The need for parathyroidectomy in renal hyperparathyroidism has fallen due to improved medical control, a retrospective US survey reporting a 30% decline in the 1990s.³⁶ Currently, 1–2% of these patients will undergo surgery annually, with 10% ultimately requiring parathyroidectomy.³⁷ The cut-off point for deciding on a surgical option is not well established. The National Kidney Foundation Kidney Disease Quality Outcomes Initiative (KDOQI) suggest that patients with PTH >800 pg/mL associated with hypercalcaemia and/or hyperphosphataemia, despite medical therapy, should be offered parathyroidectomy.³⁸ Uncontrolled renal HPT results in morbidity classically from pruritis, the severity of which has been directly correlated to intact PTH levels,³⁹ bone pain, fractures or calciphylaxis and increased mortality rates.⁴⁰ In addition, a survival benefit has been demonstrated in renal failure patients undergoing parathyroidectomy.⁴¹

The optimal operative strategy for these patients is debatable. The main options include total parathyroidectomy versus subtotal parathyroidectomy (a 3.5-gland parathyroidectomy), with or without autotransplantation. In addition, the practice of simultaneous transcervical thymectomy varies.

A recent international survey assessing surgical practice in the management of renal hyperparathyroidism primarily within Europe obtained analysable results from 86 different surgeons performing renal parathyroidectomy.⁴² The survey suggests that 20.9% of respondents operated without any pre-operative imaging. When used, the most popular imaging modalities are ultrasound (36%) and sestamibi

Figure 76.1 Four-gland parathyroidectomy specimen during renal parathyroidectomy in secondary hyperparathyroidism.

scintigraphy (9.3%), with both in combination in 33.7%. Respondents reported that 98.8% perform subtotal or total parathyroidectomy, with or without immediate autotransplantation (Figure 76.1). In addition, 74.4% routinely perform transcervical thymectomy with 25.6% prepared to perform a transsternal exploration during initial surgery.

In the study, the practice of autotransplantation (AT) is extremely variable: 40.7% perform immediate AT while 36% do not. Smaller percentages tailor their practice to ioPTH results or dialysis techniques. The forearm is the implantation site of choice in 72.7% and the sternocleidomastoid in 16.4%. Graft function is assessed with serum PTH monitoring from grafted versus non-grafted forearms in 62.9% of cases, with 13.6% ($n = 5$) performing a temporary implantectomy ('Casanova test') and one using sestamibi scintigraphy (2.6%).

Parathyroid cancer

Parathyroid cancer is the cause of primary hyperparathyroidism in approximately 1% of cases. In advanced cases it has a high morbidity and mortality rate, mortality usually caused by intractable hypercalcaemia. If parathyroid cancer is suspected either pre-operatively or intra-operatively, the most likely way of achieving cure is through thorough surgical resection of the tumour and any involved surrounding tissue; the only appropriate surgical option is therefore BPE.

The involved parathyroid gland tends to invade immediately surrounding tissues including ipsilateral thyroid lobe, recurrent laryngeal nerve and ipsilateral strap muscles. If these structures are involved clinically, most surgeons advocate en bloc resection, avoiding breach of the tumour capsule to minimize risk of tumour seeding, with ipsilateral level 6 clearance if there is evidence of nodal involvement (Figure 76.2). Failure to perform en bloc resection or to clear the ipsilateral neck at revision surgery carries a significantly higher risk for local recurrence and death.^{43, 44} Because of failure to make a correct clinical diagnosis at the time of first surgery and/or different management beliefs, en bloc resection only occurs in

Figure 76.2 Right superior parathyroid carcinoma removed en bloc with right thyroid lobe.

approximately 12% of cases with up to 86% of patients having inadequate resection at first surgery.^{45, 46}

Failed pre-operative localization

Pre-operative sestamibi localization is negative in up to 20% of PHPT patients. This is reported to occur with increased incidence in multigland disease (32%). In a recent analysis of over 2600 patients with PHPT at a single institution, a curative operation was performed in 90.4% with a negative MIBI compared to 97.5% with localization ($P < 0.001$).

4D-CT is an emerging technique that uses high-resolution CT images, multiplanar reformats and perfusion characteristics to identify abnormal parathyroid glands in patients with hyperparathyroidism. 4D-CT correctly identifies unilateral vs bilateral disease in 90% of patients, potentially reducing the need for BPE.⁴⁷

Failed MIP

MIP may require conversion to BPE when there is failure to find a pre-operatively imaged gland or failure of ioPTH to drop to below 50% baseline at 10 minutes after adenoma excision, suggesting multigland disease.

This is especially significant in double adenoma. In a dual institution study of patients undergoing bilateral exploration, the ioPTH incorrectly indicated success after removal of the first adenoma in 55% of cases of double adenoma.⁴⁸ In comparison between the two groups, the authors found that the second adenoma was significantly smaller than the first in the false positive group ($p = 0.03$).

THE OPERATION OF BILATERAL PARATHYROID EXPLORATION

The patient is ideally consented before the day of surgery. The surgeon reviews the diagnosis, the indications for surgery and any imaging performed. The aims of the operation are defined. The incidence of adverse events should be

cited according to the surgeon's audited data. Specific risks include surgical failure and disease recurrence, recurrent laryngeal nerve damage and post-operative haematoma. The option of no surgery with its risks and consequences is discussed to enable an informed decision.

On the day of surgery, the neck is marked for level of incision by sitting the patient in a neutral position looking straight ahead. A surgical marker places a line at the bony soft-tissue junction at the level of the sternoclavicular joints.

The procedure is normally performed under general anaesthesia. The patient is intubated with a north-facing armoured endotracheal tube. The patient is placed in a supine position with 30 degrees of head elevation. Where possible, the neck is extended using a sandbag placed under the shoulders with the head stabilized on a headring.

The surgical field is prepared and draped. An incision of approximately 5 cm is made through skin and platysma. To optimize access, a subplatysmal flap is raised to approximately 1 cm above the cricoid cartilage and laterally superficial to the sternomastoid muscles. An inferior flap does not enhance surgical access. The strap muscles are separated at the linea alba. Occasionally, the linea alba is hard to identify as the muscle bodies are closely approximated. In this situation, the strap muscles are followed inferiorly towards the sternal notch as the muscles diverge caudally.

The plane between the deep straps and the thyroid lobe is developed from medial to lateral. The thyroid lobe is partially delivered from deep to the straps by lateral retraction of the ipsilateral strap muscles while the thyroid lobe is digitally retracted medially by the surgeon with a single layer of surgical gauze between the lobe and the middle finger. Fibrous bands are separated by the action of opening the surgical scissors in a medial to lateral direction. Bands that fail to divide are normally small blood vessels under tension which require bipolar diathermy. Once the lobe is adequately mobilized, a suture may be placed through the lobe in a cephalocaudal direction to enable the assistant to retract the thyroid out of the operative field. Simultaneously, the strap muscles and carotid sheath are retracted laterally so that the area directly surrounding the dorsal thyroid and tracheo-oesophageal gutter may be explored. A dry surgical field is vital as bleeding causes tissue discoloration and may create problems with parathyroid identification, especially with normal suppressed glands. Rinsing the wound with saline may help.

A successful search for the parathyroid glands requires a thorough knowledge of their surgical anatomy and embryology. The surgeon should understand the positions of parathyroid ectopia, which are mandated both embryologically and by the effects of increasing gland mass and deglutition.

The search should proceed in a methodical way. Ideally, no gland should be removed until all are visualized, but in a significant number of cases only one adenomatous gland and two suppressed/normal glands are found. In this situation it is acceptable to remove the enlarged gland, note the position of the identified normal glands and record the identity of the missing gland.

The superior gland is the more constant in position and generally lies on the posterior surface of the thyroid gland within 1 cm of the cricothyroid joint and posterior to the recurrent laryngeal nerve. As the thyroid lobe is retracted out of the neck and onto the trachea, its relationship with the nerve is inverted so the nerve lies deep to the superior parathyroid (Figure 76.3). An enlarged superior gland often works its way into a retropharyngeal/retro-oesophageal position by the combined actions of swallowing and gravity. It is found by identifying the inferior thyroid artery laterally, the recurrent laryngeal nerve inferomedially and entering the retropharyngeal space by mosquito dissection above the artery. Gentle soft-tissue dissection will identify the gland, which can be drawn out by gentle traction on its pedicle (Figure 76.4). If no gland is evident, the retropharyngeal compartment and the posteromedial surface of the superior thyroid pole should be explored, the latter often requiring full mobilization of the pole by division of the superior vascular pedicle.

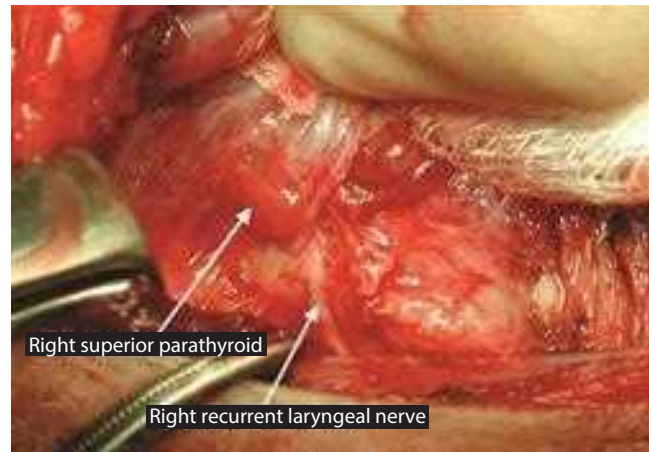

Figure 76.3 Demonstrating the inverted relationship between the right superior parathyroid and the right recurrent laryngeal nerve when the right thyroid lobe is retracted onto the trachea.

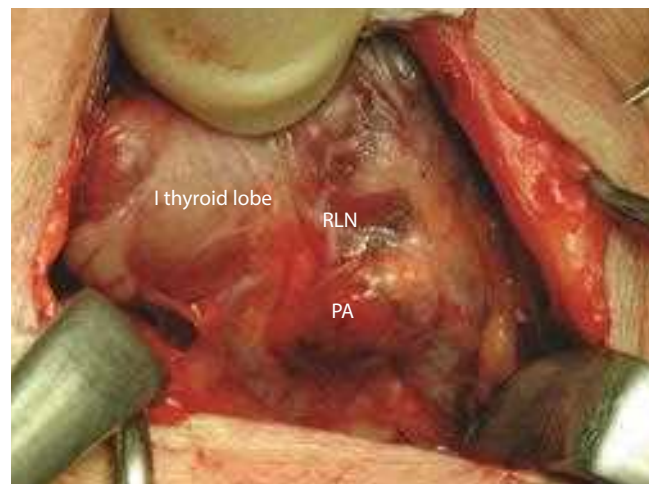

Figure 76.4 Left thyroid lobe retracted medially and enlarged left superior parathyroid adenoma (PA), having been delivered from the retro-oesophageal gutter, lying on top of the left recurrent laryngeal nerve (RLN).

Figure 76.5 Left thymic remnant being delivered from the mediastinum and containing an ectopic inferior parathyroid adenoma.

The inferior gland is typically found near or within the thyrothymic tract, extending from the lower pole into the superior mediastinum, and it usually lies in a plane anterior to the nerve. Again, fascia is carefully dissected from the inferior pole out towards the recurrent laryngeal nerve. Progressive dissection into the thyrothymic tract will usually identify the gland. Further search for the inferior gland by delivery of the thymus into the neck is required only if an adenoma has not been identified on either side of the neck. This is to avoid devascularizing a normal but suppressed gland. If no gland has been found, the lower pole itself should be carefully inspected as a gland can often be found deep to the fascia compressed onto the thyroid.

Thymic delivery is effected by dissection inferiorly, anterior to the carotid artery, but medial to the recurrent nerve and lateral to the trachea at the level of the clavicle. The thymus continues as an extension of the thyrothymic tract and may be delivered from the chest by gentle and progressive traction on its capsule (**Figures 76.5** and **76.6**).

Surgical failure necessitates a thorough review of all dissected areas with documentation of clearly identified parathyroids and those missing. A ‘second look’ often

Figure 76.6 Delivered thymic remnant containing ectopic adenoma.

identifies parathyroids which have changed colour due to devascularization or bruising.

If a superior gland, which is of 4th branchial arch origin, is missing, then inspection behind the hyoid, larynx, pharynx and within the carotid sheath at inferior thyroid artery level is performed. The possibility of an intra-thyroidal gland must be considered, best identified with ultrasound. Hemithyroidectomy is performed only if there are good grounds for suspecting an intra-thyroidal adenoma. If an inferior gland is missing, the carotid sheath is explored from the level of the superior thyroid artery down to the sternoclavicular joint.

Failure after such a meticulous and sequential operation occurs in a small minority of patients. The possibility of an incorrect diagnosis must be considered. The surgeon must accept that the gland may be beyond the dissected field and that further imaging studies are required. Accurate operative documentation is essential. Before closing, blood may be taken for PTH assay from the upper IJV and lower IJV on each side as this may help narrow the subsequent search by suggesting the area of the rogue gland. Further surgery is then dictated by the severity of the hyperparathyroidism, positive imaging and patient consent.

KEY POINTS

- Bilateral parathyroid exploration (BPE) is normally reserved for multigland disease, familial disease, cases with negative imaging and revision surgery.
- When performing BPE, the surgeon should be aware of the embryology of the parathyroid glands and hence the most likely positions of ectopia for a missing gland.
- In 80% of cases, a gland on one side is symmetrical with that on the other, so finding the corresponding contralateral gland may aid the search for a missing gland.
- The dissection should be as bloodless as possible to avoid discoloration of surrounding tissues, which makes parathyroid identification difficult, particularly when glands are suppressed.
- The commonest position of an ectopic superior gland is retro-oesophageal, and an inferior intra-thymic.

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: parathyroidectomy, hyperparathyroidism and imaging.

INTRODUCTION

The surgical management of primary hyperparathyroidism has evolved from open neck exploration to minimally invasive surgery since the first successful parathyroidectomy was performed by Felix Mandl in Vienna in 1925. Minimally invasive parathyroidectomy (MIP) is now the treatment of choice for patients with sporadic hyperparathyroidism, with a parathyroid tumour localized by pre-operative imaging. The success of the technique is attributable to the improvements in pre-operative localization with sestamibi scanning and high-resolution neck ultrasound. This chapter describes the indications and technique of MIP in the management of sporadic primary hyperparathyroidism.

Primary hyperparathyroidism (HPT) is a common medical problem and is the most frequent cause of hypercalcaemia in the outpatient setting. The incidence of the disease has increased over the last decade worldwide,^{1, 2} with the disease being more prevalent in women and with advancing age.^{3, 4} Primary HPT is caused by a solitary adenoma in 80–85%, hyperplasia in 15–20%, usually in familial syndromes,⁵ and carcinoma in less than 1% of cases.⁶ Surgical extirpation of the gland is the mainstay of treatment in this condition.

Bilateral neck exploration has been considered the gold standard in the surgical management of primary parathyroid disease. However, with the emergence of improved pre-operative parathyroid localization with high-resolution ultrasound scan, sestamibi and SPECT

scans, the technique of MIP has evolved.^{7–9} The operation is performed under local anaesthesia (superficial cervical block) and intravenous sedation^{10, 11} or general anaesthesia.¹²

The success of the procedure has been demonstrated in numerous studies with or without intra-operative PTH assay.^{9, 10, 12, 13} The advantages of performing minimally invasive parathyroid surgery have been shown to be lower cost,¹⁴ shorter operating time,^{15, 16} shorter stay in hospital^{12, 16} and improved cosmesis and patient satisfaction.¹⁷ Technically, the operation is performed with a small incision measuring 2–3 cm on the neck and excludes the extra-thyroidal approaches via the axilla or chest wall.

Surgical anatomy of the parathyroid glands

The success of parathyroid surgery must lie in the ability of the surgeon to know a parathyroid gland when he sees it, to know the distribution of the glands, where they hide, and also to be delicate enough in technique to be able to make use of this knowledge.

Edward D. Churchill (1931)¹⁸

This statement should fundamentally apply to all surgeons practising parathyroid surgery, more so in minimally invasive surgery. A thorough understanding of the embryology and anatomy is essential before performing the technique of MIP.

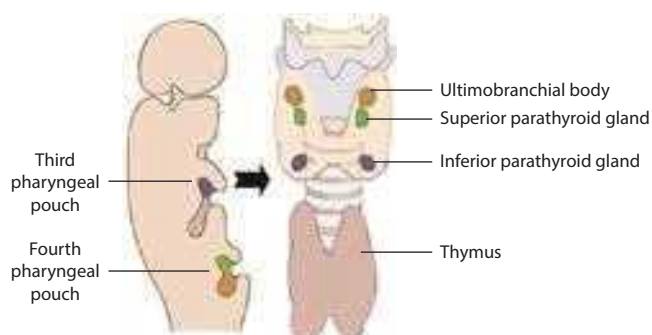

Figure 77.1 Diagram of normal pharyngeal organ development.

The superior parathyroid glands and ultimobranchial body derive from the fourth pharyngeal pouch. The inferior glands originate from the third pharyngeal pouch along with the thymus. Reproduced with permission from Chen H, Senda T, Emura S, Kubo K. An update on the structure of the parathyroid gland. *Open Anat J* 2013; 5: 1–9.¹⁹

Parathyroid glands are usually four in number and usually lie on the posterior surface of the thyroid gland, each with its own connective tissue capsule. The glands develop from the third and fourth pharyngeal pouches in the fifth week and descend to join the thyroid gland by about the seventh week of development. The inferior parathyroid gland arises from the superiorly located third pouch and the superior from the inferiorly located fourth pouch, as shown in **Figure 77.1**. This anatomical positioning of the parathyroid is linked to the development of the thymus. The thymus originates from the caudal portion of the third pharyngeal pouch and as it descends into the thorax, the inferior parathyroid usually accompanies it. The inferior parathyroid detaches from the thymus during the migration and takes its position on the posterior surface of the thyroid gland. Occasionally the inferior parathyroid moves with the thymus into the thorax and rests in an ectopic position.

The anatomical landmark that helps the surgeon in identifying the parathyroid gland intra-operatively is the inferior thyroid artery. The superior parathyroid glands are usually located within a circumscribed area about 2.5 cm above the intersection of the recurrent laryngeal nerve (RLN) with the inferior thyroid artery and the inferior glands located about the same distance below it. However, both the glands may be located outside the normal position and this is more commonly seen with the inferior parathyroid glands. Variations in the position of the superior glands include the upper thyroid pole in the posterior aspect of the neck, the retropharyngeal or retroesophageal space or rarely intra-thyroidally.^{20, 21}

The inferior parathyroid glands have a wider distribution and may be located anterior, inferior or lateral to the inferior thyroid pole besides its conventional position. They may be seen in ectopic positions in the neck close to the thyrothymic ligament or within the cervical portion of the thymus or carotid sheath and, rarely, intra-thyroidally. They may also be located ectopically in the anterior mediastinum or in the aortopulmonary window.^{20, 21}

It is not uncommon to confuse fat, accessory thyroid nodules or even lymph nodes with parathyroid glands.

The parathyroid glands are usually vascular and bleed or bruise easily, unlike fat or thyroid tissue.²¹ The glands are softer than thyroid tissue and lymph nodes. A simple technique to differentiate parathyroid from non-parathyroid tissue is to apply gentle pressure with a fine surgical instrument to the parathyroid glands; they appear to move inside their own capsule unlike non-parathyroid tissue.

INVESTIGATIONS FOR PARATHYROID DISEASE

The most important aspect in the use of minimally invasive parathyroid surgery is to establish the correct diagnosis and localize the disease accurately. Primary HPT can be differentiated from other forms of hypercalcaemia by careful history, physical examination and laboratory investigations. The disease has evolved from the classical symptomatic to asymptomatic form. Most patients today present with abnormal biochemistry results and do not have any manifestations of the disease.

The presence of the disease is confirmed biochemically with elevated calcium and parathyroid hormone levels, in the presence of normal renal function. It is important to measure vitamin D levels as the disease is characterized by low plasma levels of 25-hydroxyvitamin D and high plasma levels of 1,25-dihydroxyvitamin D. An autosomal dominant condition that mimics primary HPT is benign familial hypocalciuric hypercalcaemia (FHH), and this is excluded by measuring 24-hour urinary calcium excretion.

PRE-OPERATIVE IMAGING

The only localizing study indicated in a patient with untreated primary HPTH is to localize an experienced parathyroid surgeon.

J.L. Doppman²²

For many years until the development of MIP, the role of pre-operative imaging was considered to be less important than the skill of the surgeon. Imaging in parathyroid disease has evolved over the last 60–70 years, with significant improvement in pre-operative localization. For MIP, it is essential to have a ‘road map’ of the anatomical location of the parathyroid gland and this is usually achieved by non-invasive modalities in the form of ultrasound and sestamibi scan, computed tomography (CT) and magnetic resonance imaging (MRI)²² (**Figure 77.2**).²² The invasive modalities are usually reserved for re-operative parathyroid surgery.

Imaging with sestamibi is the first-line investigation using the single-radioisotope technetium-99m (^{99m}Tc) sestamibi followed by high-resolution ultrasound scan. Recent studies have shown the combination of sestamibi with SPECT to be superior to single modality imaging^{23, 24} and effective in detecting posterior glands.

Figure 77.2 Sestamibi/CT functional overlay showing a left superior parathyroid adenoma. The tumour has dropped in the retro-oesophageal position and is not viewable on ultrasound scanning.

Ultrasound scanning (USS) has a complementary role to sestamibi and is useful in assessing the anatomy of the neck. It can easily differentiate parathyroid glands from thyroid nodules, which may be seen in up to 40% of patients. However, USS is operator-dependent and may miss smaller and deeper glands.

Where the scans are discordant, the current practice is to perform a CT or MRI scan for further confirmation of the adenoma. As a single modality, CT and MRI are of little use in localizing parathyroid adenomata for a minimally invasive approach. Their role is more in localizing ectopic disease or in the context of re-operative surgery.

INDICATIONS FOR MIP

The indications for MIP are no different from the conventional cervical exploration – symptomatic or asymptomatic patients fulfilling the established NIH criteria.²⁵ The technique is reserved for patients with uniglandular disease with concordant scans. Where there is discordance, absent imaging or negative scans MIP should not be performed. A scoring model for uniglandular disease has been developed by Kebebew et al²⁶ and includes: single site on sestamibi scan, single site on ultrasound, concordant localization, serum calcium >1 mg/dL above the upper normal limit, and PTH twice the upper limit of normal. The predictive value of the scoring system is 100% and therefore patients with a score of more than 3 should be offered MIP. Conditions that make patients unsuitable for MIP are listed in [Box 77.1](#).

BOX 77.1 Contradictions to MIP

- Multiglandular disease
- Family history of MEN or familial hyperparathyroidism
- History of irradiation
- Previous neck surgery
- Chronic renal insufficiency
- Lithium therapy

OPERATIVE STEPS

Preparation and incision

The surgery may be performed under general anaesthesia or local anaesthesia with intravenous sedation (LA+IVS). All patients have a superficial cervical block with 20 mL of 0.25% Marcaine infiltrated on the involved side. Patients have an ultrasound scan on the morning of the surgery with pre-operative skin marking, and the image acts as the ‘road map’ to the adenoma ([Figure 77.3](#)). The patient is positioned on the table supine with slight neck extension by placing a gel pad or pillow behind the shoulder blades. The patient’s head is supported in a gel donut and hyperextension is thereby prevented. The table is tilted 30 degrees in a reverse Trendelenburg position. The surgical site is prepped and sterile-draped from the chin to the sternal notch.

The skin incision is made according to the position of the adenoma that is pre-operatively marked by ultrasound. Either a medial or a focused lateral approach may be used to remove the adenoma. The medial approach is more suitable for a superficial inferior adenoma whereas the lateral approach is useful in picking a posterior inferior or a superior adenoma. We routinely use the focused lateral approach for superior and inferior adenomas. A 2–2.5 cm incision is placed along the skin crease overlying the medial border of the sternocleidomastoid muscle corresponding to the position of the parathyroid adenoma ([Figure 77.3](#)).

Once the skin incision is made, the platysma is divided gently by electrocautery and the subplatysmal plane is developed using blunt scissors. The medial edge of the sternocleidomastoid muscle is identified and the fascia divided superiorly and inferiorly. Any small vessel encountered is cauterized. The sternocleidomastoid muscle is retracted laterally and the lateral edge of the strap muscles is exposed. The plane below the muscles is entered and the strap muscles are retracted medially to expose the thyroid. By this technique, of medial retraction of straps and lateral retraction of the jugular vein underlying the sternocleidomastoid, most parathyroid glands are identified in the neck.

Figure 77.3 Incision for MIP, positioned over medial border of left sternomastoid (20 mm).

Exposure of the inferior parathyroid adenoma

The inferior parathyroid glands are usually seen at the inferior pole of the ipsilateral thyroid lobe or in or around the thyrothymic ligament. The adenomas are usually seen anterior to the RLN and inferior to the inferior thyroid artery. Once the plane between the straps and sternocleidomastoid is exposed, the thyroid is retracted medially and anteriorly. Using blunt artery forceps the parathyroid is circumferentially dissected free from the thyroid and the gland is gently lifted using vascular forceps, taking care not to fracture the parathyroid. Tributaries to the gland are clamped with a small haemostat and ligated. The gland is then excised and sent for histological evaluation. Adenomas located in the thyrothymic ligament or even in the thymus can be removed by this approach.

Exposure of the superior parathyroid adenoma

The superior adenoma is usually located in an area above the intersection of the inferior thyroid artery with the RLN, posteriorly in the retropharyngeal or in the retrooesophageal space. The thyroid gland is retracted medially and the inferior thyroid artery is identified along with the RLN. In the case of large adenomas the artery may need dividing, as they lie usually posteriorly. Once the adenoma is identified, the dissection is performed in the avascular plane posterolaterally and, using the vascular forceps, the gland is gently mobilized, taking care not to injure the RLN. The pedicle, located posteromedially, is identified, clipped and divided. If the adenoma cannot be located in the positions described, one may need to consider that the adenoma may be intra-thyroidal. In this scenario, a decision for open-neck exploration is advised.

Once the adenoma is excised and haemostasis achieved, the wound is irrigated. The platysma and the skin are

closed with subcuticular Vicryl Rapide, and Steristrips or glue applied to the wound.

Confirmation of cure

Most centres recommend the use of intra-operative PTH (IOPTH) levels to ensure that the adenoma is resected and also to assess cure. When this is achieved, the PTH levels fall to 50% of the pre-operative value at 10 minutes and this is predictive of cure in 98% of cases.²⁷

COMPLICATIONS

The complications of MIP are rare in the best of hands and in centres of excellence. They are listed in [Box 77.2](#).

BOX 77.2 Complications of MIP

- Recurrent laryngeal nerve palsy
- Bleeding
- Hypoparathyroidism (rare)
- Persistent disease
- Failure to cure

POST-OPERATIVE CARE

Patients are routinely prescribed analgesia and calcium supplementation on discharge. On discharge, irrespective of symptoms of hypocalcaemia and patients are generally advised to take calcium for a minimum of 24–48 hours post excision. While most of these cases are performed as day cases, patients are monitored for a minimum of 4–6 hours for any signs of haematoma. A patient leaflet on wound care is provided on discharge. Patients are reviewed in clinic at 4–6 weeks post-surgery, and calcium and PTH levels are checked to confirm cure.

KEY POINTS

- Confirm diagnosis of PHPT.
- Perform localization studies.
- Concordant studies: consider MIP.
- Ensure adequate exposure to perform operation safely.
- Establish protocol to manage post-operative hypocalcaemia and bleeding.

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: parathyroid and reoperative parathyroid surgery.

BACKGROUND

General introduction

Primary hyperparathyroidism (PHPT) is a disease characterized by elevated serum calcium and parathyroid hormone (PTH) levels. It is a common disorder although multiple factors can influence its incidence such as regional influences, nutritional status, the availability of routine biochemical screening, sex (incidence higher in females), previous irradiation and age. Where the average incidence is 4.3/1000 in the United States, in women aged between 55 and 75 years the incidence can rise up to 21/1000.¹ It is most frequently caused by a single benign adenoma and is associated with a range of symptoms. The parathyroid glands play a key role in regulating the calcium homeostasis through an interaction between PTH, serum ionized calcium and vitamin D with the gastrointestinal tract, kidney and skin. Calcium is the single most potent activator of PTH release and, when its levels decrease, the calcium-sensing receptor (CaSR), situated on the parathyroid chief cells, is activated and stimulates the release of PTH.²

Historically, patients with hyperparathyroidism would present with advanced clinical features such as fractures, skeletal deformities, 'brown tumours', renal calculi and even kidney failure. After the discovery of the PTH and the introduction of routine biochemical screening with the auto-analyzer in the 1970s, a significant change took place such that most patients were diagnosed at an earlier stage, with an associated dramatic increase in presentations for surgery.

Historical perspective on surgical management

The only cure for PHPT is to surgically remove the hyper-functioning parathyroid adenoma or adenomata (in the case of multigland disease) or to reduce the bulk of parathyroid tissue in patients with hyperplasia. The historical evolution of surgery for PHPT, as well as the surgical strategies after operative failure, can be considered in three distinct phases. The first phase was the 'learning curve'. While the first documented removal of a parathyroid adenoma by Bland-Sutton in 1910 was successful, he was certainly not aware of the pre-operative diagnosis.³ Most of the early documented intentional parathyroid procedures in the 1920s were associated with failure for a variety of reasons that may still plague parathyroid surgeons today. In Vienna in 1925, Hirsch undertook a four-gland parathyroid exploration which turned out to be negative with no tumour found. The patient was subsequently diagnosed with fibrous dysplasia, which was the wrong diagnosis. Also in Vienna in 1925, Mandl performed the first initially successful intentional parathyroidectomy, although a number of years later the patient developed recurrent disease and died.⁴ In 1927, Churchill performed a total of seven parathyroid explorations on the same patient before finally removing a large mediastinal adenoma. Unfortunately, his patient died post-operatively of renal failure, albeit cured of his hyperparathyroidism.⁵

The second phase was the open four-gland exploration approach. With an increasing understanding of

parathyroid anatomy and embryology over subsequent decades, open four-gland parathyroid exploration became the gold standard procedure for patients with hyperparathyroidism, providing cure rates in experienced hands of over 95% with minimal complications. In that phase, failure in the 5% of patients was largely related either to surgery being performed by an inexperienced surgeon, or to the presence of an ectopic parathyroid adenoma, usually located in a mediastinal position. Multigland disease was readily managed since all four parathyroid glands were routinely identified and any large glands removed.

The third and current phase of minimally invasive parathyroidectomy (MIP) was ushered in with the report of the first endoscopic parathyroidectomy by Gagner in 1996.⁶ The initial techniques employed endoscopic assistance, but it soon became clear that a more direct approach via a 2cm open mini-incision (either central or lateral) was feasible and much more direct.⁷ The perceived advantages with a minimally invasive approach were patients with less post-operative pain, smaller scar and shorter hospital stay, and MIP has now become standard of care, with reported cure rates of over 95%, at least in the short term.⁷ Unlike open four-gland parathyroid exploration, the most common cause of failure in MIP is the presence of multigland disease. Up to 15% of patients have historically been reported to have multigland disease present, which represents the number who, in theory, require more than one gland excised to achieve normocalcaemia.⁸ However, with the advent of MIP, aiming at a pre-operatively identified parathyroid abnormality, a much higher frequency of solitary adenomas of 96% was found.⁸ The extent of the pre-operative workup influences the number of observed solitary adenomas. Lee came to a supporting conclusion comparing the presence of multigland disease before and after the introduction of MIP and found that the incidence of multiple enlarged glands being removed dropped from 15% to 4%, although there was no documented change in the incidence of surgical failure. These findings indicate that many enlarged glands in patients with multigland disease do not contribute to hypercalcaemia.⁹

Numerous techniques have been introduced to minimize the risk of failure during MIP. The most widely utilized is the intra-operative measurement of serum PTH levels (IOPTH) first introduced by Irvin.¹⁰ Many authors claim this reduces the risk of failure, although there are no convincing data to support this proposal. IOPTH works best when not required, when a single localized adenoma is removed at MIP, but it fails most often when most needed, especially in the presence of multigland disease. Therefore, we recommend IOPTH is not utilized, rather emphasis is placed upon high-quality concordant imaging for localization, providing a success rate of 98% as documented in our last published series of over 100 successive cases.¹¹ If a single abnormal gland cannot be localized, then open parathyroidectomy is still offered.

While short-term failure is no higher in patients having a MIP, there is increasing concern that long-term recurrence may be rising. For example, after having performed more than 17 000 parathyroid operations having,

Norman has recently abandoned the unilateral MIP claiming that the procedure carries a 10-year recurrence rate of 4–6%.¹² He recommends that the only way to achieve 10-year cure rates of over 95% is to examine all four parathyroid glands.¹² The group claims that no diagnostic tool such as intra-operative PTH (IOPTH) is able to confirm with enough certainty that all the abnormal glands have been removed. They also argue that several studies have shown that 20% of patients have more than one abnormal, enlarged gland, and in 16% an initial IOPTH drop after removing one enlarged gland will still require the removal of additional tumours.^{12–14} As previously noted, in general, the experience is that high-quality imaging, with appropriate selection for MIP based upon concordant localization studies (4D CT, sestamibi scan and ultrasound), is the most appropriate means of minimizing initial parathyroidectomy failure to around 2% (Figure 78.1). When that inevitably occurs, reoperative parathyroidectomy can still be undertaken (by experienced surgeons) with very high success rates and minimal complications (Figure 78.2a,b).¹⁵

Anatomy and embryology of difficult locations

The parathyroid glands are small tan brown organs which arise from the dorsal aspect of the pharyngeal pouch in the fifth week and descend in the direction of the caudal thyroid gland. They are soft, weigh 35–55 mg, and measure 2–7 mm in length.¹⁵ Multiple shapes, ranging from leaf to bean form, are found.¹⁶ Adenomas are usually oval, red-brown masses that can replace the normal parathyroid gland, although haemorrhagic and cystic lesions can also be seen. An adenoma can weigh anywhere from 50 mg to several grams. On histologic examination, parathyroid chief cells will be seen clustered around capillary networks.¹⁶ Localization studies may help the surgeon locate any pathological glands; success in parathyroid surgery, however, is mainly based upon a thorough knowledge of

Figure 78.1 4D CT scan showing a left retropharyngeal undescended superior adenoma.

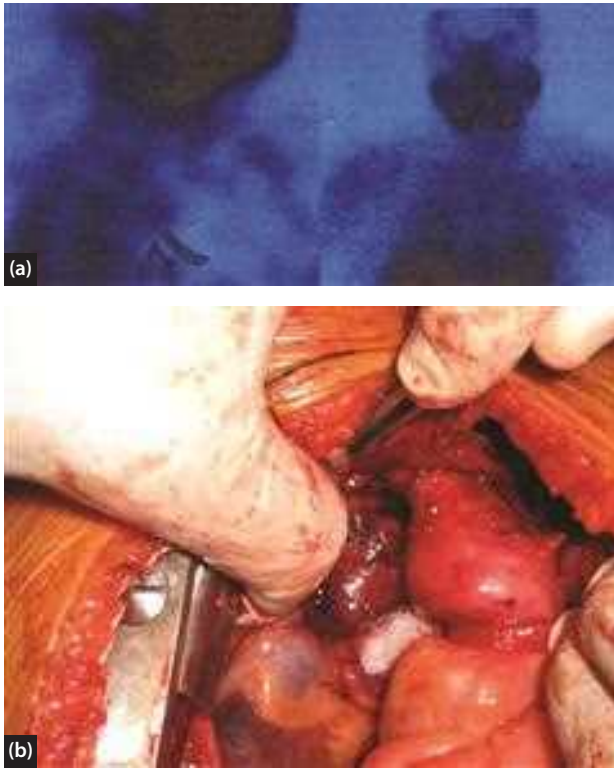

Figure 78.2 (a) Sestamibi scan of fifth ectopic adenoma in aorta pulmonary window. (b) Operative photo of removal of right inferior parathyroid adenoma in aorta pulmonary window.

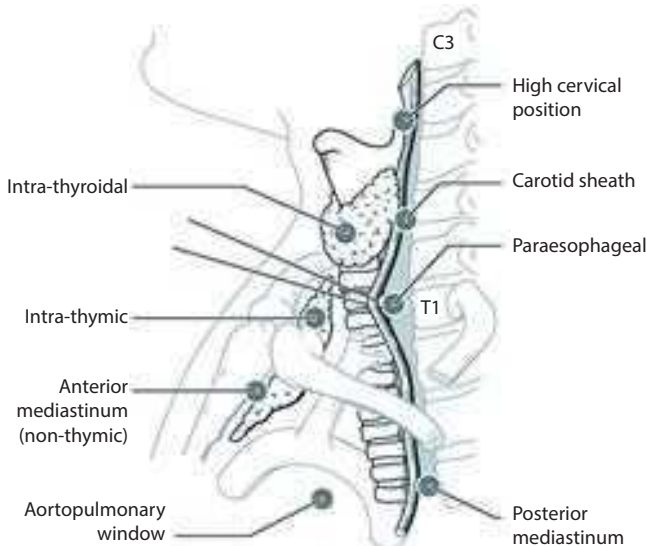

Figure 78.3 Common ectopic locations of missed parathyroid adenomas leading to surgical failure.

the anatomy and a thorough understanding of the embryology of the glands (**Figure 78.3**).

The first procedure is the golden opportunity to cure the patient. Reoperative surgery for failure is almost always a more challenging procedure due to loss of normal anatomical planes, as well as the presence of scarring and fibrosis that may obscure the classic appearance of both normal and abnormal parathyroid glands that experienced surgeons rely on.

LOCATION OF THE SUPERIOR PARATHYROID GLANDS (PIV)

The superior glands arise from the dorsal wing of the fourth pharyngeal pouch and descend in a caudal direction with the thyroid gland itself. Most superior parathyroid glands (PIVs) are located immediately adjacent to inferior cornu of the thyroid cartilage, close to the recurrent nerve, cranial to the branch of the inferior artery nerve. Exposure of the posterior aspect of the thyroid lobe is made by displacing the gland inwards and retracting the jugular–carotid bundle outwards. After this simple exposure, the superior glands are then found immediately superior to the junction of the recurrent laryngeal nerve and the inferior thyroid artery.¹⁷

These glands are closely associated with the recurrent nerve and so, when mobilizing them, especially with a minimal invasive approach, identification and dissection of the nerve are of vital importance. However, when the superior gland is abnormal, it tends to migrate posteriorly and downwards. Therefore, when it is not in immediate contact with the thyroid, it should be sought lateral to or behind the oesophagus, bearing in mind that the lower a superior descended gland travels the more posterior it becomes.

The origin of the pedicle is usually at the upper third of the thyroid lobe and can be located by simple traction on the pedicle. The superior parathyroid gland can also be situated just under the perithyroidal sheath, close to the posterior aspect of the lobe. Quite often a flattened parathyroid adenoma is located at the posterior aspect of the upper pole of the thyroid lobe which may easily be missed when one does not know where to look for it.

LOCATION OF THE INFERIOR PARATHYROID GLANDS (PIII)

Because of a longer descent, the inferior parathyroid glands (PIII) have a much higher variability in location when compared with the superior parathyroid glands; the inferior parathyroid glands arise from the dorsal aspect of the third pharyngeal pouch and, following the development of the thymus, they descend in a caudal-medial direction. Over 40% are situated at the posterior aspect of the thyroid lobe from the inferior thyroid artery to the lower pole of the lobe and along the thyrothymic ligament. PIII is very rarely situated posteriorly and becomes more anterior the lower it descends. Quite often these glands are located at the posterior aspect of the lower pole of the lobe, situated anterior to the recurrent nerve. The thyrothymic ligament is a common location for a gland and it can be situated at the thymic upper pole. It is important to remember that, in 80% of patients, the location of the inferior and superior parathyroid glands is symmetrical when compared with the glands on the contralateral side of the neck.¹⁸

Definitions of failure – persistent disease vs. recurrent disease

Persistent hyperparathyroidism is defined as the presence of an elevated serum calcium and inappropriately elevated

or non-suppressed serum PTH within 6 months of the initial surgical procedure; recurrent hyperparathyroidism is defined as the same biochemical scenario developing after at least 6 months of hypercalcaemia. Persistent PHPT (80–90%) is much more common than recurrent (10–20%) PHPT. While this definition is somewhat arbitrary, it acts to separate out those patients with multigland disease in whom hypercalcaemia appears subsequent to an initial successful operation, presumably since the second adenoma was present but inactive at the time of initial surgery. Even in the most experienced hands, persistent hyperparathyroidism following failure at initial surgery for PHPT will never reach zero although centres with a high turnover of cases should achieve an initial success rate of 95–98%.¹³

As noted, there is a conceptual difference between failure following an open parathyroidectomy, where this is largely due to either surgical inexperience or ectopic location, and failure after MIP, where this is largely due to the presence of multigland disease in the neck that has not been identified on pre-operative localization studies. Recurrent hyperparathyroidism due to multigland disease may even develop after several years, often being associated with a familial disorder; in contrast, the development of a second adenoma is very rare and mostly seen in patients who have had previous irradiation.¹⁹ Parathyroid carcinoma should also be considered in the differential diagnosis of failure and in some situations a recurrence corrects an original misdiagnosis for an atypical adenoma. Local recurrence can be a parathyroid carcinoma, although this can also be seen after capsular rupture of benign lesions (parathyromatosis).

INVESTIGATION OF PERSISTENT OR RECURRENT DISEASE (THE THREE ‘R’S)

Before undertaking any second exploration in the neck for recurrent primary hyperparathyroidism it is of vital importance to understand fully the causes for the failure of the initial operation. The workup before any reoperative exploration should consist of ‘the three R’s’; **reconfirm** the diagnosis, **review** the operative and pathology reports, and **repeat** the imaging.

Reconfirm the diagnosis and reassess the patient

The diagnosis of PHPT can only be made again if other causes of hypercalcaemia are excluded. In the first place serum analysis and 24-hour urine should be repeated to look for raised PTH and calcium to confirm the diagnosis of PHPT. Elevated PTH with normal calcium can occur in up to 30% post-op due to hungry bone syndrome (secondary response to bone remineralization), low vitamin D levels, impaired renal hydroxylation of vitamin D-25 or decreased peripheral PTH sensitivity or an impaired renal function. Elevated calcium in the presence of suppressed PTH suggests

a misdiagnosis such as bone metastases. A modestly elevated serum calcium and serum PTH can be seen in familial hypocalciuric hypercalcaemia (FHH), which mimics PHPT and is a well-recognized cause of failure in an index case. It is of crucial importance to assess a family history properly to be able to exclude FHH because the disorder is not cured by parathyroidectomy. FHH is caused by various mutations in the gene coding for the CaSR. The CaSR responds to serum calcium and mediates feedback inhibition of PTH release. A loss-of-function mutation results in a rising of the calcium threshold that triggers reduction of PTH secretion. Serum concentration of calcium is thus maintained at higher levels since more calcium is needed to trigger negative feedback. This results in hypercalcaemia, and since more calcium is sequestered in the serum, this often results in hypocalcuria.²⁰ FHH is excluded by demonstration of a 24-hour urinary calcium/creatinine ratio greater than 2%. A family history of PHPT should be sought in order to exclude not only FHH but also other familial endocrinopathies such as MEN 1 and MEN 2A.

Review the operative and pathology reports

It is important to consider factors that might have made the previous surgery difficult such as a very short neck, a coexisting multinodular goitre, or a poorly placed incision, in order to be able to form an operative strategy. It is then vital to obtain and review the operative and pathology reports to determine which parathyroid glands have already been identified or removed. Issues such as who performed the procedure (experience), what kind of procedure was performed (MIP or four-gland exploration) and what was removed (parathyroid normal or abnormal; fat; nodes) all need to be identified. In addition, more detailed information, such as the position of glands identified and/or removed and the time that was spent exploring the neck looking for sites of ectopic parathyroid to be explored, should be documented. Is there anything abnormal to be noted in the report such as thyroid nodules or lymph nodes that might have formed distracting conditions during surgery and the pathology reports should be assessed thoroughly?

Repeat the imaging

A reoperative procedure for PHPT without a positive localization study will most likely lead to a second failed procedure and is a potential recipe for disaster. Localization studies are mandatory although there is no consensus as to which provide the best information. Because the specificity and sensitivity for each method vary greatly, combined localization studies, commencing with the least invasive, are generally recommended.²¹

Our own recently published series showed that 4D CT had an accuracy of 91% in reoperative cases and is significantly more accurate than either sestamibi or ultrasound.²² In another study it was reported that imaging before reoperation with sestamibi has a 59% identification rate,

ultrasound 36%, CT 41% and selective venous sampling 78%.¹⁵ Non-invasive imaging studies (ultrasound, sestamibi, 4D CT) are the studies of first choice, with invasive procedures such as venous sampling and arteriography used only if non-invasive studies are inconclusive or conflicting. In evaluating venous sampling it is important to realize that the study does not image the abnormal parathyroid gland but rather provides information to the surgeon regarding the region where the parathyroid is located.²³ Sometimes image-guided fine-needle aspiration (FNA) with biochemical assessment of the diluted aspirate (not cytological examination) may help distinguish a parathyroid tumour from other structures. A recent report demonstrated that fewer patients now undergo invasive studies (56% versus 73%), which was attributed to improvements in imaging technology.²⁴ The anatomical diagnosis should ideally be established by a concordance of the results of at least two investigations. When used together, imaging techniques correctly identify abnormal glands in nearly 95% of cases.²⁵

CONSERVATIVE OPTIONS

Although parathyroid surgery forms the only definite cure for PHPT, the risks and benefits of surgery need to be appropriately considered and discussed with the patient. When there is an urgent need to treat hypercalcaemia or surgery is contraindicated, or the patient decides against it, non-surgical alternatives are available.

For acute treatment of severe hypercalcaemia, intravenous saline solution loop, diuresis and bisphosphonates are recommended.²⁶ Subcutaneous calcitonin is also an option, but its efficacy is limited to the first 2 days. Cinacalcet is a calcimimetic drug and lowers PTH secretion by enhancing receptor sensitivity to extracellular calcium. Normocalcaemia can be achieved after 1 day of treatment, the response to cinacalcet can be persistent and it is generally well tolerated.³⁰ The drug has been shown to be effective in reducing or normalizing serum calcium levels in several groups of patients with PHPT, including patients with mild to moderate PHPT, parathyroid carcinoma, and in PHPT as a part of MEN type 1.²⁷ Cinacalcet at low dosages is well tolerated, but side effects are more frequent and severe when relatively high doses are needed to control hypercalcaemia. The most common adverse events are nausea, vomiting and paresthesias.²⁶ Cinacalcet may be of benefit in a wide spectrum of PHPT, offering a novel therapeutic option for the control of hypercalcaemia in PHPT patients who are not able to undergo parathyroidectomy. To what extent the reduction of serum calcium translates into a clinical benefit, particularly in patients with mild to moderate hypercalcaemia, is currently unknown.²⁸

SURGICAL APPROACH

In a reoperative situation, a focused exploration is the goal, aiming to locate only the abnormal gland and remove it

without disturbing normal glands, mostly positioned in scar tissue and easily damaged or devascularized. There is almost no role for a blind open four-gland exploration in the reoperative situation.

