase the delivery of high-value care (Wright et al., 2008).

Much of palliative medicine practice involves helping patients and families come to terms with serious illness and establish a care plan that reflects their goals. For example, in the United States, where 88% of hospitals with over 300 beds now have available specialist palliative care consult teams, a significant proportion of the work done by these services involves the management of difficult communication scenarios in critical care or advanced illness such as incurable cancer or end-stage heart failure (Center to Advance Palliative Care, 2012). Although symptom management is also key, communication is perhaps the most important and powerful skill that specialist palliative care clinicians bring to these cases. In fact, many palliative care clinicians believe that their specialist 'procedure' is the family meeting. Recognition of and investment in this unique skill set are important in the ongoing success and growth of palliative care as a medical specialty. Expansion of palliative care practice to the outpatient setting, where problems are no less difficult yet time constraints more prescient, further highlights the need for highly skilled communication.

While the benefits of good communication are significant, the reality can be difficult to achieve amidst the demands of daily clinical practice. In part, this difficulty stems from the enormous complexity of the clinical scenarios. For example, conflict is common within and between patients, families, and staff, and when tensions run high, communication is challenging regardless of one's skill level. In addition, clinical encounters may be further complicated by the recent disclosure of medical errors,

prior communication mistakes, or mistrust. Even in what appear to be the most routine settings challenges arise, as the skill set necessary to communicate well in clinical medicine is not necessarily intuitive, and may differ significantly from how clinicians approach communication in their personal lives.

Unfortunately, too few physicians have received adequate communication skills training and many experience low self-efficacy and avoid difficult discussions. A number of studies have documented that physicians can be taught to improve their communication skills, and such training needs to be widely disseminated (Fallowfield et al., 2002a; Back et al., 2007; Tulsky et al., 2011). Once learned, clinicians do best to assume a conscious daily practice utilizing proven communication techniques.

Difficult discussions are a reality of clinical palliative care practice. These conversations span from delivering bad news, to discussing prognosis, eliciting goals of care, identifying treatment options, and saying goodbye. They are made more challenging by high levels of emotion, cultural differences and the clinician's own prior history and attitudes. This chapter, using the available evidence, will present an outline of what comprises quality in communication and discuss the impact of communication on patient outcomes. Furthermore, we will describe what has been observed to occur in actual clinical practice, and conclude by presenting a framework with which to approach palliative care clinical encounters. We will offer concrete strategies and tips to best meet the needs of patients and families confronting serious illness.

What is 'good communication'?

As a start, all good clinical communication must meet the general criteria for 'patient-centeredness' (Institute of Medicine Committee on Quality of Health Care in America, 2001; Epstein et al., 2005; Epstein and Street, 2007). This framework includes four core components: (1) eliciting and understanding the patient's perspective, (2) understanding the patient's psychosocial context, (3) achieving a shared understanding of the problem and its appropriate treatment in the context of the patient's preferences and values, and (4) empowerment, by involving patients actively in decision-making. Patient-centred communication reflects the spirit and values inherent in palliative medicine.

Good communication, particularly in palliative medicine, must also account for the powerful role of affect, and most difficulties encountered are the result of inattention to this critical domain.

Affect refers to the feelings and emotions associated with the content of the conversation. Feelings such as anger, guilt, frustration, sadness, and fear modify our ability to hear, to communicate, and to make decisions. For example, after hearing bad news, most patients are so overwhelmed emotionally that they are unable to comprehend very much about the details of the illness or a treatment plan. Some studies have shown that emotion affects processing; people who are in negative moods may pay more attention to how messages are given than to the content of the messages (Bohner et al., 1994). Thus when patients are experiencing high levels of negative affect and caregivers do not ameliorate this affect, patients may be less likely to receive the health-care providers' messages. Unfortunately, in conversations between doctors and patients emotion is frequently not acknowledged and physicians miss opportunities to do so (Levinson et al., 2000; Pollak et al., 2007).

Physicians, as well as patients, experience many emotions as they care for people approaching the end of life. In addition to its effect on their own communication, physician affect plays an important role in patients' reactions to medical information. In one study, women were randomly assigned to view a video of an oncologist who was portrayed as either worried or not worried while presenting mammogram results. Those watching the 'worried' physician received less information, experienced higher anxiety levels, and perceived the situation as more severe compared with those watching the 'non-worried' physician (Shapiro et al., 1992).

When seriously ill patients and families are asked what is most important in their communication with physicians, several domains emerge (Wenrich et al., 2001). They want physicians to provide adequate information that is straightforward and understandable. They want clinicians to be receptive to when patients are ready to talk, and would like a balance between honesty and empathy. They want their doctors to elicit and respond to patient concerns, and they want them to attend to emotion. The overwhelming majority of patients with serious illness state that they want as much information as possible about symptoms, treatments, and side effects (Hagerty et al., 2004). However, that information is qualified, as 15–20% do not wish to discuss survival. And, among those that do want such information, they vary in when they want to hear it during the course of illness. Of note, giving more information to patients does not appear to increase anxiety, whereas greater encouragement of patient decision-making does increase stress (Gattellari et al., 2002). Patients overwhelmingly prefer an open-ended, empathic approach (Dowsett et al., 2000). They also prefer to maximize the quality of interactions, rather than the quantity thereof; when they are satisfied with the style and type of communication, patients tend to think that an encounter was longer than its actual duration (Cape, 2002).