Operative strategy for previous failed open parathyroidectomy

If localization studies have provided a lateralization or a more specific regionalization, a focused re-exploration on the side of localization is performed. If the patient had a standard anterior approach through a cervical incision at the first operation, the same skin incision is used, followed by a lateral approach, in the plane lateral to the strap muscles and medial to the sternocleidomastoid muscle (SCM), rather than the standard approach between the strap muscles. This approach is preferred to avoid heavily scarred planes from the previous anterior neck exploration.

The dissection begins from the medial aspect of the SCM muscle, finding the plane medial to the internal jugular vein then continuing that down to the pre-vertebral fascia, which is often virgin, unscarred tissue. The thyroid lobe can then be identified. The recurrent laryngeal nerve should be identified at this stage using the inferior approach as described for reoperative thyroid surgery.²⁹ The nerve is located in the trachea-oesophageal groove below the plane of initial surgery and tracing it upwards. As the carotid sheath is retracted to the lateral side, the neck is explored superiorly to the level of the hyoid bone, inferiorly to the brachiocephalic vessels and posteriorly in the trachea-oesophageal plane.²⁹ Common missed positions of the inferior parathyroid are the inferior and posterior surface of the thyroid gland beneath a thin layer of the capsule, the thyrothymic ligament and the thymus tissue situated in the anterosuperior mediastinum. A parathymus (a parathyroid gland that remained undescended during embryological development) may leave an inferior gland, as high as the mandibular angle. An inferior adenoma positioned here is thus located more superior than the superior parathyroid gland.

During the thorough search along the embryological descent of the gland itself, we dissect towards the superior mediastinum and on the way open and explore the carotid sheath, removing a major portion of the thymus. For the search of the superior parathyroid, the superior pole vessels should then be ligated to facilitate exposure of the superior-posterior side of the thyroid and the trachea-oesophageal groove can be explored by entering this area immediately posterior to the inferior thyroid artery. The technique of palpating the posterosuperior mediastinum digitally can be used to exclude large adenomas that might have been missed in the initial operation. This superior adenoma would thus be situated inferior to the inferior parathyroid gland (PIII).^{30, 31}

If the above strategy fails to locate any abnormal parathyroid tissue despite imaging having demonstrated a possible candidate lesion on that side, the contralateral side should not be blindly explored at the time. Bilateral reoperative surgery after a previous bilateral exploration

has the potential to lead to bilateral recurrent laryngeal nerve palsy and tracheostomy. Under these circumstances, surgery for the contralateral side should be deferred and reconsidered after further imaging.

Operative strategy for previous failed MIP

Minimal invasive unilateral exploration has now become the procedure of first choice for most first-time parathyroid procedures. In a reoperative situation after a unilateral-focused operation for the first operation, the approach should depend upon the initial incision placement and operative approach. For an adenoma localized to the same side as the initial procedure, if a lateral mini-incision approach was initially utilized, an anterior cervical approach should be considered instead of the lateral approach extending the scar to a classic Kocher incision. However, if a midline mini-incision or videoscopic approach was utilized initially, then a lateral approach second time around is preferable. Should the adenoma be localized to the contralateral side to the initial operation, a lateral mini-incision approach on that side is entirely appropriate.

Mediastinal exploration

Most mediastinal adenomas are located in the posterior mediastinum or in the anterior mediastinum just superior to the aortic arch and can usually be explored from the same cervical approach. Previous extensive cervical surgery (particularly if a cervical thymectomy had been attempted and the thymic tissue was disrupted) may prevent a cervical delivery and necessitate a median sternotomy. Likewise, a large adenoma lying below the aortic arch may not be deliverable and may require a sternotomy. An adenoma located deep in the middle mediastinal window requires a thoracotomy. Confident localization must be obtained before the surgeon proceeds to mediastinal exploration (Figure 78.2a,b). There is absolutely no role for blind mediastinal clearance in the futile hope of retrieving or devascularizing a non-localized tumour.

REVIEW: RESULTS AND POST-OPERATIVE COMPLICATIONS

Results

For patients with persistent or recurrent hyperparathyroidism, pre-operative localization studies and a focused surgical approach can result in a 95% success rate with a minimum of complications.³² However, management of persistent or recurrent hypercalcaemia after failed initial surgery remains one of the greatest challenges in endocrine surgery. Neither the cure rates nor the complication rates of reoperative surgery have changed significantly over the last few decades despite the revolutionary development of imaging.

Although multigland disease is still the most important cause for primary failure, Thompson demonstrated that 40% of missed abnormal glands reside in a normal anatomical position.³³ Despite the success rates for reoperative surgery varying from 82% to 98%, the fact that most missed adenomas are located in abnormal anatomical positions challenges all surgeons to strive for a primary cure to prevent a patient having to face the risks of reoperation.³⁰

The rates of persistent hyperparathyroidism after surgery vary considerably around the world, with some centres reporting rates as high as 24% and other centres in Europe and Australia rates as low as 2–3%. This, of course, may simply reflect referral pattern in these countries where most primary operations are performed by experienced endocrine surgeons.^{32, 33} However, Lew reported a failure rate for reoperative parathyroid surgery of 2.9%, of which most failures (76%) were due to failure of the surgeon to locate the abnormal gland.^{34, 35} Only 24% of missed adenomas in this study were caused by multigland disease.³⁵ Their group also concluded that the surgeon's judgement and experience are paramount, especially in these cases.

Complications

The most significant complication of reoperative parathyroid surgery is a recurrent laryngeal nerve injury, resulting in vocal cord paralysis. Despite the difficulty of dissecting in scarred tissue planes, the permanent nerve injury rate is exceptionally low in most published series, ranging from 0.4% to 4%, and the rates of permanent hypocalcaemia in reoperative parathyroid surgery have been reported to be in the range of 5–11% in the most recent series.^{36–40} The use of intra-operative nerve monitoring was studied recently by comparing nerve injury rates. Since there was only one unintentional nerve injury in each group, the authors concluded that, although monitoring can be performed safely, it does not decrease the injury rate.⁴¹ Careful dissection and visualization of the nerve remain the best protection against injury. However, if the surgeon decides to use intra-operative nerve monitoring, employing it routinely in these cases is more effective to gain more experience with the technique and to be able to make best use of it in the reoperative setting.

Permanent hypocalcaemia is the other significant complication of reoperative parathyroid surgery, where the normal glands may have been damaged, biopsied, or all three normal glands may even have been excised during the first operation.

SUMMARY

Patients with recurrent or persistent PHPT present a challenge, even for the experienced parathyroid surgeon. It is crucial to reconfirm the diagnosis, consider the risks and benefits of the reoperation, and review the operative notes and pathology reports and the results of localization tests. The success rates are high in the hands of an experienced surgeon who has excellent knowledge of the embryology

and anatomy of the parathyroid glands. The complication rate of recurrent laryngeal nerve injury and permanent hypocalcaemia is acceptable but considerably higher than during initial parathyroid operations. Most missed

adenomas seem to be located in a normal anatomical position, which challenges all parathyroid surgeons to strive for a primary cure in the first operation and to prevent a patient needing to face the risks of reoperation.

KEY POINTS

- The only cure for PHPT is to surgically remove the hyperfunctioning parathyroid adenoma or adenomata.
- Unlike open four-gland parathyroid exploration, the most common cause of failure in MIP is the presence of multi-gland disease.
- High-quality imaging, with appropriate selection for MIP based upon concordant localization studies (4D CT, sestamibi scan and ultrasound), is the most appropriate means of minimizing initial parathyroidectomy failure.
- Persistent PHPT (80–90%) is much more common than recurrent (10–20%) PHPT.
- The workup before any reoperative exploration should consist of ‘the three R’s’: reconfirm the diagnosis, review the operative and pathology reports, and repeat the imaging.
- In a reoperative situation, a focused exploration is the goal, aiming to locate only the abnormal gland and remove it without disturbing normal glands.
- The most significant complications of reoperative parathyroid surgery are recurrent laryngeal nerve injury and permanent hypoparathyroidism.
- The success rates are high in the hands of an experienced surgeon who has excellent knowledge of the embryology and anatomy of the parathyroid glands.
- Most missed adenomas seem to be located in a normal anatomical position, which challenges all parathyroid surgeons to strive for a primary cure in the first operation and to prevent a patient having to face the risks of reoperation.

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: thyroid surgery, complications, haematoma, recurrent laryngeal nerve injury, oesophageal injury, tracheal injury, airway complications, hypoparathyroidism, hypothyroidism and thyroid storm. The evidence in this chapter is mainly levels 3 and 4. The clinical recommendations are mainly B and C.

INTRODUCTION

Complications in thyroid and parathyroid surgery are uncommon but significant when they occur. Averting the complications should begin pre-operatively with an assessment of risk factors for potential complications and a thorough discussion with the patient outlining the risk factors, treatment approaches and outcomes. Sound anatomical knowledge and meticulous surgical technique aid in minimizing complication risk. Post-operatively, close observation of the patient is the key to identifying and managing problems early and successfully, leading to a better overall outcome.

SEROMA

The incidence of seroma formation is low, occurring in 1–7% of cases. Seromas are more likely to occur after surgery for a large goitre or a total thyroidectomy. Post-operative neck swelling should be taken seriously and monitored for rapid enlargement or tenderness. In most cases, seromas are managed conservatively with observation and

by reassuring the patient.¹ When seromas are painful or lead to tightness, aspiration of the fluid using sterile technique eases the patient's discomfort but may need to be repeated several times before reaccumulation of the fluid stops. Placing a drain into the dead space left after the surgery may also be helpful. If there is a concern of infection, the aspirated fluid should be sent for culture and antibiotics should be started. In the majority of patients, seromas resolve over 6–8 weeks with watchful waiting.¹

INFECTION

Infection of the surgical site is quite rare in thyroid and parathyroid surgery, occurring in less than 1% in most cases series. These surgeries are considered clean by the Centers for Disease Control and the National Safety Network criteria for wound classification and do not require peri-operative antibiotics.² In certain instances, using a peri-operative antibiotic selectively may be reasonable given a patient's risk factors for potential infection.

Intra-operatively, if there is a break in sterility or another source of contamination such as entry into the

aerodigestive tract is identified, then antibiotics are warranted. Superficial wound infections are treated with local wound care and oral antibiotics. Deep wound infections are more serious: they require incision and drainage with wound culture, placement of a drain in addition to i.v. antibiotics and investigation for the source, which is often a missed aerodigestive injury.^{3, 4} Cervical infections after thyroid and parathyroid surgery should never be underestimated and should be treated definitively and swiftly to prevent mortality from this complication.⁵

HAEMATOMA

Minimizing the risk of post-operative haematoma begins pre-operatively by identifying risk factors for each patient that contribute to an increased likelihood of a post-operative haematoma. Several articles have defined significant risk factors including male gender, older age, smoking, large thyroid, benign pathology, antiplatelet/anticoagulation therapy and Graves' disease.^{6, 7} Obtaining a good history is important; hypertension and taking herbal supplements such as fish oil increase the risk of bleeding and potential haematoma formation.⁸ Following surgery, hypertension, vomiting and excessive coughing or sneezing can induce haematoma formation.^{8, 9}

Maintaining meticulous haemostasis intra-operatively, particularly at the end of the case, is essential. There are several thermal haemostatic instruments that can be used including monopolar cautery, bipolar cautery and vessel-sealing devices, none of which confers better haemostasis over another. Many surgeons utilize the Valsalva manoeuvre to identify and control any potential areas of bleeding prior to closure.¹ Drains do not decrease the rate of post-operative haematoma; in fact one study shows that a drain is a risk factor for haematoma. Drains should be used very selectively in this setting and, because they increase the risk of infection, antibiotics should be administered while the drain is in place.^{10–13} Haemostatic agents may be used in the thyroid bed but they have not been shown to decrease the rate of haematoma. Most haematomas occur within the first 6–12 hours after surgery. However, a small percentage of haematomas form greater than 24 hours after surgery and up to 1–2 weeks afterwards.^{6, 14} Haematomas can be superficial (above the strap muscles) or deep (below the strap muscles). As the haematoma expands, it causes venous and lymphatic congestion which exacerbates laryngopharyngeal oedema leading to eventual airway compromise. Decompressing and evacuating the clot is the first and most important manoeuvre in order to help alleviate airway narrowing. While the patient is awake, the incision is released and the strap muscles are incised to release pressure from the haematoma.¹⁵ Securing the airway is paramount; placement of an endotracheal tube when necessary is preferred. If this is not possible, then an emergency tracheostomy may be needed. The patient is then returned expeditiously to the operating theatre for haematoma evacuation, identification and control of the bleeding source. After achieving complete haemostasis, the wound is closed again.^{1, 15} Most

patients who return to the operating room for haematoma evacuation recover well from this second procedure and are discharged the day after surgery.

RECURRENT LARYNGEAL NERVE INJURY

In the pre-operative setting, a thorough history and physical examination should be performed to identify any concurrent factors such as significant smoking history, lung cancer or reflux disease, affecting the voice quality of the patient. Pre-operative laryngoscopy should be performed on all patients to document baseline vocal cord function.^{16, 17}

Intra-operative direct visualization of the recurrent laryngeal nerve (RLN) lowers the rates of temporary and permanent RLN injury rates and is considered the gold standard.^{18–21} Intra-operative neural monitoring (IONM) is an important complement to visualization of the nerve. IONM have shown a trend towards lower RLN injury rates but statistical proof is lacking in part due to lack of adequate statistical powering of most studies. IONM aids in mapping the RLN, in assessing nerve function, and in identification of an injured nerve segment.^{16, 22, 23} Having real-time monitoring allows the surgeon to change the technique or the amount of retraction that is causing harmful impact on the RLN.¹⁶ When injury is suspected, identification of the injured segment, assessment of the injury and the possibility of repair should be explored. The RLN injury should be managed appropriately at the time of identification.^{24, 25}

An analysis of 27 articles, reviewing more than 25 000 patients undergoing thyroidectomy, found the average post-operative vocal cord paralysis (VCP) rate was 9.8% and ranged from 0% to 18.6%.²⁶ Post-operative laryngoscopy should be performed to reliably document post-operative glottic function and for early identification of VCP to initiate appropriate management.¹⁶ There are multiple methods for restoring voice quality in patients who have vocal cord dysfunction. In the first 3 months, cordal injections can enhance contact between the vocal cords and improve swallowing, voice and cough. If the injury is permanent, procedures like thyroplasty and medialization laryngoplasty can be performed.²⁷ These methods rely on placement of a structural implant to reapproximate the injured cord with the normal cord. Finally, reinnervation is another option that can be accomplished by mobilizing a functioning nerve, typically the ansa cervicalis to the distal RLN stump. It may take several months to regain voice function after this procedure.²⁷

INJURY TO THE EXTERNAL BRANCH OF THE SUPERIOR LARYNGEAL NERVE

IONM can be very helpful in intra-operative identification of the external branch of the superior laryngeal nerve (EBSLN), as up to 20% of EBSLN are subfacial

and visually unidentifiable.²⁸ A precise surgical technique with careful superior pole dissection and ligation of the superior pole vessels on the gland itself is important.^{29, 30} Understanding the anatomical variations of the EBSLN course is the best guide for protecting the nerve. With monitoring there is a standardized approach to identification and dissection of the EBSLN.³¹

Post-operatively, the surgeon should inquire about voice strength, pitch and fatigue. If the patient has any of these complaints, EBSLN injury should be suspected and a formal voice evaluation with videostroboscopy as well as speech therapy should be performed.²⁹

HYPOPARATHYROIDISM

For patients with thyroid cancer, substernal goitre, Graves' disease and reoperation, hypoparathyroidism is a significant concern. Pre-operative Vitamin D, serum calcium and PTH evaluations are helpful in establishing a baseline for calcium homeostasis prior to surgery. If the vitamin D is low, replacement before surgery is helpful in order to decrease risk of symptomatic hypocalcemia secondary to lack of calcium absorption.³²

Meticulous dissection with preservation of the parathyroid glands and their blood supply is required to avert hypoparathyroidism.³³ The standard method for preserving the parathyroid glands and their blood supply is capsular dissection. The glands are mobilized and reflected away from the thyroid gland while keeping their blood supply intact.^{20, 21, 24} Disruption of parathyroid gland vascularity is the most common reason for post-operative hypoparathyroidism. If a parathyroid gland seems non-viable after surgical dissection, a portion may be sent for frozen section to confirm parathyroid tissue and the remainder can be autotransplanted into the sternocleidomastoid muscle.³⁵ Inadvertent removal of one or more parathyroid glands with the thyroid can also cause hypoparathyroidism.³⁶

Post-operatively, serum calcium levels can be checked to determine the need for calcium supplementation. Some surgeons give post-operative calcium supplementation to all patients. Hypoparathyroidism can be temporary, less than 6 months post-surgery (8–30%) or permanent, more than 6 months post-surgery (1.7–3.5%).^{19, 32} In the acute setting with serum calcium levels less than 1.75 mmol/L, i.v. calcium gluconate is administered to alleviate symptoms which can include paraesthesia, muscle cramps and spasms, twitching, tetany, seizures and cardiopulmonary dysfunction. If serum calcium is at least 2 mmol/L, then it is treated with oral calcium carbonate and vitamin D. For patients with a history of gastric bypass surgery or reflux disease, calcium citrate is used instead of calcium carbonate because it is better absorbed in these patients.³⁷ The starting dose of calcium is usually 500–1000 mg three times a day with upward titration if symptoms persist. For vitamin D administration, the most active form, 1,25-dihydroxy D3 (calcitriol), is used with a starting dose of 0.25 µg each day. Ionized calcium, phosphorous, PTH and vitamin D should be checked at regular intervals if

the patient is not improving. The goal is to maintain a low-normal serum calcium with normal phosphorous levels and low urinary calcium excretion.³² For patients with permanent hypoparathyroidism, maintaining calcium and phosphorous levels is more difficult and requires routine monitoring and changes to supplementation as needed. Urine calcium levels tend to increase over time and lead to renal insufficiency. Osteoporosis is also a concern for these patients because their bone resorption is decreased.³² A new treatment option is recombinant PTH (rhPTH), an injectable synthetic human PTH administered subcutaneously once or twice a day.³⁸ It has been shown to maintain serum calcium levels, decrease phosphorous levels and decrease or eliminate the need for vitamin D supplementation. From a physiological standpoint, there is improved bone turnover and a decreased urinary calcium level.^{38, 39}

AERODIGESTIVE INJURY

In patients with known thyroid cancer with a concern for tracheal or oesophageal invasion, a thorough workup including imaging and endoscopy should be completed pre-operatively. This is helpful for surgical planning and for avoidance of aerodigestive injury.

During surgery, inadvertent entry into the oesophagus or trachea is uncommon but, when it occurs, it is usually secondary to adherent tumour or lymph nodes.

Tracheal injuries can be small or large. Small injuries can be repaired primarily with absorbable sutures.⁴⁰ If primary closure is not possible, segmental tracheal resection may be performed or a tracheostomy tube placed. Oesophageal repair includes debridement of the tissues edges with two-layer closure of the mucosa and muscle separately. A strap muscle may be used to buttress the repair. A closed drainage system is placed, antibiotics and parenteral nutrition are started and the patient is kept nil by mouth for 7–10 days when a contrast swallow is done to check for a leak.^{40–42} If there is no leak, a soft diet is introduced. Long-term complications from a leak include stricture and fistula, both of which require further workup and treatment.⁴²

HYPOTHYROIDISM

Surgical hypothyroidism should be a point of pre-operative discussion for any patient undergoing thyroid surgery. Typically, the starting dose for levothyroxine is 1.6–1.8 mcg/kg/day and is titrated based on thyroid function tests thereafter. Patients with thyroid cancer may need a higher dose in order to suppress growth of cancer cells.⁴³

For patients who have undergone lobectomy, there is a 15–50% risk of abnormal thyroid function after surgery with the need for levothyroxine. Hashimoto's disease, higher TSH or lower free T4 or a smaller remaining lobe increase the likelihood of requiring T4 supplementation.^{44, 45}

Bloods should be checked 6–8 weeks after surgery because the half-life of levothyroxine is 7 days and it takes about this period of time to reach a steady level.^{43, 46, 47}

HYPERTHYROIDISM

Patients with hyperthyroidism secondary to Graves' disease and less often toxic multinodular goitre or a toxic nodule are at risk for development of thyroid storm throughout the disease course. Usually an external source such as infection, surgery, trauma or increased iodine intake is the inciting factor for thyroid storm.⁴⁸ Multiple systems are affected in thyroid storm – cardiopulmonary, thermoregulatory, metabolism, neurological and gastrointestinal. It is quite rare to develop this extreme form of thyrotoxicosis but when it occurs, early recognition and prompt supportive treatment are essential for survival.⁴⁸ Pre-operatively the surgeon needs to discuss with the patient the risks of thyroid storm and the importance of compliance with medication up to the day of surgery. Thyroid function tests should be checked regularly prior to surgery to ensure that free T4 and free T3 levels remain within an acceptable range. If free T4 is above 20 pmol/L and the free T3 remains high, surgery is postponed until those levels decrease appropriately.⁴⁸

In the operating theatre, a shift in vital signs alerts anaesthesia to the possibility of thyroid storm. Tachycardia, dysrhythmia (usually atrial fibrillation), high fever and respiratory changes are the most common symptoms.⁴⁸ Cooling the patient, administering a beta blocker and hydrocortisone are initiated to mitigate the associated symptoms. Concurrently, antithyroidal medication, PTU or carbimazole is also started to stop synthesis of new hormone and to prevent peripheral conversion of T4 to T3. Of note, most anaesthetists give a dose of Dantrolene in this situation because the symptoms of malignant hyperthermia and thyroid storm are difficult to differentiate.⁴⁸ Post-operatively, patients with thyroid storm need close monitoring and continuation of supportive care until thyroid hormone levels normalize and the patient is no longer symptomatic.

AIRWAY CONCERNS

Determining potential airway risk pre-operatively is the best way to minimize airway complications both during intubation and post-operatively. Recognizing patients who are at higher risk because of their disease extent, by a thorough pre-operative assessment recognizing shortness of breath, dysphagia and hoarseness helps guide anaesthesia and surgical planning.^{49, 50} Patients with large goitres, substernal goitres and invasive cancers have a higher risk of airway complications. If there is concern for a substernal component or tracheal narrowing, neck and chest CT scan should be performed.⁵⁰ Anaesthetics should be consulted early in the workup of these patients so that a joint anaesthetic–surgical plan can be developed pre-operatively. In some instances, a planned tracheostomy may be considered if there is significant tracheal narrowing, a long-standing goitre or thyroid cancer. On the day of surgery, anaesthesia and surgery jointly decide the best approach based on the patient's pre-operative findings.^{49, 51} Options include induction and traditional intubation or use of a glidoscope, awake fiberoptic intubation or planned tracheostomy. At the completion of the surgery, the surgeon and anaesthetist should discuss the likelihood of

success with extubation.⁵¹ The majority of patients can be safely extubated and will experience improvement in airway symptoms. Some patients may need prolonged intubation if there is concern for tracheomalacia, which is rare. In other cases, a tracheostomy may be done at the end of the surgery, because of intra-operative detection of significant tracheal narrowing or bilateral RLN injury.^{1, 52} Any patient who has a difficult airway or airway complications at the time of surgery should be counselled in the post-operative setting about these difficulties and instructed to convey this information prior to future surgeries.

HYPERTROPHIC OR KELOID SCAR

During the pre-operative visit, a thorough history of prior operations and scar formation is key to having the best possible outcome for the surgical scar. All old scars should be examined for healing issues. In a patient with known keloid formation, a surgical as well as post-surgical plan is developed. The skin should be marked in the holding area just prior to surgery while the patient is still awake in order to find the most natural skin crease for the incision. In theatre, less is more for closing these incisions including use of suture and manipulation of the tissues. Steroid injections can also be employed prior to skin closure.¹ A tension-free closure also helps minimize scarring. Close follow-up for hypertrophy or keloid formation post-operatively and early plastic surgery or dermatology consultation are important so that advanced options for scar treatment can be explored in a timely manner. Post-operatively patients should be educated about sun exposure and use of sunscreen on the incision as well as use of over-the-counter scar care products to aid in minimizing scar formation.¹

BEST CLINICAL PRACTICE

- ✓ Pre-operatively, a thorough history, physical examination and laryngoscopy can help identify risk factors that can increase the likelihood of intra-operative and post-operative complications and also provide the opportunity to discuss post-operative expectations with the patient.
- ✓ Intra-operatively a sound anatomical knowledge, meticulous surgery, avoidance of harmful manoeuvres and use of complementary technology such as nerve monitoring can help avert complications.
- ✓ Post-operative active surveillance for complications, especially in high-risk patients, and early identification with appropriate management of complications are of paramount importance.

KEY POINTS

- The post-operative course starts in the pre-operative setting with a detailed discussion about surgery, risks and benefits.
- Knowledge of the anatomy and excellent surgical technique are essential for positive outcomes.
- Early recognition of complications with applicable treatment offers better outcomes.

THYROID AND PARATHYROID SURGERY: AUDIT AND OUTCOMES

David Chadwick

Introduction	893	Other uses of audit data	896
Outcomes: Establishing the magnitude of risk.....	893	Conclusion.....	897
Outcomes: Comparison between providers	896	References	897

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: thyroidectomy, parathyroidectomy, complications, hypocalcaemia, laryngeal nerve palsy and outcomes.

INTRODUCTION

Surgery of the thyroid and parathyroid glands is generally considered very safe. Mortality is minimal, so relevant outcomes relate mainly to the avoidance of specific surgical complications. These are reasonably well defined, and their incidence may depend to a large extent upon the operative skill of the surgeon, thereby providing an ideal opportunity for clinical audit.

OUTCOMES: ESTABLISHING THE MAGNITUDE OF RISK

Accurate knowledge of the frequency of surgical complications may be considered important for many reasons. These include: assistance in patient counselling and consent for surgery; use in surgical decision-making in selection of patients for surgery; identification of risk factors which influence complication rates, particularly if these can be modified to improve results; and provision of benchmarking data by which surgeons can be compared, with the aim of improving surgical performance.

The principal complications to be addressed, related to thyroid and parathyroid surgery, are the following:

- **Post-operative bleeding**, particularly that which requires re-exploration of the neck/evacuation of a haematoma, to protect the airway.
- **Hypocalcaemia**, secondary to the disturbance of parathyroid function. This may occur in the early

post-operative phase, usually during the index admission, and may or may not require treatment. In a proportion of these cases, hypocalcaemia will be transient, as parathyroid glands recover their function, but a smaller proportion may progress to permanent hypoparathyroidism.

- **Recurrent laryngeal nerve (RLN) injury**, leading to vocal cord paralysis. As with hypocalcaemia, this may be transient, with recovery of function occurring over a variable time period, or permanent.
- **Persistent hypercalcaemia**, in surgery for primary hyperparathyroidism, where this outcome represents a failure to cure the disease.

Other complications exist, but estimates of their incidence are highly unreliable, due to considerable variation in their definition, perceived impact, detection strategies and geographical factors. For example:

- severe wound infection is rare, and the definitions of milder infection vary widely between studies
- evidence of superior laryngeal nerve injury may be subtle, and frequently is not actively sought
- some complications are simply extremely rare and also influenced by the nature of the presenting disease (e.g. tracheomalacia, chyle leak).

For this reason, the remaining discussion will focus on the principal complications of bleeding, hypocalcaemia and recurrent laryngeal nerve injury.

Estimates of the rates of these complications may derive from individual (often retrospective) case series reported in the medical literature or from large-scale prospective audits/registries designed to measure these outcomes.

Interpretation of the data from retrospective case series is prone to several difficulties. First, there may be issues of case selection bias. Even within a consecutive series, the rationale for the selected time period of study is often not stated, and clusters of complications either side of this time interval can significantly affect results, particularly in smaller series. Many publications do not explicitly record the degree of missing data, nor cases excluded from analysis or lost to follow-up.

Second, studies often vary greatly in the definitions of relevant complications, and in the strategy for their detection. This is particularly relevant for hypocalcaemia and recurrent laryngeal nerve palsy (RLNP). Calcium levels may be uniformly measured after surgery, but hypocalcaemia may be defined in several ways: for example, any result below the local reference range; a result below various other biochemical thresholds; the presence or absence of hypocalcaemic symptoms; the requirement for treatment with calcium and/or vitamin D supplements; or combinations of these variables. Such differences in definitions may result in widely disparate estimates of hypocalcaemia rate, even when applied to the same group of patients.¹ Early hypocalcaemia may also be avoided by the use of prophylactic calcium/vitamin D supplements, and protocols vary greatly between surgeons in this regard.

Likewise, the diagnosis of post-operative RLNP is dependent on the incidence and timing of post-operative laryngeal examination.²⁻⁴ Voice changes after thyroidectomy are commoner than documented RLNP, but vocal cord palsy may also be asymptomatic and is often transient. Many surgeons do not routinely arrange post-operative laryngeal examination, and the available methods for performing such examinations differ in their accuracy. It is clear that routine laryngeal examination reveals much higher rates of RLNP than where vocal cord function is assessed solely on the basis of vocal symptoms and that the earlier in the post-operative course such examination occurs, the higher will be the rate of (at least transient) RLNP.^{3,4} For these reasons, rates of RLNP are extremely difficult to compare across retrospective case series.

For both hypocalcaemia and RLNP, the point at which the complication is described as 'permanent' is also variable. Recovery may occur beyond 12 months post-operatively, but data on very long-term follow-up are harder to obtain, and may be incomplete. Results at 6 months may represent a reasonable compromise, but this approach risks overestimation of truly permanent outcomes.

Third, results may be affected by variation in case mix, which is often poorly described. Relevant variables might include, for instance, re-operative versus first-time surgery, indication for surgery (e.g. malignant versus benign), and extent of thyroidectomy and of concomitant central compartment lymphadenectomy.

Fourth, there may be use of 'inappropriate denominators'. For instance, the rate of hypocalcaemia within a series of thyroidectomies will be influenced by the proportion of

cases having bilateral surgery, as hypoparathyroidism will not usually result from unilateral dissection. The overall rate of hypocalcaemia will therefore be artificially low if unilateral lobectomies are included in the denominator. This is often inadequately described in published series. Similar considerations apply to recurrent laryngeal nerve injury, where the rate of RLNP per patient may differ significantly for a given rate per nerve at risk, because bilateral surgery carries twice the risk of injury to one or other nerve.

Finally, retrospective series are prone to publication bias, reflecting individuals' tendency only to publish 'good' results. Genuinely excellent outcomes might thus be reported from some highly specialized centres and represent an aspirational target, but these may not reflect more general, routine practice.

Regarding persistent hypercalcaemia after surgery for primary hyperparathyroidism (HPT), additional considerations apply in interpreting the available literature. Although historical series^{5,6} report cure rates of over 97%, there has been a resurgence of interest in recent years in performing targeted surgery, following localization studies such as sestamibi and ultrasound scanning. Such surgery may be performed via a mini-incision open method or by various endoscopic techniques. Recent case series, frequently reporting only targeted surgery, are therefore restricted to a subgroup of patients, with obvious abnormalities on imaging, who may potentially have larger adenomas and therefore be 'easier' to cure. Conversely, the limitations of pre-operative imaging in excluding multi-gland disease may reduce the cure rate in a proportion of targeted cases, while those with entirely negative imaging are possibly the most difficult to cure, in turn affecting the results of bilateral exploration.⁷ Individual units' or surgeons' results may therefore be dependent not only on the quality of the surgery but on referral practices and case selection, and they can be reliably compared only if information on all their operated HPT cases is made available.

Despite these concerns, some estimate of risk can be made, and **Table 80.1** summarizes recent results from larger case series.

Prospective audits and registries may partly avoid some of these problems, as they may be able to apply more consistent definitions of relevant outcomes, remain contemporaneous and potentially collect uniform information on case mix and other factors which might influence outcomes. They also have the potential to study much larger numbers of patients than would be feasible in most single centres, thereby increasing the precision of any risk estimates.

The best-established national registries examining global results of thyroid and parathyroid surgery are the Scandinavian Quality Register²¹ and the UK-wide Audit of the British Association of Endocrine and Thyroid Surgeons (BAETS).²²

The Scandinavian Quality Register²¹ was established in 2004 and receives data on thyroid, parathyroid and adrenal surgery, submitted from multiple centres across Sweden (and Denmark). Coverage is high, with participating units accounting for over 90% of the cases currently being performed in Sweden, and with a full spectrum of thyroid pathology being represented.

The BAETS National Audit²² was initiated in 2000 and currently receives data on thyroid, parathyroid, adrenal and endocrine pancreatic surgery from BAETS members, via a standardized electronic pro forma. The distribution of pathology represented is similar to that of the Scandinavian Registry, although coverage within the UK is lower, at about 35% of thyroid cases (estimated from English Hospital Episode Statistics).

Results from both registries have been published in national reports^{21, 22} and, as is apparent in Table 80.1, show rates of complications generally higher than the best results previously reported in the medical literature.

It is likely, therefore, that they represent a more realistic assessment of the true rate of complications in routine practice, for the reasons alluded to above.

Even within large, specifically designed registries, however, difficulties remain in providing reliable estimates of risk. These include the following:

- **Data entry issues.** Registries and large prospective audits are dependent on entry of data by external agents, such as by hospital coding departments or individual members of a host specialty association. Such data may therefore be liable to incomplete case acquisition,

TABLE 80.1 Summary rates of complications in recent large case series and national registries

	Reference	Re-exploration for haemorrhage	Early RLNP	Permanent RLNP	Early hypocalcaemia*	Late/permanent hypocalcaemia*	
Single centres	Burkey et al ⁸ (n = 13817) (Thyroid and parathyroid)	0.3%

† Routine post-operative laryngoscopy

variations in how the definitions of index complications are applied, incorrect coding and data transposition errors.

- **Data quality issues**, in particular the possibility of duplicate entries, and the rates of missing data.²² The latter are particularly liable to affect estimates of risk, as it is feasible that poorer outcomes may be more frequent within the cohort whose data on that outcome are missing.
- **Choice of a suitable period of analysis**, balancing the need to provide the most contemporaneous data against the advantages of greater patient numbers which might be provided by a longer time period of study. Comparisons between individual units' or surgeons' results may be especially prone to misinterpretation in this regard, due to the greater random variation existing around point estimates of risk with small patient numbers.

These considerations aside, it is likely that national registries provide the most realistic estimates of risk for the purposes of consent and provision of benchmarking data.

OUTCOMES: COMPARISON BETWEEN PROVIDERS

A natural use of audit and registry data is to compare surgical performance between surgeons or hospitals. This may be useful for individual surgeons, to reassure themselves that their practice is satisfactory, or to identify areas where performance might be improved, and so enhance the quality of care. Such considerations may also contribute significantly to surgeons' appraisal processes and, in the UK, to revalidation with professional regulatory bodies (General Medical Council). With appropriate refinement, such data may also assist patients and service commissioners in selecting hospitals or surgeons.

This issue has recently gained increasing attention in the UK, with the introduction of NHS England's Consultant Outcomes Publication process,²³ through which individual surgeons' outcomes for various subspecialty procedures have been made available in the public domain. For thyroid surgery, this was first made publically available in 2013, using data derived from the BAETS audit, via a web-based portal. These data have been updated annually since 2013.²⁴

In addition to the above-mentioned problems, further difficulties exist in using audit data for this purpose, particularly issues of random variation and case mix.

Even when the overall risk of a surgical complication is known, the exact number of events observed in any given series of operations will be subject to some random variation. Statistical methods can help identify when the observed variation is within that expected by chance, and traditionally confidence intervals are calculated, outlining the limits beyond which chance is less likely to explain the observed variation. Selection of appropriate confidence limits, however, is difficult. Set too widely, they risk designation of all surgeons as 'within control limits', and so miss those whose performance may in fact be lower

than average. Set too tightly, they risk inappropriate identification of surgeons as 'outliers', with the potential for damage to reputation and career.

With any operation, the risk of certain complications occurring may also be affected by case mix, for example variation in patient characteristics, such as age or comorbidity, or in surgical complexity. Surgeons taking on more complex cases might be expected to have a higher complication rate, even if their performance is no worse than the average.

In some surgical fields, the factors affecting results are well defined, allowing for risk adjustment, to allow for case mix. In endocrine surgery, however, there are no established, validated models for this purpose.

For thyroidectomy, factors identified from individual case series as potential confounders include:

- patient age and gender^{10, 18, 25}
- extent of thyroid resection (lobectomy versus subtotal versus total thyroidectomy)^{10, 14, 16, 18, 25}
- re-operative versus first-time surgery^{10, 14, 16, 25, 26}
- malignant versus benign disease^{14, 18, 26}
- Graves' disease versus other benign diseases¹⁴
- central neck dissection, in addition to thyroidectomy^{27, 28}
- goitre size and retrosternal versus cervical goitre^{29, 30}
- surgeon caseload/experience^{19, 31, 32}

As mentioned above, however, it is difficult to combine the results from these disparate studies into a unified mathematical model of risk-adjustment, and it is likely that only analyses from prospective registries will have the power and consistency of definition of relevant variables to do this. A preliminary, multivariate analysis from the BAETS dataset³³ has been a first step towards this, generating estimates of odds ratios for those factors most strongly affecting certain complications, namely:

- for bleeding: extent of thyroidectomy and patient age
- for early hypocalcaemia: Graves' disease, age, gender and level 6 node dissection
- for late hypocalcaemia: cancer diagnosis and particularly level 6 node dissection.

It must also be recognized that risk-adjustment models can only make allowance for those variables included within the original dataset, and that other, unrecorded, factors may influence results, for instance patient comorbidity or ethnicity^{34, 35} or thyroid volume.³⁰

There remains an urgent need to explore this issue further, if accurate comparison is to be made between surgeons, on the basis of registry data.

OTHER USES OF AUDIT DATA

Published registry data^{21, 22} also provide interesting insights into:

- use and accuracy of pre-operative investigations, such as fine-needle aspiration cytology (FNAC)

- trends over time in the management of certain conditions, e.g. the gradual replacement of subtotal by total thyroidectomy for most benign conditions, or the increasing trend to perform pre-operative localization studies in first-time primary hyperparathyroidism
- management and staging of thyroid cancer, particularly variations in the extent of 'prophylactic' lymph node surgery
- rare diseases, including medullary thyroid cancer and parathyroid cancer
- trends in the use of technological innovations, such as a slow increase in intra-operative laryngeal nerve monitoring, more rapid increase in the use of vessel sealing devices, such as the Harmonic scalpel or Ligasure, and decreasing use of intra-operative PTH monitoring during parathyroidectomy.

KEY POINTS

- Assessment of complication rates of thyroid and parathyroid surgery from published data is prone to many limitations.
- Large case series and national registries suggest the following range of risk estimates:
 - Re-operation for bleeding 0.2–4.2%.
 - Early/transient recurrent laryngeal nerve palsy 0.7–5.1%.
 - Persistent recurrent laryngeal nerve palsy 0.2–1.0%.
 - Persistent hypocalcaemia (bilateral thyroid resection) 0.3–6.3%.
- There is a need for validated risk-adjustment models to be developed, if outcomes are to be accurately compared between healthcare providers.

CONCLUSION

Surgeons are coming under increasing scrutiny and they need to demonstrate that their outcomes are acceptable, for their own satisfaction in addition to meeting the needs of patients, commissioners and regulatory bodies. This is particularly pertinent to thyroid and parathyroid surgery, as outcomes are clearly under the direct influence of the operating surgeon, and publication of these outcomes is already occurring in the public domain.

Estimation of complication rates from published case series is highly problematic. Participation in national registries contributes to more accurate analysis of outcomes, and is recommended to all surgeons with an interest in thyroid and parathyroid surgery.

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: thyroid, thyroidectomy, litigation, malpractice, informed consent and medicolegal.

INTRODUCTION

England and Wales have among the highest level of personal injury damages awards in the world, with an increasing frequency of claims. In England, the number of surgery claims received by the National Health Service Litigation Authority (NHSLA), which manages negligence and other claims against the NHS on behalf of its member organizations, rose by 66% from 2009 to 2013 with General Surgery representing 33.8% and Others – including ENT – 2.5%. Since 2011 the annual payments made by the NHSLA in respect of clinical negligence have exceeded a billion pounds per year.

Clinical negligence claims in 2013/14 were 11 945 compared with 10 129 in 2012/13. In 2013/14, 44% of clinical negligence claims were resolved without a payment and 79% of the small number of cases that were decided in court (historically less than 5%) were successfully defended at trial.

THE LAW

A successful claim of medical negligence is required to prove that:

- the treatment received fell below the reasonable/accepted standard of competence that a patient had a right to expect – **breach of duty of care**
- the patient suffered an injury or loss – **damage**

- it is more likely than not that the injury would not have occurred or been less severe if appropriate treatment had been given, i.e. there is a link between the breach of duty and the injury – **causation**.

The claim must be brought within a specific time after the injury – **period of limitation**.

Successful damages awards will reflect two elements:

- pain, suffering ‘loss of amenity’
- financial loss and extra expenses caused by the injury.

THE LIKELIHOOD AND FACTS AROUND LITIGATION AND THYROID SURGERY

Legal systems around the world differ but, in general, cases that arise from medical negligence that end up in court are civil prosecutions. In relation to thyroid surgery the studies described below provide some insight into the likelihood and outcome of claims or prosecutions reaching court subsequent to thyroid surgery.

Europe

From England, the NHSLA recorded 17 claims related to thyroidectomy and vocal cord dysfunction between 1995 and 2005.¹

A German report² reviewed outcomes of 75 thyroidectomy-related malpractice claims in which expert opinion was provided by a single ‘witness’ over a 15-year period. Unilateral vocal cord palsy was the cause of the action in 28%, bilateral vocal cord palsy in 29%, hypoparathyroidism (all patients requiring calcium and vitamin D) alone in 13%. In 37% of the cases more than one major complication occurred. The claimant was successful in 77% of bilateral RLN palsies, 24% of unilateral palsy and 25% in post-operative hypoparathyroidism.

A prior German study³ found that between 1975 and 1998 thyroidectomy represented 1% of litigation cases. A successful claim was more likely if a second operation was necessary, if the goal of the operation had been missed, or if any kind of complication was followed by a fault in post-operative care.

USA

Three studies are based on data from the Physicians Insurers Association of America said to represent 60% of privately insured physicians in the United States and 25% of malpractice claims.

Over a 24-year period, approximately 2 585 000 thyroidectomies were performed. The authors⁴ estimated from their study that 5.9 claims are filed per 10 000 thyroid operations. Of thyroidectomy-related claims, 11% went to trial and a third (2 per 10 000) resulted in an indemnity payment.

Between 1986 and 2007, 112 closed claims (claims made irrespective of whether dismissed, settled or went to trial) were identified involving iatrogenic vocal cord palsy.⁵ Of these, 42% resulted from thyroid and parathyroid surgery. Failure to recognize the complication and consent issues were responsible for 36% and 19% of the claims respectively.

A review of 315 closed malpractice claims related to otolaryngology–head and neck surgery between 1978 and 2007 found that nerve injuries accounted for 20.3% of claims including the accessory (5.4%) and recurrent laryngeal nerve (3.5%); 5.1% of claims related to thyroidectomy.⁶

Two studies from the USA have assessed thyroid-related claims that went to court, the cases identified by review of legal databases.

Of 30 thyroid-related post-verdict cases (1987–2000), 33% were associated with surgical complications.⁷ In respect of nine RLN injuries, the claim related to lack of informed consent in seven cases. In six of eight cancer-related cases, the claim related to delayed diagnosis.

The second study identified 33 cases that went to court in relation to alleged negligence associated with thyroid surgery between 1989 and 2009.⁸ Of these, 46% involved RLN injury (five bilateral, five unilateral, five unspecified), and 6% delayed diagnosis. The majority of the seven claims where the outcome favoured the plaintiff were filed because of a lack of informed consent.

Finally, a review of 81 spinal accessory nerve injury claims that went to trial (1985–2007) found that the causative procedure was lymph node biopsy (68%), and neck

dissections in only 5%. Lack of informed consent and failure to diagnose the injury were the basis of the allegation in 21% and 20% respectively.⁹

CONSENT TO SURGERY

The importance of adequate informed consent prior to an intervention cannot be overstated, most importantly for best patient care and, secondly, as indicated above, your avoidance of undesired consequence if a claim of negligence is submitted.

In the UK, the General Medical Council document *Consent: patients and doctors making decisions together*¹⁰ includes imperatives (as an overriding duty) with regard to providing information on diagnostic uncertainty, options for treatment, the potential benefits and risks. In addition the document recommends that it is your duty to ensure patients understand information and how this can be enhanced.

Further clarification on who may obtain consent, what should be discussed and how it should be recorded is provided in *Good surgical practice* published by The Royal College of Surgeons (2014).¹¹

Risks will usually be ‘side effects, complications, failure of an intervention to achieve the desired aim’. Additional information in the form of information leaflets can be useful, and is recommended, but should not be considered as a replacement for a thorough discussion with the patient.¹²

Historically if a claim for litigation arose in the UK, a legal test (*Bolam*) was applied to determine whether the conduct of a doctor could be supported by a responsible body of medical opinion. In the *Sidaway* judgment that followed it was for doctors to decide how much to inform a patient of the risks of a treatment. Since early 2015, following a judgment in the Supreme Court (*Montgomery v. Lanarkshire Health Board*), this no longer applies to the law on consent. It is now required that a doctor takes ‘reasonable care to ensure that the patient is aware of any material risks involved in any recommended treatment and of any reasonable alternative or variant treatments’. A material risk is one to which a reasonable person would be likely to attach significance, i.e. a risk that might alter the particular patient’s decision.

WHEN THINGS GO WRONG

In the UK, since 2014, NHS providers have been required to comply with a duty of candour. It places a legal duty on hospitals and other providers to inform and apologize to patients, or their families if there have been mistakes in their care that led to death, severe or moderate harm. The duty of candour legislation applies to all Care Quality Commission registered providers since 2015. This contractual statutory requirement is, of course, in addition to the ethical duty of a doctor to inform patients and their families when an incident has occurred.

*Good surgical practice*¹¹ emphasizes the requirement to inform patients as soon as possible of any harm that has occurred, to apologize and to offer reassurance.

A useful overview of the background and threshold levels at which disclosure should be applied can be found via the RCS website.¹³

A CLAIM ARISES...

The plaintiff's/defendant's solicitors will instruct an expert witness to provide a report on possible breach of duty and/or condition and prognosis. An expert witness should provide, from knowledge and experience, an independent and balanced opinion **for the court** (not the instructing lawyers) on the facts of a case, an explanation of 'technical' issues, a view on what is considered 'reasonable', and matters of causation (symptoms or condition) that have arisen as a result of damage.

Some of the typical issues on which an expert witness may be asked to provide an opinion in a thyroid/parathyroid medical negligence claim are discussed below with current relevant 'evidence'.

IMPACT OF A DELAY IN CANCER DIAGNOSIS

For patients with differentiated or medullary thyroid cancer there are staging and prognostic scoring symptoms that allow an opinion on outcome from the time of actual diagnosis. The expert, in relation to the impact of delay, is unlikely to be able to state (as is often asked) what might have been the prognosis at a previous point in time. The evidence base on the clinical significance of any delay in the diagnosis of thyroid cancer is very limited.

A study using data from the Korean Central Cancer Registry¹⁴ assessed the impact of delay from thyroid cancer diagnosis to first curative treatment and found the small number of deaths in these patients precluded precise estimates. The lowest mortality was observed for patients who had surgery between 1 and 4 weeks after diagnosis but there was no clear pattern of increased risk found with delay of up to 12 weeks in thyroid cancer.

In a study cohort of 1355 patients with DTC,¹⁵ factors influencing the prognosis of patients who died found that cancer mortality was 4% in patients who underwent initial therapy within a year, compared with 10% in the others. The 'delay' group had twice the cancer mortality at 30 years (6% compared to 13%).

In contrast, a study including 47 patients with a delayed diagnosis of differentiated thyroid cancer as a consequence of initial benign cytology – median delay 52 months; range 13–205 months – found no difference in 5-year disease-free survival when compared with a historical cohort of patients treated with 'immediate' surgery.¹⁶

FAILURE TO PERFORM A SECOND FNA OF A SUSPICIOUS THYROID NODULE

False negative thyroid FNA rates of <3%–10.2%^{17, 18} are reported in patients subsequently confirmed as having thyroid cancer. As suspicious features on ultrasound are reported in 90% of patients with thyroid cancer and false negative FNA,¹⁷ inadequate cytology (Thy1) or benign cytology (Thy2) in association with sonographic features

of concern indicates at the very least a need for further FNA as recommended in the British Thyroid Association Guidelines.¹⁹

RECURRENT LARYNGEAL NERVE PALSY AND INTRA-OPERATIVE NERVE MONITORING

Risk factors for vocal cord palsy include Graves' disease, post-operative bleed, retrosternal, malignant, recurrent benign and malignant goitre, no identification of the recurrent laryngeal nerve.^{20–23}

At thyroidectomy, intermittent intra-operative nerve monitoring (IONM) is useful for identification of the recurrent nerve and its branches, but loss of signal in at least one in three cases is not associated with post-operative nerve dysfunction. The limitation of intermittent IONM is that injury to the nerve from whatever cause is identified after the event. Implicit in its use is that IONM is carried out in the recommended manner.²⁴

There are two key issues in the context of litigation.

- There is a lack of evidence that intermittent IONM is associated with a decrease in the risk of permanent vocal cord palsy at first time^{25–28} and reoperative thyroidectomy.²⁸ Temporary nerve dysfunction in both operative scenarios appears to be reduced with IONM use.^{25, 29}
- If nerve monitoring is used, what is the appropriate next step if there is loss of signal on the first side of a bilateral thyroid procedure? Continue with the second side or abandon the operation and await laryngoscopy? The risk of bilateral vocal cord palsy at thyroidectomy is variously reported as 1 to >3 per thousand cases.^{30, 31} The next step will clearly depend upon the indication for surgery (benign vs malignant disease), the experience of the surgical team, the nature of the signal loss and familiarity with the technicalities of IONM. Two studies from the same unit^{32, 33} propose staged thyroidectomy in this worrying scenario; both have limitations that affect the interpretation of their results.

The natural evolution from intermittent to continuous IONM and evolving technology may help resolve the limitations associated with its use.

APPROPRIATENESS OF AN INPATIENT STAY OF LESS THAN 24 HOURS AFTER THYROIDECTOMY IN THE CONTEXT OF NECK HAEMATOMA/HYPOCALCAEMIA

The instructing solicitors might enquire as to the safety of a less than 24 hour inpatient stay for a patient who developed neck haematoma after day-case surgery.

Risk factors for post-operative bleeding include reoperative surgery and bilateral procedures. Life-threatening neck haematoma that requires reoperation will occur in 0.6–2.1% of cases.^{31, 34–37} Although most will occur within 6 hours of surgery, 20–37% will occur after 6–24 hours and 0–10% after 24 hours.^{35, 36, 38}

An assessment of parathyroid function after completion or total thyroidectomy is mandatory. National specialist databases record post-operative hypocalcaemia rates of 21% (British Association of Endocrine and Thyroid Surgeons) after total thyroidectomy for MNG and, from Scandinavia, 6.4% patients required i.v. calcium after bilateral thyroidectomy.³⁴

Post-operative measurement of serum calcium/PTH and/or routine calcium supplementation is used to identify and minimize risks of significant hypocalcaemia. Be aware that in patients who become hypocalcaemic, the lowest level of serum calcium is on or after the second post-operative day.^{39,40} If a patient is discharged too soon, they may develop severe untreated hypocalcaemia.

EXPERIENCE OF THE SURGEON

There are an increasing number of publications to support the concept that high-volume thyroid surgeons have better patient outcomes than low-volume surgeons. This is

reported for post-operative neck haematoma,^{41,42} hypocalcaemia,^{42,43} adequacy of thyroidectomy in patients with thyroid cancer⁴⁴ and RLN palsy.^{22,42,43} There is, however, little consistency in what constitutes a high-, intermediate- or low- volume surgeon (**Table 81.1**).

Surgeon experience is particularly important in relation to paediatric cases.⁴⁵ Children whose thyroidectomy or parathyroidectomy was performed by a low-volume surgeon (<30 endocrine cervical per year) had more endocrine complications than those whose operation was performed by a high-volume surgeon (11% compared to 5.6%). Sosa⁴⁶ reported complication rates after thyroidectomy/parathyroidectomy in 1199 patients 17 years old or younger. Children had significantly higher endocrine-specific complication rates than adults after parathyroidectomy and thyroidectomy. Even when thyroidectomy is performed by high-volume surgeons, 7% of patients will require intravenous calcium⁴⁷ and post-operative hypocalcaemia is reported in 34% of children <10 years of age.⁴⁸

TABLE 81.1 Variation in classifications of thyroid surgeon operative volumes

Author	Year	Low volume	Intermediate volume	High volume
Sosa ⁴⁹	1998	1–9 per year		>100 per year
Tuggle ⁴⁵	2008			>30 per year
Kandil ⁴²	2013	<10 in 10 years	10–99 in 10 years	≥100 in 10 years
Loyo ⁴³	2013	≤9 per year	9–23 per year	>23 per year
Dehal ⁴¹	2014	<10 in 10 years	10–99 in 10 years	≥100 in 10 years
Adkisson ⁴⁴	2014	–		≥30 per year
Landerholm ⁵⁰	2014	–	<50 per year	–

KEY POINTS

- Ensure that thyroid function and serum calcium are normal prior to and after surgery. This is your responsibility unless someone else has agreed to take over these aspects of care.
- Ensure at the very least that the content and legibility of your clinical record, the consent form and the operation note would stand up to scrutiny by an 'expert' third party.
- The contents of an operation note should include that indicated in *Good surgical practice*. It would seem entirely appropriate and necessary in the context of thyroid/parathyroid surgery (for your potential benefit in a claim) to record findings related to the parathyroid glands and their preservation as well as the recurrent laryngeal nerves.
- Ensure that for complex patients (e.g. the non-compliant thyrotoxic patient) there is adequate peri-operative support from endocrinology colleagues.
- Post-operative laryngoscopy should be performed in a patient with post-operative voice symptoms.
- The defence of a claim will depend upon your statement of:
 - what you did – were you the appropriate surgeon?
 - why you did it – what were the indications for operation?
 - what your notes say
 - how you managed the complication(s).
- Be reassured that complications are not necessarily due to error.

CLINICAL EVALUATION OF THE PITUITARY PATIENT

Sean Carrie, John Hill and Andrew James

Introduction	905	Neuro-ophthalmological features of pituitary disease.....	910
Clinical manifestations of hormone deficiency.....	905	Conclusions	913
Clinical manifestations of excess hormone secretion.....	906	References	913

SEARCH STRATEGY AND EVIDENCE BASE

Data in this chapter may be updated by a Medline search using the keywords pituitary disease and pituitary adenoma and focusing on clinical features and ophthalmological assessment. The evidence in the chapter is mainly levels 3 and 4 but also with some level 2 evidence.

INTRODUCTION

The commonest lesion arising in the pituitary gland is a pituitary adenoma.¹ The clinical manifestations of pituitary adenomata may relate to their endocrine effects of hormone deficiency, hormone excess or a combination of both.² In addition there may be a physical effect related to a space-occupying lesion. Occasionally the presentation may be acute with infarction into a previously undiagnosed pituitary adenoma. Increasingly, with the widespread use of sophisticated imaging techniques, lesions within the pituitary gland may be identified before they become symptomatic, the so-called 'pituitary incidentaloma'.³

CLINICAL MANIFESTATIONS OF HORMONE DEFICIENCY

The syndrome of pituitary hyposecretion occurs when the mass effect of a lesion within the pituitary gland compresses the normal tissue leading to a reduction or absence of the normal secretion of pituitary hormones. This resulting hypopituitarism ([Figure 82.1](#)) affects the reproductive system most commonly.⁴ Typically, women experience oligomenorrhoea or amenorrhoea with associated infertility; men commonly experience symptoms of hypogonadism, with increasing loss of libido and erectile dysfunction and associated infertility. There is a characteristic delayed onset of puberty in those adolescents affected.

Figure 82.1 Hypopituitarism.

A specific effect of growth hormone hyposecretion in children and adolescents may result in reduced growth velocity and short stature. Thyrotropin (TSH) deficiency leads to mild hypothyroidism with low but not absent levels of circulating T4 and T3. The thyroid is capable of low-grade autonomous secretion of thyroid hormones so symptomatically and biochemically central hypothyroidism is not as profound as primary thyroid failure. It is, however, often missed due to 'TSH-only' screening policies in primary care when a TSH can be normal but inappropriately so for the low levels of circulating T4 and T3.

Adrenocorticotrophic hormone (ACTH) deficiency results in symptoms of lethargy, postural hypotension and electrolyte disturbance (hyponatraemia) but, again, this may not become manifest until the patient with a pituitary adenoma is placed under physiological stress with an intercurrent infection or illness and is unable to mount an appropriate cortisol stress response. Varying degrees and combinations of hormone insufficiency may be manifest in a patient with a pituitary adenoma and invariably present with insidious onset.

Prolactin (PRL) is a pituitary hormone related to the lactation response, with its own functional suppressive effect on pituitary luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which constitutes nature's own 'natural contraceptive'. It is under tonic inhibition from hypothalamic dopamine delivered down the pituitary stalk. As a result, anything interrupting the secretion of dopamine can cause an ambient rise in PRL, commonly between 1000 mU/L and 5000 mU/L (NR < 450), often referred to as 'stalk hyperprolactinaemia'.⁵ PRL is therefore the last hormone to become deficient in the presence of a pituitary lesion. Clinically hypoprolactinaemia is significant only if it occurs in the postpartum period as part of Sheehan's

syndrome. This is a vascular problem and not usually related to the presence of a pituitary adenoma.

Diabetes insipidus is a deficiency of one of the posterior lobe pituitary hormones, arginine vasopressin (AVP), previously known as antidiuretic hormone (ADH). Diabetes insipidus is much rarer at presentation in patients with pituitary adenomas whatever their size and, if present, alternative diagnoses, such as craniopharyngiomas, germinomas, metastases or inflammatory pituitary lesions (sarcoidosis, Generalized Polyangiitis, Langerhans cell histiocytosis) should be considered. Of course, surgical intervention is a recognized cause of diabetes insipidus which may be just transient or permanent following transphenoidal or transcranial surgery. The clinical effects of pituitary deficiency are shown in [Table 82.1](#).

Pituitary hormones can be given pharmacologically (e.g. GH, AVP (DDAVP), LH (HCG) or FSH) or the end-organ hormone can be replaced (e.g. hydrocortisone, thyroxine, testosterone, oestrogen/progesterone) to ensure homeostasis titrated to normal physiological and clinical function.

CLINICAL MANIFESTATIONS OF EXCESS HORMONE SECRETION

Excessive hormone secretion by a pituitary adenoma produces several classical clinical syndromes ([Table 82.2](#)).

Prolactinoma

The commonest type of secreting pituitary adenoma is the prolactinoma, accounting for approximately 40% of adenomas.¹ Prolactin is a peptide hormone that stimulates mammary tissue to produce milk. The hormone also counteracts the effects of dopamine, which is thought to be responsible for sexual arousal. This antagonist effect of PRL is thought to cause reduced libido and impotence.

Until the 1970s surgery was the mainstay of treatment for prolactinoma but, following the introduction of the dopamine 2 receptor agonist Bromocriptine, the majority of prolactinomas are now treated medically. Bromocriptine has a significant side effect profile in certain patients (nausea, nasal stuffiness, postural hypotension) and hence newer dopamine agonists such as

TABLE 82.1 Pituitary hormone deficiency: modes of presentation

Hormone deficiency	Presentation
Hypogonadism (LH/FSH)	Amenorrhoea Infertility Erectile dysfunction Loss of libido
Hypoadrenalism (ACTH) (hypocorticosteroidism)	Malaise Hypotension Hypoglycaemia Hyponatraemia
Hypothyroidism (central (TSH))	Tiredness, lethargy, dry hair, dry skin
Growth hormone deficiency	Lethargy, reduced exercise capacity, central adiposity, reduced muscle mass, premature coronary artery disease, reduced bone density and short stature
AVP (ADH) deficiency	Diabetes insipidus (polyuria/polydipsia) Hypernatraemia Dehydration/coma

TABLE 82.2 Excess pituitary hormone secretion

Hormone in excess	Clinical manifestation
Prolactin (prolactinoma or stalk compression)	Galactorrhoea Amenorrhoea infertility and loss of libido
Growth hormone	Acromegaly
ACTH	Pituitary-dependent Cushing's disease
TSH (TSHoma)	Central thyrotoxicosis (rare)
FSH/LH (gonadotrophinoma)	Macrogonadism (extremely rare)

Figure 82.2 Clinical features of hyperprolactinaemia.

Quinagolide (non-ergot) and Cabergoline have become useful alternative drugs in the management of prolactinomas. Dopamine agonists will reduce PRL levels whatever the cause but in addition will cause significant tumour shrinkage and involution in true prolactinomas – often diagnostically so. Non-shrinkage of a pituitary lesion (on serial MRI) despite a good suppression of PRL means that the lesion is unlikely to be a true prolactinoma and the elevated PRL is due to ‘stalk hyperprolactinaemia’. This may change management towards a more surgical approach.

Recent concern has been raised about the potential for Cabergoline to cause cardiac valvulopathy with long-term high-dose use.⁶ The most recent analyses, however, reassure us that this is unlikely to occur in prolactinoma patients in the doses we use in endocrine practice.⁷

CLINICAL FEATURES

See [Figure 82.2](#) and [Table 82.3](#).

The presenting features of a prolactinoma are related to hyperprolactinaemia, the mass effect of the tumour and other associated endocrine insufficiencies or more rarely pituitary apoplexy.

HYPERPROLACTINAEMIA

The features of hyperprolactinaemia in females and males are shown in [Table 82.3](#). Osteoporosis occurs in both

TABLE 82.3 Clinical features of prolactinoma/hyperprolactinaemia

Patient gender	Clinical features
Female	Galactorrhoea Loss of libido Infertility Irregular menses Osteoporosis
Male	Loss of libido Gynaecomastia Infertility Osteoporosis

males and females as a result of oestrogen and testosterone deficiency, and bone density should be assessed appropriately as part of the initial and long-term management strategy.

The tumour may present with features related to that of an expanding mass within the pituitary fossa, reduction in visual fields and/or acuity as a result of pressure on the under surface of the optic chiasm, or more rarely with involvement of cranial nerves within the cavernous sinuses (III, IV, VI). Headache may be present and is considered to be related to stretching of the overlying dura. Very large prolactinomas may present with hydrocephalus and deterioration in cortical brain function with lateral extension resulting in temporal lobe

symptoms which usually resolve with surgical resection or more commonly dopamine agonist-induced tumour involution.

DIFFERENTIAL DIAGNOSIS OF HYPERPROLACTINAEMIA

Hyperprolactinaemia is also associated with conditions other than pituitary adenomas (Table 82.4). In particular 'stalk compression' of the hypothalamic pituitary pathway by any form of mass lesion in the pituitary fossa may interrupt dopamine inhibition of prolactin-secreting cells resulting in hyperprolactinaemia as previously mentioned.

Acromegaly

Acromegaly is a disorder of adults as a consequence of the overproduction of growth hormone which results in significant changes to the patient's appearance over considerable time. If growth hormone excess occurs before fusion of the epiphyses in adolescence, the condition is known as pituitary gigantism.

The commonest underlying cause of acromegaly is that of a spontaneously occurring pituitary adenoma, although rarely it may be a result of a genetic syndrome such as multiple endocrine neoplasia type I (MEN I – along with parathyroid and pancreatic endocrine tumours), GSP mutations, McCune–Albright syndrome⁸ or more recently familial acromegaly due to mutation in the aryl hydrocarbon receptor protein.⁹

Pituitary tumours occasionally co-secrete other hormones such as growth hormone and prolactin (somatomatotroph adenomas) occasionally with the additional secretion of TSH causing central hyperthyroidism. Co-secretion of prolactin often indicates a co-responsivity to the suppressive effects of dopamine agonists.

INCIDENCE

Acromegaly has an incidence of 3–4 per million per year with an incidence in the general population of

TABLE 82.4 Differential diagnosis of hyperprolactinaemia

Underlying cause	Differential diagnosis
Physiological	Pregnancy Breastfeeding Mental stress
Drugs	Drugs antagonizing the effects of dopamine including major tranquilizers (phenothiazines and haloperidol) Metoclopramide Domperidone and methyldopa and the combined oral contraceptive pill
Diseases	Chronic renal failure Hypothyroidism Bronchogenic carcinoma Sarcoidosis Idiopathic

approximately 60 cases per year. This condition affects all races and both sexes with patients typically presenting between the ages of 40 and 50 years.¹⁰

CLINICAL FEATURES

Acromegaly has an insidious onset with features of bone and soft-tissue overgrowth. The initial features include changes in shoe size, ring size and coarsening of facial features (Figure 82.3). However, symptom onset is non-specific with sweating, lassitude and musculoskeletal pain resulting in a concomitant delay of diagnosis. The mean time to diagnosis is 8 years with a range of 6–10 years.¹¹

Table 82.5 includes the features commonly associated with a diagnosis of acromegaly. Consideration of these should prompt further investigation.

Acromegaly is recognized as causing reduction in life expectancy by up to 10 years in those untreated.¹¹ Suppression of growth hormone levels to < 1 µg/L and normalization of IgF1 (age and sex adjusted), returns the death rate to that expected of the normal background population.¹² The increase in mortality is related to duration of symptoms prior to diagnosis, disease duration, increasing age and presence of complications at diagnosis.¹³

Reduction in morbidity and mortality relies upon prompt diagnosis and early investigation and treatment. General practitioners and primary care physicians should be alert to the possibility of acromegaly in patients presenting with coarse features, excess sweating, increased ring or shoe size and sleep apnoea,¹⁴ resistant hypertension unresponsive to three or more agents and/or difficult-to-control diabetes.

Cushing's disease

Cushing's syndrome is the term applied to a wide group of disorders with symptoms and signs due to chronic exposure to excess glucocorticoid, irrespective of the underlying cause. The commonest cause is exogenous steroid treatment.

Cushing's disease is the term applied to Cushing's syndrome of pituitary origin (pituitary-dependent adrenal hyperplasia). The disease was described by Harvey Cushing in 1932 as pituitary basophilism.

Table 82.6 shows the causes of endogenous Cushing's syndrome and their approximate frequency.

AETIOLOGY

Cushing's disease often presents with non-specific symptoms which may be slowly progressive and therefore missed as a developing condition in primary care. The mean time to diagnosis after the first presenting symptom is 6 years.¹⁵ Chances to diagnose are often missed in clinical consultations. Cushing's disease mimics common conditions such as obesity, poorly controlled diabetes and hypertension and consideration may not be given to its possibility by the treating doctor.

Figure 82.3 Clinical features of acromegaly.

TABLE 82.5 Features commonly associated with acromegaly

Disorder type	Feature(s)
Musculoskeletal	Macroglosia, enlargement of lips, hands and feet Prominent brow Prognathism, interdental separation Skeletal abnormalities – degenerative osteoarthritis Carpal tunnel syndrome and hearing loss
Cardiovascular	Hypertension Cardiomyopathy Arrhythmias Heart failure
Respiratory	Obstructive sleep apnoea
Metabolic	Diabetes mellitus Excess sweating
Gastrointestinal	Colonic polyps

TABLE 82.6 Aetiology of Cushing's Syndrome

Cause of Cushing's Syndrome	F:M	%
ACTH-dependent ^a		
Cushing's disease	3.5:1 ^b	70
Ectopic ACTH syndrome	1:1	10
Unknown source of ACTH ^c	5:1	5
ACTH-independent	4:1	10
Adrenal adenoma	1:1	5
Adrenal carcinoma		<2
Other causes (PPNAD, AIMAH, McCune-Albright)		

Note: PPNAD primary pigmented nodular adrenal disease, AIMAH ACTH-independent massive adrenal hyperplasia.

^a In women 9:1 ratio of Cushing's disease to ectopic ACTH

^b Male preponderance in children

^c Patients may ultimately prove to have Cushing's disease, ectopic CRH <1% of all cases of ACTH-dependent disease

Figure 82.4 Clinical features of Cushing's disease.

Untreated, Cushing's disease is associated with a 50% mortality rate at 5 years, commonly as a result of cardiovascular complications.¹⁶ Significant morbidity results from irreversible organ damage over a prolonged period.

CLINICAL FEATURES OF CORTISOL OVERPRODUCTION

The features of excess cortisol exposure are well described – the typical central obesity, plethora and spontaneous purpura (Figure 82.4). However, it is important to realize that certain features are of more diagnostic value than others (Table 82.7).¹⁷

It is important to assess the use of exogenous glucocorticoid and in particular the use of inhalers and skin creams. Several photographs of the patient's appearance over a period of months to years may also indicate the developing changes in appearance associated with Cushing's disease.

TABLE 82.7 Clinical value of symptoms and signs of Cushing's disease

Clinical diagnostic value	Symptoms and signs
High	Skin atrophy Proximal myopathy and wasting Bruising Childhood growth arrest Osteoporosis
Medium	Oedema Striae Moon face Facial hirsutism Labile mood
Non-specific	Buffalo hump Hypertension Diabetes mellitus Plethora Acne

NEURO-OPHTHAIMOLOGICAL FEATURES OF PITUITARY DISEASE

The relationship between the optic chiasm and pituitary gland is intimate with lesions expanding superiorly out of the pituitary fossa impacting on the chiasm.

Afferent visual pathway

The optic nerves transverse the orbit and pass through the optic canal where their dural sheath fuses to the wall of the canal. In up to 4% of patients the optic nerves may be dehiscence of bone as they traverse the lateral wall of the sphenoid sinuses.¹⁸ The intra-cranial portion of the optic nerve passes superiorly and medially to form the optic chiasm. Chiasm is named after the Greek letter chi but in life more closely resembles the letter H. Within the chiasm 50% of the axons within each optic nerve decussate to run in the opposite optic tract to the centres higher in the brain.

The location of the chiasm relative to the pituitary gland varies. In the vast majority it lies directly above the pituitary fossa but in a minority of patients it may either be anterior (pre-fixed), or posterior to the pituitary (post-fixed) above the dorsum sellae. On average¹⁹ it lies approximately 10 mm above the pituitary gland, although in a minority (14%) it may be as little as 2 mm above it.

Efferent pathways

Within the cavernous sinus on either side of the pituitary fossa lie the cranial nerves responsible for eye movements and papillary responses to light. Figure 82.5 shows the relationship of the oculomotor, trochlear and abducens nerves within the cavernous sinuses. The oculomotor is the nerve most frequently involved by pituitary adenoma expansion. Also within the cavernous sinuses lie the ophthalmic and maxillary divisions of the trigeminal nerve.

Figure 82.5 Cavernous sinus.

Ophthalmic presentations related to pituitary disease

The classic presentation of an expanding non-functioning pituitary tumour is a bitemporal hemianopia caused by compression of the axons within the chiasm (Figure 82.6).

Typically a superior quadrantanopia occurs initially as the axons subserving the temporal visual fields are involved initially by the pituitary compression from below. It should be noted that visual acuity can also be affected. In addition, pituitary tumours do not always respect the midline and can give an asymmetrical visual field defect. A pre- and post-fixed chiasm would produce variable hemianopias, an important consideration when assessing the visual fields.

Clinically patients may not be aware of selective visual field loss, although with progression symptoms may become apparent, for example failing to notice the edges of a doorway when walking through it and bumping into it. Prolonged compression of the optic fibres results in atrophy of the optic disc noted on fundoscopy. More severe or generalized atrophy is associated with a poorer prognosis to visual recovery.²⁰

Formal assessment of visual fields should be undertaken by a specialist technician to minimize operator dependency and ensure accuracy. Static perimetry techniques (Goldman visual field assessment) have largely been replaced by kinetic perimetry. The Humphrey visual field analyser (Figure 82.7) consists of a bowl-shaped background of set luminescence. The patient fixates on a central target and presses a button when a light stimulus in the periphery is perceived. Testing takes up to 30 minutes for both eyes and is largely automated, reducing margins for error.

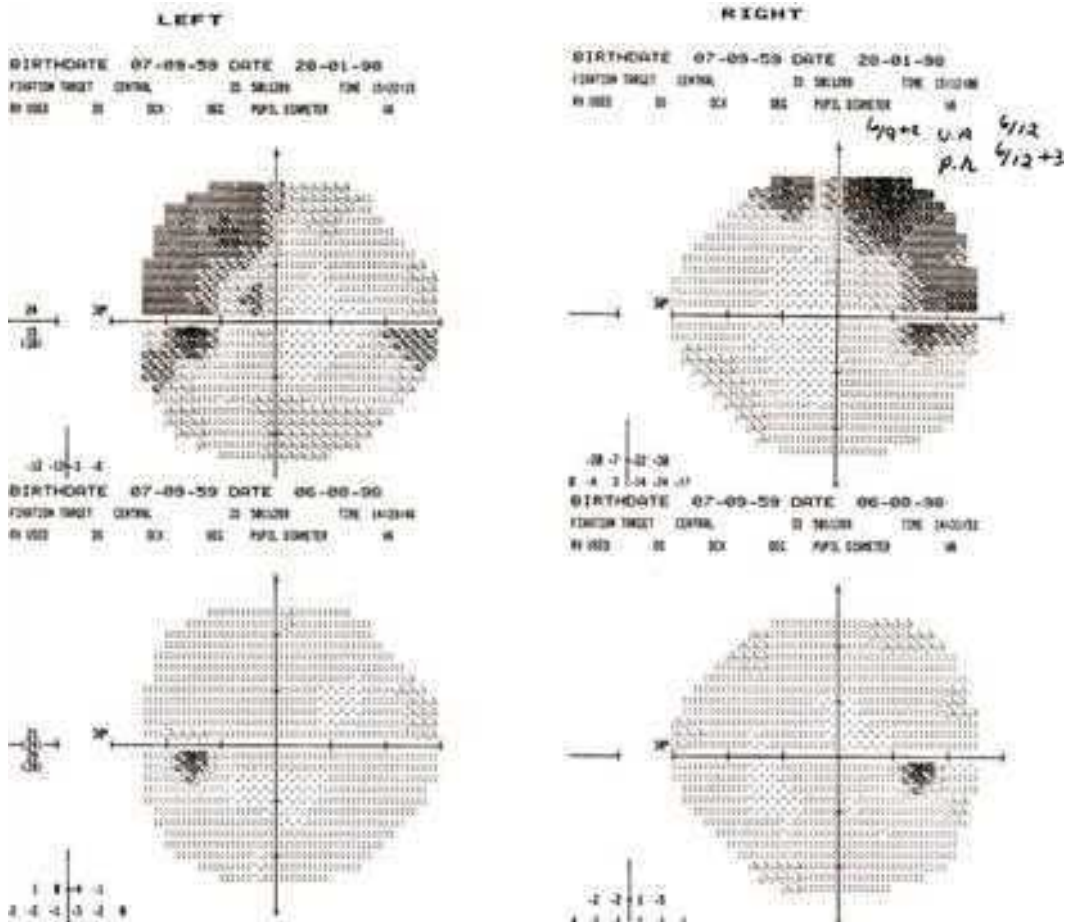

Figure 82.6 Bitemporal hemianopia.

Figure 82.7 The Humphrey visual field analyser.

Motor nerve involvement

Pituitary tumours also have a tendency to compress or invade the cavernous sinus as they expand. In the majority of cases this involvement is asymptomatic but pituitary apoplexy characteristically presents with severe headache and, on occasion, acute oculomotor nerve palsies and hemianopias with loss of acuity. However, all cranial nerves within the cavernous sinus may be involved with palsies potentially affecting III, IV and VI. There is a consequent diplopia and reduced range of ocular movement. Involvement of the sympathetic fibres may result in a Horner's syndrome and facial sensation may be disturbed by involvement of the ophthalmic and maxillary divisions of the trigeminal nerve. Visual field disturbances are much more common than those of ocular motor nerves but in each case formal assessment, documentation and management should be undertaken by a specialist neuro-ophthalmologist.

Vision following surgical decompression

All large series demonstrate a majority of patients experience visual improvement following surgery to macroadenomas with optic apparatus involvement. A study of 67 patients undergoing resection of adenomas compressing the visual pathway reported 88% showing improvement of visual function, despite half of those having significant optic atrophy.²¹ Another study demonstrated normalization in 35% of eyes and improvement in 60%.²⁰ In keeping with most studies the duration and severity of visual field involvement directly affects prognosis for visual recovery. Recovery of vision can be equally dramatic with medical management of a macroprolactinoma with dopamine agonists. Radiotherapy treatment alone is rarely if ever used in this situation as it can pose an additional threat to the optic apparatus. Surgical debulking is invariably recommended prior to adjuvant radiotherapy.

TSHomas

Pituitary thyrotrophin-secreting adenomas (TSHomas) are extremely rare tumours causing hyperthyroidism by chronic

stimulation of a normal thyroid gland. In the past 50 years approximately 50 cases have been reported in literature.²²

Patients present with signs and symptoms of hyperthyroidism, commonly thyrotoxicosis and a goitre with a vascular bruit. The characteristics of this condition are centrally driven thyrotoxicosis with high levels of thyroid hormones in the presence of detectable and invariably elevated TSH and alpha subunit levels.

Gonadotrophinoma

These tumours are often indistinguishable from other non-functioning pituitary adenomas as they are usually 'silent' and not associated with excess secretion of LH and FSH. Therefore, they are usually detected upon histological analysis following operative intervention for a clinically and biochemically non-functioning pituitary macroadenoma.

Non-functioning adenomas

A systematic review of pituitary adenomas in 2004 reported an estimated prevalence of 16% in the population.¹ Non-functioning adenomas are the most common subgroup requiring surgical intervention.

Occasionally, apparently functionless pituitary adenomas will stain for ACTH in the absence of biochemical or clinical cortisol excess. It is important to note this category of pituitary adenoma, the so-called 'silent corticotrophinoma', as they are more prone to physical recurrence and require more assiduous post-decompressive surveillance and early recourse to external beam radiotherapy (EBRT) is often indicated.

True null cell adenomas are rare, accounting for less than 10% of non-functioning adenomas biopsied and examined histologically.

Non-functioning adenomas commonly present as expanding pituitary lesions (visual disturbance), as hypopituitarism or as lesions found incidentally on CT or MRI of the brain. The clinical manifestations of hypopituitarism and stalk compression have already been discussed.

These patients with non-functioning adenomas should be assessed for the loss of visual fields and visual acuity, as well as an assessment of pituitary hormone status. Management may involve serial MR imaging for small asymptomatic lesions, or a combination of surgery or radiotherapy for symptomatic lesions.

Pituitary apoplexy

This is an uncommon but well-described clinical presentation found in a small minority of pituitary adenomas.²³ It occurs as a result of either haemorrhage into or infarction of a pituitary adenoma and may be the presenting feature of a previously undiagnosed tumour.²⁴ The typical features are of a sudden severe headache mimicking subarachnoid haemorrhage, which may be associated with a deterioration in visual acuity or visual fields. Subsequently an acute loss of pituitary hormones may produce acute adrenal insufficiency or diabetes insipidus or the so-called 'triple response' of transient diabetes insipidus rapidly followed by a period of syndrome of inappropriate antidiuretic hormone (SIADH) and

hyponatraemia due to disordered AVP leakage with ultimate exhaustion of AVP stores and a return to diabetes insipidus.²⁵ It is important to recognize this phenomenon acutely and in the post-operative period as it requires close monitoring of serum and urine electrolytes/osmolalities and fastidious attention to fluid balance, fluid type and the timely use of fluid restriction or DDAVP® administration dependent on which phase the patient is going through.

Larger tumours are more prone to bleeding and more rapidly growing lesions may be at a high risk of apoplexy.²³ Initially, aggressive medical management is appropriate with high dose steroids both to replace the acute adrenal insufficiency and to provide anti-inflammatory effect if visual disturbance is minimal, provided there is close observation of the patient. Deterioration in symptoms or lack of spontaneous improvement indicates the need for surgical intervention.²⁶

KEY POINTS

- All lesions involving the pituitary fossa should undergo a formal endocrinology assessment.
- The commonest secreting adenoma is a prolactinoma, the majority of which are managed medically.
- Untreated, acromegaly and Cushing's Disease are life shortening conditions.
- Macroadenomas may not produce a classical bitemporal field defect.
- Pituitary apoplexy is an emergency and may require surgical intervention.

INVESTIGATION OF PITUITARY DISEASE

Thozhukat Sathyapalan and Stephen L. Atkin

Introduction	915	Investigating posterior pituitary dysfunction	919
Investigating anterior pituitary dysfunction.....	915	References	920

SEARCH STRATEGY

The information in this chapter is taken from standard UK endocrinology clinical practice. It reflects expert opinion (level 4 evidence) with regard to endocrinology tests currently performed in the UK.

Data in this chapter may be updated by a Medline search using the keywords: prolactin, IGF-1, ACTH stimulation test, dexamethasone suppression test, pituitary function testing, SIADH, diabetes insipidus, Cushing's disease, acromegaly, pituitary adenoma and hypopituitarism.

INTRODUCTION

The pituitary gland lies in the sella turcica which is situated in the middle cranial fossa at the base of the brain. It is linked functionally to the hypothalamus by the pituitary stalk. The anterior pituitary secretes growth hormone (GH), thyrotropin or thyroid-stimulating hormone (TSH), corticotropin or adrenocorticotrophic hormone (ACTH), follicle-stimulating hormone (FSH) and luteinizing hormone (LH), all of which are under positive stimulatory control, and prolactin (PRL) which is under the inhibitory control of dopamine. The posterior lobe releases arginine vasopressin (AVP, also called antidiuretic hormone) and oxytocin.

INVESTIGATING ANTERIOR PITUITARY DYSFUNCTION

The anterior pituitary hormonal secretion is regulated by hypothalamic releasing and inhibitory factors delivered via portal capillaries, and by negative feedback inhibition of the respective hormones secreted by the target endocrine glands such as the thyroid gland and adrenal cortex.

The presentation of anterior pituitary disease, most commonly associated with a structural lesion, may result from:

- local mass effects – causing headache, visual field defects and ocular nerve palsies
- pituitary hormone deficiencies – producing wide-ranging effects as a result of single or multiple deficiencies, with

GH and gonadotropins (LH and FSH) usually affected first, followed much later by ACTH and TSH

- pituitary hormone hypersecretion – usually arising as a consequence of neoplastic proliferation of particular cell types within the gland.^{1, 2}

Investigation includes:

- tests for hormone hyper- or hyposecretion, by measuring TSH and thyroxine, FSH/LH and testosterone or oestradiol and prolactin – dynamic testing is required for the ACTH/cortisol axis and determination of GH deficiency or excess
- imaging – MRI is the modality of choice for radiological assessment
- neuro-ophthalmological evaluation, including assessment of visual acuity and visual fields.³

Investigating anterior pituitary hormonal hypersecretion

Pituitary masses may present with a typical clinical syndrome resulting from hypersecretion of one or more anterior pituitary hormones. Alternatively, they may present through compression of surrounding structures such as the optic chiasm or the adjacent normal pituitary, causing hypopituitarism. Functional pituitary tumours can produce a complex picture of combined hormonal excess and/or deficiencies.

LABORATORY INVESTIGATION

The presenting clinical features of functional pituitary adenomas (e.g. acromegaly, Cushing's syndrome) guide the laboratory studies. However, for a sellar mass with no obvious clinical features of hormone excess, laboratory studies are geared towards determining the nature of the tumour and assessing the possible presence of hypopituitarism. When a pituitary adenoma is found incidentally on MRI scan, the initial hormonal evaluation will be guided by the history and clinical examination to look for signs of hormone excess including: (i) prolactin; (ii) insulin-like growth factor-1 (IGF-I); (iii) 24-hour urinary free cortisol and/or overnight oral dexamethasone (1 mg) suppression test; (iv) α -subunit, FSH and LH; and (v) thyroid function tests (free T4 and TSH). Additional hormonal evaluation may be indicated based on the results of these tests (Table 83.1). Pending more detailed assessment of hypopituitarism, 8 a.m. cortisol and testosterone levels, and thyroid function tests usually identify patients with pituitary hormone deficiencies that require hormone replacement before further testing or surgery.⁴

Diagnosis of hyperprolactinaemia

Basal morning PRL levels should be measured to assess hypersecretion. It may be necessary to measure prolactin levels on different occasions when clinical suspicion is high. Since prolactin may be elevated as a stress response in a random sample, cannulated prolactin levels with samples taken through a cannula at 60-minute intervals after insertion to reduce this stress response can be helpful.⁵ In patients with markedly elevated PRL levels (>2000 mU/L), results may be falsely lowered because of assay artefacts (the high-dose hook effect); sample dilution is required to measure these high values accurately, but it is rare with modern assays. Falsely elevated values may be caused by aggregated forms of circulating PRL, which are biologically inactive (macroprolactinemia).⁶ Hypothyroidism should be excluded by measuring serum TSH and T4 levels.

Diagnosis of acromegaly

Age- and gender-matched serum IGF-I levels are elevated in acromegaly. Consequently, an IGF-I level provides a useful laboratory screening measure when clinical features raise the possibility of acromegaly. Due to the pulsatility of GH secretion, measurement of a single random GH level is not useful for the diagnosis or exclusion of acromegaly and does not correlate with disease severity. The diagnosis of acromegaly is confirmed by demonstrating the failure of GH suppression to <1 μ g/L within 1–2 hours after a 75 g oral glucose load.⁷ PRL is elevated in approximately a quarter of patients with acromegaly. Thyroid function, gonadotropins and sex steroids may be reduced because of tumour mass effects. Since most patients will undergo surgery with glucocorticoid coverage, tests for ACTH reserve in asymptomatic patients could be deferred until after surgery.⁸

Diagnosis of Cushing's disease

The diagnosis of Cushing's syndrome is based on laboratory documentation of endogenous hypercortisolism.⁹ Measurement of 24-hour urine free cortisol is often used as the screening test, ideally two collections with measurement of creatinine that should not differ by more than 10% to indicate adequacy of collection. Alternatively, the failure to suppress plasma cortisol after an overnight 1 mg dexamethasone suppression test can be used to identify patients with hypercortisolism. However, this test has a false positive rate of 2% in the normal population, 13% in obese subjects and 23% in hospital inpatients and is not favoured by many clinicians. A low-dose dexamethasone suppression test is also used to confirm hypercortisolemia, which has a higher sensitivity of 98% for screening Cushing's syndrome. This is done by administering 0.5 mg of dexamethasone 6 hourly for 48 hours at 9 a.m., 3 p.m., 9 p.m. and 3 a.m., and should lead to complete suppression of cortisol to <50 nmol/L in normal subjects with serum cortisol measurement at baseline and 48 hours. As nadir levels of cortisol occur at night, elevated midnight samples of cortisol are suggestive of Cushing's syndrome and this test will require admission to hospital. More recently, however,

TABLE 83.1 Baseline tests to evaluate pituitary hormone hypersecretion

Disorder	Tests	Comments
Acromegaly	Serum IGF-I	Interpret IGF-I relative to age- and gender-matched controls
	Oral glucose tolerance test with GH obtained at 0, 60 and 120 min	Normal subjects should suppress growth hormone to <1 μ g/L
Prolactinoma	Serum prolactin	Prolactin levels can be higher in patients who take medications including antidepressants, antipsychotics and antiemetics as well as some over-the-counter medications and homeopathic remedies MRI of the pituitary if prolactin significantly elevated (<2000 mU/L)
Cushing's disease	24-hour urinary free cortisol	Ensure urine collection is total and accurate ideally with 2 \times 24-hour samples with measurement of creatinine that should not differ by more than 10%
	Dexamethasone (1 mg) at 11 p.m. and plasma cortisol measured at 8 a.m.	Normal subjects suppress to <1.8 μ g/dL (< 50 nmol/L)
	ACTH assay	Distinguishes adrenal adenoma (ACTH suppressed) from ectopic ACTH or Cushing's disease (ACTH normal or elevated) after biochemical confirmation of hypercortisolemia

midnight salivary free measurements have been used which are simpler. Basal plasma ACTH levels often distinguish patients with ACTH-independent (adrenal or exogenous glucocorticoid) from those with ACTH-dependent (pituitary, ectopic ACTH) Cushing's syndrome.¹⁰ Mean basal ACTH levels are about eightfold higher in patients with ectopic ACTH secretion compared to those with pituitary ACTH-secreting adenomas. However, extensive overlap of ACTH levels between these two disorders (ectopic ACTH versus pituitary ACTH-secreting adenoma) precludes using ACTH to make the distinction.¹¹

If the investigations are highly suggestive of pituitary Cushing's disease, then pituitary MRI with gadolinium enhancement is undertaken but it is often not sensitive enough to detect small (<2 mm) pituitary ACTH-secreting adenomas. In this case, bilateral inferior petrosal sinus ACTH sampling before and after corticotropin-releasing hormone (CRH) administration may be required to distinguish a pituitary lesion from ectopic ACTH-secreting tumours that may have similar clinical and biochemical characteristics.¹² Simultaneous assessment of ACTH concentrations in each inferior petrosal vein and in the peripheral circulation provides a strategy for confirming and localizing pituitary ACTH production. Sampling is performed at baseline and 2, 5 and 10 min after intravenous bovine CRH (1 µg/kg) injection. An increased ratio (>2) of inferior petrosal to peripheral vein ACTH confirms pituitary Cushing's syndrome. After CRH injection, peak petrosal-to-peripheral ACTH ratios of ≥ 3 confirm the presence of a pituitary ACTH-secreting tumour when there is unequivocal endogenous hypercortisolemia. The sensitivity of this test is >95%, with rare false-negative results encountered in patients with aberrant venous drainage. Petrosal sinus catheterizations are technically difficult, and about 0.05% of patients develop neurovascular complications.

Most ACTH-secreting pituitary tumours are <5 mm in diameter, and about half are undetectable by sensitive MRI. The high prevalence of incidental pituitary microadenomas diminishes the ability to distinguish ACTH-secreting pituitary tumours accurately by MRI.

Diagnosis of TSH-secreting adenomas

TSH-producing macroadenomas are rare but are often large and locally invasive when they occur. Patients usually present with thyroid goitre and hyperthyroidism, reflecting overproduction of TSH. Diagnosis is based on demonstrating elevated serum free T4 levels, inappropriately normal or high TSH secretion, and MRI evidence of a pituitary adenoma.¹³ The commonest cause of elevated FT4 and normal or high TSH is failure to comply with treatment for hypothyroidism and taking thyroxine supplementation a few days prior to thyroid function tests. It is, however, also important to exclude other causes of inappropriate TSH secretion, such as resistance to thyroid hormone, an autosomal dominant disorder caused by mutations in the thyroid hormone β receptor and resistance to thyrotropin.¹⁴ The presence of a pituitary mass and elevated α -subunit levels are suggestive of a TSH-secreting tumour.

Diagnosis of non-functioning and gonadotropin-secreting pituitary adenomas

Clinically non-functioning tumours often present with optic chiasm pressure and other symptoms of local expansion or may be incidentally discovered on an MRI performed for another indication.¹⁵ Menstrual disturbances or ovarian hyperstimulation rarely occur in women with large tumours that produce FSH and LH. More commonly, adenoma compression of the pituitary stalk or surrounding pituitary tissue leads to attenuated LH and features of hypogonadism. PRL levels are usually slightly increased due to stalk compression. Most non-functioning tumours respond poorly to medical treatment, but these can be given an empirical treatment with a dopamine agonist, unless decompression of the chiasm is warranted if prolactin levels are raised.

Free α -subunit levels may be elevated in 10–15% of patients with non-functioning tumours. In female patients, peri- or postmenopausal basal FSH concentrations are difficult to distinguish from tumour-derived FSH elevation.

Testosterone levels are usually low, despite the normal or increased LH level, perhaps reflecting reduced LH bioactivity or the loss of normal LH pulsatility. Because this pattern of hormone levels is also seen in primary gonadal failure and with ageing, the finding of increased gonadotropins alone is insufficient for the diagnosis of a gonadotropin-secreting tumour. For non-functioning and gonadotropin-secreting tumours, the diagnosis usually rests on immunohistochemical analyses of resected tumour tissue, as the mass effects of these tumours usually necessitate resection.¹⁶ Although acromegaly or Cushing's syndrome usually present with unique clinical features, clinically unapparent somatotroph or corticotroph adenomas can be excluded by a normal IGF-I value and normal 24-hour urinary free cortisol levels.

MAGNETIC RESONANCE IMAGING

Sagittal and coronal T1-weighted magnetic resonance imaging (MRI), before and after administration of gadolinium, allows precise visualization of the pituitary gland with clear delineation of the surrounding structures. Adenoma density is usually lower than that of surrounding normal tissue on T1-weighted imaging, and the signal intensity increases with T2-weighted images. The high phospholipid content of the posterior pituitary results in a 'pituitary bright spot'.

Sellar masses are commonly encountered as incidental findings on MRI, and most of these are incidentalomas. In the absence of hormone hypersecretion, these small lesions can be safely monitored by MRI, which is performed annually and then less often if there is no evidence of growth. Resection may be considered for incidentally discovered macroadenomas, as about one-third become invasive or cause local pressure effects. If hormone hypersecretion is evident, specific therapies are indicated. When larger masses (>1 cm) are encountered, they should also be distinguished from non-adenomatous lesions including meningiomas (associated with bony hyperostosis), cranio-pharyngiomas (usually calcified and hypodense) and gliomas (hyperdense on T2-weighted images).

OPHTHALMOLOGICAL EVALUATION

Visual field assessment that uses perimetry techniques should be performed on all patients with sellar mass lesions that abut the optic chiasm. Bitemporal hemianopia or superior bitemporal defects are classically observed, reflecting the location of these tracts within the inferior and posterior part of the chiasm. Homonymous cuts reflect postchiasmal lesions and monocular field cuts prechiasmal lesions.