Physicians are likely to be challenged trying to achieve a balance between being honest and straightforward and not being discouraging. Helpful approaches include leaving open the possibility that unexpected 'miracles' might happen (at least not disputing patient claims of such), discussing outcomes other than a cure that can offer patients hope and meaning, and helping patients prepare for the losses they may experience. Patients cope better when physicians emphasize what can be done, explore realistic goals, and discuss day-to-day living (Clayton et al., 2005). Although patients must receive adequate information to make informed choices,

they wish to receive that information in an emotionally supportive way (Parker et al., 2001).

Given the stress of decision-making, one might imagine that patients and families would welcome recommendations and, indeed, in a recent study of surrogate decision-makers for critically ill patients, 56% preferred a recommendation (White et al., 2009). However, given the large minority that feel otherwise and the great variability seen in communication preferences more generally, particularly from people from different cultures (Blackhall et al., 1995), we draw the conclusion that it is always prudent to ask patients and families about their communication preferences before entering into some of these sensitive topics.

Good communication in this patient population also includes techniques that allow for more accurate assessment of anxiety and depression and increased disclosure of patient concerns (Maguire et al., 1996; Fogarty et al., 1999). These include maintaining good eye contact, asking open-ended rather than closed-ended questions, focusing on the patient's concerns as well as the agenda for the visit, responding to the patient's affect, asking about the patient's life outside of their illness and the healthcare environment, attending to psychosocial concerns, and ensuring that non-verbal behaviour signifies attentiveness. In contrast, closed-ended or leading questions, focusing on physical aspects of illness, and offering of advice and premature reassurance inhibit patient disclosure of concerns (Maguire et al., 1996). Patients want to discuss emotional concerns but are frequently unwilling to bring them up spontaneously and may need to be prompted (Detmar et al., 2000).

Another quality of good communication is to 'ask before telling'. Patients often carry misperceptions or incomplete information obtained from the popular media, folklore, or friends and family. It is easier to deal with this information if it is discussed directly. Thus, it is usually helpful to ask patients about their understanding of their illness before educating them. Furthermore, one study of intensive care unit (ICU) family conferences observed that allowing families more opportunity to speak may improve family satisfaction (McDonagh et al., 2004).

Published literature also provides clear signals about factors associated with patient dissatisfaction, which further inform our approach here, and our working definition of 'good communication' in the setting of serious illness. These include a lack of warmth or friendliness, emotional distance, failure to consider patient concerns or expectations about the encounter, unclear explanations about a diagnosis or its cause, and the use of medical jargon (Korsch et al., 1968; Attree, 2001).

Finally, communication with family members includes some special considerations. Family members value being included in the decision-making process, and value open, honest communication (Tilden et al., 2001). In addition, they want assistance throughout this difficult time, whether via practical support at home, psychosocial support, or more concretely via medical equipment to facilitate daily caregiving. Providing compassionate support throughout the often foreign experience of caregiving is an important function of the palliative care team, and is facilitated by honest, open, empathic communication (Rabow et al., 2004). Family members also want honest information and disclosure. They have a dislike for the notion of 'false hope,' and feel that the avoidance of prognostic discussions and disclosure is an unacceptable way for clinicians to help them be hopeful (Apatira

et al., 2008). They want to be listened to and feel heard, and there is an association between the proportion of time families speak and their rated satisfaction with clinical encounters in the intensive care setting, as well as a decreased perception of conflict (McDonagh et al., 2004). They also desire privacy, and hope to be contacted after a patient's death.

In summary, good communication in palliative medicine adopts a modern, patient-centred, biopsychosocial-spiritual framework, and focuses on eliciting patient concerns, identifying their agenda, providing complete information, but doing so in a way that allows patients and families to digest what they hear. It is respectful, empathic, inclusive, and efficient, seeks to elicit patients' goals and preferences, and to match these to an individualized plan of care. Finally, great attention is paid to the role of affect and difference, and each patient and family member is treated as a unique individual.

What are the outcomes of 'good communication?'

A growing literature describes the many benefits of good communication, particularly in the setting of palliative care and end of life. Discussions about end of life are associated with greater patient acknowledgment of terminal illness, preferences for comfort care over life extension, and receipt of less intensive, life-prolonging care and more palliative end-of-life care (Trice and Prigerson, 2009). Good communication is associated with significantly decreased anxiety in patients with cancer (Fogarty et al., 1999). Honest disclosure, along with the inclusion of sensitive yet pessimistic statements, is also associated with improved prognostic concordance between physicians and their patients (Robinson et al., 2008). Applied appropriately, good communication leads to a better matching of treatments with patients' preferences and goals.