HISTOLOGICAL EVALUATION

Immunohistochemical staining of pituitary tumour specimens obtained at transsphenoidal surgery confirms

clinical and laboratory studies and provides a histological diagnosis when hormone studies are equivocal and in cases of clinically non-functioning tumours.

Investigating anterior pituitary hormonal hyposecretion (hypopituitarism)

The clinical manifestations of hypopituitarism depend on which hormones are lost and the extent of the hormone deficiency. Biochemical diagnosis of pituitary insufficiency is made by demonstrating low levels of trophic hormones in the setting of low target hormone levels ([Table 83.2](#)).¹ For example, low free thyroxine in the setting of a low

TABLE 83.2 Tests of pituitary sufficiency: dynamic pituitary hormonal testing

Hormone	Test	Blood samples	Interpretation
Growth hormone ¹⁹	Insulin tolerance test: Regular insulin (0.05–0.15 U/kg i.v.)	–30, 0, 30, 60, 120 min for glucose and GH	Glucose <40 mg/dL (2 mmol/L); GH should be >3 µg/L (5 mU/L)
	Glucagon stimulation test: 0.5–1.5 mg of glucagon i.m.	0, 30, 60, 90, 120, 150, 180, 210, 240 min for GH	Peak GH should be >3 µg/L (5 mU/L)
	GHRH test: 1 µg/kg i.v.	0, 15, 30, 45, 60, 120 min for GH	Normal response is GH >3 µg/L (5 mU/L)
	L-arginine test: 30 g i.v. over 30 min	0, 30, 60, 120 min for GH	Normal response is GH >3 µg/L (5 mU/L)
	L-dopa test: 500 mg p.o.	0, 30, 60, 120 min for GH	Normal response is GH >3 µg/L (5 mU/L)
ACTH	Insulin tolerance test: ¹⁸ Regular insulin (0.05–0.15 U/kg i.v.)	–30, 0, 30, 60, 120 min for glucose and GH	Glucose <40 mg/dL (2 mmol/L); cortisol should increase by >7 µg/dL (180 nmol/L) or to >20 µg/dL (550 nmol/L)
	Glucagon stimulation test: 0.5–1.5 mg of glucagon i.m.	0, 30, 60, 90, 120, 150, 180, 210, 240 min for cortisol	Cortisol should increase by >7 µg/dL (180 nmol/L) or to >20 µg/dL (550 nmol/L)
	CRH test: 1 µg/kg CRH i.v. at 8 a.m.	0, 15, 30, 60, 90, 120 min for ACTH and cortisol	Basal ACTH increases two- to fourfold and peaks at 20–100 pg/mL
	Metyrapone test: ²⁰ Metyrapone (30 mg/kg) at midnight	Plasma 11-deoxycortisol and cortisol at 8 a.m.; ACTH can also be measured	Plasma cortisol should be <4 µg/dL to ensure an adequate response Normal response is 11-deoxycortisol >7.5 µg/dL or or ACTH >75 pg/mL
	Standard ACTH stimulation test: ACTH 1–24 (Cosyntropin), 0.25 mg i.m. or i.v.	0, 30, 60 min for cortisol and aldosterone	Normal response is cortisol >21 µg/dL and aldosterone response of >4 ng/dL above baseline
	Low-dose ACTH test: ACTH 1–24 (Cosyntropin), 1 µg i.v.	0, 30, 60 min for cortisol	Cortisol should be >21 µg/dL
	3-day ACTH stimulation test consists of 0.25 mg ACTH 1–24 given i.v. over 8 hours each day	0 and 72 hours for cortisol	Cortisol should be >21 µg/dL
TSH	Basal thyroid function tests: T4, T3, TSH	Basal tests	Low free thyroid hormone levels in the setting of TSH levels that are not appropriately increased
	TRH test: 200–500 µg i.v.: 0, 20, 60 min for TSH and PRL		TSH should increase by >5 mU/L unless thyroid hormone levels are increased. Evoked prolactin response indicates lactotrope integrity
LH, FSH	Basal LH, FSH, testosterone, oestrogen		Basal LH and FSH should be increased in postmenopausal women Low testosterone levels in the setting of low LH and FSH
	GnRH test: GnRH (100 µg) i.v.	0, 30, 60 min for LH and FSH	In most adults, LH should increase by 10 IU/L and FSH by 2 IU/L Normal responses are variable
Multiple hormones	Combined anterior pituitary test: GHRH (1 µg/kg), CRH (1 µg/kg), (or insulin stress test or glucagon stimulation test), GnRH (100 µg), TRH (200 µg) are given i.v.	–30, 0, 15, 30, 60, 90, 120 min for GH, ACTH, cortisol, LH, FSH and TSH	Combined or individual release hormone responses must be elevated in the context of basal target gland hormone values and may not be uniformly diagnostic

or inappropriately normal TSH level suggests secondary hypothyroidism. Similarly, a low testosterone level without elevation of gonadotropins suggests hypogonadotropic hypogonadism.

Provocative tests may be required to assess pituitary reserve.¹⁷ GH responses to insulin-induced hypoglycaemia, arginine, l-dopa, growth hormone-releasing hormone (GHRH) or growth hormone-releasing peptides (GHRPs) can be used to assess GH reserve. Corticotropin-releasing hormone (CRH) administration induces ACTH release, and administration of synthetic ACTH (cosyntropin – Cortrosyn) evokes adrenal cortisol release as an indirect indicator of pituitary ACTH reserve.

ACTH reserve is most reliably assessed during insulin-induced hypoglycaemia.¹⁸ However, this test should be performed cautiously in patients with suspected adrenal insufficiency because of enhanced susceptibility to hypoglycaemia and hypotension. Insulin-induced hypoglycaemia is contraindicated in patients with active coronary artery disease or seizure disorders. The glucagon stimulation test is also used for dynamic pituitary function testing and can be used safely when insulin is contraindicated.

INVESTIGATING POSTERIOR PITUITARY DYSFUNCTION

The neurohypophysis, or posterior pituitary gland, is formed by axons that originate in large cell bodies in the supraoptic and paraventricular nuclei of the hypothalamus. It produces two hormones: (i) arginine vasopressin (AVP), also known as antidiuretic hormone; and (ii) oxytocin. AVP acts on the renal tubules to reduce water loss by concentrating the urine. Oxytocin stimulates postpartum milk letdown in response to suckling.

AVP deficiency causes diabetes insipidus (DI), characterized by the production of large amounts of dilute urine. Excessive or inappropriate AVP production predisposes to hyponatremia if water intake is not reduced in parallel with urine output.

Deficiency of AVP secretion: diabetes insipidus

Decreased secretion or action of AVP causes diabetes insipidus and is characterized by the production of abnormally large volumes of dilute urine. The 24-hour urine volume is >50 mL/kg body weight and the osmolarity is <300 mOsmol/L. The polyuria produces symptoms of urinary frequency, enuresis, and/or nocturia, which may disturb sleep and cause mild daytime fatigue or somnolence. It is also associated with thirst and a commensurate increase in fluid intake (polydipsia). Clinical signs of dehydration are uncommon unless fluid intake is impaired.

INVESTIGATION

When clinically suspected, a 24-hour urine should be collected on an *ad libitum* fluid intake to confirm polyuria.

If the volume exceeds 50 mL/kg per day, polyuria is present. If the osmolarity is >300 mOsmol/L, the polyuria is due to a solute diuresis and the patient should be evaluated for glucosuria or other less common causes of excessive solute excretion. However, if the 24-hour urine osmolarity is <300 mOsmol/L, the patient has a water diuresis and should be evaluated further to determine which type of DI is present.

Except in the rare patient who is clearly dehydrated under basal conditions of *ad libitum* fluid intake, the evaluation should begin with a fluid deprivation test. The test should be started in the morning and water balance should be monitored closely, with hourly measurements of body weight, plasma osmolarity and/or sodium concentration, and urine volume and osmolarity.

If fluid deprivation does not result in urine concentration (osmolarity >300 mOsmol/L, specific gravity >1.010) before body weight decreases by 5% or plasma osmolarity/sodium exceeds the upper limit of normal, the patient has severe pituitary or severe nephrogenic DI. These disorders can usually be distinguished by administering desmopressin (DDAVP, 0.03 µg/kg s.c. or i.v.) and repeating the measurement of urine osmolarity 1–2 hours later. An increase of >50% indicates severe pituitary DI, whereas a smaller or absent response is strongly suggestive of nephrogenic DI.

The differential diagnosis of DI may also be facilitated by MRI of the pituitary and hypothalamus. In most healthy adults and children, the posterior pituitary emits a hyperintense signal in T1-weighted midsagittal images. This ‘bright spot’ is almost always present in patients with primary polydipsia but is invariably absent or abnormally small in patients with pituitary DI. It is usually also small or absent in nephrogenic DI, presumably because of high secretion and turnover of vasopressin. A normal bright spot virtually excludes pituitary DI, is unlikely in nephrogenic DI, and strongly suggests primary polydipsia.

Excess AVP secretion: syndrome of inappropriate ADH secretion

Excessive secretion or action of AVP results in the production of decreased volumes of more highly concentrated urine. If not accompanied by a commensurate reduction in fluid intake or an increase in insensible loss, the reduction in urine output results in excess water retention with expansion and dilution of all body fluids. In some patients, excessive intake results from inappropriate thirst. If the hyponatremia develops gradually or has been present for more than a few days, it may be largely asymptomatic. However, if it develops acutely, it is almost always accompanied by symptoms and signs of water intoxication that may include mild headache, confusion, anorexia, nausea, vomiting, coma and convulsions, and it could be lethal.

AETIOLOGY

Hyponatremia and impaired urinary dilution can be caused by a primary defect in the regulation of AVP secretion or

action or can be secondary to a recognized non-osmotic stimulus such as hypovolemia, hypotension, nausea or glucocorticoid deficiency. The primary forms are generally referred to as syndromes of inappropriate ADH secretion (SIADHs). They have many different causes, including ectopic production of AVP by lung cancer or other neoplasms; ectopic release by various diseases or drugs; and exogenous administration of AVP, desmopressin or large doses of oxytocin.

SIADH is a diagnosis of exclusion that can usually be accomplished with routine historic, physical and laboratory information. In a patient with hyponatremia, the possibility of simple dilution caused by an osmotically driven shift of water from the intracellular to the extracellular space should be excluded by measuring plasma glucose and/or plasma osmolality. Normal results of liver function tests, lipids and glucose concentration exclude rare causes of artifactual pseudo hyponatraemia (hyperproteinaemia and hyperlipidaemia) or hyperosmolar hyponatraemia, where water moves from the intracellular to the extracellular compartment (in severe hyperglycaemia).

SIADH needs to be confirmed by results of paired serum and urine samples: serum hyposmolality must be <275 mOsm/kg (normal range: 275–295 mOsm/kg), and urine osmolality >100 mOsm/kg and sodium ≥ 30 mmol/L, in the absence of hypovolaemia, hypervolaemia, adrenal or thyroid dysfunction and use of diuretics.^{21, 22} Paired serum and spot urine samples need to be sent for osmolality and sodium to confirm both hyponatraemia and SIADH. Serum osmolality measurement is not necessary when there is an obvious contributory cause. It can confirm true hyponatraemia (<275 mOsmol/kg) and rules out the rarer hyperosmolar hyponatraemia and pseudo hyponatraemia (serum osmolality ≥ 275 mmol/L).²³

Urine osmolality (normal range 300–900 mOsm/kg) is needed to confirm SIADH but it also helps in differentiating it from two other conditions. By definition, SIADH is an incomplete suppression of antidiuretic hormone (urine osmolality >100 mOsm/kg); a spot urinary osmolality <100 mOsm/kg indicates appropriate complete suppression. Complete suppression of antidiuretic hormone is seen in psychogenic polydipsia (history of mental illness) and malnutrition (history of heavy alcohol consumption).²⁴

Urinary sodium concentration is helpful when the cause of hyponatraemia is not apparent from the history and examination or when SIADH is suspected. In euvolaemic hyponatraemia (including SIADH), the urinary sodium is ≥ 30 mmol/L.^{22, 25} Hypervolaemic hyponatraemia should be apparent clinically; because of the reduced effective circulating volume, the kidney concentrates the urine (>100 mOsm/kg) and conserves sodium (<30 mmol/L; but it can be higher when the patient is taking diuretics).²² The clues to hypovolaemia in the history include obvious fluid loss (through diuretics, for example) or third space fluid loss, when fluid with high sodium content is sequestered in a body space, as occurs in burns patients. The urinary sodium concentration in all hypovolaemic hyponatraemia is <30 mmol/L except when the kidney is the site of the loss, for example with diuretic use, salt-losing nephropathy, or mineralocorticoid deficiency.²⁶

When the fluid status is difficult to determine clinically, low serum concentrations of urea and uric acid indicate SIADH, and a raised concentration of urea is more likely to reflect hypovolaemia.²⁴

KEY POINTS

- Pituitary adenomas can cause local mass effects as well as hyper- or hyposecretion of pituitary hormones.
- Magnetic resonance imaging of the pituitary is the modality of choice for imaging pituitary pathology.
- Visual field assessment using perimetry techniques should be performed on all patients with sella mass lesions that abut the optic chiasm.
- The initial hormonal evaluation of a pituitary adenoma will be guided by the history and clinical examination for evidence of hormone insufficiency or excess.
- Biochemical diagnosis of pituitary insufficiency is made by demonstrating low levels of trophic hormones in the setting of low target hormone levels. Provocative tests may be required to assess pituitary reserve.
- Dynamic pituitary function testing is required for testing the integrity of the ACTH/cortisol axis and determination of GH deficiency or excess.
- Water deprivation testing can be useful for the diagnosis of diabetes insipidus.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: pituitary, adenohipophysitis, neurohipophysitis, adenoma, macroadenoma, non-functioning adenoma, prolactin, prolactinoma, growth hormone, acromegaly, adrenocorticotrophic hormone, Cushing's disease, Cushing's syndrome, thyroid-stimulating hormone and gonadotrophins. Secondary search criteria included epidemiology, aetiology, management and pathogenesis. Particular focus has been placed on the epidemiology, aetiology and management of key disorders of the pituitary with level 1 and 2 evidence reported wherever possible.

INTRODUCTION

Disease of the pituitary gland may result in a broad spectrum of clinical phenotypes.^{1,2} This is perhaps unsurprising given the function of the pituitary as the 'conductor of the endocrine orchestra'. Consisting of both an anterior and a posterior portion, respectively termed the adenohipophysitis and the neurohipophysitis, the pituitary lies immediately below the hypothalamus.

Anterior pituitary (adenohypophysis)

FUNCTION

The anterior pituitary secretes thyroid-stimulating hormone (TSH), adrenocorticotrophic hormone (ACTH), growth hormone (GH), prolactin (PRL) and the gonadotrophins follicle-stimulating hormone (FSH) and luteinizing hormone (LH) (Table 84.1). Their secretion is subject to marked clinical rhythms and varies widely between the different hormones. Gonadotrophin release is, for instance, well recognized to follow a 28-day cycle in women, where it is critical for ovulation and implantation. ACTH follows a circadian rhythm and normal GH secretion is pulsatile, with more pulses secreted

during sleep. Knowledge of these fluctuations is important, both for the recognition that isolated measurement of pituitary hormones or their downstream mediators may be misleading and because loss of a recognizable rhythm may indicate disease, such as in Cushing's disease. Interestingly, seasonal rhythms are known to impact on pituitary hormone synthesis in other species but are unlikely to be of significance in humans.

ANATOMY

The anterior portion of the pituitary may be divided into three constituent parts. The largest of these is the pars anterior, which constitutes approximately 80% of gland volume.³ A smaller contribution to pituitary mass is made by the pars intermedia, which is well developed in the foetus, and the pars tuberalis, which forms from an upward extension of the anterior wall of the gland and wraps around the lower end of the pituitary stalk.³

FUNCTION AND FEEDBACK

Secretion of hormones from the pituitary gland is controlled by the hypothalamus. For the hypophysiotrophic cells of the anterior gland, this regulation is derived by

TABLE 84.1 Principle pituitary hormones and their regulators, secreting cell and action

Pituitary hormone		Abbreviation	Secreting cell	Downstream target	+ve feedback	-ve feedback	Effects
Anterior pituitary	Adrenocorticotrophic hormone	ACTH	Corticotrophs	Adrenal gland	CRH	Cortisol	Corticosteroid secretion
	Growth hormone	GH	Somatotrophs	Liver Adipose tissue	GHRH	IGF-1 Somatostatin	Growth Modulation of lipid/ carbohydrate metabolism (effects modulated by insulin-like growth factor 1; IGF-1)
	Luteinizing hormone	LH	Gonadotrophs	Gonads	GnRH Oestrogen	Sex steroids Inhibin (FSH)	Reproductive system development Gametogenesis
	Follicle-stimulating hormone	FSH					
	Prolactin	PRL	Lactotrophs	Breast	TRH	Dopamine	Lactation
Thyroid-stimulating hormone	TSH	Thyrotrophs	Thyroid	TRH	T4 and T3	Thyroid hormone (T4 and T3) synthesis and release	
Posterior pituitary	Oxytocin		Supraoptic and paraventricular nuclei (hypothalamus)	Myoepithelial cells (uterine) Prefrontal cortex	Cervix stretch Suckling		Supports lactation Uterine contraction Emotional bonding
	Antidiuretic hormone	ADH		Liver Kidney Brain Vasculature	Reduced plasma volume/osmolality Angiotensin II Cholecystokinin	Atrial natriuretic peptide	Regulate water retention Induce vasoconstriction

Note: CRH: corticotrophin-releasing hormone; GHRH: growth hormone-releasing hormone; GnRH: gonadotrophin-releasing hormone; TRH: thyrotrophin-releasing hormone; IGF-1: insulin-like growth factor 1; T4: thyroxine; T3: triiodothyronine.

neural stimuli and feedback from circulating hormones, whether these are secreted by the anterior pituitary itself (such as growth hormone (GH)) or a target organ (such as thyroxine). Active hormones influence pituitary hormone production both by directly exerting feedback on anterior pituitary cells and, more significantly, by inducing the synthesis of neurohormones by hypophysiotrophic neurons, which are then transported down their axons and released into the pituitary portal circulation, from where they are carried to target cells in the anterior pituitary.

These neurohormones will have either a stimulatory or an inhibitor effect on the cells of the anterior pituitary gland. Stimulatory neurohormones include gonadotrophin-releasing hormone (GnRH), thyrotrophin-releasing hormone (TRH), corticotrophin-releasing factor (CRF) and GH-releasing hormone (GHRH). The inhibitory neurohormones include somatostatin, which inhibits the release of GH, and dopamine, which inhibits prolactin release.

PITUITARY GLAND VASCULATURE AS IT RELATES TO TESTS FOR NORMAL FUNCTION

The pituitary gland arterial blood supply derives from the superior and inferior hypophyseal arteries, both of which are branches of the internal carotid artery. The superior hypophyseal arteries supply a plexus which is closely

associated with the median eminence of the hypothalamus and the axons of the hypophysiotrophic neurons within the hypothalamus. These vessels then form a pituitary portal circulation, which runs down the pituitary stalk into sinusoids in the anterior pituitary. The venous drainage of the gland is into the cavernous sinuses. These are venous lakes, which contain the last part of the internal carotid arteries, and cranial nerves III, IV, V and VI. They are connected across the midline by a variable array of intercavernous connecting veins and they drain into the superior and inferior petrosal sinuses. The venous connections are of importance when considering inferior petrosal sinus sampling as a method of locating secreting adenomas.

Posterior pituitary (neurohypophysis)

The posterior pituitary sits in continuity with the hypothalamus and secretes oxytocin and antidiuretic hormone (ADH, otherwise known as vasopressin).³ These are released from the axons of supraoptic and paraventricular neurons that run through the pituitary stalk from the hypothalamus. Granules of oxytocin and ADH are stored at the distal end of these axons and are released into the systemic circulation when stimulated to do so.

KEY POINTS

PITUITARY GLAND STRUCTURE,
FEEDBACK AND FUNCTION

Structure

- The pituitary gland is formed of both an anterior portion (itself split into three constituent parts) and a posterior portion.
- Pituitary venous drainage is into the cavernous sinuses.

Feedback

- Release of pituitary hormones is governed by hypothalamic input and systemic feedback.

Function

- The pituitary gland is the 'conductor of the endocrine orchestra' – responsible for coordinating metabolism, growth and reproduction.

THE SPECTRUM OF PITUITARY DISEASE

There are a wide range of pathologies of the pituitary gland, the clinical manifestations of which reflect the complexity of a diverse organ formed of two constituent parts and various different cell types. Broadly, anterior pituitary diseases include congenital hypopituitarism and isolated growth hormone deficiencies, in addition to the development of functioning and non-functioning pituitary adenomas. This chapter will focus on clinical presentations arising from the development of anterior pituitary adenomas. Disease of the posterior pituitary tends to be acquired and will also be discussed, albeit in less detail.

CONGENITAL PRIMARY HYPOPITUITARISM

A large number of genes have now been associated with congenital hypopituitarism. Mutations seen in genes encoding specific cell types or hormone subunits generally give rise to isolated pituitary hormone deficiencies; mutations in genes responsible for early pituitary development result in combined hypopituitarism. A complete outline of congenital hypopituitarism is beyond the scope of this chapter but key disorders and – where known – their underlying genetic aetiology are discussed.

Congenital combined pituitary hormone deficiency

Recessive mutations of the chromosome 5q gene *PROP1* underlie the majority of cases of combined pituitary hormone deficiency, accounting for approximately 50% of familial cases.⁴ The deficiency in hormone production resulting from mutations of *PROP1* is variable but

generally accounts for growth hormone, TSH and prolactin deficiency. More significant deficiency of these same hormones occurs with mutations of the chromosome 3p gene *POU1F1*, though TSH deficiency may present later in childhood and is in some instances preserved.⁵

Combined pituitary hormone deficiency may also arise as part of a syndrome, as is the case in septo-optic dysplasia, Rieger's syndrome and holoprosencephaly.⁶ Septo-optic dysplasia carries an incidence of approximately 1:10 000 and both sporadic and familial cases have been described with *HESX1*, *SOX2* and *SOX3* implicated in the pathogenesis of this disorder.⁷ Hypoplasia of both the pituitary and optic nerve is seen as a consequence, in addition to defects of the midline forebrain. This commonly results in neurological defects. Visual impairment and variable endocrine deficiencies – the most common of which are isolated GH deficiency and combined TSH and ACTH deficiency – are also seen.

Reduced levels of GH have also been noted in the autosomal dominant condition Rieger's syndrome, which encompasses a constellation of craniofacial and eye abnormalities. Conversely, holoprosencephaly is more commonly associated with posterior hormone deficiency and diabetes insipidus. Mutations in the sonic hedgehog (SHH) pathway are thought to result in this condition, which is characterized by a failure of the prosencephalon (the embryonic forebrain) to develop into two hemispheres.⁸

KEY POINTS

CONGENITAL COMBINED PITUITARY
HORMONE DEFICIENCY

- This may occur as part of a syndrome or independent of non-pituitary clinical features.
- Mutations in *PROP1* and *POU1F1* are responsible for most non-syndromic cases.
- Syndromic causes include septo-optic dysplasia, holoprosencephaly and Rieger's syndrome.

Congenital isolated pituitary hormone deficiency

Congenital isolated hormone deficiencies are rare but both familial and sporadic cases of specific anterior and posterior pituitary hormone deficiencies have been reported.

ISOLATED GONADOTROPHIN DEFICIENCY (HYPOGONADOTROPHIC HYPOGONADISM)

One of the most fascinating forms of isolated hormone deficiency is that of isolated GnRH-deficiency (IGD). This may be sporadic or of X-linked, autosomal dominant or autosomal recessive inheritance.⁹ It is characterized by hypogonadism, which itself results from LH and FSH deficiency and is thus alternatively termed hypogonadotrophic hypogonadism (HH).

IGD may occur alone or in association with a loss of sense of smell (anosmia). Kallmann syndrome refers to the association of anosmia with IGD. This accounts for approximately 60% of subjects with IGD and affects approximately 1:10000 males and 1:40000 females.¹⁰ Around three quarters of patients with Kallmann syndrome exhibit olfactory bulb agenesis on neuroimaging.¹¹

Patients with IGD may present early in life or during adulthood. When present at birth, IGD is associated with the development of a micropenis and cryptorchidism.⁹ Later in life patients with IGD demonstrate evidence of hypogonadism, the most notable clinical consequence of which is limited development of secondary sexual characteristics. ‘Scratch and sniff’ tests can be used to formally test for anosmia. Treatment is targeted towards both stimulating gametogenesis with pulsatile GnRH or combined gonadotrophins and inducing secondary sexual characteristics with gonadal steroids. A number of causative genes have been mapped for Kallmann syndrome and normosmic IGD,¹² as summarized in **Box 84.1**.

ISOLATED GH DEFICIENCY

Congenital deficiency of GH occurs in every 1:4000–1:10000 births and may have a familial component.¹³ Four distinct forms have been characterized. In type IA congenital isolated GH deficiency large homozygous mutations in the GH-encoding *GH1* gene result in exceptionally low levels of GH, even on provocation. Antibodies are generated against GH on treatment so that the adult’s final height is low. Smaller mutations in either *GH1* or *GHRH* are seen in type IB isolated GH deficiency, in which a similar but milder GH deficiency is seen.

Congenital isolated GH deficiency type II is an autosomal dominant disorder in which patients present with short stature.¹⁴ It is now recognized that this condition arises as a result of a splice site mutation in intron 3 of the *GH1* gene. This produces a mutant 17.5kDa molecule containing a deletion between amino acids 32 and 71 (the Del32-71-GH deletion), which has a dominant negative effect and prevents secretion of wild-type GH. As a consequence, supplementation with GH is generally an effective treatment for this condition.

BOX 84.1 Isolated GnRH deficiency (IGD)-associated genes. These account for approximately 50% of all cases of IGD

FGF8

Type III isolated GH deficiency is X-linked and may be associated with agammaglobulinaemia. Its pathogenesis is yet to be fully elucidated.¹⁵

KEY POINTS

CONGENITAL ISOLATED GROWTH HORMONE DEFICIENCY

Type Ia

- Autosomal recessive
- GH undetectable
- Anti-GH antibodies raised against exogenous GH

Type Ib

- Autosomal recessive
- GH low but no anti-GH antibodies raised

Type II

- Autosomal dominant
- Short stature – effectively managed with GH replacement

Type III

- X-linked
- Associated with agammaglobulinaemia
- Causative gene not yet known

ISOLATED TSH DEFICIENCY (CENTRAL HYPOTHYROIDISM)

Central hypothyroidism describes underactivity of the thyroid gland resulting from insufficient TSH stimulation. It is rare, affecting around 1:50000 live births, and both sporadic and familial cases have been described.¹⁶ There are existing programmes already in place to screen for hypothyroidism, such as the ‘blood spot’ test used within the UK NHS. In the absence of this, infants may present with non-specific symptoms and failure to thrive. In cases of established central hypothyroidism, hormonal assays reveal low free thyroxine (fT4) with inappropriately normal or low TSH levels.

ISOLATED ACTH DEFICIENCY

ACTH deficiency is generally associated with other pituitary hormone deficiencies and isolated ACTH deficiency is vanishingly rare, with only a few cases reported to date. Symptoms may vary from failure to thrive to signs of acute adrenal insufficiency.¹⁷

ACQUIRED PRIMARY HYPOPITUITARISM

Aetiology

Hypopituitarism may arise in later life through a variety of aetiologies which include tumour growth, radiotherapy, pituitary infarction, pituitary gland infiltration, trauma and infection.¹⁸ These are summarized in **Table 84.2**.

TABLE 84.2 Causes of acquired hypopituitarism

Category	Examples
Neoplasia	Non-functioning pituitary adenomas Functioning pituitary adenomas Parapituitary tumours Craniopharyngioma Meningioma Metastatic deposits Chordoma Glioma
Iatrogenic	Radiotherapy Pituitary Cranial Nasopharyngeal Surgery (see Trauma)
Systemic disease	Sarcoidosis Haemochromatosis Langerhans cell histiocytosis Granulomatosis with polyangiitis (Wegener's disease) Lymphocytic hypophysitis
Infection	Tuberculosis Pituitary abscess
Vascular	Subarachnoid haemorrhage Pituitary apoplexy Sheehan's syndrome
Trauma	Traumatic brain injury Direct pituitary trauma (e.g. surgery)

PITUITARY APOPLEXY AND SHEEHAN'S SYNDROME

Overview

Pituitary apoplexy refers to a medical emergency in which infarction of the pituitary gland occurs due to haemorrhage or ischaemia. Predisposing factors include radiotherapy, coagulation disorders, the use of anticoagulants and a reduction in intra-cranial pressure.¹⁹ Pituitary infarction due to postpartum haemorrhage has also been described and is termed Sheehan's syndrome.²⁰

Clinical assessment

Pituitary apoplexy should be considered in all patients presenting with a sudden-onset headache, vomiting, visual impairment, meningism and reduced consciousness. This constellation of symptoms may be accompanied by second, third, fourth and/or sixth cranial nerve palsies.

Patients with pituitary tumours should be considered at risk of apoplexy and should be provided with information regarding relevant signs and symptoms. In those who are not known to harbour pituitary adenomas, a detailed history is required to identify symptoms of pituitary dysfunction.¹⁹ Subsequent clinical examination should focus on the cranial nerves and visual fields for confrontation. More formal assessment of the visual fields can be undertaken using the Humphrey visual field analyser or Goldmann perimeter and can be undertaken once the patient is clinically stable.

Endocrine workup

In all patients suspected to have pituitary apoplexy, blood samples should be sent to assess electrolytes, renal function, liver function, full blood count and clotting. Assessment of anterior pituitary hormones and their downstream mediators is also required and should include cortisol, fT4, prolactin, TSH, IGF1, GH, LH, FSH and gonadotrophins.²¹

Diagnostic imaging

An urgent MRI or dedicated pituitary CT should be performed in patients with suspected apoplexy.²¹ High signal will be seen on both T1- and T2-weighted MRI images.

Management

The first priority in managing a patient with pituitary apoplexy is to ensure haemodynamic stability. Empirical steroid therapy is used in patients who are haemodynamically unstable, demonstrate reduced visual acuity or who have a reduced consciousness level. It is recommended that a 100–200 mg bolus of hydrocortisone is used as initial therapy, followed by either continuous intravenous infusion of hydrocortisone or 6-hourly intra-muscular injections.²¹

In patients who are not haemodynamically unstable, steroid treatment is considered in those for whom 9 a.m. serum cortisol is less than 550 nmol/L. Patients with mild, stable or improving symptoms can be managed conservatively; in cases with severe or progressive visual impairment or altered mental state, early surgery provides the optimal chance for neurological recovery. The decision on whether to proceed to surgery must be taken by a multi-disciplinary team with appropriate expertise in endocrinology, ophthalmology and neurosurgery. If conservative management is elected for and a new visual deficit arises, decompressive surgery should be reconsidered.

KEY POINTS

PITUITARY APOPLEXY

- Pituitary apoplexy is a medical emergency in which infarction of the pituitary gland occurs.
- It should be considered in all patients with sudden-onset headache, meningism, reduced consciousness and visual impairment.
- Pituitary hormones should be assayed.
- Urgent MRI or focused pituitary CT should be undertaken in all patients suspected of pituitary apoplexy.
- Use empirical steroid therapy if the patient is haemodynamically unstable.
- Early surgery may support recovery in patients with severe or progressive symptoms.

LYMPHOCYTIC HYPOPHYSITIS

This rare chronic inflammatory condition of the pituitary most commonly presents in late pregnancy or in the first postpartum year.²² It is considered to be autoimmune in

origin and antipituitary antibodies have been implicated in its pathogenesis. A lymphoplasmacytic infiltrate is seen and causes variable destruction, oedema and fibrosis of the pituitary parenchyma with resultant mass effects and hypopituitarism. Corticosteroids may play a role in the management of this condition but its natural history is yet to be determined. Spontaneous recovery has been reported.

Investigations

Biochemical and imaging tests used in cases of suspected hypopituitarism are complex and discussed in [Chapter 83](#). Briefly, these investigations are employed both to identify and determine the extent of hormone deficiency, and to elucidate the cause of the hormone deficiency. Biochemical analyses to identify hypopituitarism include both the assessment of basal hormone levels and dynamic testing. Additional investigations such as angiotensin-converting enzyme (ACE), ferritin, hCG and aFP may be required to identify an underlying cause for the hypopituitarism, and imaging with MRI is mandatory. In some instances biopsy may be required to determine the aetiology of an underactive pituitary gland.

Anterior pituitary hormone replacement

[Table 84.3](#) summarizes the clinical features associated with adult-onset anterior pituitary hormone deficiency.

GROWTH HORMONE DEFICIENCY AND REPLACEMENT

Clinical features of GH deficiency

Adult-onset growth hormone deficiency occurs in 1/10 000 persons. It is specifically associated with a triad of poorer skeletal health, increased cardiovascular risk and impaired quality of life (QOL).^{18, 23} Patients with GH deficiency most frequently report reductions in their energy and vitality, and manifest greater emotional liability, impaired socioeconomic performance and poorer relationship-building than matched control subjects.²⁴

TABLE 84.3 Clinical features associated with adult-onset anterior pituitary hormone deficiency

Hormone deficiency	Symptoms and signs
Gonadotrophins (LH and FSH)	Male: Loss of secondary sexual hair, erectile dysfunction, testicular atrophy Female: Anovulatory cycles, oligomenorrhoea, amenorrhoea
Prolactin	Inability to lactate
Growth hormone	Poor skeletal health, increased cardiovascular risk, impaired quality of life
ACTH	Addisonian features without hyperpigmentation
TSH	Weight gain, cold insensitivity, constipation, dry skin, hair loss, fatigue
ADH	Polyuria, polydipsia

Given the vital role of GH in lipid, protein and carbohydrate metabolism, it is perhaps unsurprising that GH deficiency is associated with increased cardiovascular risk. This is specifically conferred by a cacophony of changes that include increased central fat deposition, decreased lean mass, increased total and low-density lipoprotein cholesterol, increased triglycerides, a reduction in insulin sensitivity and hypertension.²⁵ Endothelial dysfunction has also been reported, as has an increase in inflammatory markers, the development of microvascular abnormalities and changes in cardiac size and function.²⁶

A reduction in bone turnover is a further consequence of GH deficiency and bone mineral density falls as a consequence. There are in addition reports of a resultant increase in the risk of radiologically diagnosed vertebral fractures and clinically identified non-vertebral fractures. GH deficiency is also seen to negatively impact on exercise capacity, renal function and the maintenance of healthy skin.²⁵

Rationale for GH replacement

There is no evidence to date to conclude that GH replacement eliminates the excess mortality seen in instances of GH deficiency and the degree to which GH replacement should be administered remains controversial.^{25, 27} In many countries universal replacement is provided to all patients with deficiency in order to counter the deleterious clinical features outlined above. For a number of European countries, however, GH replacement is provided only to those with impaired QOL or reduced bone mass. Guidelines published by the UK National Institute for Health and Care Excellence (NICE) in 2003 restrict GH to patients with severe GH deficiency (GH < 9 mU/L) and impairment of QOL (defined as a QOL-Assessment of Growth Hormone Deficiency in Adults (AGHDA) score of greater than or equal to 11).²⁸

Treatment and monitoring

In paediatrics GH is generally administered at a dose based on each patient's body weight and surface area. A similar approach in adults resulted in a number of side effects, including significant fluid retention, and this dosing strategy is consequently not commonly used. Management of adult GH deficiency instead relies on dose titration.²⁵ Respective starting doses of 0.2 mg/day and 0.3 mg/day are recommended for males and females, though this dose should be reduced to 0.1 mg/day in older patients. Serial IGF-1 measurements are then used to monitor GH replacement with a target of the middle-upper end of the age-matched IGF-1 range. In the steady state IGF-1 levels should be repeated at least annually. Repeat measurements are nevertheless required 6 weeks after each dose change. Close monitoring of markers of HbA1c, lipids and bone mineral density are also required during treatment with GH.

GH replacement cannot be continued in cases of active malignancy, in patients with idiopathic intra-cranial hypertension and in patients with proliferative retinopathy as a consequence of diabetes mellitus.

KEY POINTS**ISOLATED GH DEFICIENCY**

- Isolated GH deficiency is associated with poor skeletal health, impaired quality of life and increased cardiovascular disease.
- There is no absolute evidence for a reduction in mortality following GH replacement.
- Guidelines differ. Current UK NICE guidelines advocate treatment if quality of life is impaired.
- Dose titration is required to establish the correct GH regime.
- GH replacement may be contraindicated in certain circumstances.

THYROID-STIMULATING HORMONE DEFICIENCY AND REPLACEMENT

Once-daily thyroxine is sufficient for hormone replacement in central thyroid hormone deficiency.²⁹ Given that TSH is deficient, it cannot be used to identify the optimal replacement dose. This should instead be estimated based on clinical assessment and measurement of circulating (free) thyroid hormone levels, which are conventionally recommended to be in the middle or upper part of the albeit rather broad normal range. It is important that fT4 levels are taken prior to ingestion of thyroxine on the day of sampling.

GONADOTROPHIN DEFICIENCY AND REPLACEMENT

Oestrogen and testosterone replacement are respectively the usual method of sex hormone replacement for males and females with gonadotrophin deficiency. Gonadal steroid replacement will not, however, induce fertility. Patients who are seeking to conceive must therefore receive gonadotrophin therapy.²³

Therapy in males

Testosterone replacement is required by males with gonadotrophin deficiency both to relieve the symptoms of hypogonadism (such as a reduction in libido) and to counter the long-term consequences of hypogonadism (such as osteoporosis). A link between testosterone deficiency and cardiovascular disease has been postulated but is far from proven. When given as replacement, testosterone may be administered via the transdermal route as a gel or patch, as an intra-muscular depot or as oral therapy. Patient preference, pharmacokinetics, treatment burden and cost should be considered in choosing between administration routes when initiating testosterone therapy.

The Endocrine Society has published guidelines for the management of adult men receiving testosterone therapy.³⁰ These advise that patients are evaluated within 3–6 months of treatment initiation in order to assess both response to treatment and the presence of adverse effects. Serum testosterone levels should be monitored at 3–6 months after treatment initiation and kept within the mid-normal range.

Baseline assessment and regular reassessment of haematocrit is required as excess androgen replacement is known to cause polycythaemia. Bone mineral density assessment is also advised within 2 years of testosterone replacement initiation in patients with osteoporosis or previous low trauma fracture. Prostate-specific antigen (PSA) levels also require regular monitoring in patients for whom initial levels exceed 0.6 ng/mL. The adverse sequelae of testosterone replacement remain uncertain and further research is required to conclude whether there is any association with increased prostate volume and a greater burden of cardiovascular disease.

Induction of spermatogenesis can occur with both gonadotrophin injections and subcutaneous pulsatile infusions of GnRH. Patients should be aware that this induction of spermatogenesis takes at least 3 months and may require over a year of therapy.

Therapy in females

Oestrogen is required by women of premenopausal age and may be administered as oral or transdermal therapy. The risks postulated for the use of hormone replacement therapy (HRT) in postmenopausal women are not thought to apply to the premenopausal setting.

Gonadotrophin injections and subcutaneous pulsatile infusions of GnRH are successful treatments for both hypothalamic gonadotrophin deficiency and primary pituitary disease. Ultrasound monitoring is required to assess ovarian response.

ACTH DEFICIENCY AND REPLACEMENT

Glucocorticoids are generally required in instances of ACTH deficiency. Strategies for effective glucocorticoid replacement are discussed elsewhere in this book and apply to this setting.

EMPTY SELLA SYNDROME

Empty sella syndrome (ESS) refers to a rare condition in which the sella turcica – a saddle-shaped depression of the sphenoid bone that forms the pituitary fossa in which the pituitary gland ordinarily sits – appears on radiological imaging to be partially or completely filled with cerebrospinal fluid.³¹ This occurs as a consequence of the herniation of the suprasellar subarachnoid space into the intrasellar space, with resultant compression of the pituitary gland. Both primary and secondary forms of ESS have been described.

In primary ESS weakness of the diaphragma sella or increased intra-cranial pressure is thought to promote arachnoid membrane herniation. This most commonly occurs in obese women and both hypertension and headache are common concomitant features. Hypopituitarism is uncommon and management is supportive. ESS is considered to be secondary in instances in which it follows pituitary radiation, surgery, infection or infarction. Clinical findings in cases of secondary ESS commonly include visual abnormalities and symptoms reflecting loss of pituitary function.

PITUITARY ADENOMAS

Benign tumours arise within the pituitary gland and have been recognized in as many as one in four persons in post-mortem and radiological studies. Only a small proportion of these are clinically apparent. These result in considerable morbidity both as a consequence of the production of excess pituitary hormone and through mass effect from compression of surrounding structures.

Definitions

Pituitary adenomas are benign neoplasms which do not typically metastasize and which may be categorized into those that produce hormones and those that fail to efficiently secrete their gene product.³² These are respectively termed 'functioning' and 'non-functioning'. Functioning adenomas may arise from any one (or more) of the anterior pituitary cell types and are commonly categorized by their cytodifferentiation. While the majority produce a single hormone, 1–30% express more than one hormone and are described as plurihormonal.

Pituitary tumours are additionally classified by size, with those exceeding 1 cm in diameter termed macroadenomas and those less than 1 cm in diameter referred to as microadenomas.

Pathophysiology

There has been considerable interest in pituitary tumorigenesis and a number of potential subcellular therapeutic targets have been delineated.³³ Our understanding of the development of pituitary adenomas nevertheless remains incomplete. A number of mechanisms have been implicated in pituitary tumorigenesis, including tissue plasticity and the dysregulation of both transcription and the cell cycle through a number of specific tumour-initiating and tumour-promoting factors.

Although no single initiating factor has been identified as pathognomonic for pituitary adenoma pathogenesis, these tumours are monoclonal and intrinsic molecular events are thus thought to lead to pituitary tumorigenesis. These early events are recognized to include epigenetic changes and increasing pituitary chromosome instability. Despite this, pituitary adenomas are invariably benign and their mitotic activity remains at relatively low frequency with key mutations found in common malignancies (such

BOX 84.2 Key molecular mechanisms implicated in pituitary tumour pathogenesis

Oncogene activation: e.g. GNAS, CCND1, HMGA2, FGFR4 and H-Ras

Tumour suppressor gene inactivation: e.g. AIP, MEN1, PPKAR1A, Rb and BRG1

Cyclin mutation: e.g. the CCNB2 cyclin and CDKN2A cyclin-dependent kinase inhibitor

Securin overexpression: PTTG has been found to be overexpressed in pituitary tumours

as p53 mutations) only rarely found. Proliferative restraint may be conferred by mechanisms required to ensure the tissue plasticity required by the pituitary gland to maintain physiological homeostasis. **Box 84.2** summarizes key molecular mechanisms implicated in pituitary tumour pathogenesis.

An understanding of the growth of pituitary adenomas is also important for delineating symptoms relating to their mass effect. Extension of pituitary adenomas outside of the pituitary fossa may occur in a superior, inferior or lateral direction (**Table 84.4**).

Investigations

BIOCHEMISTRY

Biochemical evaluation of pituitary function involves both direct assessment of hormone levels and dynamic testing. This is discussed in more detail below.

IMAGING

Imaging of the pituitary is covered in more detail in **Chapter 83**. In summary, imaging may be used to identify both intrinsic and extrinsic pituitary abnormalities in suspected adenomas (**Figures 84.1–84.4**).^{34, 35}

The identification of an intrinsic lesion within a normal-sized pituitary in a patient with clinical features of a functioning adenoma may, however, be misleading because there is a significant background prevalence of asymptomatic pituitary adenomas in the general population. Concluding in a systematic review published in 2004, Ezzat and colleagues, for instance, identified an overall prevalence of pituitary adenomas of 16.7% (14.4% in autopsy studies and 22.5% in radiological studies).³⁶

TABLE 84.4 Extrinsic pituitary adenoma spread

Direction of extrinsic pituitary spread	Expected symptoms	Notes
Superior, into the suprasellar cistern	Visual field defects: superior temporal quadrantanopia, bitemporal hemianopia	Most common direction of spread
Lateral, into the cavernous sinus	Usually asymptomatic	
Inferior, into the sphenoid sinus	Usually asymptomatic Possibility of CSF rhinorrhoea or meningitis	May result in a connection between the CSF spaces and the nose

Figure 84.4 Sagittal T1-weighted MRI showing haemorrhage into a macroadenoma. H, area of haemorrhage; ss, sphenoid sinus.

A more recent review authored by Karavitaki in 2012 reported a prevalence of 78–94 cases/100000 inhabitants.³⁷ It is also apparent that small functioning adenomas may not be visible on imaging.

Imaging is also used to provide information on invasion or displacement of adjacent structures if a tumour extends out of the pituitary fossa (termed an extrinsic pituitary abnormality).

VISUAL FIELD ASSESSMENT

Pituitary tumours result in visual field defects in some, but not all, patients.³⁸ When present, the typical visual field abnormality is a bitemporal superior quadrantanopia or hemianopia, but this will depend on the position of the optic chiasm in relation to the pituitary. The earliest detectable abnormality is loss of perception of a red target.

In most cases the visual field impairment is reversible if detected and treated early. It is thus imperative that all patients with pituitary tumours who complain of visual disturbance are referred for an ophthalmologist's opinion and visual field testing. Similarly, visual field assessment is vital pre- and post-operatively in patients with a macroadenoma that abuts the optic nerves or chiasm, even if there are no ocular symptoms.³⁸

Functioning pituitary adenomas

PROLACTINOMA

Prolactin

Human prolactin is a protein consisting of 199 amino acids. It has similarities with GH and, though its predominant and most active form is a monomer, it also circulates as a dimer and polymer. Serum assessment of prolactin level is a reliable measure of this hormone and is used for both the diagnosis of prolactinoma and to monitor the effect of treatment. Circulating levels are higher in women than in men.

Prolactin regulation occurs via neural and feedback pathways to the hypothalamus and anterior pituitary. Inhibitory factors – PIF – and releasing factors are involved in the control of prolactin release. The main PIF is dopamine. Around 12–28% of cells in the normal anterior lobe produce prolactin. The control of secretion is complex and a wide range of factors and conditions influence prolactin secretion.

The main site of action of prolactin is the mammary gland where it acts to prepare for milk production and to maintain it.

Prolactin excess

Physiologically high levels of prolactin are to be expected during pregnancy and lactation. Pathological causes of hyperprolactinaemia include autonomous secretion of prolactin by a pituitary prolactinoma and loss of PIF from the hypothalamus. Levels of prolactin may be very high in prolactinomas and can exceed 10 000 mU/L. It is important to note that non-functioning adenomas may cause a moderate rise in prolactin levels of up to approximately 2000 mU/L.³⁹ This is likely a consequence of a loss of PIF due to stalk compression by the adenoma. Prolactin may also be elevated in GH-secreting adenomas as it can be produced in excess along with GH.³⁹

Clinical features Physiological and pathological hyperprolactinaemia provide negative feedback on the hypothalamo-pituitary axis and suppress the release of GnRH. Clinical sequelae of hyperprolactinaemia include galactorrhoea. Amenorrhoea may also occur in women as a consequence of reduced gonadotrophins.^{39, 40} Men are usually relatively asymptomatic but low gonadotrophin levels may reduce the secretion of testosterone, causing loss of libido.⁴⁰ Importantly, prolactinomas may cause few symptoms and no pituitary macroadenoma should be assumed to be non-functioning unless serum prolactin is less than 2000 mU/L.

Management Dopamine agonists, such as bromocriptine and cabergoline, are the first-line treatment for prolactinomas.^{40, 41} Serum prolactin levels can be used to monitor their effect, as can neuroimaging. It is expected that prolactin levels will fall and that the tumour will shrink with dopamine agonist therapy but neither is guaranteed. Surgery or radiotherapy may be used in patients intolerant of or resistant to dopamine agonist therapy, and serum

prolactin levels would again be used to monitor the result of either of these interventions.⁴²

KEY POINTS

PROLACTINOMA

- Prolactin has an important role in preparing for lactation.
- Prolactin is physiologically raised during lactation and in pregnancy.
- Mild hyperprolactinaemia may occur in stress, with use of antidopaminergic drugs and in pituitary stalk compression.
- Prolactinomas can cause very high levels of prolactin and may result in galactorrhoea or amenorrhoea.
- Dopamine agonists are first-line treatment.

SOMATOTROPH ADENOMAS (SOMATOTROPHINOMAS)

Growth hormone

Also known as somatotrophin, GH is a single-chain 191 amino acid protein synthesized by somatotrophic cells, which contribute approximately half of the cells of the anterior pituitary. GH acts either directly on cells when it binds to GH receptors, or indirectly when it triggers the production of insulin-like growth factors (IGFs), which are mainly synthesized in the liver. IGF-1 is the most important of the IGFs and its mean concentration reflects that of GH over time. Concentrations of both GH and IGF-1 can be measured in serum but, because normal secretion of GH is pulsatile and the hormone has a short half-life in circulation, unlike IGF-1 which has a long half-life, the concentration of IGF-1 is a very useful indicator of mean GH output.

The pulsatile release of GH means that the volume secreted may be varied by the frequency or the amplitude of its pulses. When considering the diurnal rhythm, output is highest during slow-wave sleep. Over a lifetime, output is highest during adolescence and decreases with age. A random GH is normally less than 5.5 mU/L.

GH is anabolic and stimulates protein synthesis. It is essential for normal growth and protein metabolism. It also induces lipolysis and is secreted during hypoglycaemia, raising energy from body stores. Conversely, hyperglycaemia suppresses GH output. GH is also known to antagonize insulin, which is why acromegaly (excess of GH) may induce the onset of diabetes mellitus or make it worse.

Growth hormone excess: acromegaly

Excess GH results from the development of a functioning somatotroph adenoma.⁴³ If this occurs prior to closure of the epiphyseal plate, the result is gigantism. Excess GH after epiphyseal plate closure is referred to as acromegaly.

Clinical features The clinical features that characterize acromegaly derive largely from GH/IGF-1 excess but may also reflect excess prolactin, given that it is co-secreted in approximately 30% of tumours.⁴⁴ Common signs and

TABLE 84.5 An overview of the symptoms, signs and complications of acromegaly

Symptoms	Signs	Complications
<ul style="list-style-type: none"> • Sweating • Arthralgia • Headaches • Increased shoe size • Increased hand size • Preoccupation with appearance can result from physical changes 	<ul style="list-style-type: none"> • Musculoskeletal • Enlargement of the hands and feet • Myopathy • Osteoarthritis • Deepening of the voice • Coarsening of the facial features • Jaw growth and macroglossia • Obstructive sleep apnoea commonly seen • Soft-tissue swelling • Carpal tunnel may result 	<ul style="list-style-type: none"> • Metabolic syndrome • Hypertension • Insulin resistance • Ischaemic heart disease • Cerebrovascular disease • Congestive cardiac failure • Visual field defects • Obstructive sleep apnoea • Colonic polyp formation

symptoms of acromegaly are summarized in [Table 84.5](#), as are the complications of this condition.

Diagnosis Random estimation of serum GH levels is unreliable as a consequence of its pulsatile release. Current Endocrine Society guidelines propose measurement of the downstream GH mediator IGF-1 in patients with features or conditions typically associated with acromegaly and in patients with a pituitary mass.⁴⁵ Acromegaly should subsequently be confirmed by identification of a lack of GH suppression to less than 1 µg/L in the presence of hyperglycaemia following on oral glucose load.⁴⁴ It is important to measure other pituitary hormones in view of potential pan-hypopituitarism. Serum calcium is also worth assessing as hypercalcaemia may result from the stimulation of renal 1α-hydroxylase by GH. MRI demonstrates a pituitary tumour in 98% of cases following biochemical diagnosis.

It is important to screen for conditions associated with acromegaly following diagnosis. This should include evaluation for hypertension, multinodular thyroid enlargement, diabetes mellitus, osteoarthritis, sleep apnoea and cardiovascular disease. Patients should also be screened for colonic neoplasia.

Management First-line treatment for most patients is transsphenoidal surgery.⁴⁶ Endoscopic approaches are increasingly employed to improve the success of this procedure, recurrence rates for which currently stand at 6% at 5 years.⁴⁷ Specific complications of surgical intervention include hypopituitarism, transient mild syndrome of inappropriate antidiuretic hormone (SIADH – see ‘Post-operative pituitary function’ below) and CSF leak. Surgery should be considered even in those patients for whom cure is not expected (such as in the case of large invasive macroadenomas), because it improves cure rate with medical management.⁴⁸

Radiotherapy is rarely used as a primary treatment for somatotroph adenomas but may be employed if transsphenoidal surgery is unsuccessful.^{49, 50} GH levels fall slowly after radiotherapy and may not return to normal for many years after treatment, meaning that adjunctive medical treatment is usually required and must be monitored at least annually. Side effects of radiation treatment include a risk of hypopituitarism and an approximate 2% increase in the incidence of second tumours within the

radiation field. Newer approaches to radiation therapy include intensity-modulated radiotherapy (IMRT) and stereotactic radiosurgery (SRS).⁵¹

Three broad classes of drugs are used in the medical management of acromegaly.⁵⁰ Long-acting somatostatin analogues suppress GH secretion in approximately two thirds of patients with acromegaly, with symptomatic improvement common. Tumour volume reduction is seen in a significant proportion of patients managed with somatostatin analogues.^{52, 53} Side effects include colic, diarrhoea and the development of gallstones.

Dopamine agonists also lower GH and IGF-1 levels but do not usually return these hormones to normal levels. Cabergoline is known to be more effective than bromocriptine and restores IGF-1 to normal in approximately one third of acromegalic patients.⁵⁴ Finally, for those patients who do not respond to somatostatin analogues, pegvisomant is indicated. This acts by inhibiting GH receptor functional dimerization. IGF-1 should be used to monitor response to this therapy and has been reported to return to normal in more than 90% of patients.^{55, 56}

KEY POINTS

FUNCTIONING SOMATOTROPH ADENOMA

- Acromegaly results from GH excess occurring after closure of the epiphyseal plate.
- Profound changes in physical appearance occur in untreated GH excess.
- Failure to suppress GH during a 75 g oral glucose tolerant test and elevated IGF-1 confirm the diagnosis of acromegaly.
- Transsphenoidal surgery is first-line therapy.
- There are long-term consequences to GH excess, including the metabolic syndrome and increased risk of colonic polyposis.

CORTICOTROPH ADENOMAS (CORTICOTROPHINOMAS)

ACTH

ACTH is a 39 amino acid peptide. It is derived from a large precursor protein which is found in the corticotrophic cells of the anterior and intermediate lobes of the pituitary, in some neuronal cell groups, in peripheral chromaffin cells

and some immune cells. In the anterior pituitary, 6–10% of cells are corticotrophs.

ACTH usually has a short circulating half-life and it is more usual to assay plasma cortisol levels and 24-hour urinary free cortisol production to screen patients for Cushing's syndrome. Both can be reliably measured. In normal subjects, plasma cortisol levels are highest in the morning and lowest at night. In Cushing's syndrome, this rhythm is absent and both plasma cortisol and urinary free cortisol levels are elevated.

Normal ACTH output is regulated by CRF and vasopressin. These two potentiate each other, but CRF output is suppressed by high circulating levels of glucocorticoids, whereas vasopressin is not. ACTH acts mainly on the adrenal cortex which secretes glucocorticoids, mineralocorticoids and androgens.

ACTH excess: Cushing's syndrome and Cushing's disease

Clinical features These are outlined in [Table 84.6](#). They may gradually worsen over a period of years prior to a formal diagnosis being established.

Diagnosis Establishing a diagnosis of Cushing's syndrome is complex as a consequence of the diurnal rhythm of cortisol release. Endocrine Society guidelines advise testing for Cushing's syndrome in patients with early-onset features such as osteoporosis and hypertension, and patients with progressive symptoms typical of Cushing's syndrome. The first aim in investigating Cushing's syndrome is to confirm elevated cortisol. The underlying cause must then be clarified.

Is this Cushing's syndrome? Circulating glucocorticoid levels and 24-hour urinary free cortisol can be measured by routine laboratory assays. Investigations commonly employed to screen for excess cortisol secretion are outlined in [Table 84.7](#). Two late-night salivary cortisol measurements may also be used for initial testing.

Physiological causes of hypercortisolism should be ruled out prior to confirming Cushing's syndrome. These include alcohol dependence, morbid obesity, poorly controlled diabetes mellitus, physical stress and pregnancy.

TABLE 84.6 Symptoms and signs of Cushing's syndrome

Symptoms	Signs
Mood disturbance	Change in facial appearance – 'moon facies'
Impairment of short-term memory	Development of striae
Loss of libido	Hirsutism
Irregular menstrual cycles	Easy bruising
	Weight gain & centripetal fat distribution
	Proximal myopathy
	Hypertension
	Osteoporosis/osteopenia
	Impaired glucose tolerance

TABLE 84.7 Investigations used to screen for Cushing's syndrome⁵⁷

Test	Comments
24-hour urinary free cortisol	This is a useful screening test but should not be used in isolation for diagnosis because of a significant false negative rate.
Circulating glucocorticoid levels	Levels are measured by routine laboratory assays. Normal plasma cortisol levels are subject to large diurnal variation and the precise levels will depend on the laboratory used. In our institution, University Hospitals Birmingham NHS Foundation Trust, Birmingham, UK, normal levels are 180–550 nmol/L at 09:00 and <130 nmol/L at 00:00. Loss of diurnal rhythm is a feature of Cushing's syndrome.
Overnight dexamethasone suppression test	Dexamethasone is administered at midnight and serum cortisol assayed at 09:00. Plasma cortisol is effectively suppressed in normal subjects but not in patients with autonomous ACTH secretion.

What is the underlying cause? Once cortisol excess has been confirmed, its aetiology must be identified in order to differentiate Cushing's disease from Cushing's syndrome.^{57, 58} This must be defined if treatment is to be appropriate and effective. Raised cortisol levels may be a consequence of excess production from the adrenal glands themselves, as in an adrenal adenoma or carcinoma, or due to excessive stimulation of the adrenal cortex by overproduction of ACTH, secreted from the pituitary or an ectopic source. The commonest cause of Cushing's syndrome is excess ACTH from the pituitary (70%), termed Cushing's disease.

The following investigations and results are used to determine the underlying cause of Cushing's syndrome:

- **ACTH:** If the source of excess glucocorticoids is adrenal, the plasma ACTH level will be suppressed.
- **Hypokalaemic alkalosis:** This is a feature of Cushing's syndrome due to ectopic ACTH, but not of Cushing's disease.
- **The high-dose dexamethasone suppression test:** This is used to differentiate between a pituitary source and an ectopic source of ACTH. While there are several variations of this test, the broad approach of this investigation is to exploit the differential sensitivity of feedback with increasing doses of dexamethasone between different causes of ACTH-dependent Cushing's syndrome. At low doses of 0.5 mg four times a day, for instance, the powerful glucocorticoid dexamethasone will suppress secretion of ACTH in normal subjects but not in subjects with autonomous ACTH secretion. However, pituitary secretion of excess ACTH is not totally autonomous, and so high doses of dexamethasone (2 mg four times a day) will suppress ACTH output from the pituitary. Conversely, ectopic sources of ACTH are more autonomous and suppression will not occur with either low- or high-dose dexamethasone.

TABLE 84.8 The dexamethasone suppression test

	Normal	Pituitary Cushing's	Ectopic Cushing's
Low-dose dexamethasone	Suppression of plasma cortisol and UFC	No effect	No effect
High-dose dexamethasone	Suppression of plasma cortisol and UFC	Suppression of plasma cortisol and UFC	No effect

A common approach to this test is to administer 2 mg dexamethasone orally every 6 hours for 48 hours. Serum cortisol is assessed prior to and following the administration of dexamethasone. Unfortunately, this test is not invariably accurate because 10–20% of ACTH-secreting pituitary adenomas do not suppress on high dose whereas 50% of ACTH-secreting bronchial carcinoid tumours show some suppression on high dose. It is therefore important to have additional evidence of a pituitary adenoma before concluding that the cause of Cushing's syndrome is a pituitary adenoma as opposed to an ectopic source of ACTH. This test is summarized in [Table 84.8](#).

- **CRF test:** If CRF is administered, ACTH levels will rise in normal subjects. This response is exaggerated in Cushing's disease but is typically absent if the source of ACTH is ectopic. However, once again this test is not foolproof. Up to 10% of pituitary adenomas do not respond to infused CRF as would be expected and a few ectopic ACTH-producing tumours do respond by secreting more ACTH.
- **Metyrapone test:** This is a sensitive test of ACTH reserve but is now used less frequently given the wide availability of ACTH assays. Briefly, metyrapone blocks glucocorticoid metabolism and should therefore result in a rise in ACTH. This response is usually exaggerated in Cushing's disease, but not if the source of ACTH is ectopic.⁵⁹
- **Inferior petrosal sinus sampling:** This is an invasive test used to define the source of excess ACTH, usually in instances in which pituitary MRI is normal or equivocal.⁶⁰ Given that Cushing's disease results from a microadenoma in more than 90% of cases, it is postulated that MRI identifies a causative lesion in only one third to two thirds of cases.⁶¹ Inferior petrosal sinus sampling is regarded as the 'gold standard' for the diagnosis of Cushing's disease.⁶² It may also predict adenoma lateralization, although it is usually accurate in only two thirds of patients, and holds out the prospect of localizing the source of ACTH within the pituitary itself.

This is an invasive technique, requiring cannulation of both inferior petrosal sinuses under radiographic control via the femoral vein. With the catheters in place, samples can be taken for hormonal assay. After baseline samples are taken to assay the pituitary hormone levels from each side, CRF is administered intravenously and further samples are taken to measure the effect on pituitary hormone output. High levels of ACTH in blood obtained from IPSS are strongly indicative of a pituitary source

of ACTH. A differential between the levels of ACTH in the IPS and peripheral sample is further evidence of a pituitary source. If this is combined with a CRF test, a rise in the ACTH levels can be demonstrated with CRF. This raises the sensitivity of the test to 95%. Although there are large venous connections between the cavernous sinuses, the venous blood between the two may not mix very much.⁶³ If there is a marked difference in the ACTH levels between the two sides, without a similar asymmetry in the levels of the other pituitary hormones (prolactin, GH, FSH, LH), tumours can be localized by this technique.

Management This section refers only to the management of Cushing's disease. The first-line approach in most instances is selective adenectomy via transsphenoidal surgery. Delayed normalization of cortisol levels following this procedure is not uncommon and complications of surgery are high as a consequence of patients' poor pre-operative performance status.⁶⁴ Up to 25% of patients will develop a recurrent adenoma.⁶⁵

Second-line treatment generally involves the use of radiotherapy.⁶⁴ Control of cortisol levels will not occur for a number of years (mean period of 2 years) and may induce hypopituitarism.

Medical management of Cushing's disease is often required during radiotherapy to control cortisol levels. Medical therapy is also indicated in instances in which surgery fails to control cortisol output or to treat acute, potentially life-threatening disease complications such as opportunistic infections, psychosis and severe hypertension.⁶⁶ Approaches include pituitary-directed treatments such as somatostatin analogues, administration of adrenal blocking drugs including mitotane and ketoconazole, and in a proportion of patients use of glucocorticoid antagonists such as mifepristone. Combination therapy is often required.

Bilateral adrenalectomy was previously favoured as the treatment of choice for Cushing's disease and may still be indicated if pituitary surgery, radiotherapy and medical treatment fail to control cortisol levels.⁶⁷ A laparoscopic approach can be used to reduce morbidity. An important complication of bilateral adrenalectomy is Nelson's syndrome.⁶⁸ This describes the rapid enlargement of a pituitary lesion as a consequence of the loss of negative feedback from high cortisol levels following adrenalectomy. It presents with visual and ocular effects, in addition to hyperpigmentation as a consequence of high circulating levels of ACTH. Prophylactic radiotherapy can be used to minimize the risk of this complication.

KEY POINTS

CORTICOTROPH ADENOMA

- Cushing's disease results from a functioning corticotroph adenoma.
- Hypercortisolaemia results in mood disturbance, loss of libido, change in facial appearance, proximal myopathy, weakened skin, easy bruising and a raft of other signs.
- Investigations into suspected Cushing's syndrome should first identify hypercortisolaemia and subsequently locate the source of the hypercortisolaemia.
- Inferior petrosal sinus sampling is essential when there is doubt about the origin of ACTH-dependent Cushing's syndrome.

TSHOMA

TSH

TSH induces release of both T4 and, to a lesser extent, T3. Most T4 is converted to T3 within the peripheries. In cases of primary hyperthyroidism, negative feedback from fT4 and fT3 results in inhibition of TSH release.

TSH excess

TSH secreting adenomas are rare and represent only a very small percentage of functioning adenomas.^{69, 70}

Clinical features Patients may present with features of hyperthyroidism but on investigation for this will be identified to have inappropriately normal or elevated TSH levels.

Establishing a diagnosis Thyroid function tests are a key first-line investigation. If a TSHoma is suspected following thyroid function testing, an MR scan of the pituitary gland should be undertaken. Tumours may be micro- or macroadenomas.

Management Surgical excision, radiotherapy and medical treatment are all options for the management of TSHomas. These tumours respond well to somatostatin analogues.⁶⁹ They can, however, be more aggressive than standard pituitary adenomas and long-term biochemical and imaging follow-up is therefore appropriate. Radiotherapy can be considered if surgical cure is not possible.

GONADOTROPHINOMAS

These seldom present as functioning tumours. The diagnosis of a gonadotrophinoma is usually made on immunohistochemical analysis of non-functioning adenoma tissue following surgery.

FSHOMA

FSH

FSH is secreted by the gonadotrophin cells of the anterior pituitary and shares an alpha-subunit with LH, TSH and HCG. The specific actions of FSH, conferred by its beta-subunit, include stimulating germ-cell maturation, initiation

of follicular growth in females and regulation of androgen-binding production from Sertoli cells in males. FSH secretion is enhanced by activin and reduced by inhibin.

FSH excess

FSH-secreting adenomas are seen more commonly in men and premenopausal women but are nevertheless rare.

Clinical features FSH-secreting pituitary adenomas are usually asymptomatic. Clinical features in male patients generally relate to tumour mass effect and the development of hypogonadism. An association between FSHoma and macroorchidism has also been reported, particularly in prepubertal males.⁷¹ Development of an FSHoma in a premenopausal woman can result in ovarian hyperstimulation syndrome. This manifests as abdominal bloating secondary to increased ovarian size or the accumulation of ascites. FSH-secreting adenomas arising in postmenopausal women are invariably asymptomatic and present a significant diagnostic challenge.

Establishing a diagnosis Measurement of FSH is key in women.⁷² In premenopausal women, elevated serum oestradiol with inappropriately high FSH is indicative of an FSHoma. LH is usually normal or suppressed, differentiating the clinical picture from that of polycystic ovarian syndrome. In postmenopausal women, a raised FSH may represent an FSHoma and warrants further investigation, with a higher index of suspicion confirmed by concomitant suppression of LH. Pituitary MRI is required to assess for a macroadenoma and this may often be the first-line investigation in men, who generally present with mass effect, though FSH should also be assessed.⁷² Ultrasonography may additionally be employed in premenopausal women and in men in order to respectively identify ovarian cysts and macroorchidism.

Management Management requires multidisciplinary team input. Options include watchful waiting, surgery and radiotherapy.⁷³ Medical therapy is not generally effective for gonadotroph adenomas.

Non-functioning pituitary adenomas

These do not present with overt hormone excess and are instead characterized by the consequence of a space-occupying lesion spreading out of the pituitary fossa. They may be associated with partial or complete hypopituitarism. This classically involves a progressive loss of pituitary hormone secretion with gonadotrophins (LH and FSH) affected first, followed by GH, TSH and ACTH. Children may present with cessation of growth or delayed puberty.⁷⁴

Diagnosis of non-functioning adenomas relies on both neuroimaging and the biochemical assessment of pituitary function. Prolactin should also be assessed but may be elevated in non-functioning pituitary adenomas. It is essential both that any hormone deficiency is corrected and that asymptomatic functioning adenomas are identified, particularly in the case of prolactinomas as medical management may render surgery unnecessary.

PITUITARY CARCINOMA

Pituitary carcinoma accounts for less than 0.1% of all tumours and is most commonly ACTH- or prolactin-secreting, though a significant proportion are non-functioning.⁷⁵ These tumours are more likely to be p53 positive. By definition, pituitary carcinomas feature evidence of metastatic disease. Metastases are more likely to be systemic (to liver, bone, lungs and the lymphatic system) than craniospinal. Mass effects predominate and surgery forms the mainstay of management. There is some evidence for the use of chemotherapy but data from controlled trials are lacking. Favourable responses have been reported with use of the alkylating agent Temozolomide.⁷⁶ Palliation may otherwise be afforded through medical management with dopamine agonists for malignant prolactinomas, and from the use of radiotherapy. Prognosis is poor and most patients die within a year.⁷⁵

FAMILIAL PITUITARY TUMOUR SYNDROMES

Familial pituitary tumours are rare and account for less than 1 in 20 pituitary adenomas. They are nevertheless recognized to occur as part of multiple endocrine neoplasia type 1 (MEN 1), multiple endocrine neoplasia type 4 (MEN 4), Carney complex and familial isolated pituitary adenomas.

Multiple endocrine neoplasia type 1

MEN 1, alternatively known as Wermer's syndrome, is characterized by dermal tumours (including lipomas, lentiginosis and angiofibromas) in addition to tumours of the parathyroid, pancreas and pituitary. This occurs as a result of mutations in the *MEN1* gene and genetic analysis is recommended in patients with a strong family history and recurrent neoplasia in the organ distribution described above.⁷⁷

Multiple endocrine neoplasia type 4

MEN 4 has only recently been described and occurs as a consequence of mutations in the *CDKN1B* tumour susceptibility gene.⁷⁸ The number of patients with MEN 4 remains low and there are consequently not yet guidelines in place for the management of patients with MEN 4.

Pituitary adenomas are the second most common tumour type occurring in patients with *CDKN1B* mutations.⁷⁷

Carney complex

Pituitary adenomas are seen in approximately one in five patients with this rare autosomal dominant condition.⁷⁹ Other tumours seen include myxomas of the breast, skin and heart, in addition to adrenal testicular and thyroid tumours.

Familial isolated pituitary adenomas

Familial isolated pituitary adenomas (FIPAs) represent 2% of all pituitary adenomas.⁸⁰ Around one in five cases of FIPA are thought to result from mutations of the aryl hydrocarbon receptor-interacting protein (AIP) gene, which causes pituitary adenoma predisposition of variable penetrance. Gigantism is a particular feature of AIP mutations and germline *AIP* mutations have been shown to correlate with the development of large pituitary adenomas.

POST-OPERATIVE PITUITARY FUNCTION

In functioning adenomas, successful surgery should correct the excess hormone secreted by the adenoma. It may, however, additionally render the patient deficient in other pituitary hormones and is unlikely to restore hormone levels which were deficient pre-operatively.

Hormone assays are used to assess the results of treatment. In microadenomas a resolution of the hormonal excess and persistently normal or low levels of that hormone indicate a cure and are a more accurate method of assessing the results of treatment than imaging. It is essential to test for all the pituitary hormones because the patient may develop a deficiency of any of them. If the pituitary is irradiated, the onset of hypopituitarism may be gradual. Lifelong follow-up is important, as recurrence or hypopituitarism can occur years later.

Patients should be advised that they may experience headaches following their procedure, that they must double their hydrocortisone dose if they are unwell and that they should not discontinue their medication without prior discussion with a health professional. Importantly, patients should also be advised not to drive following surgery until their vision is reassessed and to avoid sporting activities for 6–12 weeks.

FUTURE RESEARCH

There are a number of promising areas of future research in pituitary disease. Advances in genetically engineered mouse models and DNA sequencing technology may provide insight into mechanisms underlying tumour pathogenesis and invasiveness, leading to personalized genetic characterization and tailored treatments.

Chemokines (signalling proteins secreted by cells) have been identified as novel regulators of normal and tumour

pituitary cell function; studies targeting chemokine networks may reveal novel therapeutic approaches for managing pituitary tumours.⁸¹

The role of tyrosine nitration in pituitary disease has also been studied; elucidation of mechanisms and biological functions of tyrosine nitration in pituitary tumourigenesis could potentially provide biomarker targets for novel pharmacological agents.⁸²

KEY POINTS

- The pituitary gland plays an important role in regulating reproduction, metabolism and growth.
- Production of pituitary hormones is subject to marked cyclical rhythms, necessitating dynamic testing to diagnose some pituitary hormone excesses or deficiencies.
- Hypopituitarism may be congenital or acquired, and may feature isolated or combined hormone deficiencies.
- Benign pituitary adenomas are common, though many do not present clinically. They may be functioning or non-functioning.
- In functioning adenomas, clinical characteristics are determined by the effects of the excess hormone.
- Extrinsic growth of a pituitary adenoma can result in visual field impairment, or rarely CSF rhinorrhoea and meningitis.
- Management of post-operative pituitary hormone deficiencies requires specialist multidisciplinary team input led by an experienced endocrinologist.

Technical pearls for tumour removal	944	References	949

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: pituitary tumours, pituitary surgery, revision pituitary surgery, recurrent pituitary tumours and functional pituitary adenomas.

INCIDENCE OF RECURRENT PITUITARY TUMOURS

Recurrence of pituitary adenomas after traditional microsurgical removal is not uncommon. In the relevant literature, recurrence rates for pituitary adenomas vary between 7% and 21%.¹ Similarly, it is clear that regrowth after incomplete tumour removal is a very likely event, being reported in 39–75% of cases.^{2–9} Risk factors for recurrence include incomplete resection at the initial surgery, frank invasion of the cavernous sinus, tumour type and strong expression of pituitary tumour transforming gene.^{10–12} Gross total removal rates after endoscopic endonasal approach (EEA) removal of primary non-recurrent pituitary adenomas have been reported to be high, in the range of 77–96%.^{13–16} In a meta-analysis of endoscopic surgery for pituitary adenomas, Tabae and colleagues reported the overall gross total resection rate to be 78%.¹⁷ The main factor limiting total resection was frank invasion of the cavernous sinus.¹⁷

Cavallo et al. noted a recurrence rate of 9% (59 of 635) of pituitary adenomas. After retrospectively analysing the patients who recur, they noticed that at primary surgery 38.9% of them (23 of 59 patients) had a lesion with negative predictive factors, such as a cavernous sinus invasion, high labelling index or young age at diagnosis.¹⁸

Surgery for recurrent tumours is indicated in the presence of mass effect or systemic effects of persistent hormonal hypersecretion, as observed in Cushing's disease and acromegaly/gigantism. Small recurrences confined to the lateral cavernous sinus region must be considered for radiation treatment.

PRE-OPERATIVE EVALUATION

In addition to the necessary clinical and diagnostic information used to indicate revision surgery, additional information should be sought in order to improve the safety and efficiency of subsequent surgery. Accordingly, the aims of the pre-operative evaluation are:

- to identify sequelae of the previous procedure that may hinder the efficient creation of a sinonasal corridor (e.g. significant sinonasal scarring or the presence of a foreign body used for the previous reconstruction)
- to develop an understanding of the reconstructive options available
- to identify any contraindications to surgery, such as active, untreated infection
- to identify sequelae of the previous procedure that may increase the risk of subsequent procedures (e.g. pseudoaneurysm).

Office-based nasal endoscopy is useful to guide the surgical planning, particularly in the setting of revision surgery. This allows the surgeon to assess the sinonasal cavity for surgical approach and reconstructive options, as well as to rule out sinonasal sequelae and the presence of infection. First, nasal endoscopy provides the surgeon with the necessary information to determine what form of reconstruction was performed prior to the revision (i.e. free graft or nasoseptal flap, NSF). Furthermore, careful inspection of a potential NSF will guide reconstructive options, in the event that a large cerebrospinal fluid (CSF) leak requiring vascular reconstruction occurs during the surgery. During the conventional transseptal approach with a microscope, there is risk of septal perforation or compromise of the sphenopalatine artery (SPA) or posterior septal artery, which supply the nasoseptal flap (Hadad-Bassagasteguy flap).¹⁹ Therefore, in patients who have been operated on in this fashion previously, alternative flaps or other techniques will need to be considered in the event that a vascularized reconstruction is necessary (see ‘Reconstruction options’ below).

Meticulous radiological assessment is crucial when planning a revision pituitary surgery, particularly when dealing with recurrent functional microadenomas. Dedicated magnetic resonance imaging (MRI) of the sellar and parasellar regions can demonstrate tumour location, status of the medial cavernous sinus wall, distance of the lesion to the optic apparatus, signs of stalk deviation and degree of scarring tissue the surgeon may expect to find.

Any patient who underwent a previous transsphenoidal procedure must be considered for a vascular study in order to evaluate the internal carotid arteries (ICAs). It is very important to rule out the presence of pseudoaneurysm from previous cavernous sinus manipulation particularly if the same skull base team did not perform the original surgery. Furthermore, imaging such as computed tomography angiography (CTA) can be very helpful in ruling out previous vascular complications and can be used in the image guidance system localizing the ICAs, which may be completely exposed out of their canal due to the previous surgery. The CTA is also useful in determining the presence of buttress materials left during the previous procedure.

Complete endocrine evaluation is always necessary before any pituitary procedure in order to establish the patient’s baseline and to rule out or confirm pre-operative hormonal deficits. This evaluation includes assessment of the following hormones:

- prolactin
- growth hormone (GH)
- insulin-like growth factor 1 (IGF-1)
- cortisol
- adrenocorticotrophic hormone (ACTH)
- thyroid-stimulating hormone (TSH)
- free triiodothyronine (T3)
- total thyroxine (T4)
- testosterone
- luteinizing hormone (LH)
- follicle-stimulating hormone (FSH).

Patients with hypopituitarism require appropriate replacement to avoid peri-operative complications, particularly if their cortisol levels are found to be low. Conversely, if cortisol levels are normal, the patients do not receive a steroid stress dose during anaesthetic induction to prevent confusion in the immediate post-operative lab values. Diabetes insipidus (DI) must be ruled out and addressed properly when present; the anaesthesiology and post-operative care teams must be aware of this condition and maintain the use of desmopressin when it is detected before surgery.

Patients with tumours causing compression of the optic apparatus must also be evaluated by ophthalmology. As with the endocrine assessment, this seeks to establish a baseline for post-operative comparison. If the patient has no objective visual deficit but the original tumour presented with optic compression, the ophthalmological evaluation is also required.

INTRA-OPERATIVE IMAGING NAVIGATION AND POSITIONING

In the setting of revision surgery, pre-operative imaging plays a critical role; this is in part due to the close relationship to important orbital and intra-cranial structures. Transsphenoidal approaches to the sella demand a high degree of surgical precision and an accurate understanding of the pertinent anatomical relationships.²⁰ This task can be challenging in patients with altered anatomy and poor anatomical landmarks, frequent in those patients who have had previous surgery or who have disease invading or engulfing the surrounding structures.^{21, 22}

Both osseous and neurovascular structures may serve as important landmarks during transsphenoidal approaches to the sella. Hence, both computed tomography (CT) and MRI have their advantages and disadvantages: CT scans are generally optimal for identifying bone integrity and bony landmarks, while MRI is more suited for soft-tissue differentiation. The CT can also provide additional surface points during surgery and thus increase navigation accuracy.

The authors find that intra-operative navigation is especially useful during revision surgery, where normal anatomical structures may be distorted and, as mentioned above, there is a need to rule out previous vascular complications.^{23, 24} In this setting, we resort to MRI navigation with the intent to better define the interface of tumour and normal anatomy fused with CTA, which can demonstrate more clearly the bony formation and changes caused by the previous procedure and the vascular structures. Ideally, fusion of the two modalities allows for discrimination of the tumour not only with surrounding soft tissue but also with the ICA and other vessels for more complex tumours, such as the relationship with the basilar artery and anterior circulation. That said, the surgeon often finds the tumour/gland interface to be misleading and must rely on direct observation during dissection to achieve optimal resection rates. These tumours may expand superiorly to

the suprasellar space, laterally to the cavernous sinus or inferiorly to the clivus. Information regarding key anatomical landmarks can be provided by the intra-operative image guidance system and are valuable in order to achieve safe tumour removal.²⁵

Prior to setting up the intra-operative navigation system, the surgical team must decide if there is a need to fix the head of the patient. The authors typically use a three-pin Mayfield head clamp when there is cavernous sinus invasion (because electromyographic monitoring precludes the use of paralytics) or if there is more than 180 degrees of

internal carotid encasement.²⁶ In cases where intra-operative monitoring is not necessary, the patient's head rests on a horseshoe head holder (Figure 85.1a). In these cases, a mask attached to a transmitter is placed on the face of the patient (Figure 85.1b) covered by clear drapes during the entire procedure, which is tracked by the optic system and allows dynamic image guidance (Figure 85.1c,d).

Finally, the authors always prepare the abdomen and the lateral thigh for a potential fat or fascia lata graft respectively (or in a high-risk patient, for the possibility of harvesting muscle to patch an injured artery) (Figure 85.1e).

Figure 85.1 Patient and image guidance positioning. (a,b) The patient is supine with the head slightly tilted to the right, resting on a horseshoe head holder. The navigation mask and transmitter are placed on the patient's face; the abdomen has been prepared. (c,d) The patient's face is covered with transparent sterile drapes and surrounded by standard drapes. (e) In this case both the abdomen and thigh were prepped; the head is secured on a Mayfield head holder and the navigation transmitter is attached to it.

TECHNICAL PEARLS FOR TUMOUR REMOVAL

Recurrent tumours must first be distinguished between secreting or non-secreting; this classification carries implications during the procedure itself regarding the goals of surgery (total resection versus debulking). Appropriate workup is performed as outlined in previous chapters to establish the endocrine profile of the lesion. Functional tumours, such as those seen in the setting of Cushing's disease, acromegaly/gigantism and hyperprolactinemia, on average have a higher recurrence rate than non-functional tumours (15–30% versus 10% respectively).²⁷

The first and foremost surgical pearl is to maximize the exposure of the sphenoid sinus and sella. A recent study demonstrated that the lack of exposure during initial tumour removal was a significant cause for recurrence.²⁸ For this reason, the sphenoid keel must be completely removed or drilled down to expose the sphenoid floor; this manoeuvre provides the necessary working angle for the cranial to caudal exposure. Removing all bony septations within the sphenoid sinus maximizes horizontal exposure, thus, providing access from lateral wall to lateral wall with clear visualization of the lateral opticocarotid recesses (LOCR), when is present (Figure 85.2a). We favour the use of a high-speed drill for the removal of septations in lieu of rongeurs because the drill provides more control. These inter- and intra-sinus septations often end on a dehiscent ICA and their removal with a blunt forcep or rongeur may fracture the ICA canal and lacerate the vessel.²⁹

When drilling down the face of the sella, enough bone must be removed as to expose the 'four blues'.³⁰ These represent the walls of the cavernous sinus laterally and the intercavernous sinuses superior and inferiorly (Figure 85.2b). The authors typically drill the face of the sella until its wall is very thin, and then use a Kerrison rongeur as a dissector to separate and then lift the bone off the dura, avoiding the urge to bite the bone with the rongeur. This technique helps to avoid an inadvertent internal carotid injury as well as tears in the cavernous sinus wall. Bone that does not fracture with a gentle pull from the Kerrison rongeur indicates the need for further drilling. In addition, drilling of the sellar floor and the surrounding bone provides the ability to retract the internal carotid artery laterally and the use of a cotton tip applicator³¹ to manipulate the tumour from below.

Once the bone is satisfactorily removed, one frequently encounters the material that was previously used for reconstruction; most often this is a fat graft that turns into dense scar. Typically, fat becomes too fibrous to remove with a two-suction technique; thus, the authors typically use dissectors and true-cutting instruments to separate and remove the fibrosis. During this phase of dissection, CTA-based image guidance is helpful to define those areas of the ICA that became dehiscent from previous exposures. If there is bone protecting the ICA, sharp dissection can be used to separate the tissues safely.

Once the dura of the sella is well exposed, a feather blade (Mizuho; Tokyo, Japan) is used to make the incision,

usually starting in the centre of the sella and carrying it down vertically. The dura is separated from the underlying gland or tumour with a ball probe, avoiding separating the two layers of dura. The incision is then extended laterally towards the cavernous sinus using 45° angled microscissors, both superior and inferiorly. The superior cuts must be performed parallel to the sphenoid floor, so as to avoid violation of the arachnoid membrane of the diaphragm sellae and a subsequent CSF leak. A dissecting instrument is then used to explore the tumour and identify landmarks, including the medial wall of the cavernous sinus and the diaphragm sellae. The use of navigation and endonasal acoustic Doppler sonography probes (Mizuho; Tokyo, Japan), to confirm intra-operative anatomy, is prudent in all revision cases.³²

Figure 85.2 Exposure for resection of a pituitary microadenoma. (a) The sphenoid sinus has been entered; observe the bony landmarks and the relation between the septation and the right ICA. **(b)** The face of the sella has been removed, from ICA to ICA and from superior to inferior intercavernous sinuses. Note the proximity between the ICAs, narrowing the operative corridor. ICA, internal carotid artery; LOCR, lateral opticocarotid recess.

Tumour consistency dictates the instrumentation choices. Tumours that are soft are dissected and debrided using a two-suction technique. More fibrous tumours require the use of microscissors or a side-cutting power instrument (Myriad, NICO Corporation; Indianapolis, Indiana). The authors find that the ultrasonic aspirators currently available are aggressive and may inadvertently draw neurovascular structures into the instrument.

If a solid or extremely fibrous tumour is encountered but it is not invading the cavernous sinus, an extracapsular dissection is attempted, provided that the lesion is of reasonable size. Extracapsular dissection is safer than powered instrumentation and the surgeon can define the landmarks and planes for dissection while freeing the tumour from the surrounding structures. It is crucial to find the compressed pituitary gland early during this dissection in order to avoid extracapsular resection of the gland along with the tumour and consequent panhypopituitarism. The dissection must take place between the pituitary gland and tumour interface. If the lesion is very large, it can be debulked before these manoeuvres are employed.

A cotton tip applicator is a practical and relatively atraumatic retractor that decreases the risk of damaging the arachnoid membrane and producing a CSF leak while retracting the descending diaphragma sellae. More importantly, this manoeuvre greatly assists in identifying the tumour–gland interface, exposing the plane of dissection.^{31,33}

RECONSTRUCTION OPTIONS

Rescue flap

A rescue flap is elevated in most patients undergoing an endoscopic endonasal resection of a pituitary adenoma.³⁴ In this setting, the rescue flap allows the mobilization of the pedicle from the face of the sphenoid, therefore allowing for a wide sphenoid opening without compromising the blood supply to the nasoseptal flap. The rescue flap technique avoids the donor site morbidity associated with a nasoseptal flap.³⁵ A rescue flap harvest begins by incising the mucosa over the rostrum of the sphenoid sinus from the lateral wall of the nose at the level of the sphenoid ostium, carrying the incision over the sphenoid rostrum, and then anteriorly into the nasal septum mucosa (for approximately one third to half of the septum following the sagittal plane). Recently, the authors have incorporated an additional inferior incision as a modification to the original description, to increase the pedicle inferior mobility.³⁶ At the end of tumour resection, if a nasoseptal flap is not needed, absorbable packing reapproximates the pedicle to the bony rostrum.

Endoscopic reconstruction with free tissue grafts

Free tissue grafts are commonly used to reconstruct skull base defects after an EEA for a recurrent pituitary adenoma. Typically, they are used to reconstruct small to

moderate (i.e. less than 1 cm), low-flow CSF leaks; however, in revision cases, there may not be a middle turbinate from which to harvest a graft if an EEA was performed at the time of primary resection. In this scenario, a variety of techniques such as a ‘bath plug’ repair or inlay–onlay strategy with acellular dermis or fascia lata may be employed. Regardless of which reconstructive tissues are employed, a multilayer technique and complete defect coverage are critical to achieve a dependable reconstruction.

First, a subdural or epidural inlay graft of collagen matrix (Duragen, Integra Life Sciences) or fascia lata is placed; this helps to stop (or at least reduce) the flow of CSF and decrease the dead space. Collagen matrix is pliable and soft, thus allowing for its safe manipulation around neurovascular structures. This subdural or epidural graft should extend beyond the dural margins, ideally 5–10 mm in all directions. If the graft is placed in the subdural space, a subsequent inlay graft of acellular dermis or fascia lata is placed in the epidural space (between the dura and the skull base). Occasionally, the bony edges are not adequate to support an inlay graft; the graft is then placed extracranially as an onlay (on the nasal side of the defect). It is critical that the edges of the defect are meticulously denuded of mucosa to allow for revascularization of the graft and to avoid mucocele formation.

Once the in- and onlay grafts are in place, a free tissue graft is applied if one is available. Healing of free mucosal grafts (i.e. take) is excellent; however, they are limited by size and the fact that they can only be used as onlay grafts. If a mucosal graft is not available, the reconstruction is bolstered with a free fat graft, typically harvested from the abdomen, or a free fascial graft, which can be fascia lata or temporalis fascia. The final layer consists of non-adherent packing such as absorbable gelatin sponge squares and expandable sponge packing or the balloon of a Foley catheter to further bolster the reconstruction. Any nasal packing is removed 3–5 days after the procedure.

Nasoseptal flap takedown

Increasingly, we have encountered patients who have had prior NSF placement for reconstruction. Although the authors generally do not use a nasoseptal flap for the reconstruction of a CSF leak associated with pituitary surgery (since the success rate with free tissue grafts is excellent), they do try to reuse the flap in patients who have had one previously. This manoeuvre has been termed ‘the nasoseptal flap takedown technique’.³⁷

The edges of the flap and the nasal mucosa can usually be clearly defined; however, the longer the period after the first surgery, the more difficult this delineation becomes. Once this interface is identified, the edges of the flap can be followed down to its pedicle (usually found overlying the pterygoid wedge). This pedicle must be preserved during the second surgery. The edges of the flap are mobilized centripetally using the sharp end of a Cottle elevator, thus exposing the underlying bony edges of the prior surgical defect. The nasoseptal flap is then elevated in a distal to proximal fashion towards the pedicle. Any soft-tissue structure that was exposed as part of the primary

operation will heal and adhere to the undersurface of the flap (periosteal side) and therefore commonly requires a two-surgeon, four-hand sharp dissection. The pedicle is then mobilized from the underlying bony pterygoid wedge, and the flap is stored in the nasopharynx. Once the extirpative portion of the case is complete, the flap is repositioned over the defect.

There are some specific limitations of the nasoseptal flap takedown that do not apply to primary nasoseptal flap skull base reconstructions: its shape is defined

by the healing process over the defect (as it heals and contracts, the flap conforms and moulds itself to the defect); it is less pliable and will retain the shape of the previous defect; it tends to migrate out of the nasopharynx into the surgical field due to increased stiffness and fibrosis. These must be kept in mind when the takedown is performed.

A case illustration of a 45-year-old female who presented with a recurrent adenoma is shown in [Figures 85.3](#) and [85.4](#).

Figure 85.3 Case illustration 1. This 45-year-old female presented with a recurrent adenoma expanding into the suprasellar space and abutting the optic chiasm; her initial surgery was performed endonasally elsewhere. Pre-operative coronal (a) and sagittal (b) contrast T1-weighted MR imaging reveals the tumour on the superior left portion of the sella; the gland is seen inferiorly and to the right. Note the relation of the lesion to the optic chiasm. Post-operative coronal (c) and sagittal (d) contrast T1-weighted MR imaging confirms a thorough resection of the tumour with decompression of the optic apparatus; note the enhancing nasoseptal flap (white arrow).

Figure 85.4 Case illustration 2. Stepwise depiction of the case illustration surgery shown in [Figure 85.3](#). **(a)** Sphenoid sinus exposure; note the poor definition of the surgical landmarks. **(b)** The sellar bony opening is expanded with the use of a high-speed drill. **(c)** Scar tissue is displaced by blunt dissection and rongeur removal. **(d)** The Cottle dissector is used to elevate the buttress material employed in the previous surgery from the underlying dural replacement. **(e)** The sella is outlined, from ICA to ICA and from superior to inferior intercavernous sinuses. Note the dural replacement. **(f)** The dura has been opened and the pituitary gland and tumour (*) are visible. **(g)** The double-suction technique is employed to debulk the lesion (*). **(h)** Sharp dissection enables safe removal of the tumour (*) from the optic apparatus. **(i)** The last tumour remnants (*) are separated from the optic chiasm with a fine dissector. **(j)** Final view after tumour removal, prior to reconstruction; the right superior hypophyseal artery (Sup. hyp. art) has been preserved. **(k)** The dural defect is plugged with a collagen matrix replacement. **(l)** A left nasoseptal flap, raised during the approach, is applied over the defect (dotted line). Observe the pedicle arising from the left sphenopalatine foramen.

POST-OPERATIVE MANAGEMENT

All patients submitted to an endonasal endoscopic resection for a recurrent pituitary tumour are sent to an intermediate care unit after surgery where specific monitoring for DI and hypotension secondary to acute hypocortisolism can take place. If the patient is already on desmopressin and/or steroid replacement pre-operatively, these are maintained and rigorous electrolyte surveillance is performed. If pituitary function is normal before surgery, patients are monitored clinically and with prolactin and cortisol serum levels the morning after the procedure. If hypocortisolism is detected, steroid replacement is instated. If new onset DI is observed and the patient is awake and coherent, oral fluid replacement with water is encouraged. If sodium levels remain stable after the initial 48 post-operative hours, it is likely that the posterior gland recovers function and there will be no permanent DI. Otherwise, if desmopressin is initiated, the patient must be challenged by the endocrinologist with increasingly lower doses to determine whether function is still present or is permanently gone.