Outside the setting of serious illness, patient perceptions of physician empathy are correlated with improved patient satisfaction and adherence to recommended treatments (Kim et al., 2004). A high-quality patient–doctor relationship is also linked with improved outcomes with regards to general health in the family practice setting (Sans-Corrales et al., 2006). And, in the psychiatric setting, an inclusive communication style that attends to patient beliefs and provides information about the recommended treatment is associated with improved satisfaction and better medication adherence (Bultman and Svarstad, 2000). Other specific styles of communication are known to be associated with good outcomes as well. For example, clinician statements associated with increased family satisfaction in the ICU setting include assurances that the patient will not be abandoned and will not suffer, and expressions of support of family decisions regardless of their nature (Stapleton et al., 2006). Finally, from a negative perspective, patients appear more likely to sue their physicians if they feel that they have failed to display empathy or to properly inform them about their diagnosis or recommended treatments (Levinson, 1994). Even in the event of undesirable outcome, patients and family members genuinely desire open, honest communication and disclosure, and the converse is more likely to lead to litigation (Forster et al., 2002). Overall, the published literature suggests that the quality of physician–patient communication significantly impacts health outcomes (Stewart, 1995).

Of note, good communication maps to several of the recently lauded beneficial outcomes of involving specialist palliative care practitioners in patient care. For example, in patients with advanced cancer, palliative care reduces re-hospitalizations, inappropriate ICU transfers, and chemotherapy in the last 30 days of life, while also increasing quality of life, quality of death, and possibly even length of life (Hearn and Higginson, 1998; Zhang et al., 2009; Temel et al., 2010, 2011). This reduction in the provision of unwanted, inappropriate, or unnecessary interventions is likely a result of good communication as defined above, wherein the matching of patient goals and values to a specific treatment plan results in appropriately aggressive care when warranted, but minimizes undesired or inappropriately aggressive care in the late stages of illness.

Current communication practice

Given what is known about what constitutes good communication and its powerful effects on patient care, it is natural to look to actual encounters and to see how close practising clinicians come to meeting these quality standards. Unfortunately, clinicians probably have an inflated perception of their communication ability. For example, in one study of trainee self-assessments about the quality of their communication in end-of-life situations, there was no significant correlation in their assessments with those of patients, family members, or instructors, suggesting poor self-awareness (Dickson et al., 2012). Evidence suggests that clinicians tend to avoid discussing negative prognostic information unless specifically requested, or they present it in an overly optimistic light (Lamont and Christakis, 2001; Daugherty and Hlubocky, 2008; Leydon, 2008). Furthermore, physicians appear to overestimate prognosis in general, with less accuracy as the length of the patient–doctor relationship increases, and also for those patients with cancer diagnoses (Christakis and Lamont, 2000; Glare et al., 2003). Other literature suggests that clinicians may believe they have conveyed key prognostic information effectively, while the patient still does not understand, or does not even recognize that a prognosis was rendered (Fried et al., 2003). This may, in part, be due to the commonplace use of medical jargon in communication, which is known to be poorly understood by many patients (Hadlow and Pitts, 1991; Lerner et al., 2000). Given these findings, not surprisingly, patients tend to rate physicians poorly with regards to issues of discussing prognosis and dying (Curtis et al., 2004). This well-intentioned omission is likely more harmful in the end, as it may impair the ability of patients and families to prepare for the end of life, to adapt their hopes and goals, and can even cause heightened fear or anxiety (Fallowfield et al., 2002b).

When surveyed after the death of a loved one, families sometimes report dissatisfaction with the quality of communication and care provided. For example, when the hospital is the place of death, bereaved family members tend to report insufficient contact with physicians, inadequate emotional support, and insufficient information about the dying process (Teno et al., 2004). In the intensive care setting, evidence suggests that at least half of families experience inadequate communication with physicians (Azoulay et al., 2000). Direct assessments of physician communication behaviour echo these family reports. Oncologists, for example, often seem to neglect patients' expressions of emotion,

generally responding to empathic opportunities with terminating statements rather than exploring the emotional content in patients' statements (Pollak et al., 2007). Patient statements of difficult emotion may be rather subtle, and these cues are often missed by oncologists (Butow et al., 2002). Studies of physicians talking to patients about do-not-resuscitate orders or advance care planning have shown that they rarely adhere to the described standards for such conversations (Tulsky et al., 1995, 1998; Smith et al., 2006).

Physicians also tend to interrupt, and to redirect patients too early. In one study, physicians interrupted patients after an average of 23.1 seconds, and only 28% of patients were even allowed to complete their initial statement of concern. In addition, last-minute concerns were more common when patients were interrupted early; those who were not interrupted only used 6 more seconds of time (Marvel et al., 1999). The use of more open-ended, patient-centred communication methods is thus likely to improve the efficiency of the clinical encounter, by ensuring that patients' concerns are elicited upfront, thereby minimizing last-minute concerns while one's hand is on the doorknob at the end of a visit. In addition, rather than assessing patients' goals and preferences, and recommending a concordant plan of care, physicians tend to ask closed-ended questions about specific treatments, without adequate context.