Patients with Cushing's disease are observed more closely, with ACTH levels checked during and after surgery and cortisol sampling every 6 hours for the initial post-operative 48 hours. This period of time is usually sufficient to determine whether steroid levels will drop enough to cause symptoms ('crashing'). If cortisol levels drop below 5 mcg/dL, steroid replacement is initiated regardless of the patient's clinical status.

Patients with acromegaly or gigantism do not require specific measures other than cortisol and prolactin

sampling the morning after surgery. Long-term remission is assessed with GH and IGF-1 levels, typically in an endocrinology clinic within the first 6 weeks after the operation.

Whether and which nasal packing is necessary is determined by the reconstructive technique. As previously mentioned, packing is kept in place for the initial 3–5 days after the procedure. For the first 24 hours, the same antibiotics given during anaesthetic induction (typically cefepime and vancomycin, when needed) are maintained. An oral broad-spectrum antibiotic is used after that for as long as the packing is in.

All patients are seen at the otolaryngology clinic within the first week of discharge; the nasal packing is removed and endoscopy is used to assess healing and debridement of crusting. The degree of crusting will ultimately determine the frequency of visits the patient must endure during the recovery period for nasal hygiene.

CONCLUSION

In summary, recurrent pituitary adenomas are an excellent indication for an endoscopic endonasal approach. The wide-field visualization afforded by the endoscope allows a superior level of safety where the surgeons can observe the key sphenoid landmarks. As with any reoperation, there is a need for adequate preparation before the procedure and adequate planning for surgical resection and reconstruction. Intra-operative image guidance plays a crucial role in avoiding complications, particularly of the vascular kind.

KEY POINTS

Pre-operative management and planning

- Meticulous radiological investigation with head CTA and pituitary MRI is required.
- Assess pituitary function.
- Assess visual function.
- Conduct endonasal evaluation with office endoscopy (rule out infection, assess reconstruction options).

Image guidance

- Fusion between CTA and MRI increases accuracy.
- CT bone window can be used to provide additional reference points.

Intra-operative management

- Bone removal and exposure are paramount to adequate tumour resection.

- Image guidance and acoustic Doppler sonography help to avoid vascular injuries.

Skull base reconstruction

- The rescue flap minimizes nasal morbidity while securing the flap pedicle.
- Free tissue grafting is effective for the majority of CSF leaks after pituitary surgery.

Post-operative management

- Endocrine function and electrolyte levels must be closely monitored.
- Clinic visits are key to preventing excessive crusting and infection.

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: adjuvant treatments for pituitary tumours.

OVERVIEW OF PITUITARY ADENOMAS

The incidence of clinically overt pituitary adenomas is around 15–20 per million per year. Fifty to sixty percent are microadenomas and these, by definition, regain trophic stability after a period of deregulated post-induction growth. A further proportion of pituitary macroadenomas grow slowly or not at all and may not require intervention if bioactive hormone secretion is not a feature. Overall, approximately one third of pituitary adenomas require surgical intervention at least once, and as their prevalence is relatively high – 2.5 cases per 10 000 – pituitary adenomas constitute the third most common intra-cranial tumour requiring neurosurgical intervention. Occult pituitary adenomas are more common still, with histological evidence of pituitary adenomas at the time of death from unrelated causes in 11–14% of the population.^{1,2}

Approximately 50% of newly diagnosed pituitary adenomas are prolactinomas. Endocrinologically inactive adenomas account for 30%, somatotrophinomas for 15–20%, corticotroph adenomas for 5–10% and thyrotroph adenomas for less than 1%.³ Limited dural invasion is fairly typical in all macroadenomas and slow expansion over a period of years expected. Aggressive expansion, requiring repeated surgery and adjuvant treatment is atypical, and frank metastatic spread is exceptionally rare.⁴

Non-specific symptoms

Headaches typically associated with pituitary adenomas are non-specific, variable in their characteristics and insidious in onset. They can mimic classical migraine, tension headaches, sinusitis and various causes of facial pain. Analgesics, tricyclic antidepressants at low dose, verapamil and beta-blockers can sometimes be helpful, as can a trial of withdrawing dopamine analogues if possible (e.g. bromocriptine). Headaches caused by haemorrhage that originates within a pituitary mass (pituitary apoplexy) or haemorrhage following pituitary infarction (e.g. in some cases of Sheehan's syndrome) are characteristic of meningeal irritation and tend to start abruptly. Headaches can be cured by transsphenoidal surgery or precipitated by the same.

PRIMARY TREATMENT

With the exception of prolactinomas, first-line treatment for pituitary adenomas that hypersecrete or cause mass effects remains transsphenoidal decompression. This remains the case if the lesion extends into the suprasellar cistern although, if the diaphragma is substantially intact, a pterional or subfrontal approach is sometimes preferred. Outcomes depend critically on the skill of the operator, but even the most gifted and experienced surgeons are rarely able to fully excise a pituitary macroadenoma.

Meningitis and damage to visual apparatus or vascular structures is rare with standard or endoscopic surgery, but longer-term problems of hypopituitarism, impaired olfaction or gustation and a tendency to sinusitis if the nasal septum is damaged or displaced are more common. Endoscopic transsphenoidal surgery requires more generous access and has a higher risk of CSF leakage.

WHY IS ADJUVANT TREATMENT NEEDED?

Most clinically significant pituitary disease results from sporadic pituitary adenoma formation. Complete excision of a pituitary adenoma of any description is far from a universal surgical outcome. Approximately 30% of non-functioning pituitary macroadenomas increase in size to some extent within 5–10 years of the original surgical intervention⁵ and micro-invasion of surrounding structures is common.⁶ Certainly for endocrinologically inactive macroadenomas the aim of primary surgical intervention is debulking rather than attempted complete excision as this addresses immediate issues of space occupation and seems in many cases to discourage remnant growth. Even in optimistic series, clinically significant residual tumour tissue is present in at least 20% of cases.⁷ After surgery for tumour recurrence, almost 40% of patients experience a sustained remission,⁸ yet up to 60% of functioning pituitary macroadenomas remain biochemically active after primary treatment^{9, 10} and, particularly for these, adjuvant treatment may be required.

Recognition of the benign nature of the vast majority of pituitary adenomas, technical advances in transsphenoidal surgery, particularly more effective and comfortable ways to close the bony deficit in the pituitary fossa and sphenoid, nagging concerns about potential long-term side effects of radiotherapy and improved screening with the ready availability of high-quality (and X irradiation-free) MRI has made watchful waiting the norm.

If the adenoma extends laterally into a cavernous sinus, proximal to the carotid syphon and cranial nerves without any danger of impingement on the optic apparatus, other treatments are likely to be first line.

PROLACTINOMA

A dopaminergic drug, typically cabergoline (0.25–1 mg once or twice a week) or bromocriptine (2.5–10 mg daily) is first-line treatment for prolactinomas. Although dopamine agonists are not teratogenic, current best practice at the time of writing, with no clear rationale, is to stop dopamine analogues when pregnancy is confirmed. Symptomatic tumour regrowth during pregnancy is unusual. The convenience and excellent side-effect profile of the long-acting, ergot-derived D2 agonist cabergoline made it the preferred treatment in most cases until 2007 when (along with pergolide) an association with valvular heart disease was described^{11, 12} At the low doses used for prolactinoma rather than Parkinson's disease, the same

association has not been demonstrated in pituitary disease^{13, 14} and echocardiographic screening is not generally considered necessary.

Microprolactinoma

Where drug treatment is not first-line owing to side effects or costs, microadenectomy in symptomatic premenopausal women may be curative if a suitably skilled and experienced surgeon is available. If fertility is not required and galactorrhoea is not an issue, oestrogen replacement may be a satisfactory alternative to a dopamine agonist. Postmenopausally, it may be perfectly appropriate to offer no specific treatment other than reassurance. Microprolactinomas occasionally spontaneously resolve (about 7% overall, increasing to almost one third after a pregnancy) but change little in size in response to dopamine analogues.

Macroprolactinoma

It is rare for surgical decompression alone to bring prolactin output from a macroprolactinoma into a range when no further treatment is required. Biopsy is rarely required to confirm the diagnosis, but very occasionally surprisingly large prolactinomas release very modest amounts of prolactin and are mistaken for endocrinologically inactive macroadenomas that are assumed to be restricting portal dopamine flow by compressing the pituitary stalk. Surgery may be appropriate, however, if the patient's compliance with tablet treatment is poor or if the patient is intolerant of dopamine analogues, usually because of psychoses or intractable nausea and dysphoria. Prolactinomas are rarely resistant to dopamine analogues but occasionally response times are relatively prolonged.

Unless accompanied by haemorrhage and altered blood or cystic degeneration, 90% of macroprolactinomas can be expected to shrink with dopamine analogue treatment,¹⁵ to the extent that, if the sphenoid bone has been eroded, a CSF leak may result. A small proportion of macroprolactinomas involute completely after long-term dopamine analogue treatment and treatment can be cautiously withdrawn without tumour recurrence.

The second generation alkylating chemotherapeutic agent temozolomide, related to the imidazotetrazines used primarily for grade IV astrocytomas (i.e. glioblastoma multiforme) and sometimes for oligodendrogliomas, has been used successfully for exceptionally rare and resistant cases of malignant pituitary adenomas including a case of malignant (i.e. metastatic) prolactinoma.¹⁶ Anecdotally, a useful effect of temozolomide has been reported in approximately two thirds of 16 pituitary carcinomas and 30 aggressive pituitary adenoma cases.¹⁷

SOMATOTROPHINOMA

Even in the hands of experienced surgeons, primary transsphenoidal decompression of somatotroph adenomas in isolation has only a 50:50 chance of achieving immediate

and longer-term biochemical remission. At least one third of post-operative patients have persistent disease despite additional medical therapy.¹⁸ Even if the GH response to a glucose load meets the current criterion of ‘cure’, i.e. GH suppression to <1 mcg/L after a 75 g oral glucose load, a further post-operative cohort continues to experience subtle symptoms that significantly impair quality of life, associated with a normal or only modestly elevated IGF1. Persistent disease is associated with an approximately fourfold increased risk of colorectal carcinoma and with widespread arthralgia and arthritis, impaired glucose tolerance, hypertension, carpal tunnel syndrome, sweating, obstructive sleep apnoea and dysmorphophobia, all of which contribute to a 30% increase in all-cause mortality¹⁹ and all of which need individual and specific management irrespective of ongoing pituitary function or dysfunction.

Somatostatin analogues

Evidence for a beneficial effect of somatostatin analogue treatment before pituitary surgery is inconsistent and unconvincing. In the event that surgery and sometimes repeated pituitary surgery does not secure remission, or when surgery is inappropriate owing to comorbidity, infirmity, technical difficulty (i.e. tumour remnants are out of reach) or because it does not concord with the patient’s wishes, long-acting somatostatin analogues are typically the adjuvant treatment of first choice. Somatostatin analogues are reasonably well tolerated, although they produce variable abdominal cramping and bloating that diminishes over time but may recur for a short time after each injection. Accumulation of biliary sludge resulting from reduction in gallbladder motility is rarely a problem. A modest degree of remnant tumour shrinkage (typically by about one third volume (10–50%) in a third to a half of cases^{20–22} probably results from a reduction in the size of individual somatotroph cells and hence in overall tumour size rather than an absolute reduction in somatotroph cell numbers. Circulating growth hormone and IGF1 levels drop fairly rapidly into the reference range in about 50% of cases, and typically the efficacy of treatment becomes more pronounced over time such that, after about 5 years, most patients have circulating GH levels within the ‘normal range’. Doses are titrated up if control is not achieved after several months’ treatment, but over time it may be possible to reduce the dose or increase the dosing interval further.²³ Long-term treatment has significant economic costs and can over time become irksome for patients for whom uncomfortable and socially disruptive injections are a life sentence. For many patients who are not put into remission by initial surgery, somatostatin analogues are used until such time as fractionated radiotherapy takes effect.

Newer long-acting and broad spectrum somatostatin receptor ligand with high affinity to receptor subtypes 1,2,3 and 5 (pasireotide) and chimeric somatostatin and dopamine receptor agonists – dopastatins²⁴ (BIM-23A760²⁵) – have yet to show any particular advantage in terms of comfort or control.²⁶

Growth hormone receptor antagonists

Pegvisomant is a growth hormone (GH) antagonist with a half-life of greater than 70 hours delivered as a daily or weekly subcutaneous bolus.^{27, 28} It interferes with growth hormone signalling and by so doing produces a high rate of normalization of insulin-like growth factor 1 in patients with somatotroph adenomas, including those in whom somatostatin analogues alone are insufficient to gain control of hormone secretion.^{29, 30} Used in isolation, reduced feedback inhibition results in a concurrent increase in circulating growth hormone levels by about 75%. Concerns that tumour growth may accelerate if pegvisomant is used in patients without concurrent somatostatin analogues or prior radiotherapy have not been substantiated, at least during the first 3 years of treatment,³¹ although increases have been reported in around 2% of cases.³² The prohibitive costs of these analogues and side effects, particularly liver function abnormalities that affect approximately 25% of patients, albeit transient, mean that its place in acromegaly management alone and in combination with somatostatin analogues has yet to be established.³³

Dopamine receptor agonists

Cabergoline, a second-generation long-acting dopamine agonist, reduces GH to within the reference range in a quarter to a third of patients with acromegaly^{34, 35} and reduced IGF1 to within the reference range in one third,³⁶ an effect that is additive to that of somatostatin analogues³⁶ and independent of prolactin levels.³⁷ Despite these data, controversy persists, with groups reporting no effect of cabergoline but efficacy with quinagolide,³⁸ and others contending that bromocriptine has no effect and cabergoline only modest efficacy in fewer than 10% of patients as an adjunct to treatment with somatostatin analogues.¹⁹

Conventional fractionated radiotherapy

Radiotherapy is no longer an automatic adjunct to pituitary tumour surgery owing to the ease and safety of follow-up with MRI and computerized visual fields, and the expectation that remnant growth will be minimal and predictable. Nevertheless, it remains a useful and safe but relatively slow-acting treatment in selected patients in whom progression of unresectable tumour or excess hormone secretion persists.³⁹ In patients who have yet to complete their families the significant ongoing risk of hypopituitarism over the first 8–10 years is a further contraindication, given the expense of ovulation induction and restoration of male fertility using exogenous gonadotrophins.⁴⁰ External beam radiotherapy is remarkably safe, but long-term effects of external beam radiotherapy on cerebral vasculature and on the induction of secondary brain tumours within the radiation field, which amounts to a 2–4% risk at 20 years, is a more significant concern in young patients.^{41, 42}

Early side effects of radiotherapy are generally limited to tiredness during the latter stages of treatment and for several weeks after treatment, and occasionally headaches

and transient loss of a small amount of scalp hair, particularly with the older linear accelerator protocols using just three trans-cerebral windows.

Stereotactic radiosurgery

Stereotactic or gamma knife radiosurgery for acromegaly allows radiotherapy to be delivered in one rather exhausting and uncomfortable day for the patient rather than fractionated over several weeks. Somatotrophinomas are not the pituitary adenoma subtype most amenable to Gamma knife radiosurgery owing to their size when they tend to come to treatment.⁴³ In patients who for the most part have already failed conventional treatment with surgery, conventional fractionated stereotactic radiotherapy and drugs, local tumour control is typically achieved in 37–100% and hormonal control in 17–82% within 2–3 years. New pituitary hormone deficiency occurs in 33–40% of patients over this time^{44–48} but otherwise side effects are minimal.⁴⁹

CORTICOTROPHINOMA

Corticotroph adenomas are typically microadenomas at diagnosis and extension beyond the confines of the sella is unusual. Nevertheless, even in the most optimistic published series, pituitary surgery alone fails to induce remission in Cushing's disease in 10–30% of cases and as many as 10% of patients are still obviously affected in the long term. If surgical remission is achieved, there remains a significant, persistent and unpredictable tendency to relapse that affects almost one third of patients by 10 years.

Depending on the clinical circumstances, disease that clearly persists immediately after attempted transsphenoidal microadenectomy may be addressed by a further, more radical transsphenoidal clearance often within hours or days of the first approach. If preservation of pituitary function, in particular fertility, is a priority and no obvious microadenomatous remnants are visible on pituitary imaging, laparoscopic bilateral adrenalectomy rather than pituitary radiotherapy or a further transsphenoidal approach may be preferred. Nelson's syndrome, disinhibition of corticotroph remnant growth following bilateral adrenalectomy owing to reduced glucocorticoid feedback, is rare, particularly so if very little corticotroph adenoma tissue is present in the fossa, and there is no established rationale for prophylactic pituitary radiotherapy in these circumstances. Although lifelong treatment with glucocorticoids and mineralocorticoids is required, cure is immediate and the morbidity of the procedure itself low.

Many different groups of drugs have been proposed as useful in Cushing's disease, including metyrapone, mitotane, ketoconazole, etomidate, aminoglutethimide, trilostane, mifepristone, sodium valproate, dopamine D2 agonists, reserpine, serotonin antagonists, somatostatin receptor agonists, Bexarotene (a retinoid targeted to retinoid X receptors), the NF-kappaB inhibitor parthenolide, PPAR-gamma receptor ligands and Lapatinib, a tyrosine

kinase inhibitor that interrupts the human epidermal growth factor receptor 2 (HER2) pathway.

In practical terms metyrapone, a steroid 11 β -hydroxylase inhibitor that has been available in Europe for the last 50 years (500 mg–4 g daily in divided doses) is a reliable, reversible inhibitor of adrenal cortisol synthesis and secretion. It is sometimes used to improve overall metabolic and tissue status prior to transsphenoidal surgery or occasionally to help determine whether more invasive treatment of mild hypercortisolaemia is likely to yield symptomatic benefit. Metyrapone is also exploited as an interim adjunctive therapy while waiting for pituitary radiotherapy to reduce corticotroph function or as sole treatment in the longer term if patients are unable or unwilling to tolerate surgery, as its effects are not subject to tachyphylaxis. The drug should not be used in pregnancy or during lactation, but otherwise significant side effects are few, other than gastrointestinal upset and mild hirsutism.⁵⁰ Even if hypocortisolaemia is avoided, the effects of a rapid fall in circulating cortisol levels to within normal limits may for some patients result in depressed mood, arthralgia and in the slightly longer term by disappointment that weight loss is not sustained and that dyslipidaemia, hypertension and impaired glucose tolerance may continue to need specific treatment. Failure of the phenotype to completely regress even after full biochemical remission contributes to a significantly reduced quality of life in the long term and demoralizing recognition that, despite biochemical remission, the perceived pre-morbid 'self' may be very slow to re-emerge.

Ketoconazole, an imidazole derivative used to treat mycoses by inhibiting fungal sterol synthesis, is also used when physical treatments such as transsphenoidal surgery are inappropriate or have failed or the effects of radiotherapy are awaited. Although unlicensed for this indication in the UK, ketoconazole is believed to be effective in reducing circulating cortisol levels in up to 70% of cases – an endpoint that does not equate with remission.⁵¹

Mitotane is a hepatotoxic, neurotoxic and teratogenic adrenal cytotoxic agent that is highly persistent in the body and generally reserved for unresectable, metastatic or relapsed adrenal cortical carcinoma. It has been used in Cushing's disease (i.e. pituitary-dependent Cushing's syndrome) as first- or second-line treatment⁵² but is slow to induce remission, not well tolerated, requires monthly plasma level monitoring and, even if effective in the short term, does not prevent recurrence of the disease in most patients over a median of 13 months.⁵²

Etomidate is an intravenous inducing agent that at sub-anaesthetic doses (0.1 mg/kg per hour) powerfully inhibits adrenal 11 β -hydroxylase.⁵³ It has a very rapid onset of action and can be easily titrated against circulating cortisol levels in a high dependency setting.⁵⁴ For patients in whom metyrapone or ketoconazole is ineffective in controlling severe hypercortisolaemia, etomidate as a continual infusion is uniquely effective and can be used to rapidly suppress otherwise intractable neuropsychiatric symptoms and give tissues time to recover from high-level cortisol exposure prior to bilateral adrenalectomy.

Centrally acting drugs such as sodium valproate, cabergoline and cyproheptadine are rarely effective. The broad spectrum somatostatin receptor agonist pasireotide shows only partial efficacy in a minority of patients and is associated with significant side effects such as impaired glucose tolerance and frank diabetes⁵⁵ in the majority. Mifepristone, a synthetic steroid inhibitor of progesterone receptors used as an emergency contraceptive, is also a powerful type 2 glucocorticoid receptor antagonist. It is approved by the FDA as a therapy to diminish the metabolic effects of hypercortisolaemia in Cushing's syndrome.

Even in remission, patients with a history of corticotroph adenoma have an increased standardized mortality ratio compared to age-matched controls.

THYROTROPH ADENOMA

Debulking transsphenoidal adenomectomy is the primary treatment of choice for thyrotroph adenomas. Even if primary surgical treatment restores euthyroidism in this rare secretory subtype (which accounts for less than 1% of pituitary tumours coming to surgery), external beam radiotherapy to the pituitary bed is often strongly considered as early adjuvant treatment as thyrotroph adenomas have a particular propensity to recur and as, if they do, the presence of thyrotoxicosis, which would be a significant additional surgical risk, can only be directly controlled at the expense of further disinhibition of thyrotroph function. Somatostatin analogues are effective in suppressing thyrotrophin release but tumours typically escape control over time.

PITUITARY CARCINOMAS

The limited dural invasion often seen in pituitary adenomas explains the occasional persistence of symptoms of excess hormone secretion even in the presence of an apparently empty sella. Pituitary carcinoma presenting as metastatic pituitary disease, however, is fortunately rare, constituting less than 0.2% of pituitary adenomas.⁵⁶ Over the last 50 years fewer than 150 have been reported in the literature, 36% of which were prolactinomas and 30% corticotroph adenomas.⁵⁷ The correlation between behavioural characteristics and mitotic markers such as *p53* mutation and Ki-67 is too weak to allow pre-emptive treatment and the diagnosis only becomes apparent when repeated imaging discloses aggressive trophic characteristics and

metastatic spread. In addition to debulking and radiotherapy, the orally active second-generation alkylating agent temozolomide has been used in cases of aggressive pituitary adenomas and pituitary carcinomas having previously been reserved for malignant glioma. In a recent series of 44 patients, three cycles of treatment (200 mg/m² daily for 5 days every 28 days) produced a response rate of around one third of patients, with reduction in tumour volume, or more typically, reduction in the rate of tumour progression. It is of some interest that, at the time of writing, several patients who have received ipilimumab, a cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4) monoclonal antibody used to treat metastatic melanoma, have rapidly developed anterior pituitary failure presumably of autoimmune origin. Whether this could be used in extremis in pituitary carcinoma has not yet been explored.⁵⁸

ENDOCRINOLOGICALLY INACTIVE ADENOMAS AND GONADOTROPHINOMAS

No specific management options are available after surgery and radiotherapy, although agents such as dopamine analogues have been tried. *In vitro*, the dopamine-somatostatin chimeric compound BIM-23A760 has been shown to have very modest antiproliferative actions,⁵⁹ but any medical therapy for endocrinologically inactive pituitary adenomas is a triumph of optimism over evidence. Endocrinologically inactive pituitary adenomas are sensitive to radiotherapy and trophic stasis or tumour shrinkage after a medium of 12.5 Gy delivered by stereotactic radiosurgery (gamma knife) controls tumour size in at least 90% of patients, with reduced risks of secondary tumour induction and cerebral vasculopathy compared to standard fractionated radiotherapy.^{60, 61}

CRANIOPHARYNGIOMA

At one time craniopharyngioma was thought to be relatively radioresistant, and some centres withhold radiotherapy after primary surgery pending an evaluation of further growth even when initial decompression has been relatively modest.⁶² Aggressive attempts to resect craniopharyngioma are associated with significant morbidity, and experimental therapies such as intracystic P32, bleomycin or yttrium-90 have not gained acceptance.^{63, 64}

KEY POINTS

- Surgical outcomes of pituitary adenoma treatment continue to depend very heavily on the innate skill of specialist surgeons.
- In adults, LINAC remains a very effective and safe treatment that reduces significant craniopharyngioma and pituitary tumour space occupying-recurrence 5-fold.
- A significant minority of non-cystic macroprolactinomas involute completely after prolonged dopamine agonist treatment.
- In acromegaly, quality of life depends primarily on attention to the management of obstructive sleep apnoea, arthritis, orthodontic problems, dysmorphophobia and cardiovascular risks.
- Metyrapone is a reliable and safe inhibitor of adrenal cortisol synthesis and secretion in the medium if not long term.

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed and Medline search using the following keywords: paranasal sinuses, maxillary sinus, ethmoid sinus, frontal sinus, nasal cavity, nasal bone, nasal cartilages, nasal mucosa, nasal septum and turbinates. Evidence presented in this chapter is Levels 3 and 4 while recommendations are Grace C.

INTRODUCTION

This chapter outlines the embryological development of the nose and paranasal sinuses, neurovascular and anatomical structures of the external nose, nasal cavity and nasal septum. A surgically relevant approach to the paranasal sinus anatomy is discussed with a focus on fixed anatomical landmarks and the concept of the horizontal and vertical components of the paranasal surgical box. The anatomical descriptions and surgically relevant anatomical concepts are based on standard text, peer reviewed journals referenced in the bibliography and the author's personal experience.

DEVELOPMENT OF THE NOSE AND PARANASAL SINUS

Traditional teaching of paranasal sinus anatomy focused on embryological development and pathways of pneumatization with limited clinical application. These descriptions are included for completeness but the emphasis in this chapter is on the surgically relevant anatomy

External nose and nasal cavity

The nose develops from a number of mesenchymal processes around the primitive mouth during the fourth week of gestation. Collections of neural crest cells undergo proliferation and form the nasal placodes. Sinking of the nasal placodes

leads to formation of the nasal pits which further deepen to form the nasal sac. Adjacent mesoderm cells proliferate to give rise to the medial and lateral nasal prominences of the frontonasal process which surround the nasal pit and sac to eventually become the nares (Figure 87.1).

The maxillary processes grow anteriorly and medially to fuse with the medial nasal prominences and frontonasal process to close off the nasal pits and form separate nasal cavities. The primitive nasal cavity and mouth are initially separated by the bucconasal membrane. This membrane gradually thins as the nasal sacs extend posteriorly and

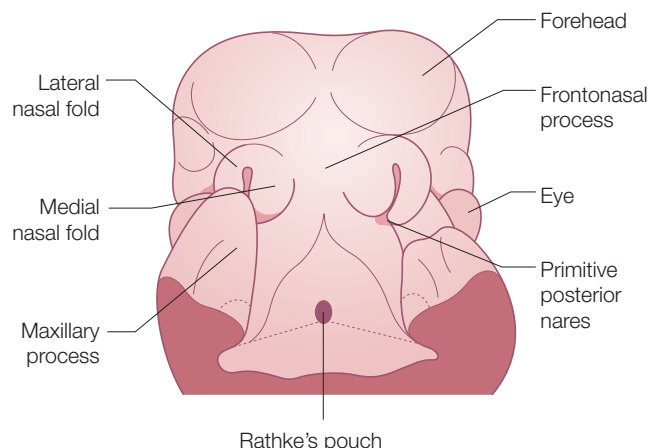

Figure 87.1 Embryological development of the primitive nose and palate during fusion of the maxillary process to the lateral and medial nasal prominences.

BOX 87.1

Failure of the buconasal membrane to break down during embryological development results in choanal atresia

eventually breaks down to form the choanae. Failure of this membrane to break down results in choanal atresia.

The frontal and maxillary processes fuse to give origin to the lateral two thirds of the upper lip, superior alveolar ridges and palatal shelves. The medial nasal prominences fuse with the maxillary process to form the philtrum and medial crus of the lower lateral cartilages. The lateral nasal prominences form the nasal bones, upper lateral cartilages and lateral crus of the lower lateral cartilages.

Palate and nasal septum

The septum develops from the posterior midline growth of the frontonasal process in the root of the oral cavity and extends posteriorly to the opening of Rathke's pouch. The primitive or primary palate begins to form anteriorly with fusion of the maxillary and frontonasal processes. As the nasal cavities enlarge, the palatal processes, derived from lateral maxillary mesoderm, grow medially towards each other and the nasal septum. Initially, the palatal processes are vertically oriented and lateral to the tongue (Figure 87.2). Further growth of the jaw and oral cavity enables the palatal processes to migrate medially towards the midline and fuse (Figure 87.3). The fusion begins along the posterior margin of the primitive palate and progresses from anterior to posterior to form the secondary palate. Partial notching of the posterior hard palate represents an incomplete fusion of the secondary palate and may indicate a submucous cleft. A midline dehiscence in the fusion of the primary and secondary palate forms the incisive foramen.

Maxillary sinus

The maxillary sinus is the first sinus to appear between the 7th and 10th weeks of gestation. The maxillary sinus

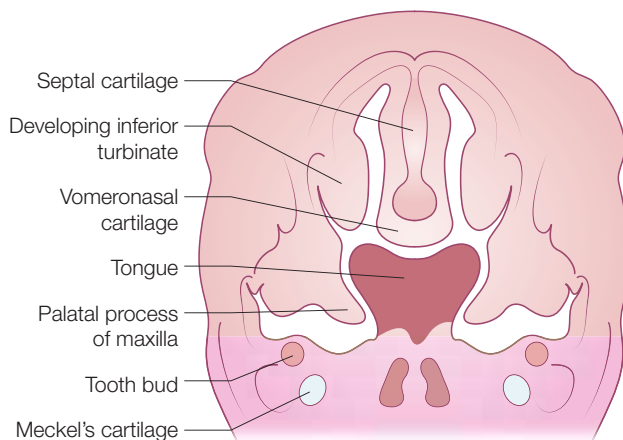

Figure 87.2 Section through the developing palate of a 20 mm human foetus. The palatal shelves are positioned vertically due to occupation of this space by the tongue.

appears as a shallow groove expanding from the primitive ethmoidal infundibulum into the mass of the maxilla. Expansion and absorption results in a small sinus cavity present at birth. Rapid growth of this cavity occurs during childhood until age seven followed by gradual enlargement, reaching its final size by age 17–18 years. Growth may continue beyond this period with extensive pneumatization involving the entire hard palate (Figure 87.4).

Any disruption or abnormality in the development of the maxillary sinus may result in maxillary sinus aplasia or hypoplasia. Maxillary sinus hypoplasia is present in up to 10% of CT scans.¹ Radiographic diagnostic criteria for maxillary hypoplasia include: (1) enlargement of the vertical orbit, (2) lateral position of the infraorbital

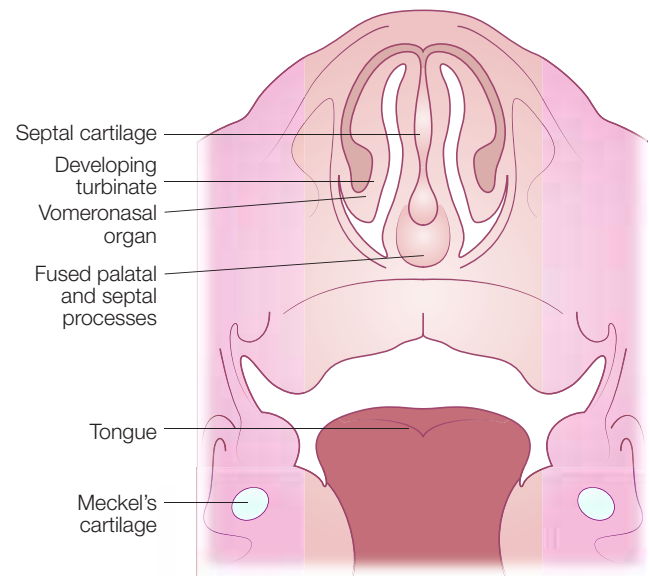

Figure 87.3 Section through the developing palate of a 48 mm human foetus. With further growth of the oral cavity to accommodate the tongue, the palatal shelves are able to migrate medially into a horizontal position and begin to fuse in an anterior to posterior direction.

Figure 87.4 Coronal CT of extensive maxillary sinus pneumatization into the hard palate (arrows) with evidence of maxillary sinus dysfunction (left greater than right).

Figure 87.5 Coronal CT demonstrating maxillary sinus hypoplasia on the right side and maxillary sinus atelectasis on the left side.

neurovascular canal, (3) elevated canine fossa, (4) enlargement of superior orbital fissure and (5) enlargement of pterygopalatine fissure (Figure 87.5).²

Ethmoid sinus

During the 9th and 10th weeks of gestation, a series of folds called ethmoturbinals that are separated from each other by corresponding grooves appear in the lateral wall of the nasal capsule. Fusion of these folds leads to the development of crests, each with an ascending and descending portion. All permanent ethmoidal structures are present at birth and develop from these crests and the furrows between them. As a result, acute sinusitis in children often involves the ethmoid cavity which can extend laterally through the lamina papyracea causing orbital complications.

BOX 87.2

The ethmoid structures are present at birth and acute sinusitis involving this cavity can extend laterally and result in orbital complications.

Understanding the basic embryology of the four or five ethmoturbinals defines a series of lamella that must be removed in order to pass from the anterior of the sino-nasal cavity to the sphenoid sinus. In order from anterior to posterior, these lamella include: **FIRST**: agger nasi

(ascending portion) and uncinate process (descending portion), **SECOND**: bulla ethmoidalis, **THIRD**: basal lamella of the middle turbinate, **FOURTH**: superior turbinate and **FIFTH**: supreme turbinate if present.

Sphenoid sinus

The sphenoid sinus begins to develop in the twelfth week of gestation as an evagination from the sphenothmoidal recess. A small sphenoid sinus is present at birth with progressive enlargement starting at age three during pneumatization of the sphenoid bone. Three pneumatization patterns have been described with reference to the sella turcica.³ These pneumatization patterns are important for surgical planning of transsphenoid approaches to pituitary tumours. These include sellar (90%), pre-sellar (9%) and conchal (1%) type pneumatization patterns (Figure 87.6). The sellar type is most common and describes sphenoid pneumatization posterior to the sella turcica. The presellar type describes sphenoid pneumatization up to the anterior sella and the conchal type describes a shallow bowl with minimal sphenoid pneumatization and trabecular bone between the sinus and sella. The sphenoid sinuses can also pneumatize laterally into the pterygoid root resulting in the presence of a lateral sphenoid recess (Figure 87.7). This pneumatization pattern results in exposure of the neurovascular structures surrounding the sphenoid sinus.

Figure 87.7 Coronal CT of sphenoid sinus. Lateral sphenoid recess (asterisk), maxillary division of trigeminal nerve (arrow), vidian nerve (arrow head).

Figure 87.6 Sphenoid sinus pneumatization patterns. Midline sagittal CT indicating the (a) sellar (b) pre-sellar and (c) conchal types of sphenoid sinus pneumatization patterns.

The lateral recess pneumatization pathway occurs between the second trigeminal division and the vidian nerve.

BOX 87.3

The three different sphenoid sinus pneumatization patterns are described with reference to the sella turcica and include: sellar (90%), pre-sellar (9%) and conchal (1%) type. These pneumatization patterns are important for surgical planning of transphenoid approaches to pituitary tumours.

Frontal sinus

The frontal sinus is the most variable sinus in terms of size and shape. Pneumatization of the frontal bone begins during the 16th week of gestation originating from the anterior ethmoid complex. At birth, the frontal sinuses appear only as a small blind pocket that is difficult to distinguish from the anterior ethmoid air cells on imaging. With gradual pneumatization, the frontal sinuses are seen in most radiological studies by the age of 8 years. Significant frontal pneumatization does not occur until early adolescence and continues until 18 years of age. Although still developing, the relative proportions of the frontal sinus have reached adult ratios by age 10–12 years and just prior to the second growth spurt.

EXTERNAL NOSE

Skin and muscles of the external nose

The thickness of the skin and soft tissues of the nasal bridge vary according to individual skin type and anatomical location. Over the dorsum and sides of the nose, the nasal skin is thin and loosely adherent to the underlying framework. The nasal skin becomes thicker and more adherent towards the nasal tip and alar cartilages where it contains numerous sebaceous glands. The elasticity and mobility of the skin over the nose also varies according to the quality of the collagen fibers anchoring the skin to the underlying structures.

The extension of the facial SMAS (subcutaneous musculoaponeurotic system) layer continues over the nose as numerous muscles of the external nose which function to compress, dilate, depress or elevate the nostrils and nasal tip. These muscles are all supplied by branches of the facial nerve. The nasal elevators include the procerus, levator labii-superioris alaeque nasi, and anomalous nasi muscles. The depressors include the alar nasalis and depressor septi nasi muscles. Compressor muscles include the transverse nasalis and compressor narium minor. The dilator naris anterior muscle acts as a minor dilator.

The subcutaneous tissue of the nose is made up of four layers: superficial fatty, fibromuscular, deep fatty and periosteal layers. The superficial fatty layer is directly connected to the dermis. The fibromuscular layer comprises the nasal SMAS. The deep fatty layer lies deep to the SMAS and contains the neurovascular system. The deepest layer is the periosteum and perichondrium. During external approach rhinoplasty, dissection deep to the third layer

minimizes post-operative scarring and retraction because the neurovascular and SMAS structures are preserved.

BOX 87.4

Dissection deep to the third layer of the nose (deep fatty layer) minimizes post-operative scarring and retraction because the neurovascular and SMAS structures are preserved.

Vestibule

The nasal vestibule is the anterior most aspect of the nasal cavity and serves as the entry point from the external nares into the nasal cavity. The vestibule is demarcated by the limen nasi located at the caudal border of the lower lateral cartilage. The limen nasi is the location where the marginal incision is made during external approach rhinoplasty. It is lined by keratinizing stratified squamous epithelium, and coarse hairs called vibrissae, sebaceous glands and sweat glands. A layer of mucous typically covers the outer surface of the vibrissae which functions to filter airborne particles during inspiration. It is important to note that only a small part of the alar rim is composed of cartilage from the lateral crus, the majority is composed of fibrofatty tissue.

Nasal cartilages

While much focus is placed on the internal septal and turbinate anatomy, the anterior third of the nasal passage has a critical functional role and can greatly influence nasal airflow. The nasal cartilages consist of hyaline cartilage that attach to the bones of the anterior nasal aperture to form the skeletal framework of the external nose. These cartilages include the upper and lower lateral cartilages, septum and sesamoid complex.

The lower lateral cartilage is divided into medial, intermediate and lateral crus that form the natural arch of the nasal ala. The upper lateral cartilages are trapezoid shaped cartilages that attach to the dorsal septum in the midline, nasal bones cranially at the rhinion and lower lateral cartilages caudally via the scroll area.

The relationship and architecture of these cartilages form the external and internal nasal valves which are critical to nasal airflow. The external nasal valve is comprised of the septum medially, alar rim (lateral crus, sesamoid complex and fibrofatty tissue) laterally and nasal sill inferiorly (Figure 87.8). Anatomical abnormalities or compromise in the structural integrity of these components can cause external valve narrowing, stenosis or dynamic valve collapse that is exacerbated during inspiration.

The internal nasal valve, in normal development, is the narrowest portion of the nasal cavity and is bounded by the septum medially, caudal edge of the upper lateral cartilage and head of the inferior turbinate laterally and nasal floor inferiorly (Figure 87.8). The apex of the internal nasal valve is approximately 10–15 degrees in Caucasians and wider in non-Caucasian populations. Changes in the relationship of any structure within this space can cause symptoms of nasal obstruction.

Figure 87.8 Nasal valves (a) Midline sagittal CT scan with green line indicating the relative positions of the external (e) and internal (i) nasal valves. (b) Endoscopic view of the left external nasal valve including (1) septum (2) alar rim (comprised of lower lateral crus, sesamoid complex and fibrofatty tissue) and (3) nasal sill. (c) Endoscopic view of the left internal nasal valve including (1) septum (2) caudal edge of upper lateral cartilage and (3) head of inferior turbinate.

BOX 87.5

The structures of the external and internal nasal valve are critical to nasal airflow with the internal nasal valve representing the narrowest portion of the nasal cavity. The internal nasal valve is bounded by the septum medially, caudal edge of the upper lateral cartilage and head of the inferior turbinate laterally and nasal floor inferiorly.

KEY POINTS

- The upper lip and nose are considered the danger area of the face because infections in this region may be transmitted in a retrograde fashion through a valveless venous system to the cavernous sinus.

Blood supply

Arterial supply to the external nose has both external and internal carotid artery contributions. Branches of the facial artery supply the alar region and include the angular and superior labial arteries. The angular artery and its lateral nasal branch supply the nasal side wall and ala. The superior labial artery gives rise to a columellar branch that supplies the nasal sill and columella and a septal branch that supplies the anterior nasal septum. The ophthalmic artery gives rise to a dorsal nasal branch which anastomoses with the lateral nasal branch of the angular artery to supply the dorsum and nasal side wall. The nasal dorsum and nasal side wall also receive vascular supply from the external nasal branch of the anterior ethmoid artery and infraorbital artery respectively. There are rich anastomoses between these vessels on each side and between right and left sides of the nose.

The venous networks do not parallel the arterial supply but correspond to territories termed arteriovenous units. The frontomedian area drains to the facial vein and the orbitopalpebral area drains to the ophthalmic vein. The facial vein originates as the angular vein located at the inner canthus. The angular vein forms as the confluence of the supratrochlear and supraorbital veins. The upper lip and nose are considered the danger area of the face because infections in this region may be transmitted in a retrograde fashion intracranially to the cavernous sinus. This phenomenon can occur because the facial vein communicates through a valveless venous system with the cavernous sinus via the ophthalmic vein.

Nerve supply

A working knowledge of the neural supply to the external nose has clinical value when performing a nerve block to this region during procedures such as rhinoplasty or closed reduction of nasal fractures (Figure 87.9). The supratrochlear and infratrochlear branches of the ophthalmic nerve supply the skin of the nasal root, bridge and upper portion of the side wall of the nose. The infraorbital branch of the maxillary nerve supplies the remaining skin of the nasal side wall. The external nasal branch of the anterior ethmoid nerve exits between the nasal bone and upper lateral cartilage to supply the skin over the dorsum and nasal tip.

Figure 87.9 External nasal innervation (A) supratrochlear nerve (B) infratrochlear nerve (C) anterior ethmoid nerve (D) infraorbital nerve.

Lymphatic drainage

The lymphatic drainage of the external nose is directed towards the submandibular, submental and facial nodes. Drainage of the external nose is often bilateral and drainage to the parotid region may be possible.

Nasal cavity

The nasal cavity extends from the external nares to the posterior choanae, where it becomes continuous with the nasopharynx. The nasal cavity is divided into two passage ways by the nasal septum. Each side consists of a floor, roof, lateral and medial (septum) wall. The nasal floor is concave from side to side, flat anteroposteriorly and horizontally oriented. The anterior three-quarters are comprised of the palatine process of the maxilla and the posterior one-quarter by the horizontal process of the palatine bone. Approximately 12 mm behind the anterior aspect of the nasal floor is a slight depression which corresponds to the incisive canal. The incisive canal contains terminal branches of the nasopalatine nerve and greater palatine artery. The roof of the nasal cavity is formed by the skull base and slopes downward anteroposteriorly. This is important to recognize during endoscopic sinus surgery as dissection progresses posteriorly towards the sphenoid sinus.

The superior aspect of the nasal cavity including the superior septum, superior turbinate and upper aspect of the middle turbinate is lined by olfactory epithelium. With the exception of the vestibule, the remainder of the nasal cavity is lined by respiratory epithelium. The respiratory epithelium of the nasal cavity is continuous with the mucosal lining of the entire upper and lower airway system.

BOX 87.6

Three different types of epithelium within the nasal cavity consist of squamous (nasal vestibule), olfactory (superior septum, superior turbinate and upper aspect of the middle turbinate) and respiratory (remainder of nasal cavity) epithelium.

Nerve supply

Innervation of the nasal mucosa includes both autonomic and sensory components. The autonomic nervous system regulates the degree of vascular tone, turbinate congestion and nasal secretions present in the nose. Nasal secretion is regulated by the parasympathetic nervous system. Presynaptic parasympathetic fibers travel along the vidian nerve (contribution from the greater superficial petrosal (parasympathetic) and deep petrosal (sympathetic) nerves) and synapse within the sphenopalatine ganglion to innervate the nasal mucosa via postsynaptic fibers. Vascular tone and turbinate congestion is regulated by the sympathetic nervous system. Post-synaptic sympathetic fibers pass through the sphenopalatine ganglion and terminate in the nasal mucosa. The ophthalmic and maxillary divisions of the trigeminal nerve provide the sensory innervation to the nasal mucosa. Trigeminal nerve fibers also pass

through the sphenopalatine ganglion and transmit sensations of pain, temperature and touch. The lateral wall of the nose and turbinates are supplied by the posterolateral nasal nerves from V2 arising from the sphenopalatine foramen and the ethmoidal nerves arising from V1. Although an artery supplies the inferior turbinate posteriorly, the neural innervation is from the lateral wall nerves continuing caudally.

BOX 87.7

The parasympathetic nerve regulates nasal secretions, sympathetic nerve regulates vascular tone and turbinate congestion, and the trigeminal nerve controls nasal cavity sensation.

NASAL SEPTUM

The nasal septum serves many functions, including separation of the nasal airway into two nasal cavities, support of the nasal dorsum, and maintenance of the nasal tip and forms part of the nasal valves. Deviation of the nasal septum can lead to significant nasal airway obstruction and cosmetic deformity. The nasal septum consists of a bony, cartilaginous and membranous portion (**Figure 87.10**).

The bony portion is comprised of the perpendicular plate of the ethmoid bone, vomer, maxillary crest and palatine bone (**Figure 87.10**). The perpendicular plate of the ethmoid forms the upper one-third of the nasal septum. It is continuous superiorly with the cribriform plate and crista galli and abuts a variable amount of the nasal and frontal bones. Posteriorly the perpendicular plate articulates with the sphenoid crest, posteroinferiorly with the vomer and anteroinferiorly with the septal cartilage. The vomer forms the posterior and inferior nasal septum and articulates by its two alae with the sphenoid rostrum creating the vomerovaginal canals through which the pharyngeal branches of the maxillary artery travel. The inferior border of the vomer articulates with the nasal crest formed by the maxillary and palatine bones. The anterior border articulates with the septal cartilage and the posterior edge of the vomer forms the posterior free edge of the septum.

The cartilaginous portion of the nasal septum is composed of the septal or quadrilateral cartilage (**Figure 87.10**). The quadrilateral cartilage is bound firmly by collagenous fibers to the nasal bones, perpendicular plate of the ethmoid and vomer. The septal cartilage is continuous with the upper lateral cartilages towards the bridge of the nose. A projection of the septal cartilage called the sphenoidal process or septal tail extends posteriorly between the vomer and perpendicular plate of the ethmoid. The septal tail can serve as an additional source of cartilage to harvest especially during revision rhinoplasty. The inferior attachment sits within the nasal crest of the maxilla and is bound by looser connective tissue creating a pseudoarthrosis. This joint allows mobility of the septal cartilage base during flexion thereby reducing the risk of fracture or dislocation with trauma. The membranous septum is a segment of connective tissue between the caudal portion of the septal cartilage and columella.

Figure 87.10 The cartilaginous and bony components of the nasal septum.