The preponderance of the evidence from patient report and direct observation suggests that although physicians are well intentioned, the quality of their communication with patients, particularly in the setting of advanced illness, frequently does not meet the espoused quality standards. Although there are many reasons for this gap, the most likely explanation is that physicians are unprepared from their training to deal with complex communication challenges, particularly at the end of life. In a national survey of nearly 2000 students, house staff, and faculty, only 18% of students and residents reported receiving formal end-of-life care training, including communication skills training, and what they do receive is frequently inadequate (Sullivan et al., 2003).

Communication skills can be learned

Despite these difficult realities about current practice, we have learned over the last several decades that communication behaviours are readily measurable, teachable, and learnable. Good communication is ultimately the practice and performance of a series of discrete behaviours that can be observed and quantified. Practice leads to improvement. A number of studies have shown that communication skills teaching works and most educational programmes include the following elements. Learners must have the opportunity to first observe the behaviour done well, practise while being observed themselves (with either a real or simulated patient), and then receive feedback on their performance, ideally with the opportunity to try again with corrections.

One controlled trial of a communication intervention course to internal medicine residents led to significant improvements in delivering bad news (Alexander et al., 2006). Another targeted communication intervention for junior physicians in Australia improved participants perceptions of their skills, confidence, and the actual quality of their communication, as assessed via videotaped assessments before and after the intervention (Clayton et al., 2013). Courses for senior oncologists in the United Kingdom

resulted in improved communication confidence and positive behavioural changes, both initially and at 3 and 12 months, along with changes in attitudes towards patients' psychosocial needs (Fallowfield et al., 1998, 2002a, 2003). Tested in a randomized controlled trial, this intervention resulted in significant improvements in empathy, response to patient cues, and avoidance of leading questions (Fallowfield et al., 2002a). Similarly, a communication training course for oncology fellows, and more recently one to train faculty to teach communication skills, have resulted in improvements in oncologists' comfort level and skill with having difficult conversations, and teaching others to do so, respectively (Back et al., 2003b, 2009b).

Areas of uncertainty

Despite a growing and high-quality literature on effective doctor–patient communication, there remain several important areas of uncertainty. First, while it is clear that most patients and families value and desire communication that fits the 'patient-centred' model described earlier, a subset may explicitly reject central tenets of this framework. For example, not all patients wish to actively participate in decision-making (Blackhall et al., 1995). This may be a particularly important issue in cases of significant cultural difference. Sensitivity to the norms of particular cultural groups is thus an important part of effective communication in palliative care practice. In situations where shared decision-making is not desired, or is not a cultural norm, communicating within a patient-centred framework is likely to be at least ineffective, if not offensive. Assessing for this possibility upfront is important, and can be accomplished quite easily in many cases by asking an open-ended question such as, 'Some patients like to consider all the options before making a decision, whereas others prefer that their doctor makes a specific recommendation. Which of these styles appeals to you?'

Second, a minority of patients may prefer that physicians not engage with emotional issues and may not appreciate aspects of the recommended empathic communication style. As with most difficult communication scenarios, asking upfront and assessing preferences early usually goes a long way. For example, one might say: 'Some patients want their doctor to acknowledge and address the sometimes difficult emotional issues that go along with having an illness, while others prefer not to discuss these kinds of things with their physician. What's your preference about this?'

Third, in communication about serious illness, references to numbers and statistics often seem useful. Conveying information via numbers, however, is a difficult task (Apter et al., 2008). Just as many patients have low health literacy, many also have low numeracy, meaning they have difficulty fully understanding and contextualizing basic percentage estimates, fractions, and notions of risk. This issue may underlie the prevalence of misunderstanding one's prognosis in advanced cancer settings. While there is a growing literature on numeracy, including some recommendations about effective ways to present statistical information to patients, there remains much more to be studied.

Finally, the increasingly ubiquitous role of electronic health records poses a whole new set of challenges to clinician–patient communication. These include the challenge of maintaining a human connection with the patient while accessing and inputting data into a computer, as well as learning how to navigate electronic

mail communications with patients in a way that ensures safety and leaves patients feeling cared for. Little data exists in this area and studies are just beginning to emerge.

Putting theory into practice: a communication skills overview

The data presented so far describes what high-quality communication for patients and families looks like and confirms that these are skills that can be taught. The rest of this chapter will focus on strategies and tips to put these skills into practice (Back et al., 2009a). While many models of communication have been proposed (Parle et al., 1997; Lo et al., 1999; Larson and Tobin, 2000; von Gunten et al., 2000), they have in common several principles. First, given that patients vary greatly in their desire for information and participation in decision-making, one should assess patients' preferences for communication as part of the medical encounter (Pfeifer et al., 2003; Hagerty et al., 2004). One cannot presume to 'intuit' patient's wants and needs, therefore one should ask. Second, information should be given using non-technical language and in brief, understandable chunks. This allows the physician to constantly reassess the patient's verbal or non-verbal reaction to the information, as well as their desire for more information. Third, while doctors focus on medical treatments and dying, patients focus on function and relationships. Therefore, treatments should be discussed within the framework of the patient's goals rather than in abstraction. Lastly, attention to the affective component of the conversation is as important as the cognitive aspects.

The 'SPIKES' protocol for delivering bad news, serves as an excellent overall framework for most difficult conversations (Baile et al., 2000). Each letter in the acronym denotes one component of this approach, including paying attention to *S*etting, assessing the patients *P*erception, providing an *I*nvitation to the discussion, delivering *K*nowledge, offering *E*mpathy, and *S*ummarizing/strategizing (see Table 6.1.1) Paying attention to this overall schema, we offer specific strategies below.

Prepare in advance

A little effort spent on advance preparation can have a tremendous impact on the quality of the encounter. Whenever possible, important medical information, particularly bad or sad news, should be delivered during a scheduled meeting. This allows patients to prepare themselves for the type of information they will hear and to make sure that appropriate family members or friends are present. It also allows the physician to allocate the necessary time to the encounter and to come prepared with basic medical information and anticipate the most likely questions regarding treatment options, prognosis, and resources for support and guidance.

Part of the physician's preparation ought to include consideration of their own emotional state. When experiencing a strong emotion while interacting with a patient, one should ask oneself, 'Where is this coming from?'. Although it may be a result of what the physician brings to the encounter (e.g. one's own sense of mortality or how it makes one think of one's grandmother who died), it may also be a clue into what the patient is feeling. Thus, many doctors report feeling anxious when talking with a patient who has an anxiety disorder, or feeling overly sad when talking with a depressed patient. If the physician gets a sense that he or she is reflecting the patient's emotion it may help to ask the patient about this (e.g. 'I wonder if you're feeling sad?'). If the emotion is a result of the physician's reaction to the encounter, the next step is to discuss this with colleagues or confidants. In most cases, however, patients do not benefit from hearing such thoughts.

Whenever possible, communicate face-to-face

Telephones accentuate physical communication difficulties and there is no opportunity to employ the benefits of non-verbal communication. Given that over 50% of communication is non-verbal, both parties operate at a disadvantage if they cannot see each other. The physician should sit at eye level and within reach of the patient. If possible, one's pager or mobile phone should be turned off, or at least put on a quiet mode, and one should avoid interruptions. Finally, as many physicians are now compelled to interact

Praise	'You have been a truly remarkable advocate for your husband'	Back, A.L., Arnold, R.M., Baile, W.F., Edwards, K.A., and Tulsky, J.A. (2010). When praise is worth considering in a difficult conversation. *The Lancet*, 376, 866–867.

with electronic medical record systems during the office visit, they must be careful that accessing and inputting data do not compromise direct human interaction.

Use open-ended techniques

Patients and family members are more satisfied in encounters where they do much of the talking, so it is essential to develop the ability to communicate using open-ended prompts that solicit the required information from patients and family members while also not being inefficient in the face of time constraints. Rather than asking so-called closed-ended questions, which generally yield 'yes' or 'no' responses, or perhaps terminating, one-word responses, a more patient-centred communication strategy will utilize open-ended questions whenever possible. This might be as simple as to say, 'Tell me more about this back pain', rather than, 'Is it sharp, or dull?' The strategic use of open-ended framing of questions can improve patients' sense of being heard and listened to, and also improve the sense of connection patients have with their clinician.

Solicit the patient's agenda

The upfront solicitation of a patient's agenda may decrease the incidence of last-minute questions and requests at the end of a clinical encounter (Marvel et al., 1999). This is particularly important in the outpatient setting, where time pressures mandate effective, efficient communication. Here, a last-minute, unexpected 'doorknob question' or request can result in delays for subsequent patients' appointments, and also frustration on the part of both the clinician and the patient. Upfront efforts to ascertain the patient's agenda will allow one to negotiate a plan for the content of the visit within the constraints of the appointment time. Doing so can be relatively simple and straightforward, yet transformative with regards to time management. Consider asking the patient at the start of the visit, 'What were you hoping we could talk about today?' This should be followed by, 'Anything else?' This will elicit most patients' concerns, and minimize the chance of facing a 'doorknob question' later. Once these topics are out in the open, the clinician can thoughtfully propose an agenda and timeframe for each topic, also including other items which need to be discussed during the visit, such as a proposed radiographic test.

Ask permission

Physicians are not very good at predicting which patients want more and which patients want less information. Instead of assuming one should ask. For example, on a first visit one could say: 'I want to touch base with you about how you want me to handle information we get about your illness. Some patients want to know everything that is going on with their illness, the good and the bad. Other people do not want as much information and want me to speak more generally. And some would really prefer I do not discuss bad news with them but want me to discuss these issues with their family. Which kind of person do you think you are?' In addition, asking permission is an excellent way to gently move a conversation forward and engage a topic that may be threatening to a patient. For example, one might say, 'Would it be okay if we talked now about the latest tests and how your cancer is doing?'