Figure 87.11 Coronal CT of septal swell body (arrow).

The nasal septal swell body is a widened region of the anterior nasal septum located anterior to the middle turbinate at the internal nasal valve (**Figure 87.11**).⁴ Histological analysis of this tissue demonstrates an increased amount of venous sinusoids and fewer glandular elements compared to adjacent septal mucosa.⁴ The high proportion of venous sinusoids suggests the capacity to alter nasal airflow in a similar manner to the inferior turbinates.

Blood supply of the nasal septum

Both the external and internal carotid arteries contribute to the vascular supply of the nasal septum (**Figure 87.12**). The external carotid artery branches supplying the septum include the sphenopalatine and greater palatine arteries

(branches of the internal maxillary artery). The sphenopalatine artery supplies the posteroinferior septum by a branch called the posterior septal artery. The posterior septal artery is the basis of the nasoseptal mucosal flap which is the workhorse for endoscopic skull base reconstruction. The greater palatine artery enters the nasal cavity through the incisive canal to supply the anteroinferior portion of the septum. The septal branch of the superior labial artery (branch of the facial artery) contributes to the vascular supply of the caudal septum and columella. The internal carotid artery branches supplying the septum include the anterior and posterior ethmoid arteries (branches of the ophthalmic artery). The anterosuperior and posterosuperior portions of the nasal septum receive vascular supply from the anterior and posterior ethmoid arteries respectively.

The anterior ethmoid artery, posterior septal artery and septal branch of superior labial artery contribute to Kisselbach's plexus which is located along the anterior nasal septum at Little's area (**Figure 87.12**). This region is formed by the anastomosis of these arteries which terminate as a rich vascular bed of long capillary loops. Kisselbach's plexus is the most common location of epistaxis due to its rich vascular supply and susceptibility to injury from such factors as turbulent airflow and digital trauma.

BOX 87.8

Kisselbach's plexus is the most common location of epistaxis due to its rich vascular supply (confluence of the anterior ethmoid, posterior septal and septal branch of superior labial arteries) and susceptibility to injury from turbulent airflow and digital trauma.

The venous system drains via the sphenopalatine vessels into the pterygoid plexus posteriorly and into the facial

Figure 87.12 Vascular supply of the nasal septum.

veins anteriorly. Superiorly, the ethmoidal veins communicate with the superior ophthalmic system and there may be direct intracranial connections through the foramen caecum into the superior sagittal sinus.

Lateral nasal wall and turbinates

The inferior, middle and superior turbinates are internal structures found along the lateral nasal wall. The middle and superior turbinates arise from extensions of the ethmoid bones whereas the inferior turbinate is an embryologically independent osseous structure. The space between the lateral nasal wall and inferior, middle and superior turbinates is called the inferior, middle and superior meatus respectively. Each meatus is associated with the connection between a specific anatomical structure and the nasal cavity along a series of well-defined drainage pathways. The lacrimal duct drains into the inferior meatus approximately 1 cm posterior to the head of the inferior turbinate. Although not considered a true valve, the opening of the nasolacrimal duct is called Hasner's valve which is formed by small folds of mucosa. The middle meatus forms the common drainage pathway of the maxillary, anterior ethmoid and frontal sinus into the nasal cavity. The superior meatus forms the common drainage pathway of the posterior ethmoid air cells.

Turbinates are structures filled with vascular channels and venous sinusoids which serve to warm and humidify air and modify nasal airflow resistance. The turbinates continuously dilate and constrict under sympathetic control in response to environmental conditions. A process occurs every 0.5–3 hours in a normal physiological phenomenon known as the 'nasal cycle' resulting in alternating congestion and decongestion of the nasal cavities. Turbinate hypertrophy is a common cause of nasal obstruction in which the turbinates are either chronically

congested or hypertrophied due to allergic or non-allergic triggers as part of an inflammatory rhinitis conditions.

BOX 87.9

The nasal turbinates continuously dilate and constrict every 0.5–3 hours in a normal physiological phenomenon known as the 'nasal cycle'.

Blood supply of the lateral nasal wall

Both the internal and external carotid arteries supply the lateral nasal wall. The sphenopalatine artery contributes the majority of the arterial supply to the turbinates and lateral nasal wall (Figure 87.13). It enters through the sphenopalatine foramen which lies just inferior to the horizontal attachment of the middle turbinate. The sphenopalatine foramen is formed by the sphenopalatine notch of the palatine bone in articulation with the sphenoid bone. The crista ethmoidalis is a small crest of the perpendicular plate of the palatine bone located anterior to sphenopalatine foramen and serves as a consistent and reliable landmark to identify this vessel during endoscopic dissection.⁵ The sphenopalatine artery commonly branches lateral to the crista ethmoidalis with many variations in the branching pattern. In one cadaver study, 97% of specimens had two or more branches of the sphenopalatine artery medial to the crista ethmoidalis.⁶ It is critical that the surgeon is aware of these variations and controls all branches to ensure successful endoscopic ligation of the sphenopalatine artery for epistaxis. If more proximal vascular control is required, the internal maxillary artery can be ligated in the pterygopalatine or infratemporal fossa by removal of the posterior wall of the maxillary sinus.

Figure 87.13 Vascular supply of lateral nasal wall.

BOX 87.10

The crista ethmoidalis is a small crest of the perpendicular plate of the palatine bone located anterior to sphenopalatine foramen and serves as a consistent and reliable landmark to identify the sphenopalatine artery during endoscopic dissection. There are often two or more branches of the sphenopalatine artery medial to the crista ethmoidalis.

A small area along the anterior aspect of the lateral nasal wall is supplied by a branch of the facial artery. The inferior part of the lateral nasal wall adjacent to the palate is supplied by the greater palatine artery. The internal carotid artery contribution is via the anterior and posterior ethmoid arteries (branches of the ophthalmic artery) which supply the superior lateral wall. The anterior ethmoid artery traverses three compartments of the head during its course from the orbit to the olfactory fossa and into the nasal cavity. After branching from the ophthalmic artery in the orbit, the anterior ethmoid artery passes between the superior oblique and medial rectus muscles through the anterior ethmoid foramen. This portion is easily identified on pre-operative coronal CT imaging. The anterior ethmoid artery travels through the ethmoid cavity obliquely in a posterior to anterior direction either within the bone of the skull base or a mucosal mesentery. The artery traverses intra-cranially into the olfactory fossa through the lateral lamella of the lamina cribrosa. After entering the intra-cranial cavity, it gives off anterior meningeal branches before re-entering the nasal cavity through the cribroethmoidal foramen. Within the nasal cavity, it divides into the anterior and posterior nasal arteries. The anterior and posterior nasal arteries each give rise to lateral and medial branches that supply the lateral nasal wall and nasal septum respectively.

The anterior ethmoid artery is more difficult to access surgically, with only 20% of arteries found within a

mesentery that can be successfully clipped via a transnasal approach.⁷ Endoscopic removal of the lamina papyracea allows identification of the anterior and posterior ethmoid arteries between the periorbita and skull base. Alternatively, an external approach via a modified Lynch incision can be used. There is considerable overlap between the internal and external carotid arterial systems on each side and between sides of the nasal cavity which can complicate attempts at arterial ligation in the management of epistaxis.

BOX 87.11

The anterior ethmoid artery is more difficult to access endoscopically as it is only found within a mesentery that can be ligated in a small portion of cases. An external approach using a modified Lynch incision is often the preferred method of ligation.

PARANASAL SINUSES

Anatomy of the paranasal sinuses can be divided into anatomy that has surgical relevance and descriptions that are academic in nature.

Surgical anatomy of the paranasal sinuses

Traditional descriptions of paranasal sinus anatomy focus on pneumatization patterns of air cells with corresponding clefts and spaces. Such descriptions are academic and have little clinical relevance to modern endoscopic sinus surgery. Although an understanding of sinonasal anatomy is critical to ensure safe and complete endoscopic sinus surgery, the concept of pneumatization pathways and development is highly variable and often distorted by disease or prior surgery. Endoscopic sinus surgery is an exercise of anatomical dissection around fixed anatomical landmarks. Akin to traditional mastoid surgery, the sinus surgeon must identify certain key anatomical landmarks in order to delineate the limits of dissection. These landmarks must be based on fixed anatomical structures rather than variable anatomy that can be distorted or absent from disease processes or prior surgery. The goal of surgery is to identify these landmarks early during the procedure in order to provide orientation for the remainder of the operation. These consistent anatomical landmarks include: (1) the maxillary sinus, (2) the orbit from the maxillary sinus roof / orbital floor and medial orbital wall (lamina papyracea) and (3) skull base identified posteriorly by the sphenoid sinus. These defined anatomical limits establish the boundaries of the paranasal surgical box including the horizontal and vertical components of this box.⁸ The concept of the paranasal surgical box forms the basic framework of endoscopic sinus surgery (Figure 87.14).

The boundaries of the horizontal portion of the paranasal surgical box include the middle turbinate medially,

Figure 87.14 Schematic diagram of the right paranasal surgical box. (a) Horizontal component of the right surgical box with limits of dissection including medial orbital wall (blue), middle turbinate (grey), skull base (green), sphenoid sinus (yellow). (b) Vertical component of the right surgical box with limits of dissection including medial orbital wall (blue), middle turbinate (grey), skull base (green), anterior nasal beak (red). (c) Combined schematic diagram of the horizontal and vertical components of the paranasal surgical box.

medial orbital wall (lamina papyracea) laterally, floor of nose inferiorly and skull base superiorly (Figure 87.15).⁸ The boundaries of the vertical portion of the paranasal surgical box include the middle turbinate and intersinus septum medially, lamina papyracea laterally, nasofrontal beak anteriorly and skull base posteriorly (Figure 87.16).⁸

Upon completion of the maxillary antrostomy (or any maxillary sinus opening), identification of the maxillary sinus roof/orbital floor exhibits the first key anatomical landmark (Figure 87.17). This landmark first provides the location of the orbit and then provides a safe working distance from the skull base during identification of

the sphenoid sinus whether via the natural ostium or not (Figure 87.18).^{9,10} Although conceptually the floor of orbit should be below the skull base, anatomical studies have demonstrated that the maxillary sinus roof / orbital floor was below the level of the skull base (lowest portion of the cribriform plate) in 100% of cases with a mean distance of 10.1 ± 2.7 mm.⁹ This landmark was also found to be below the level of the sphenoid planum in 100% of cases with a mean distance of 11.0 ± 3.7 mm and located at approximately 50% the height of the sphenoid.⁹ As a surgical rule, staying below or at the level of the maxillary sinus roof / orbital floor as dissection proceeds posterior will avoid the skull base. Although a well-pneumatized maxillary sinus reduces the height of the posterior ethmoid cavity and may lead to poor surgical trajectory and skull base injury this surgical rule still applies.

The ethmoid bulla is attached to the medial orbital wall (lamina papyracea) laterally. With the orbital floor on view, removal of the ethmoid bulla enables identification of second key anatomical landmark (Figure 87.19). Identification of where the floor turns vertically to become the medial orbital wall enables safe exposure of the entire orbital axis and delineation of the lateral boundary of the paranasal surgical box (Figure 87.19).

The third key landmark is the sphenoid sinus/posterior skull base (Figure 87.20). The maxillary sinus roof/orbital floor landmark is used as a reference to mark the level of the sphenoid ostium. Any dissection medial to the orbital axis and below or at the level of the orbital floor will allow safe entry into the sphenoid. While structures such as the superior turbinate are incredibly useful in defining the medial boundary of dissection for the ethmoid cavity, this

Figure 87.15 (a) Endoscopic view of the right horizontal component of the paranasal sinus surgical box with the medial, lateral, superior and inferior limits of dissection visible with a single position of the endoscope. The lateral, medial and superior boundaries of the horizontal surgical box are indicated as (b) medial orbital wall (blue) (c) middle turbinate (grey) (d) skull base (green) respectively. (e) Sphenoid sinus (yellow) serves as an important landmark to identify the skull base at its most posterior position.

Figure 87.16 (a) Endoscopic view of the left vertical component of the paranasal sinus surgical box with anterior, posterior, medial and lateral limits of dissection visible with a single position of the endoscope. The anterior, posterior, medial and lateral boundaries of the vertical surgical box are indicated as (b) nasal beak (blue) (c) skull base (blue) and posterior table of frontal sinus (green) (d) middle turbinate (blue) and frontal intersinus septum (green) (e) medial orbital wall (blue) and supraorbital roof (green) respectively.

Figure 87.17 Maxillary sinus roof/orbital floor landmark. Endoscopic view of right maxillary sinus antrostomy. Asterisk indicates the position of the right maxillary sinus roof/orbital floor which serves as the first surgical landmark during endoscopic sinus surgery.

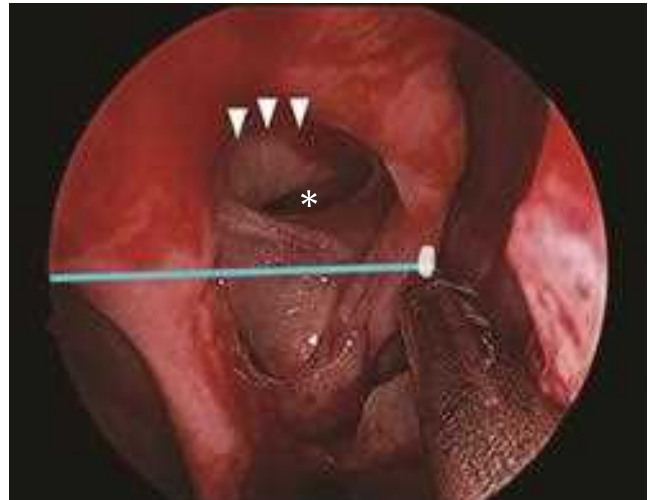

Figure 87.18 Endoscopic view of right maxillary sinus antrostomy after removal of anterior ethmoid cells and basal lamella. Line indicates the horizontal relationship between the maxillary sinus roof / orbital floor landmark and position of the sphenoid ostium. White oval indicates the relative position of the sphenoid ostium. Application of this landmark will ensure safe and easy identification of the sphenoid sinus and avoids mistaking a posterior ethmoid cell or Onodi cell (asterisk) for the true sphenoid sinus. Note that within the Onodi cell is the presence of an exposed optic nerve (arrow heads).

structure cannot be relied upon as it is often removed by pathology or previous surgery. Opening of the sphenoid ostium and removal of the anterior sphenoid wall enables clear visualization of the posterior skull base. The skull base slopes downwards from anterior to posterior, thus, the posterior skull base is at its lowest height within the horizontal portion of paranasal surgical box at the level of the sphenoid sinus (Figure 87.20). The sphenoid can be widely opened laterally as the orbital axis (and thus the lateral limit) is previously identified. Once the posterior skull base is identified, all four limits of dissection of

the horizontal portion of the paranasal surgical box are defined (Figures 87.14 and 87.15) and all cells within the confines of these boundaries must be removed.

Performing a complete dissection of the horizontal portion of the paranasal surgical box serves to define the limits of dissection for the vertical portion of the box (Figures 87.14 and 87.16). The limits of dissection that

Figure 87.19 Endoscopic view of right anterior ethmoid sinus cavity. The position of the right medial orbital wall (asterisk) is identified after removal of the ethmoid bulla. The transition from the orbital floor to the medial orbital wall is clearly delineated (arrow).

Figure 87.20 Endoscopic view of right sphenoid sinus cavity. The position of the posterior skull base (arrow) is identified after removal of the anterior wall of the sphenoid sinus. The positions of the orbital floor (asterisk) and medial orbital wall (arrow heads) landmarks are visible with a single position of the endoscope.

are defined during the complete sphenoidectomy include the medial orbital wall laterally, middle turbinate medially and skull base posteriorly. These limits are extended superiorly to define the boundaries of the vertical portion of the surgical box and all cells within the confines of these boundaries are removed (**Figure 87.14**).

BOX 87.12

- Endoscopic sinus surgery is based on the identification of key fixed anatomical landmarks including the orbital floor, medial orbital wall, sphenoid sinus and posterior skull base.
- These landmarks help to define the anatomical limits of dissection during surgery and establish the boundaries of the paranasal surgical box including the horizontal and vertical components of this box.
- The horizontal component of the paranasal surgical box includes the medial orbital wall laterally, middle turbinate medially and skull base posteriorly. These limits are extended superiorly to define the boundaries of the vertical component of the paranasal surgical box which includes the middle turbinate and intersinus septum medially, lamina papyracea laterally, nasofrontal beak anteriorly and skull base posteriorly.

DEVELOPMENTAL AND FUNCTIONAL ANATOMY OF THE PARANASAL SINUSES

The paranasal sinuses are paired structures lined by ciliated pseudostratified columnar respiratory epithelium identical to that in the lower airway. The cilia beat in a coordinated fashion to carry the mucous blanket which traps particles from the sinus into the nose through a series of well-defined pathways. The paranasal sinuses are divided into anterior, posterior and sphenoid compartments that serve as functional units based on these drainage pathways. The anterior functional unit is comprised of the maxillary, anterior ethmoid and frontal sinuses. These sinuses drain into the nose through the osteomeatal complex in the middle meatus. The posterior functional unit is comprised of the posterior ethmoid sinus and drains into the nose through the superior meatus. The sphenoid functional unit is comprised of the sphenoid sinus and drains through the sphenoid recess located medial and posterior to the superior turbinate. Although the anterior and posterior ethmoid cavities share a common name, they are completely separate functional entities with different drainage pathways and embryologic origins.

The concept of the sinonasal compartment or functional unit has clinical relevance during endoscopic sinus surgery. Once a compartment is entered with surgical instrumentation, all diseased mucosal cells within the compartment must be completely dissected in order to remove obstructive phenomenon, avoid leaving behind disconnected cells from the surgical cavity, prevent mucocele formation, re-establish post-surgical mucociliary function that is free of recirculation effects, and enable maximal delivery of topical therapy. The ultimate goal of surgery (whether limited or extensive) is the creation of a new functional sinus cavity.

Anterior functional unit

BOX 87.13 Uncinate process and maxillary sinus

- The uncinate process is a sickle-shaped bone which attaches inferiorly to the inferior turbinate and palatine bone and anterosuperiorly to the lacrimal bone.
- The posterosuperior attachment will be discussed later along with the frontal sinus.
- The true maxillary ostial opening is covered by the uncinate process and cannot be viewed endoscopically in a sinus cavity that has not been previously opened surgically.
- The uncinate, together with a fold of mucosa called the anterior and posterior fontanelle cover the opening to the maxillary sinus. Accessory ostia may be present in the fontanelle that can be mistaken for the true maxillary ostium.
- Failure to correctly identify the true ostia and connect it with the common sinus cavity may result in a phenomenon known as mucous recirculation. During recirculation, mucous is directed towards the natural opening along the mucociliary drainage pathway and re-enters the sinus through the accessory ostium.

ETHMOID BULLA

The ethmoid bulla is the largest and most consistent anterior ethmoid air cell. It attaches to the lamina papyracea laterally and has variable attachments to the skull base and basal lamella creating a series of clefts and spaces within the middle meatus that are well described, but have little clinical significance. The reader is referred to the consensus document produced by the Anatomic Terminology Group for a detailed description of anatomic terminology and nomenclature.¹¹ A variant of normal anatomy in this region is called a Haller cell. A Haller cell is an infra-orbital anterior ethmoid cell that pneumatizes into the maxillary sinus and may cause obstruction of the maxillary sinus ostium. Complete removal of the ethmoid bulla is critical to define the medial orbital wall as a landmark.

MIDDLE TURBINATE

The complex shape of the middle turbinate is divided into three segments according to the sagittal, coronal and axial planes to which it is oriented. The sagittal segment attaches to the skull base at the lateral lamella. The coronal segment creates the basal lamella which separates the anterior ethmoid (those cells draining in the middle meatus) and posterior ethmoid (draining via the superior meatus) cavities. There is no natural connection between these two cavities. This partition is often not smooth due to posterior projections of the anterior ethmoid air cells and anterior projections of the posterior ethmoid air cells. The safe working distance from the skull base established by the maxillary sinus roof/orbital floor is used as a reference point to proceed through the basal lamella and enter the posterior ethmoid cavity.⁹ The axial segment of the middle turbinate attaches to the lateral nasal wall and is the entry point of a terminal branch of the sphenopalatine artery.

FRONTAL SINUS

The vertical portion of the paranasal surgical box defines the anatomical limits of dissection of the frontal recess. The boundaries of the vertical portion of the paranasal surgical box include the intersinus septum and middle turbinate medially, lamina papyracea laterally, nasofrontal beak anteriorly and skull base posteriorly (Figures 87.14 and 87.16). Successful identification of these anatomical limits of the surgical box and removal of all cells within its confines ensures complete dissection of the frontal recess. To define the limits of the vertical portion of the paranasal surgical box, one must consider the various cells that may encroach on this space from the anterior, posterior, medial and lateral directions.

Agger nasi, posterosuperior uncinate process and frontal ethmoid cells

Anterior structures encroaching on the frontal recess include the agger nasi, lateral uncinate process and frontal cells (Figure 87.21). The agger nasi is the anterior-most ethmoid air cell and its medial border is formed by the uncinate process.¹² The degree of pneumatization of the agger nasi influences the position of the superior uncinate process and thickness of the bony nasofrontal beak.

The uncinate process can insert into the medial orbital wall, skull base or middle turbinate. Recent studies have demonstrated that the uncinate has multiple attachments in more than 50% of cases rather than a single attachment pattern (Figure 87.22).^{12, 13} Classic teaching that describes three distinct attachments of the uncinate process which determines the direction of the frontal sinus drainage pathway is neither surgically relevant nor accurate (Figure 87.22). The uncinate process inserts onto the medial orbital wall in 85% of cases.¹³ Thus, the frontal recess drainage pathway is medial to the uncinate process in 85% of cases. An uncinate process with an isolated attachment to either the skull base or middle turbinate (without attachment to the medial orbital wall) occurs in only 15% of cases.¹³ This attachment pattern leads to a surgically obvious frontal drainage pathway located lateral to the uncinate process that is easily identified at the time of surgery. The surgical rule holds true that the frontal recess is medial to the remnant uncinate process or 'vertical bar' in 85% of cases¹⁴ with the other uncinate attachments representing easy surgical arrangements.

BOX 87.14

The uncinate process inserts onto the medial orbital wall in 85% of cases resulting in a frontal recess drainage pathway that is medial to the uncinate.

Frontal cells represent cells of the first ethmoturbinal that pneumatize above the agger nasi towards the frontal sinus. According to the Kuhn classification, a type 1 frontal cell is a single frontal ethmoidal cell above the agger nasi and below the frontal sinus floor, type 2 is a tier of

Figure 87.21 Anterior structures encroaching on the frontal recess depicted by a series of onlay diagrams. (a) Left frontal recess with all cells intact prior to surgical dissection, (b) left Draf 2A frontal sinusotomy with removal of all cells encroaching on the frontal recess. The relative positions of the anterior cells are superimposed including: (c) frontal cells (green), (d) agger nasi (blue), (e) superior uncinata process (yellow).

Figure 87.22 Schematic diagram of the uncinata process with different arrangements of its superior attachment. (a) Classic teaching describes 3 distinct attachments to the medial orbital wall, middle turbinate and skull base respectively which determines the direction of the frontal sinus drainage pathway. This description is not accurate. (b) The uncinata process has multiple attachments in greater than 50% of cases rather than a single attachment.

cells above the agger nasi, type 3 is a cell pneumatizing into the floor of the frontal sinus and type 4 is an isolated frontal ethmoid cell within the frontal sinus. Using multiplanar reconstructed imaging, Wormald further modified this classification to more accurately describe type 3 cells as frontal ethmoidal cells that fill less than 50% of the frontal sinus and type 4 cells as filling greater than 50% of the frontal sinus.¹⁵ These classifications of frontal cells are primarily to ensure that the surgeon's view of a large frontal recess cell lumen will not be mistaken for the true frontal sinus. Identification of these frontal cells on preoperative imaging prevents false assumption of completion sinusotomy (see [Chapter 99](#) on the frontal sinus).

Supraorbital ethmoid and suprabulla cells

Posterior structures encroaching on the frontal recess include supraorbital ethmoid cells, suprabulla cells and

the ethmoid bulla ([Figure 87.23](#)). Supraorbital ethmoid cells are anterior ethmoid air cells that extend superiorly and laterally over the orbital roof.¹⁶ These cells are recognized on imaging giving the appearance of a septated frontal sinus on coronal view and a cell located posterior and lateral to the frontal sinus on axial view.¹⁶ Supraorbital ethmoid cells have three clinically significant features relevant to the frontal recess: (1) they can cause obstruction of the frontal recess, (2) they can be falsely mistaken for the true frontal sinus leading to incomplete surgical dissection and (3) they are associated with a low position of the anterior ethmoid artery within a mesentery because these cells pneumatize downward from the skull base behind the artery.¹⁷ The supraorbital ethmoid cell also creates a very narrow orbitocranial cleft posteriorly that can be very challenging to operate within.¹⁸ Suprabulla or frontal bulla cells are pneumatized extensions above

Figure 87.23 Posterior structures encroaching on the frontal recess depicted by a series of onlay diagrams. (a) Left frontal recess with all cells intact prior to surgical dissection, (b) left Draf 2A frontal sinusotomy with removal of all cells encroaching on the frontal recess. The relative positions of the posterior cells are superimposed including: (c) supraorbital ethmoid cell (green), (d) suprabulla cell (blue), (e) ethmoid bulla (yellow).

the ethmoid bulla up the skull base and on the posterior table of the frontal sinus. These cells can become quite large and mistaken for either the skull base or posterior table of the frontal sinus. Failure to recognize these cells on pre-operative imaging will also result in incomplete surgical dissection of the frontal recess.

BOX 87.15

- Supraorbital ethmoid cells have significant features relevant to the frontal recess as the can: (1) cause obstruction of the frontal recess, (2) be falsely mistaken for the true frontal sinus leading to incomplete surgical dissection and (3) be associated with a low position of the anterior ethmoid artery within a mesentery placing this artery at risk of injury during surgery.
- Suprabulla cells pneumatize up the skull base and failure to recognize these cells pre-operatively will result in incomplete surgical dissection of the frontal recess.

Medial structures encroaching on the frontal recess include intersinus septal cells and medially inserting unciniate process. Intersinus septal cells represent pneumatization of the frontal sinus septum. Lateral encroaching structures include frontal cells, agger nasi and a lateral unciniate process attachment.

Posterior functional unit

The posterior functional unit is comprised of the posterior ethmoid air cells with drainage into the superior meatus. A variant of normal anatomy in this region is a lateral and posterior pneumatization of a posterior ethmoid cell called an Onodi cell (Figure 87.18). Onodi cells pneumatize over the optic nerve exposing this critical structure to injury during surgery. These cells can also be mistaken

for the true sphenoid sinus leading to incomplete surgery. Application of the maxillary sinus roof/orbital floor landmark identifies the level of the sphenoid ostium and enables complete dissection of the sphenoid sinus.

BOX 87.16

Onodi cells pneumatize over the optic nerve placing the optic nerve at risk for injury during surgery. An Onodi cell can be identified on the coronal view CT sinus as giving the appearance of a horizontal septation within the sphenoid sinus.

Sphenoid functional unit

The sphenoid functional unit is comprised of the sphenoid sinus which drains into the sphenoethmoid recess. Identification of the sphenoid sinus enables the surgeon to determine the level of the posterior skull base at its lowest position. The sphenoethmoid recess is the space between the superior meatus and septum. The supreme turbinate may be seen here. The sphenoid ostium opens behind the superior turbinate and is neither medial nor lateral to it.¹⁹ Complete removal of the anterior sphenoid wall laterally enables the surgeon to identify the medial orbital wall at its posterior position. The main structures associated with the sphenoid sinus include the optic nerve, carotid artery and sella turcica where the pituitary gland is located. The pneumatization pattern of the sphenoid sinus can be variable. The different types include sellar (90%), pre-sellar (9%) and conchal (1%) pneumatization patterns (Figure 87.6). The sellar type describes sphenoid pneumatization posterior to the sella turcica. The pre-sellar type describes sphenoid pneumatization up to the anterior sella and the conchal type describes a shallow bowl with minimal sphenoid pneumatization and trabecular bone

between the sinus and sella. The sphenoid sinuses can also pneumatize laterally into the pterygoid root resulting in the presence of a lateral sphenoid recess (Figure 87.7).

CONCLUSION

The paranasal sinuses represent some of the most variable human anatomy. An understanding of the developmental

and functional anatomy is critical to understand patterns of disease and pathophysiological events in the sinuses. However, it is an understanding of the anatomical boundaries of paranasal sinuses that are critical for the surgeon to avoid major complications. Ensuring the ostia are incorporated into the common surgical cavity provides the basis for a functional post-surgical cavity rather than discreet identification of their location.

BEST CLINICAL PRACTICE

- ✓ The paranasal sinuses represent some of the most variable in human anatomy.
- ✓ Although a knowledge of the developmental and functional anatomy is critical to understand patterns of disease and pathophysiological events in the sinuses, they are often of limited assistance during surgery.
- ✓ The anatomical boundaries of the paranasal sinuses are critical for the surgeon to avoid major complications. Variable clefts, pneumatization patterns and features that are easily distorted by pathology and prior surgery are not good guides for a surgeon.
- ✓ Ensuring complete surgical dissection with ostia incorporated into the common surgical cavity provides the basis for creating a new functional neo-sinus cavity post-operatively.

FUTURE RESEARCH

- ▶ Understanding the epithelial dysfunction with intrinsic mucosal inflammation, local microbial colonization and mucociliary dysfunction as the contributing factors in patients with chronic sinus inflammation is still evolving.

KEY POINTS

- Identify key fixed anatomical landmarks to delineate the limits of dissection of the paranasal sinus surgical cavity (box) for safe and complete endoscopic sinus surgery.
- The main structures are the orbit and skull base. These are defined by (1) maxillary sinus roof (orbital floor) (2) medial orbital wall (3) sphenoid sinus roof (skull base) and (4) the lateral sphenoid wall (orbital apex).
- Paranasal sinuses are divided into anterior, posterior and sphenoid compartments that serve as functional units based on mucociliary drainage pathways.
- Once a compartment is surgically entered, all mucosal cells within the compartment must be completely dissected to create a new functional neo-sinus cavity.

OUTPATIENT ASSESSMENT

Martyn L. Barnes and Paul S. White

Introduction	977	Examination.....	978
History taking	977	References	982
Patient reported outcome measures (PROMs)	978		

SEARCH STRATEGY

Data in this chapter may be updated by PubMed MeSH searches using the following keywords: otolaryngology, diagnosis, nose and outpatients, as well as selected subheadings e.g. 'otolaryngology/diagnosis'[Majr]. Several thousand articles were identified, almost all too specific in context to guide this short overview chapter. Notable exceptions are cited. See also the future research comments.

INTRODUCTION

Rhinology is an increasingly broad sub-speciality in which outpatient assessment is adjusted to suit each individual case. This chapter explores basic rhinologic history taking, clinical examination, nasendoscopy and the use of patient reported outcome measures (PROMs). Interpretation and use of more specialist assessments such as rhinometry, facial pain and lacrimal testing are described in their respective chapters. Investigations are described in their respective chapters, for example 'Measurement of the Nasal Airway' and 'Radiological imaging in rhinology and skull base surgery'.

The aim of an outpatient assessment is to reach a diagnosis in order to guide management. In many patients this may be clear from the history alone.

HISTORY TAKING

This is best initiated by characterizing the index nasal symptom(s), noting duration, periodicity, nocturnal variation, seasonal effects, laterality, association with trauma or prior surgery, and whether there are any alleviating or provoking factors. The enquiry should cover the presence of nasal obstruction or congestion, facial pain, hyposmia, anosmia, rhinorrhoea and post-nasal discharge. Secondary symptoms such as sneezing, itch, epiphora, taste disturbance and dry mouth should be elicited where appropriate. Understanding the symptoms and their associations

is not only useful diagnostically, but also helps to create a picture of the level of quality-of-life impairment suffered. The character of any nasal discharge can give clues to an acutely infective (mucopurulent) versus chronic rhinosinusitis or inflammatory origin. Increasing unilateral nasal obstruction associated with epistaxis (often minor) or facial pain and swelling suggests neoplasia and indicates the need for urgent assessment.

It is important to enquire about allergies, hay-fever, exposure to animal dander, asthma (or more general respiratory symptoms), and aspirin hypersensitivity. A previous history of nasal trauma may suggest nasal obstruction resulting from septal fracture or dislocation causing obstruction or failure of support to the internal nasal valve. Surgical procedures such as rhinoplasty, alar base reduction, and cleft palate surgery may all be associated with similar restrictive changes on the nasal airway.

Many systemic diseases have nasal manifestations. Granulomatosis with polyangiitis (previously Wegener's granulomatosis) is a systemic vasculitis in which nasal obstruction is associated with diffuse crusting of the nasal mucosa. Other conditions such sarcoidosis, Churg-Strauss vasculitis and Bechet's syndrome have a similar presentation. Cocaine abuse and habitual nose picking can cause septal crusting, septal perforation, and saddle deformity all of which have the potential to cause nasal impairments. Immunodeficiencies and ciliary defects are also commonly associated with nasal pathology.

A history of cigarette smoking is relevant as it may potentiate allergic rhinitis, and vasomotor rhinitis is

sometimes seen as a cause of nasal obstruction during smoking cessation.

The psychological aspects of the history are important to address. Many rhinologic symptoms relate to stress, anxiety, and psychosomatic manifestations. Directed enquiry into work and home situations will often elicit a patient's own concerns to this end.

Previous and current therapeutic trials of medication and their efficacy should be recorded. Many drugs exacerbate nasal symptoms, especially common are those with anti-muscarinic effects, such as anti-prostatic medications, anti-epileptics, antidepressants, antipsychotics, antihistamines, and drugs for Parkinson's. Non-steroidal anti-inflammatory drugs (NSAIDs) such as aspirin and ibuprofen in patients who have Samter's triad (nasal polyposis, asthma and NSAID intolerance) can trigger non-infective rhinitis and rhinosinusitis. Nasal obstruction associated with vasomotor rhinitis is a side effect of a number of drugs, including antihypertensives (such as beta blockers and calcium channel blockers), sedatives, phenothiazines, antidepressants, oral contraceptives and drugs used to treat erectile dysfunction. Overuse of sympathomimetic decongestant nasal sprays can cause rhinitis medicamentosa.

PATIENT REPORTED OUTCOME MEASURES (PROMs)

Contemporary practice should include the evaluation of the full-patient presentation. This process is simplified by the routine use of PROMs – questionnaires that aim to capture and quantify the bulk of symptomatology and disease impact. These should be supplemented and validated by direct questioning and inviting patients to discuss other ways in which they have been affected. When patients complete forms prior to the appointment, the administrative burden is minimized and the exercise will add to the efficiency and efficacy of the history taking process. Capture of these data (ideally digital) should facilitate research, audit, and service evaluation.

The following are selected examples of the more prevalent and well-validated patient reported outcome measures that may be useful in a rhinology clinic (Table 88.1).

EXAMINATION

Nasal Structure / Aesthetics

A full facial aesthetic assessment should be performed in patients with external deformity or cosmetic concerns. Examination of the external nose should begin with careful inspection and palpation of the nasal bones and alar cartilages. The detail should include an evaluation of skin type, skin scars, soft-tissue envelope thickness, integrity of the upper and lower lateral cartilages, nasal tip support, tip configuration, nares shape and integrity of the external and internal nasal valves. These factors can offer useful information on the more subtle causes of nasal dysfunction such as nasal valve insufficiency. Abnormalities of relevance to function as well as cosmesis include saddle deformity, septal deviation and deficiencies of the upper or lower lateral cartilages.

Functional assessment / anterior rhinoscopy

Nasal patency is assessed through anterior rhinoscopy – examination of the anterior nose using a Thudicum's speculum and head light illumination. First the patient is asked to breathe normally through their nose, noting any difficulty or noise. A thumb is used to gently occlude each nostril in turn and assess unilateral patency, remembering that many normal subjects are unable to breathe comfortably through a single nasal airway.

The degree of alar margin or 'external nasal valve' collapse is observed on normal and on forced inspiration, again noting that some dynamic narrowing is normal. The inferior turbinates should be evaluated for congestion, mucosal thickening and the presence of exudate.

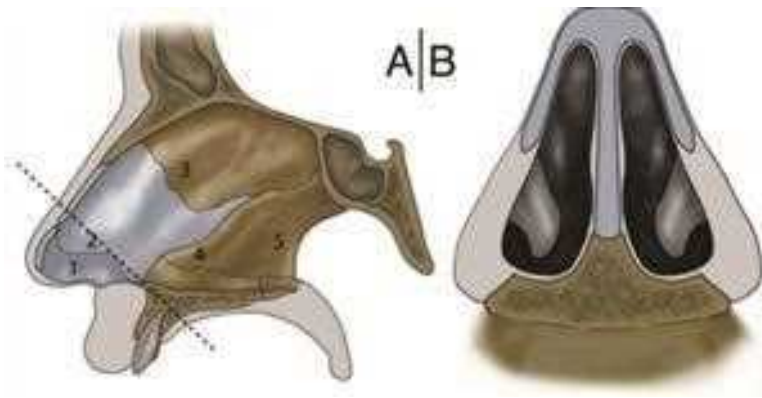

Figure 88.1 Cottle's areas of the nasal septum and the internal nasal valve region (dotted line). Deviations of the nasal septum can be classified by location and by severity. Locations include, 1 – Caudal septum, 2 – Internal nasal valve, 3 – High mid septum, 4 – Low mid septum, 5 – Posterior septum. Severity is graded 0 – No deviation, 1 – Minimal, 2 – Less than 50% lateralized, 3 – More than 50% lateralized, 4 – Fully lateralized (mucosal contact with lateral wall). This figure is released by SurgTech Ltd. (see www.SurgTech.net). They are available free of charge for anyone to use with certain provisos (see www.surgtech.net/terms). <http://www.surgtech.net/Rhino/Exam/>

The area between the inferior turbinate head, upper lateral cartilage and the nasal septum is the narrowest part of each nasal airway, termed the 'internal nasal valve' (Figure 88.1). The cross-sectional area of this space should be assessed at rest, on normal and forced inspiration. Any restriction may be due to septal deformity, turbinate engorgement or internal valve collapse. The latter may be static or dynamic due to upper lateral cartilage deformity or weakness respectively. Static internal nasal valve collapse is associated with an acute 'valve angle' at the junction of the septal and upper lateral cartilages (less than 15°). Poor septal support can also result in a

shallow valve height, with nasal restriction despite an even more obtuse angle (more than 15°). Septal obstruction elsewhere in the nose can be classified and graded as shown in Figure 88.1.

Simple tests such as the peak nasal inspiratory flow, nasal vapour condensation, or nasal valve splinting tests can be helpful adjuncts to confirm the clinical evaluation of nasal patency (Figure 88.2).

Cottle's manoeuvre (testing for improvement in nasal patency with lateral traction on the alar) tends to improve all nasal airways and is not advocated as a usefully discriminant test. Other clinical tests can be helpful – internal

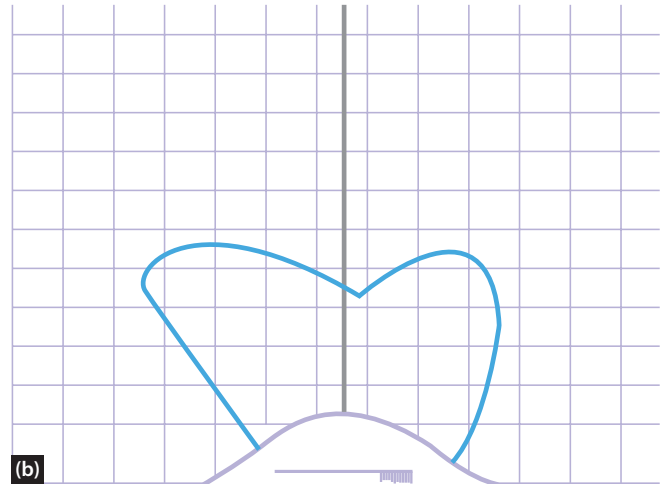

Figure 88.2 Nasal patency tests. (a,b) A vapour condensation test can be performed with a metal tongue depressor or a Glatzel calibrated mirror and gives a ready reckoning of relative flow. (c) A peak nasal inspiratory flow (PNIF) meter can evaluate overall nasal patency (normally more than 100 Lmin⁻¹ in an adult). (d) Splinting tests on the external and internal nasal valve can confirm anatomical deficiencies.

TABLE 88.2 Nasendoscopy Technique**First Pass – Front to back**

The endoscope is passed along the nasal floor, visualizing the septum and inferior turbinate. In the post-nasal space, the eustachian cushion and orifice, and the fossa of Rosenmüller are seen. Any mucopurulent post-nasal drainage can be noted. On withdrawal, the inferior meatus and, where possible, Hasner's valve are inspected.

Second Pass – Medial to the middle turbinate

Passing the endoscope medial to the middle turbinate, the sphenoid recess, superior turbinate, and slit-like opening of the sphenoid ostium are visualized. The olfactory cleft is seen more anteriorly. Head repositioning may be required, and an angled endoscope is recommended.

Third Pass – The middle meatus

Retracting, rotating the view laterally, and rolling the endoscope into the middle meatus will medialize the turbinate to expose any middle meatal mucopurulence accessory ostia or other pathology. The hiatus semi-lunaris, bounded by the uncinate and ethmoid bulla can be seen, as well as the membranous fontanelles and any associated accessory ostia. An angled endoscope is recommended.

valve collapse may respond to a trial of *Breathe-Right*® strips®. Similarly, nasal vestibule stents such as France's alar dilators®, AirMax Nasal splints®, or Max-Air Sinuscones® can have a positive effect on both valve areas.

Nasendoscopy

This is a necessary investigation for all patients referred for a specialist investigation of nasal or paranasal sinus disease. It is best performed after the application of decongestant (often combined with a local anaesthetic). The effect of the vasoconstriction on the turbinate mucosa will give a useful indication of the reversibility of any congestion. Endoscopic evaluation using a three-pass technique (Table 88.2) should enable visualization of the inferior meatus, middle meatus, superior meatus, sphenoid-ethmoidal recess, olfactory cleft, septal areas, and the nasopharynx. Narrow diameter (2.5–3.0 mm) angled endoscopes (30–45°) confer greater opportunity to look around corners into each narrow nasal meatus. Patient confidence is enhanced by initiating the examination with passes through the more patent parts of the airway, for example, on the side opposite to

any septal deviation. Conditions causing severe obstruction of the anterior airway such as a dramatic septal deviation or large polyps may preclude endoscopy beyond this level, but the clinical relevance will be obvious. Examples of the endoscopic anatomy, and common pathologic and findings are provided in Figures 88.3 and 88.4.

Endoscopic nasal biopsy

Any nasal masses should be evaluated for colour, consistency, vascularity and origin. Bilateral nasal polyps need not be biopsied unless the mucosal appearance is unusual, however, it is a sensible precaution to obtain histopathology in all primary polypectomy cases. Other endonasal masses can often be biopsied in a clinic situation, but the possibility of a vascular nature (e.g. juvenile angiofibroma) or meningo(encephalo)coele must be considered based on the appearance, location and apparent margins. In such cases, a CT with contrast or MRI scan may prevent significant complications. If a biopsy is still required, it may be best performed in the operating theatre. In all cases, preparations should be made to address any epistaxis following biopsy.

BEST CLINICAL PRACTICE

- ✓ Systematic approach to history and examination based on presenting concerns.
- ✓ Appropriate PROMs used to record presentation and clinical progress - patient completed.
- ✓ Formally recorded benefits for surgery and other interventions.

FUTURE RESEARCH

- ▶ Rarely do we formally study our greatest tool – the medical history and examination.
- ▶ In the future, the coming together of medical informatics, the electronic patient record, patient reported outcome measures, and innovative (largely patient led) data collection techniques applied to routine clinical practice will bring together a wealth of data we currently fail to recognize and interpret. This will give us greater opportunities to improve our understanding of the patient symptom journey, diagnostic implications, and the effect our interventions truly have on this. It may also trivialize clinician involvement. Such changes seem some way off yet – a good start would be a ‘Rhinology’ MeSH term.

KEY POINTS

- Well-developed skills in clinical history and examination are key to efficiently arriving at the correct diagnosis and implementing appropriate management in all our patients.
- PROMs have become an integral component of patient assessment.
- Nasal endoscopy is a necessary investigation for all patients referred for a specialist rhinologic assessment.

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed and Medline search using the following keywords: nasal obstruction, nasal mucosa, nasal blood flow, nasal cycle, nasal cilia, olfaction, nasal valve and autonomic nervous system.

INTRODUCTION

To understand the pathological process affecting the nose and the paranasal sinuses, it is important to have an understanding of the normal physiological functions of the nose.

The nose is a complex organ that forms an important part of the face and has multiple functions. Anatomically, the nose may be considered to have an external and internal component. The internal component forms the nasal cavities. The external component is prominent, pyramidal with an apex at the tip whose base is attached to the forehead. The nose projects downward with two perforated apertures, the nostrils, which are separated by the columella. The external nose is made up of cartilaginous and bony parts. The cartilaginous part consists of lower lateral cartilages and upper lateral cartilages both of which are in pairs. Fibrous tissue connects the cartilages. The internal nose is divided by the nasal septum into left and right chambers. The entrance of the internal nose: the nasal vestibule is lined by skin, and it contains appendages. The rest of the nasal entry is lined by respiratory mucosa and olfactory epithelium. Each cavity consists of a floor, roof, lateral and medial walls.¹

The principal physiological function of the nose is to humidify and warm inspired air, as well as to remove

noxious particles from the air, thus protecting the delicate distal lower respiratory tract. The nose also serves as a sense organ, housing the olfactory apparatus that allows individuals to smell substances for pleasure and defence purposes. These functions are highly dependent on the anatomical structure of the nose. The vomeronasal organ (VNO) is the peripheral sensory organ of the accessory olfactory system and is located either at the base of the nasal septum in humans or in the roof of the mouth in most amphibians, reptiles and mammals. The VNO role is to detect pheromones and other chemical signals that initiate innate behavioural response between individuals of the same species. These chemical communications facilitate social interactions such as sexual relationships.

The nasal mucosa is the first part of the airways to come in contact with the external environment, with an adult inspiring up to an estimated 10 000 litres of air daily. The nasal mucosa is very vascular containing arterioles, arteriovenous anastomoses and venous sinusoids, with a large surface area of 150 cm².² During normal breathing the nose contributes up to 50% of the resistance of the entire airway, with any change in this resistance playing a significant role to the total respiratory function.³ These vital properties allow the nasal airway to play an important role in the normal homeostasis of the body.

THE ROLE OF PARANASAL SINUSES

The paranasal sinuses are air filled cavities found in the maxilla, sphenoid, ethmoid and frontal bones. They develop from an outgrowth of the nasal cavity, and hence pathology affecting the nose also affects the paranasal sinuses. Development of the paranasal sinuses vary, with ethmoid and maxillary sinuses being present at birth and the frontal sinuses developing by the age of six, however they can also be absent. The degree of development of the sphenoid sinus differs considerably.