Ask–tell–ask

The 'ask–tell–ask' framework is an excellent guide to any difficult conversation (Back et al., 2005). It operationalizes several core components of patient-centred communication, beginning with the first 'ask', which seeks to assess a patient's current knowledge, needs, or concerns. Starting an encounter in this manner, with an open-ended question that probes the issue from the patient's perspective, can be enormously illuminating regarding the appropriate next steps in the conversation. This technique thus often saves much time, energy, and difficulty, as it helps guide the conversation more naturally to wherever it needs to go, without as much input from the clinician's presumptions or agenda. After the 'tell,' which involves giving the news or information in small, digestible, sensitive, and non-technical language, one again 'asks' what the patient heard or understood. This 'teach-back' helps to gauge the efficacy of the conversation and information transfer, and again guides subsequent aspects of the discussion.

Empathize

Patients and family members appreciate and value clinician expressions of empathy. Unfortunately clinicians frequently miss opportunities to empathize in clinical practice, often responding with more cognitive 'terminating' statements, rather than exploring the emotional content of a patient's response (Robinson et al., 2008). Appropriate use of empathy can strengthen the patient–doctor relationship, and improve communication efficacy. Furthermore, non-verbal expressions of empathy (e.g. a concerned look, a touch on the hand) may demonstrate caring, yet also risk misinterpretation. Whenever possible, it is best to use clear verbal expressions of empathy. A popular acronym of commonly used empathic responses is known as 'NURSE' (see Table 6.1.2) (Smith, 2002). These five types of empathic statements (Name, Understand, Respect, Support, Explore) are not to be used at once, but rather represent a menu of options available to the clinician managing significant patient emotions.

Praise

The use of praise can be a particularly effective way to align oneself with a patient or family, and to encourage further productive discussions in the context of difficult clinical scenarios (Back et al., 2010). In the setting of a patient or family member who aggressively advocates for life-prolonging therapies that are unlikely to benefit the patient, it is not uncommon for clinicians to feel frustrated, and at odds with the very family they are trying to help. Rather than becoming frustrated, and expressing this frustration in the clinical encounter, however, the use of praise can help to create an alliance with family. One might say, 'You have been a truly remarkable advocate for your husband'. Judicial application of this technique sometimes marks the turning point in a difficult conversation.

Use 'wish statements'

'Wish statements' are a particularly powerful way to express empathy in the context of a difficult clinical encounter when bad news is involved (Quill et al., 2001). Expressing one's wish that the situation were different can align the clinician with the patient, while also helping to acknowledge and deliver the bad news itself. In the context of discussing an abnormal imaging result, for example, a

Table 6.1.2 Mnemonics for good communication[a]

NURSE model for empathy		SPIKES method for giving bad news	
Name	'I imagine this must be upsetting' (naming the emotion)	**S**etting	Private room, silence pagers/phones, adequate time, key participants available
Understand	'I expect most people would feel that way in a situation like this'	**P**erception	'Tell me your understanding about the situation'
Respect	'I'm impressed with how well you've handled such a tough situation'	**I**nvitation	'Is it okay if we talk further about this?'
Support	'I'll be here to help you through this'	**K**nowledge	Give the news in short, digestible, clear, non-technical language, then be quiet and wait
Explore	'Tell me more about how you're feeling, and what this means for you'	**E**mpathy	Use NURSE or similar strategy to demonstrate empathy
		Summary/**S**trategy	'What kind of information would be helpful for you right now?' 'Let's talk about the next steps . . .'

[a] For further information see Schapira, L. (2008). Communication: what do patients want and need? *Journal of Oncology Practice*, 4(5), 249–253, Copyright © 2008.

patient might say, 'Does this mean my cancer is back?' Responding with a 'wish statement', as in, 'I wish things had turned out differently', acknowledges the bad news while aligning the clinician with the patient. This may lead to subsequent empathic opportunities, allowing one to further explore the important emotional issues relating to the bad news prior to discussing any medical or technical specifics.

'Hope for the best . . . '

In situations where patients or families have unrealistic expectations for the future, it can be difficult to encourage discussion about less desirable outcomes. Sometimes clinicians also worry that doing so will crush a patient's hope, and lead to distrust. Patients and families, however, dislike the concept of 'false hope,' and generally want open, honest disclosure of even bad news (Apatira et al., 2008). One way to encourage exploration of the spectrum of outcomes while maintaining alignment with a patient's hopes is to use the 'hope for the best' phraseology (Back et al., 2003a). This allows the clinician to align with the patient's hopes, while also exploring other possibilities to ensure the patient is prepared in the event that things turn out differently. One might say, 'Let's hope for the best, while we also prepare for other possible outcomes'. This can be a less ominous way to explore goals and preferences for the future, when facing a likely poor prognosis.

'Are you at peace?'

Spiritual assessment is an important component of a comprehensive palliative care consultation, particularly in serious illness or end-of-life settings. Asking the simple question 'Are you at peace?' can be an effective way to screen for spiritual and psychosocial distress (Steinhauser et al., 2006). Without uncovering and addressing such distress, patients and families may be unable or unwilling to move forward with other important discussions and decision-making. This brief screening question can thus be transformative in moving discussions ahead in difficult clinical encounters, and in helping to expand a plan of care to include attention to important spiritual and psychosocial issues.

Use interpreters

Increasingly and in nearly all countries, clinicians encounter non-native language-speaking patients. One must absolutely employ the assistance of an interpreter in such settings. However, it is equally important to avoid using family members as interpreters. Not only does this run the risk of faulty translation or reinterpretation of the physician's statements, it also places family members into the uncomfortable position of being the physician's and patient's spokesperson (Forster et al., 2002). The common practice of using bilingual young children as translators is particularly problematic. Most hospitals and health-care facilities in regions with high numbers of immigrants employ professional translators or maintain lists of language skills among facility staff members.

Putting it all together

This chapter presents specific skills and even scripts that can improve communication efficacy and patient satisfaction. Translating this knowledge into practice, however, may prove difficult for many clinicians. Busy practitioners face increasing pressure to see more patients in less time, interact with more technology, and to meet new documentation requirements and quality monitoring standards. Adding the effort to be a high-quality empathic communicator can seem daunting, particularly if one presumes this will require even more time in an already overloaded schedule.

Contrary to popular belief, effective, empathic communication probably does not take any more time than communication that ignores emotional content, and may actually be more efficient (Fogarty et al., 1999; McDonagh et al., 2004; Kennifer et al., 2009). Proactively addressing patients' needs, setting an agenda for each visit, and ensuring that patients feel heard can actually be done relatively quickly, and can avoid time-consuming problems later.

High-quality empathic communication also depends upon the mindset of the health-care provider. When clinicians feel harried or disconnected in their practice of medicine, they are unable to focus meaningfully on the patient's concerns. 'Mindfulness' refers to the practice of being consciously present in everyday activities.

An intervention that helps clinicians achieve such mindful practice has been associated with less burnout and mood disturbance among primary care physicians, and at least a subjective sense of being more present with patients (Krasner et al., 2009). Finally, it is possible that conscious daily practice of empathic communication behaviours leads to longer-term improvements in communication skill (Fallowfield et al., 2003).

Conclusion

Communication in clinical practice is not intuitive, and requires conscious practice in order to achieve competency. This is especially true in the palliative care setting, where specialists are increasingly expected to help navigate difficult clinical situations, many of which involve communication challenges, or prior communication mistakes that complicate future encounters. Good communication can be deconstructed and conceptualized as a series of discrete behaviours. It is thus measurable, teachable, and learnable. Research shows that clinicians tend to overestimate their communication abilities, and that patients and families want better communication from the medical team, especially in settings of serious illness or at the end of life. They prefer open-ended, empathic communication and honest disclosure, even in the face of a bad prognosis. Family members expect to be listened to, and heard, to be involved in decision-making, and hope to be attended to even after the death of their loved one. As compassionate caregivers, palliative care specialists, and indeed all clinicians, we owe it to our patients and families to improve the quality of our communication, and to make this a conscious component and focus of our daily practice.

6.2

Talking with families and children about the death of a parent

Mari Lloyd-Williams and Jackie Ellis

Introduction to discussing the death of a parent

Parental death is one of the most significant and stressful events children can encounter (Auman, 2007), one that could have a serious impact on adulthood. While no routine data is collected in the United Kingdom on this group, estimates suggests that over 24 000 children and young adults experience the death of a parent each year in the United Kingdom (Winston's Wish, n.d.). However, data may well reflect only those exhibiting some problem with their grief and may be underinflated (Thompson and Payne, 2000). A recent study (Parsons, 2011) found that 5% of young people have been bereaved of a parent by the time they are 16. For the majority of children, parents are the most significant people in their lives, so when one dies, life as the child knows it is disrupted and irrevocably changed. It is a time of suffering and confusion, both for the child and surviving parent. For diagnostic understanding, it is necessary that clinicians evaluate if the reaction is a part of 'normal life' or if it needs any type of specific intervention.

The parent's palliative stage of an illness exposes the child to significant levels of stress (Thastum et al., 2008; Kennedy and Lloyd-Williams, 2009a, 2009b) and yet there are limited resources available to this community of children (Lloyd-Williams et al., 1998; Dunning, 2006). Furthermore, these stress-related feelings are exacerbated because the non-bereaved community do not understand the loss or the associated pain which causes the bereaved to feel isolated and alone (Schultz, 2007).

Communication and information sharing are key factors in promoting children's coping strategies (Waskett, 1995; Christ, 2000; Rauch et al., 2003; Christ and Christ, 2006). Practitioners working in palliative care have a pivotal role in offering support to children and families and fundamental to this is their role in communicating with children and their families. While this chapter is not suggesting that all children experiencing or who have experienced the death of a parent are at risk of significant harm, they are, within the Children Act 1989 definition, 'children in need', although very rarely acknowledged as such.

Communicating with and sharing information with children is widely acknowledged as an important factor in supporting them when a parent is terminally ill or has died (Waskett, 1995; Christ, 2000; Rauch et al., 2003; Christ and Christ, 2006). Furthermore, communication within families about a parent's illness can act as a protective factor against children's distress (Kroll et al., 1998).

Research suggests that children's emotional well-being is adversely affected when a when a parent is terminally ill or has died (Christ and Christ, 2006). This anxiety is heightened when children are not provided with adequate information about their parent's illness (Beale et al., 2004).

This chapter discusses the key issues related to communicating and sharing information with families and children who have experienced parental death. Firstly, however, we briefly explore the literature that looks at the impact of early parental death. We then review the traditional theories of mourning and outline the dominant models of grief.

The impact of early parental death

A recent review (Akerman and Statham, 2011) on childhood bereavement following parental death reports that children that had lost a parent experience a wide range of emotional and behavioural symptoms often classified as 'non-specific disturbance'. The majority of children, however, do not experience serious problems (Haine et al. 2006). Even among children bereaved by parental suicide and cancer, most children reported low levels of psychological distress, suggesting a considerable degree of resilience (Ratnarajah and Schofield, 2007). This review also found that parents tend to report fewer symptoms and disorders in their children than children do themselves. The child often experiences an increase in anxiety with a focus on concerns about further loss, the safety of other family members, and fears around separation. Mild depression appears to be frequent, and can persist for at least a year (Akerman and Statham, 2011).

Akerman and Statham also found that psychiatric disorders are rare with only one in five bereaved children likely to manifest such disturbance at a level sufficient to justify referral to specialist services (Dowdney, 2000). This is most likely to take the form of depression or dysphoria (a combination of sadness and crying or irritability). Symptoms may include anxiety, depressive symptoms, fears, angry outbursts, and regression regarding developmental milestones. Across different types of potentially traumatic events, including bereavement, upward of 50% of people have been found to display resilience, suggesting that psychotherapeutic treatment should be reserved for those in genuine need (Bonanno and Mancini, 2008).

The evidence on children's bereavement outcomes is difficult to summarize and some findings contradict others (Ribbens McCarthy and Jessop, 2005). In part, this is because children

experience bereavement in a wide range of circumstances and opposite effects can cancel each other out in large-scale quantitative studies (Ribbens McCarthy and Jessop, 2005). An 8-year-old child whose lone parent dies suddenly and who enters foster care will have a different experience from a 15-year-old whose parent's death is expected. Some children are more likely to experience bereavement; additionally, significant bereavement seems to bring greater risks to those who are already disadvantaged or have faced multiple losses (Ribbens McCarthy and Jessop, 2005).

Parsons (2011) found that there may be fewer longer-term effects for childhood bereavement and that children experiencing other forms of family disruption may suffer more extensive influences on their ability to negotiate successful transition to adult life. Many cumulative, interrelating risk and protective factors mediate or moderate children's experiences (Worden, 1996; Ribbens McCarthy and Jessop, 2005). These can be at the level of the child (such as their prior experiences of loss, their preferred coping style), their family and social relationships (including their prior and ongoing relationship with the person who has died), their wider environment and culture, and the circumstances of the death (including whether the child perceives this as traumatic) (Worden, 1996; Ribbens McCarthy and Jessop, 2005).

The family is a key context for bereaved children and young people. Studies consistently point to the importance of higher levels of caregiver warmth, coping styles, and lower levels of caregiver mental health problems, discipline, and communication in protecting against negative outcomes from the death of the parents (Worden, 1996; Lin et al., 2004; Ribbens McCarthy and Jessop, 2005; Haine et al., 2006; Luecken et al., 2009; Akerman and Statham, 2011).

Very few studies have explored the impact of bereavement in adult life, particularly in the United Kingdom. A recent study (Ellis, 2009; Ellis et al., 2013) employed qualitative methodologies and narrative analysis to explore the experiences of 33 individuals (seven men and 26 women) who had experienced the death of a parent before the age of 18, in order to better understand its perceived impact on adulthood. Ellis and colleagues found that while individual experiences of bereavement were unique, five common themes were identified across the narratives that impacted on the bereavement experience: (1) disruption and continuity, (2) recognition of loss, (3) family dynamics roles and responsibility and context, (4) the public world of bereavement, and (5) identity and aspects of personal growth. The findings are very important as they provide insight into the damage and effects on the individual in adulthood as a consequence of inappropriate or neglectful management.

Traditional theories of mourning

Much of the early evidence on the impact of early parental death is premised on traditional theories of mourning. Freud (1917/1957) developed the psychoanalytic theory of mourning based on his extensive research in this area. Until the 1960s, his theory had dominated clinical understanding, in the United States and the United Kingdom, of how children perceive and respond to the death of a parent (Saler and Skolnick, 1992). Freud explored the psychological process of mourning with individuals who had lost a parent through death and normalized the process of grief.