The physiological role of the paranasal sinuses is uncertain, but a number of possible functions have been suggested.

This includes the following:

- Providing a physical buffer against injury to the face
- Vocal resonance
- Reduction of skull weight
- Humidification
- Heat insulation
- Air conditioning

NASAL BLOOD FLOW

Nasal blood flow plays a crucial part in the normal physiological function of the nose.

It can be determined using temperature change, colour change, photoelectric plethysmography, and laser Doppler techniques (Figure 89.1). There can be various combinations of blood flow based on the balance between arteriovenous shunting, arterial airflow as well as venous pooling. The main clinical variations include hyperaemia, reduced arterial perfusion and ischemia. Arteries and arterioles cause resistance while venules and sinusoids give capacitance. The nose has an abundant blood supply, from branches of both the internal and external carotid arteries. A rich vascular bed composed of predominantly arteriovenous anastomosis and venous sinusoids supply the nasal mucosa. The venous sinusoids form the erectile tissue that is located on the anterior nasal septum and the inferior turbinates. They have the ability to expand and shrink, which has an impact on the nasal resistance and nasal airflow.⁴ Animal studies have shown that venous pressure has a greater impact on the nasal airway resistance, with nasal resistance increasing by 1.2–1.3% per mmHg of venous pressure increase.⁵

NASAL MUCOSAL VESSEL CAPACITANCE

Two main mechanisms, the hydrostatic pressure of blood and the autonomic nervous system influence nasal mucosal vessel capacitance. The change in hydrostatic pressure affects the filling pressure of vessels, where increase in pressure expands the venous sinusoids. The autonomic

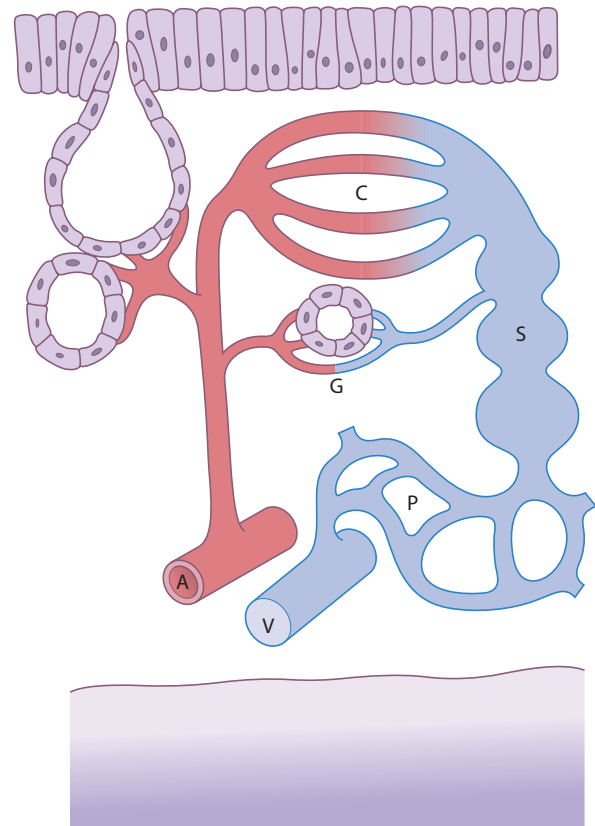

Figure 89.1 Schematic representation of the blood supply of the turbinates. A, arteriole; V, venule; C, capillaries; G, interstitial glands; P, venous plexus; S, venous sinusoids.

nervous system controls the activity of smooth muscle found in the walls of the arteriovenous anastomoses leading to changes in nasal blood flow. Other factors which also influence nasal blood flow include medication, temperature and humidity.⁶

AUTONOMIC NERVOUS SYSTEM

The nose is innervated by parasympathetic and sympathetic fibres, which have a profound impact on nasal physiological function. The parasympathetic fibres originate in the midbrain, with the post-ganglionic fibres travelling in the maxillary branch of the trigeminal nerve and providing secretomotor supply to the mucous glands in the nasal mucosa. The primary neurotransmitters are acetylcholine, which induces serous secretion and vasoactive intestinal peptide which causes vasodilation of the blood vessels of the nasal mucosa. The sympathetic innervation to the nose starts from the thoracic spinal nerves, with pre-ganglionic fibres synapsing in the cervical sympathetic ganglion. The post-ganglionic fibres travel alongside the internal carotid artery. Sympathetic fibres predominantly innervate smooth muscle in the walls of arterioles and sinusoids. The primary neurotransmitter is noradrenalin, which has the opposite effect on the nose, causing a reduction in secretomotor activity of mucous glands and causing vasoconstriction of the blood vessels. Drugs may mimic the effects of sympathetic and

TABLE 89.1 Drugs acting on the nasal mucosa

Drug Group	Mode of action	Example
Sympathomimetics and their antagonists	Compounds act on alpha 1 receptors and cause vasoconstriction	Adrenalin and noradrenaline analogues Cocaine blocks uptake of noradrenalin in nerve endings. Also acts as a local anaesthetic Drugs used for hypertension such as beta-blockers
Parasympathomimetics and their antagonists	Compounds act to cause vasodilation and increase nasal secretions	Pilocarpine causes vasodilation and watery secretions Ipratropium bromide blocks muscarinic receptors, thus preventing acetylcholine from binding
Antihistamines	Predominantly block H ¹ receptors. Histamine is found mainly in mast cells and causes vasodilation and increases plasma leaking from capillaries	Antihistamines
Local anaesthetics	Inhibit Na channel influx therefore reduce the rate of depolarization/repolarization.	Lignocaine

parasympathetic nerve supply. **Table 89.1** gives an overview of drugs frequently used and their mode of action on the nose.

EPITHELIUM-CILIARY FUNCTION

There are three types of epithelium in the nose. First, there is squamous also referred to as the transitional epithelium that consists of the vibrissae, sweat glands, and nasal vestibule (sebaceous glands). Second, there is the pseudo-stratified columnar epithelium that covers two-thirds of the posterior nasal cavity. This epithelium contains ciliated as well as non-ciliated columnar cells, basal cells as well as mucin secreting goblet cells. The nasal epithelium is located on the lamina propria and basement membrane, which are served by capillaries that facilitate fluid flow through to the nasal mucosa. Finally, there is the olfactory neuroepithelium that forms the superomedial portion of the superior turbinate, nasal root and superior septum. There are various types of cells in the olfactory epithelium but the more common are Bowman glands and ducts, bipolar receptor cells, sustentacular cells and microvillar cells. Cilia are located on the surface cells of the respiratory tract. Their role is to push mucus backwards towards the nasopharynx.

The ultrastructure of all cilia remains the same; however, nasal cilia are somewhat short. The surface membrane of a cilium encloses an organized ultrastructure. The nine outer-paired microtubules enclose a single inner pair of microtubules. The outer pairs of microtubules are linked to one another by nexins and to the inner pair of microtubules by central spokes. In addition, outer pairs of microtubules have both outer and inner dynein arms that are made up of an ATPase. There are two layers of nasal mucus film, the lower layer that is more watery and cilia move freely, and the upper viscous layer. Importantly, there are small hooks on the tips of the cilia to facilitate their movements once they enter the viscous layer.

At body temperature, cilia beat frequency ranges from 7 to 16 Hz. The frequency usually remains constant when the temperatures are between 32 and 40 °C. The cilia can beat rapidly in a propulsive stroke or slowly during the recovery phase. Notably, the propulsive period is characterized by the cilium straightening while the tip points to the viscous layer. The recovery phase sees the cilium bending over in the aqueous layer. During this process, adenosine triphosphate (ATP) is converted to adenosine diphosphate (ADP) using the enzyme ATPase that is found at the dynein arms. This magnesium ion (Mg²⁺) dependent reaction produces energy. Motion occurs whenever there is sliding of the outer pair microtubules against one another. The mitochondria located near the cell surface next to cilia's basal bodies generate the ATP.⁷

Metachronous movement of cilia propels the mucus blanket backwards, thus only those (cilia) that are at right angle to the direction of the flow form the phase. Cilia that are in the flow-direction are out of phase until the cycle completes. From the front of the nose, mucus flows posteriorly. Thereafter, mucus from the sinuses and from the lateral wall joins together with most passing through the middle meatus. The majority of mucus then passes around the Eustachian orifice before it is swallowed.

The nose is a constantly changing environment where slight fluctuations can affect the function of cilia. Dry conditions stop ciliary action and at temperatures below 10 °C and temperatures above 45 °C, ciliary movement stops. Isotonic saline preserve the activity of cilia, however, if the solutions are 5% above and 2% below the normal isotonic saline conditions, paralysis occurs. Likewise, potassium ions do not affect ciliary function except when the levels become non-physiological.⁸ Furthermore, cilia can beat above pH 6.4 as well as function in a slightly alkaline medium of up to pH 8.5 for a prolonged period. Infections in the upper respiratory tract can cause damage to the epithelium and the function of cilia also deteriorate with age.⁹

EFFECT OF SMOKING ON THE NOSE

Tobacco contains hundreds of noxious chemicals and when smoked can irritate the lining of the nose resulting in increased nasal secretions and congestion caused by impairment of mucociliary clearance. Smoking causes a reduction in the number of cilia and change in mucous viscosity. Studies have shown that eight hours after exposure to tobacco smoke the efficiency of mucociliary clearance had reduced, with heavier smokers having more marked impact.¹⁰

NASAL AERODYNAMICS

Knowledge of the aerodynamic behaviour of the nasal airway provides an aid to the decision-making process of medical and surgical management of pathological processes affecting the nose.

At rest the normal inspiratory flow rate in an adult ranges between 5 L/min to 12 L/min and has a pressure change of 50 Pa between the nostrils and the nasopharynx. During exercise the flow rate increases with a correspondent drop in pressure, where the flow rate can increase to as much as 150 L/min.¹¹

Fluid dynamic experiments of the nose (Figure 89.2) have shown that nasal flow is laminar as it enters the nasal vestibule, with no mixing of the different air layers at low velocity.

The velocity of the air increases as it passes through the nasal valve, the narrowest site of the upper respiratory tract. At this point turbulent flow is observed in the nasal cavity, with different air layers swirling together. The change from laminar to turbulent flow is paramount as it allows the velocity of the air to reduce, thus allowing prolonged contact of inspired air with the nasal mucosa and therefore allowing the nose to perform its vital functions.

Figure 89.2 Velocity streamlines.

Septal deviation and turbinate hypertrophy can cause a reduction in the cross-sectional area of the nasal mucosa and thus also affect nasal function.^{12, 13}

NASAL CYCLE

The nasal cycle is a well-recognized physiological activity whereby each side of the nose alternates the phases of congestion and decongestion.¹⁴ Vascular activity produces the changes, especially the volume of blood in capacitance vessels (venous sinusoids). The changes are cyclical and occur every 4 to 12 hours with the changes being constant for each person. The nasal cycle can be demonstrated in up to 80% of adults, however, it is not easy to demonstrate in children.¹⁵

The physiological significance of the nasal cycle is not clear. However, resistance and airflow leads to increased cyclical secretions in the side that is experiencing the greatest flow. Several factors affect the nasal cycle; these include exercise, pregnancy, hormones, infections, allergy, fear, emotions and sexual activity. The autonomic nervous system regulates many of the changes. Notably, vagal over activity can lead to congestion while high levels of CO₂ present in inspired air that is produced as a result of rebreathing may reduce the nasal resistance. Hyperventilation reverses the situation.¹⁶ Nasal congestion may also occur due to drugs that block the action of the noradrenaline. Antihistamines also produce anticholinergic effects that can halt parasympathetic activity. This results in increased sympathetic tone that improves the nasal airway. Hormonal changes seen in puberty also affect the nasal mucosa.

NASAL RESISTANCE

Nasal resistance plays a crucial role in preventing the collapse of the lower respiratory tract, notably the lungs, with nasal resistance contributing up to 50% of the total airway resistance. As nasal airway resistance is increased, it causes an increase in negative intra-thoracic pressure and in turn enhances pulmonary ventilation. Mathematically, resistance of nasal airflow is equal to the pressure of the nasal flow divided by flow rate. Nasal air flow is affected by the radius of the nose. Based on laminar flow equations, a decrease in the nasal radius can cause a four-fold decrease in nasal air flow (see Chapter 90, Measurement of the nasal airway). The presence of laminar and turbulent flow in the nasal passageway is vital to the physiology of air exchange. Nasal airway resistance is achieved through three key components. These include the nasal vestibule, the nasal valve and the inferior turbinates.

Nasal vestibule

The nasal vestibule is composed of a compliant wall that can collapse in response to the negative pressure caused by inspiration thus increasing nasal resistance. A flow of 30 L/min is the limiting rate during inspiration at which nasal airway collapse occurs at the nasal

Figure 89.3 (a) The direction of inspiratory airflow. (b) The direction of expiratory airflow.

vestibule (**Figure 89.3a**). However, this airway collapse can be prevented by activation of the ala nasi muscle during inspiration. Contraction of this muscle results in a change of the shape of the vestibule which leads to a reduction in air flow turbulence without affecting the cross-sectional area. Paralysis of ala nasi, as seen in facial nerve palsy, causes the nasal vestibule to collapse during inspiration and hence increase nasal resistance. During exercise the ala nasi muscle contracts, which increases the radius of the nasal cavity and hence reduces nasal resistance.¹⁷

Expiration has the opposite effect, as the positive pressure within the vestibule increases the radius of the nose and in turn improves nasal airflow (**Figure 89.3b**).

Internal nasal valve

This is the narrowest part of the nasal airway and helps to direct the airflow upward and backward across the anterior part of the inferior turbinate. It is found approximately 2 cm posterior to the anterior nares and has a cross-sectional area between 55–83 mm². The size of the inferior turbinate (an erectile tissue) and position of the nasal septum determines the dimensions of nasal valve.

The nasal valve is bound superiorly by the caudal end of upper lateral cartilages and septum medially. The inferior boundary is the nasal floor, laterally is the bony piriform aperture with the adjacent fibrofatty tissue and posteriorly is the head of the inferior turbinate. The nasal valve makes a significant contribution to upper airway resistance and produces the most turbulent airflow.¹² During quiet respiration, the velocity of the anterior valve ranges from 12 to 18 m/sec. The nasal valve is often referred as the internal nasal valve. Therefore any change in the size of the inferior turbinate and deviation of the septum at this level has an impact on the nasal valve. The nasal valve plays a key role clinically, and the treatment of the components that make up the nasal valve area can have a marked impact on nasal airway resistance.

The Cottle maneuver is used to assess the narrowing of the nasal valve area at rest. The test is conducted by lateralizing the soft tissue and the nasal vestibule. It is considered positive if it improves nasal airflow. Swelling of the inferior turbinate has a profound effect on nasal resistance. Consequently, treatments that aim to reduce the size of the inferior turbinate have a significant effect on the nasal resistance as opposed to that of the nasal surgery that removes septal spurs.

Inferior turbinate

The turbinates of the nose can swell and recede, thereby reducing the dimensions of the nasal cavity contributing to nasal airway resistance. The inferior turbinates are part of the nasal valve area and they help the change of laminar inspired air into turbulent flow. The large surface area and extensive blood supply of the inferior turbinate increases the interaction of inspired air with nasal mucosa which enables the nose to carry out its functions more effectively.¹⁸

Pathological processes causing enlargement of the inferior turbinate by only a small incremental increase of 1–2 mm have been shown to lead to a significant reduction in the nasal airflow velocity down to 0.42 m/s when compared to 0.89 m/s in the normal healthy nose.¹⁹

NASAL FUNCTION

The nose has various physiological functions. Respiratory functions include heat exchange, filtration, humidification, nasal neurovascular reflexes and voice modification. Olfaction functions are stimulus pathways and there is trigeminal input.

Heat exchange

The temperature of inspired air can range from –50 to 50°C. Since various racial groups live in different

environments, the nose has evolved to suit different local conditions.

Filtration

The turbinates organize the pattern of airflow, enabling the nose to exhale all of the inspired air to the airstream. This happens fairly slowly around and along the ciliated turbinates. In the process, heat and energy is emitted into the inspired airstreams thereby saturating the airborne particles as well as micro-organisms. Eventually, the particles and micro-organisms become heavier, sinking into the mucosal layer where they are processed using enzymes and immune system cells.

Olfaction

Sense of smell plays an important role in protection from danger, such as fire. It is also central in forming positive and negative memories affecting individual psychological wellbeing, socialization and interpersonal relationships, with dysfunction leading to a poor quality of life (see [Chapter 110](#). Abnormalities of Smell).

DEFENCE MECHANISMS OF THE NASAL MUCOSA

The nose has a role in protective mechanisms to prevent noxious substances entering the lower respiratory tract. This defence mechanism can be divided into mechanical and immunological defence.

Mechanical defence

The nose is able to protect the lower airway by removing particles of approximately 30 µm or upward such as pollen in inspired air. The velocity of the inspired air drops significantly after the nasal valve. As turbulence increases, so does the deposition of particles. Particles with irregular shapes resist change to the greatest extent because they have a larger surface area. Vibrissae only stop the largest particles. Mucociliary flow is the main mechanical defence of the nasal mucosa because it physically cleans inspired air. The mucociliary transport system is made up of cilia of the respiratory epithelium as well as a mucous blanket. The latter consists of a deeper layer where ciliary motion occurs as well as a superficial thicker gel layer. Viscoelastic properties enable it to trap larger particles. This mechanical defence is predominant and expels filtered particles and debris into the nasopharynx and oropharynx as well as elimination through sneezing and coughing.²⁰

Immunological defence

Mucus consists of compounds that are able to neutralize antigens through innate mechanisms, learned, and adaptive immunological responses. Immunoglobulin A (IgA) and immunoglobulin E (IgE) are found on the surface, and they act whenever the mucosa is breached. In most cases, bacterial allergens are destroyed, but there are other viruses and bacteria that require the activation of the cell-mediated immune responses. IgA is the main immunoglobulin in secretions and has distinctive characteristics. IgA has two subgroups, namely IgA₁ and IgA₂. IgA₁, with a monomeric structure, is frequent in serum while IgA₂, with a dimer structure, is common in nasal secretions.²¹ Immunoglobulin A constitutes 70% of the total proteins in nasal secretions.

EFFECT OF PREGNANCY ON THE NOSE

Pregnancy induced rhinitis (PIR) is a common problem, and has an incidence of around 22%. PIR has been defined as nasal congestion that is not present before pregnancy, but manifests itself in the second or third trimester, lasting 6 or more weeks with no known allergic cause, which then resolves completely within 2 weeks of delivery.²² The cause of PIR is still under debate as is the impact of pregnancy hormones on the nasal mucosa. Studies have shown that during pregnancy there is a decrease in mucociliary clearance and increase in nasal resistance, with oestrogen having possible role in inducing histamine receptors on epithelial cells.^{23, 24}

BEST CLINICAL PRACTICE

- ✓ Pregnancy induced rhinitis (PIR) is a common problem, and has an incidence of around 22%.
- ✓ PIR has been defined as nasal congestion that is not present before pregnancy, but manifests itself in the 2nd or 3rd trimester, lasting 6 or more weeks with no known allergic cause, which then resolves completely within 2 weeks of delivery.²²

FUTURE RESEARCH

- Nasal morbidity, unlike in disorders affecting the other senses, is difficult to quantify, yet conditions such as sinusitis are chronic and affect a significant percentage of the population.
- Continued basic science research is desperately needed that may lead to a better understanding of the physiology of nasal function to ultimately help in better treating common nasal complaints.

KEY POINTS

- The principal physiological function of the nose is to
 - humidify and warm inspired air
 - remove noxious particles from the air
 - also serves as a sense organ
- The nose has an abundant blood supply, from branches of both the internal and external carotid arteries.
- The venous sinuses form the erectile tissue that is located on the anterior nasal septum and the inferior turbinates.
- Smoking causes a reduction in the number of cilia and change in mucous viscosity.
- The nasal cycle is a well-recognized physiological activity whereby each side of the nose alternates the phases of congestion and decongestion.¹⁴
- Nasal resistance plays a crucial role in preventing the collapse of the lower respiratory tract, notably the lungs, with nasal resistance contributing up to 50% of the total airway resistance.

Acoustic rhinometry.....	994	References	997
Peak nasal flow	994		

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: rhinomanometry, acoustic rhinometry, nasal peak inspiratory flow and human. The data were supplemented by further searches and use of a personal database. The evidence in this chapter is not aimed at any specific treatments, only methods to measure the patency of the nasal airway, and based on a range of studies that include randomized clinical trials of Level 1 evidence.

INTRODUCTION

Nasal obstruction is one of the most common complaints presenting to ENT surgeons, but treatment is usually initiated without any objective measurement of nasal airflow or nasal patency. Pneumologists have access to useful normal ranges for lung function, whereas rhinologists have not established generally accepted ranges for normal nasal patency.

Establishing a normal range of nasal patency is confounded by several factors related to nasal physiology. First, the nose is directly exposed to the external environment and acts as an air conditioner to protect the lungs from infection and variations in environmental conditions, whereas the lungs operate as part of the internal environment at a constant temperature of 37°C in a sterile environment. Second, the nose is subject to spontaneous changes in nasal patency associated with the ‘nasal cycle’, with spontaneous congestion and decongestion of the large veins found in the nasal epithelium.¹ The direct exposure of the nose to the external environment and the spontaneous changes in nasal patency associated with the nasal cycle make normal or ‘physiological’ nasal patency unstable and difficult to define.²

‘Anatomical’ nasal patency is the nasal patency measured after decongestion of the nasal blood vessels by application of a topical nasal decongestant or by standard exercise. Anatomical nasal patency is a useful measure for

the nasal surgeon as it is determined solely by the hard tissues of the nose such as cartilage and bone.³

Measures of nasal obstruction usually involve measurement of nasal airflow or an assessment of the cross sectional area of the airway. The nasal airway can be considered as a simple tube, and measurement of the airflow through the tube and its driving pressure, by means of rhinomanometry, can provide a measure of nasal patency. The prime factor determining nasal patency is the cross sectional area of the nasal airway and this can be measured by means of acoustic rhinometry. Rhinomanometry provides a functional measure of nasal patency, whereas acoustic rhinometry provides an anatomical measurement of cross sectional area or nasal volume. Rhinomanometry and acoustic rhinometry are the major techniques used for measuring the nasal airway but other techniques such as measurement of nasal peak inspiratory flow can also provide useful measures of nasal patency.

This section will discuss the most commonly used measurements of nasal patency and their relevance to research and clinical practice in rhinology.

RHINOMANOMETRY

Rhinomanometry normally provides a measure of nasal resistance to airflow and measures of nasal patency in units of nasal airflow may be further calculated from

this parameter. Nasal resistance to air flow is calculated from two measurements: nasal airflow and trans-nasal pressure.⁴ Both these parameters are measured by means of differential pressure transducers (manometers) and this is why the study of nasal pressure and flow is termed 'rhinomanometry', since manometry involves the measurement of pressure. Nasal airflow can be measured by means of a flow head that usually consists of a mesh resistance inside a tube. The pressure difference across the mesh generated by airflow through the tube is used to measure airflow. Trans-nasal pressure can be measured by relating the pressure at the posterior nares to that at the entrance of the nostril, which will normally be atmospheric pressure or nasal mask pressure.

Active rhinomanometry involves the generation of nasal airflow and pressure with normal breathing. Passive rhinomanometry involves the generation of nasal airflow and pressure from an external source, such as a fan or pump, to drive air through the nose.

Active rhinomanometry can be divided into anterior and posterior methods according to the location of the pressure-sensing tube. In active anterior rhinomanometry, the pressure-sensing tube is normally taped to one nasal passage. The sealed nasal passage acts as an extension of the pressure-sensing tube to measure pressure in the posterior nares. With this method, nasal airflow is measured from one nostril at a time and the pressure-sensing tube is moved from one side of the nose to the other. Therefore, nasal resistance is determined separately for each nasal passage and the total resistance is then calculated by summing the values as shown in the formulae below.

In active posterior rhinomanometry as shown in **Figure 90.1**, the pressure-sensing tube is held in the mouth and detects the posterior nares pressure when the soft palate allows an airway to the mouth.

Total nasal airflow can be measured from both nasal passages simultaneously. The right and left nasal airflows can be measured separately by taping off one nostril at

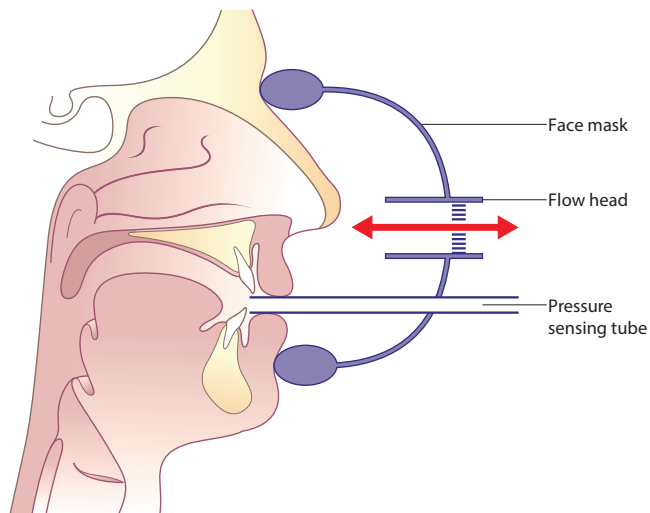

Figure 90.1 The technique of posterior rhinomanometry. This involves a pressure-sensing tube in the mouth that detects the changes in pressure in the posterior nares, and a flow head to measure nasal airflow.

a time. Total nasal resistance can be determined directly from the total nasal airflow and trans-nasal pressure with this method. A disadvantage of this method, when compared with the anterior method, is that not all subjects can obtain an airway around the soft palate into the mouth. With some training of subjects it is possible to obtain satisfactory results from about 90% of subjects.

Passive rhinomanometry involves the direction of an external flow of air through the nose and out of the mouth. The method may involve either measurement of a driving pressure at a constant flow or measurement of the flow at a constant pressure. Passive rhinomanometry is particularly useful if it is necessary to separate the upper and lower airways for experimental work.

Active anterior rhinomanometry, using surgical tape to seal a pressure-sensing tube into the nasal passage, is one of the most commonly used methods for clinical determination of nasal resistance and it is recommended by standardization committees,^{5,6} but posterior rhinomanometry has been used successfully in clinical trials on nasal surgery and nasal decongestants.⁷⁻⁹

Nasal airway resistance can also be measured by use of a head-out body plethysmograph (displacement type) and with this method the flow head is located on the side of the body-box and the pressure-sensing tube is passed along the floor of the nasal cavity. This method has the advantage that the nose is unimpeded by any mask.¹⁰

When making measurements of nasal airway resistance it is important to take several measurements with repositioning of the mask between measurements. This is to control for air leaks around the mask that are a common source of error. A single measurement of nasal airway resistance is unreliable and a standard operating procedure should be implemented to prevent investigator bias when gathering data.⁴

Nasal resistance to air flow may be calculated from the following equation:

$$R = \frac{\delta P}{V}$$

R = resistance to air flow/cm H₂O/litre per second or Pa/cm³ per second

δP = trans-nasal pressure, in cm H₂O or Pa

V = nasal air flow, in litre/s or cm³/s

This equation is a compromise that has been generally accepted by rhinologists and it does not take into consideration the separate components of laminar and turbulent air flow.^{5,6}

A plot of the dynamic relations of trans-nasal pressure and flow on an x/y plotter shows a curvilinear relationship for the $\frac{\delta P}{V}$ plot. Nasal airflow increases with increase of trans-nasal pressure, but at higher pressures there is a limitation of flow due to the increased frictional effects of turbulent airflow. The flow-limiting effect of nasal alar collapse is only apparent during rapid or close to maximum inspiratory manoeuvres.

The curvilinear relationship between trans-nasal pressure and flow means that one cannot simply determine

nasal resistance from the slope of the graph, as would be the case with a straight-line relationship. The slope of the $\frac{\delta P}{V}$ plot varies along its length and, therefore, it is not possible to describe the whole curve with a single numerical value for resistance. It is, however, possible to define the resistance at any given sample point along the curve and this has been the solution recommended for a standardized measurement of nasal resistance.^{5,6}

The positive or negative pressure at the posterior nares results in airflow through both nasal passages. The right and left nasal airflows are normally asymmetrical due to the nasal cycle and therefore a single pressure value may relate to two different airflows. It is, therefore, sensible to standardize nasal resistance by measuring both nasal airflows at the same sample pressure point rather than by measuring trans-nasal pressures at the same sample flow point.

Unilateral nasal airflow measured at a sample pressure point of 150 Pa and bilateral nasal airflow measured at 75 Pa are recommended.⁵ Other parameters may be calculated from the pressure flow curve but these are not in general use and are not generally accepted.⁶ The Asian population cannot always achieve the higher sample pressure of 150 Pa during normal quiet breathing, and the lower sample pressures of 100 and 50 Pa, respectively, are generally accepted for nasal resistance measurements in Japan.

The lower nasal pressures in the Asian population compared to Caucasians is due to smaller body size and smaller lung volume.

Total nasal resistance to air flow can be either determined directly using the posterior method of rhinomanometry or it can be calculated by combining the two separate values of nasal resistance for the two nasal passages as shown in the formula below:

$$\frac{1}{R(\text{total})} = \frac{1}{r(\text{left})} + \frac{1}{r(\text{right})}$$

The reciprocal of total resistance is equal to the sum of the reciprocals of left and right resistance.

When quoting values for total nasal resistance it should be stated whether the value was obtained by measurement of total nasal air flow using posterior rhinomanometry, or whether the air flows of the nasal passages have been measured separately.

Normal nasal airflow

As discussed above, nasal patency in health is unstable and may be even more variable in disease, therefore it is difficult to give any normal range. The variability in nasal patency is especially marked for unilateral patency as it is normal for one nasal passage to be obstructed and the other quite patent as a normal phase of the nasal cycle. However, total nasal patency is more stable because of the reciprocal relationship between the two nasal passages.¹

In adult subjects free from signs of nasal disease mean total resistance has been reported to be around 0.23 Pa cm³ s

with a range of 0.15–0.39 Pa cm³ s.¹¹ As a routine screening procedure in our laboratory we normally consider a total nasal resistance to airflow of 0.3 Pa cm³ s as an upper limit of the normal range. Cole considers any total airway resistance greater than 0.25 Pa cm³ s as obstructed.¹⁰ Nasal resistance is at a maximum in the infant at around 1.2 Pa cm³ s,^{12–13} declines to the adult value at around 16–18 years of age and then shows only a slow decline with increasing age.¹⁴ In a study on healthy male volunteers a relationship between age and nasal resistance was reported, with resistance declining with increasing age from 0.6 Pa cm³ s (age 5–12 years) to 0.29 Pa cm³ s (age 13–19 years) and 0.22 Pa cm³ s (age >20 years) in males.¹⁵ The relationship between age and nasal resistance was similar in females but in general nasal resistance was lower in females than males.¹⁵

If the nose is decongested by exercise or application of a topical decongestant then this eliminates any physiological variation in resistance and allows one to investigate the anatomical factors influencing resistance. Studies by Broms¹⁶ have provided a table of predictive values for height and nasal resistance in the decongested nose that are useful in assessing the extent of any deviation from normality in patients with nasal skeletal stenosis.

Total nasal resistance gives an overall measure of nasal function but it is a very crude measurement, as it provides no information about the separate nasal passages. Rhinologists have a dilemma when assessing nasal function as the nose consists of two separate dynamic airways. However, it is not very informative to quote the mean of unilateral resistance when measured over several hours because this mean value will have a large standard deviation due to the instability of unilateral resistance. The range of unilateral nasal airway resistance in a group of healthy volunteers when recorded over a 6–8 hour period has been shown to vary from 0.36 to 1.36 Pa cm³ s¹⁷ and 0.28–0.63 Pa cm³ s.¹⁸ This indicates that there is often almost a fourfold change in unilateral resistance associated with the spontaneous congestion and decongestion of the nasal venous sinuses.

One way to overcome the dilemma of spontaneous changes in unilateral nasal resistance is to decongest the nose prior to assessment. This solution is of use to the surgeon whose main interest may be in assessing the extent of any nasal anatomical problem,¹⁶ however one study reports that nasal patency after decongestion is not always reproducible over several months in healthy subjects¹⁹ but it is reported to be stable over shorter periods of 12 hours.⁴ However, decongestion of the nose is of no use in studying nasal physiology and pathophysiology as it is the spontaneous changes in unilateral resistance that are of interest to the physiologist and clinician. One solution is to quantify the extremes of unilateral resistance or the amplitude of the unilateral changes in resistance that occur over a period of several hours. This approach has been used to determine the unilateral changes in resistance and to assess the efficacy of nasal surgery.⁷ The disadvantage of unilateral nasal measurements is that in order to assess the amplitude of changes in unilateral nasal resistance it is necessary to make measurements

over several hours. The advantage of unilateral measurements are that they give a comprehensive assessment of the dynamic nose rather than the crude snap shot that is provided by a single measure of total resistance.

ACOUSTIC RHINOMETRY

Acoustic rhinometry has been developed from methods previously used to measure lower respiratory tract resistance. The method consists of generating an acoustic pulse from a spark source or speaker and the sound pulse is transmitted along a tube into the nose. The sound pulse is reflected back from inside the nose according to changes in the local acoustic impedance which are related to the cross sectional area of the nasal cavity. The reflected sound is detected by a microphone, which transmits the sound signal to an amplifier and computer system for processing into an area distance graph.

The cross sectional area measurements obtained with acoustic rhinometry correlate very well with area measurements made by computed tomography scans, and nasal airway resistance measured by rhinomanometry, but the accuracy of acoustic rhinometry is unreliable in the posterior part of the nose, especially when the nasal passage is congested.²⁰

Acoustic rhinometry is also subject to artefacts caused by noise and breathing.²¹ The volume of the nasal cavity (e.g. between 2 and 5 cm depth into the nose) can be calculated from the cross sectional areas across a measured distance into the nose, and nasal volumes are often used to study the effects of medical and surgical treatments.

A major advantage of the technique of acoustic rhinometry is that it provides a measure of nasal cross sectional area and volume along the length of the nasal passage, unlike rhinomanometry that is limited to measuring the effects of the narrowest point of the nasal airway on nasal airflow. Technical specifications for standard operating procedures for acoustic rhinometry have been standardized as regards the accuracy and repeatability of measurements and the acquisition of data.²²

Normal values for acoustic rhinometry

Normal values for acoustic rhinometry have the same limitations described above for rhinomanometry, due to the spontaneous changes in nasal patency associated with the nasal cycle. The normal adult value for minimum cross sectional area for a nasal passage is quoted as 0.7 cm² with a range of 0.3–1.2 cm² and this increases on decongestion to 0.9 cm² with a range of 0.5–1.3 cm².²³

The volume of the nasal cavity, between 2 and 5 cm depth into the nasal passage, has been reported to be 3.71 cm³ (3.58–3.84) in school children aged 9–11 years and 5.44 cm³ (5.21–5.67) in adults, after decongestion.²⁴

The diagnostic value of acoustic rhinometry has been investigated by Lenders and Pirsig (1990), who could distinguish various deviations of nasal structure, such as valve stenosis, septal deviation, turbinate hypertrophy and tumour masses.²⁵

The accuracy of acoustic rhinometry like rhinomanometry is dependent on the interface between the equipment and the nose. For example, the cross sectional area of the nasal vestibule is susceptible to distortion if a tube is inserted into the nose. Mispositioning of the nasal tube and air leaks are just as likely to give spurious measurements with acoustic rhinometry as face mask leaks with rhinomanometry, but with care the technique of acoustic rhinometry provides reproducible data.

PEAK NASAL FLOW

The peak inspiratory or expiratory airflow through the nose associated with maximal respiratory effort can be used as a measure of nasal conductance. The measurement is effort dependent and is less sensitive than rhinomanometry or acoustic rhinometry in determining small changes in conductance.²⁶ Expiratory measurements are likely to cause expulsion of nasal secretions into the measuring instrument, and inspiratory flow measurements are likely to cause nasal alar collapse and flow limitation. Simple peak flow instruments such as the Wright, mini-Wright, and Youlten flow meters are often used to measure peak nasal inspiratory flow (PNIF) with the use of a face mask. However, the use of more sensitive spirometers can improve the accuracy and reproducibility of nasal measurements,²⁷ and reliable measurements can be made with standard pulmonary spirometry equipment.²⁸ Measurement of PNIF may be useful for the assessment of large changes in nasal conductance such as those associated with nasal challenge and nasal decongestion,²⁹ and for this type of work the measurement of PNIF compares well with rhinomanometry for the assessment of nasal patency.

Normal values for peak nasal inspiratory flow

Normal values for PNIF have been reported in both adults³⁰ and children aged 6–11.³¹ Normal values for PNIF in a healthy adult Caucasian population have been described as related to age, sex and height with PNIF declining with age and being greater in males than females.³⁰ Mean PNIF in adult males was 143 L/min, and 122 L/min in females.³⁰

SUBJECTIVE MEASUREMENTS

Nasal sensations are important in the study of nasal disease, as it is the patient's perception of nasal sensations (symptoms) that is of primary concern to the patient. However, the clinician in the assessment and treatment of nasal disease is mainly concerned with restoring normal nasal function to the nasal airway by reducing nasal obstruction by medical or surgical means. The clinician has various objective measures of nasal function such as rhinomanometry and acoustic rhinometry but the problem is that these objective measures of nasal function do not always correlate with the patient's own assessment of nasal sensations such as the sensation of nasal airflow.³²

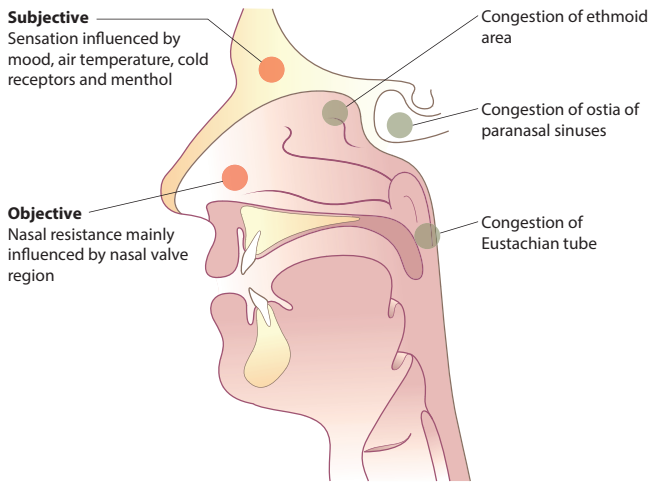

Figure 90.2 Factors that influence the patient's perception of nasal airflow and relationship to objective and subjective measures of nasal obstruction. *Objective measurements* are mainly determined by the cross sectional area of the nasal valve region at the tip of the inferior turbinate. *Subjective measurements* are influenced by the stimulation of cold receptors in the airway and the patient's perception of obstruction may be influenced by menthol and mood. Congestion in the ethmoid area, ostia of paranasal sinuses and Eustachian tube cause a perception of congestion and pressure that is unrelated to any change in nasal airway resistance as these areas are distant from the nasal valve.

The reason for the lack of correlation between the perception of nasal airflow and nasal resistance as measured by rhinomanometry may be because the resistance to nasal airflow is primarily determined by the nasal valve area, whereas the symptoms of nasal obstruction may be influenced by other areas of the nose as well as the nasal valve area, as illustrated in **Figure 90.2**.

Congestion in the ethmoid region may cause contact of ethmoid surfaces and a sensation of pressure and obstruction that would have little or no effect on nasal airway resistance. Similarly, pressure changes in the middle ear and paranasal sinuses may cause a sensation of nasal obstruction and pressure without any effect on nasal airway resistance. Another factor that may explain the lack of correlation between objective and subjective measures of nasal obstruction is that the nasal airway consists of two parallel airways and the total nasal conductance may be near normal even if one nasal passage is completely obstructed. Subjects with nasal obstruction associated with acute upper respiratory tract infection have a total nasal airway resistance that is close to normal yet they still complain of nasal obstruction because one nasal passage may be severely congested whilst the other is patent.¹⁷ Objective and subjective unilateral measures of nasal obstruction have been shown to have a much better correlation than combined bilateral measures for the two nasal passages indicating that the nose should be assessed as two separate organs rather than a single combined airway.³³

Studies on the effects of menthol on nasal sensation of airflow clearly demonstrate the lack of any correlation between objective measures of nasal airway resistance and subjective measures of airflow.³⁴ In patients with

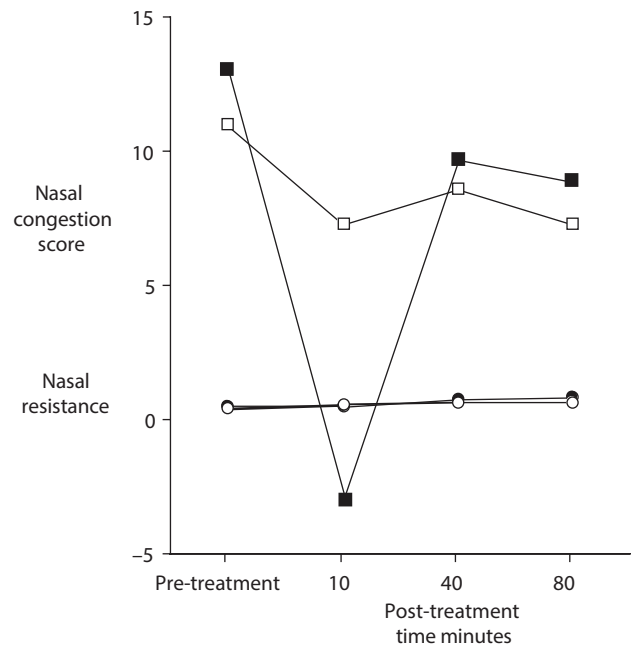

Figure 90.3 The effects of ingestion of an 11 mg l-menthol lozenge on subjective sensation of nasal congestion and nasal resistance to airflow in human volunteers with common cold. The subjective sensation of nasal congestion, measured on a 100mm visual analogue scale, was significantly reduced 10 min. after ingestion of the lozenge but nasal airway resistance as measured by rhinomanometry was unaffected. Shaded symbols represent the values for the menthol treated group and the open symbols represent the mean values for the placebo treated group.³⁴

nasal obstruction associated with common cold, ingestion of a menthol lozenge causes a great improvement in the sensation of nasal airflow without any change in nasal airway resistance, as shown in **Figure 90.3**. This is because the menthol vapour causes an increase in the sensitivity of cold receptors that detect nasal airflow, and a perception of nasal decongestion, without any objective change in nasal resistance.

Subjective scores of nasal symptoms provide the main outcome criteria for clinical trials on new treatments for rhinitis yet our knowledge of the factors influencing the perception of symptoms is still very superficial.

MEASUREMENT OF THE NASAL AIRWAY BY THE RHINOLOGIST

The rhinologist may be interested in measuring the patency of the nasal airway for two reasons: first to assess the severity of any nasal obstruction and select patients for medical and/or surgical treatment and second to assess the efficacy of any treatment in increasing nasal airflow. There is a large literature on the assessment of medical and surgical treatments aimed at improving nasal airflow and only two examples will be given here to demonstrate the usefulness of rhinomanometry in assessing patient response to surgical or medical treatments of nasal obstruction.

The efficacy of nasal surgery as a treatment for chronic nasal obstruction was demonstrated by measuring changes

Figure 90.4 The effect of Coblation inferior turbinate surgery on total nasal conductance of airflow pre-operatively, at 3 months and 32 months follow-up. The Y axis is nasal airflow patency cm^3/sec as measured by posterior rhinomanometry. The line represents normal level of airflow in health. P values relate to comparison with preoperative airflow.³⁵

Figure 90.5 Effects of xylometazoline and placebo nasal sprays on nasal conductance in subjects with nasal congestion associated with common cold. The figure demonstrates the reproducibility of the mean nasal conductance measurements over a 12 hour period in the placebo treatment group ($n = 29$). The sensitivity of rhinomanometry is demonstrated by the significant increase in mean nasal conductance over 10 hours after treatment with xylometazoline ($n = 32$).⁹

in nasal airflow by posterior rhinomanometry before and after Coblation inferior turbinate reduction surgery at 3 and 32 months post-operatively as illustrated in **Figure 90.4**. The mean baseline nasal conductance was $248.6 \text{ cm}^3/\text{s}$ (range 2.5–614.8), which improved significantly ($p = 0.033$) to $342.1 \text{ cm}^3/\text{s}$ (range 166.7–500) at 32 months post-operatively.³⁵

The efficacy of medical treatment of acute nasal obstruction associated with common cold was demonstrated by measuring changes in nasal airflow before and after treatment with a topical nasal decongestant, xylometazoline as illustrated in **Figure 90.5**. The decongestant effect of xylometazoline was significantly greater than placebo, as shown by the nasal conductance at 1 hour (384.23 versus $226.42 \text{ cm}^3/\text{s}$; $p < 0.0001$).⁹

BEST CLINICAL PRACTICE

- ✓ Nasal surgery for the treatment of nasal obstruction should be guided by objective measurement of nasal airway patency pre- and post-operatively

FUTURE RESEARCH

- The major deficiency in our knowledge concerning measurement of the nasal airway is that there is no generally accepted standard measurement to assess the degree of obstruction of the nasal airway.
- Rhinomanometry is generally accepted as the 'gold standard' for the assessment of nasal obstruction but this technique is only available in research centres and is not generally used in the clinic. Even when rhinomanometry is used, there is a choice between various techniques such as anterior and posterior, and various sample pressures (75 Pa for posterior, and 150 Pa for anterior) that make it difficult to compare results from different laboratories.
- Standardization of rhinomanometry was attempted in 1984⁵ but little progress has been made since then. The new recommendations for standardization of rhinomanometry and acoustic rhinometry add little more than mathematical modelling to the older standardization recommendations.⁶
- The introduction of acoustic rhinometry was initially proclaimed as a method that would replace rhinomanometry but this has not taken place as the technique is not quicker or more reproducible than rhinomanometry.
- A major problem in measuring the nasal airway is the lack of any generally accepted reference tables for nasal patency related to age, height, sex and race etc. and future research is needed to provide some reference values for the rhinologist for each of the methods described above.²
- Measurements of the nasal airway will be restricted to research laboratories unless a cheap and portable instrument is developed for use in the clinical setting and some progress has been made in establishing the use of the much cheaper and easily used peak flow meter to measure nasal obstruction in adults and children.³⁰⁻³¹

KEY POINTS

- Objective and subjective measurements of nasal conductance do not correlate well for bilateral measures but do correlate for unilateral measures
- The spontaneous changes in unilateral nasal resistance associated with the nasal cycle cause great variability in physiological nasal airflow
- Subjective measurements are important as they relate directly to symptoms
- Decongestion of the nose eliminates the effects of the nasal cycle and allows the measurement of anatomical nasal airflow
- Acoustic rhinometry provides anatomical rather than functional measurements of the nasal airway
- Rhinomanometry is generally accepted as the 'gold standard' for measurement of nasal airway resistance
- Acoustic rhinometry and rhinomanometry in their current forms have not found a routine place in the day to day assessment of patients in the rhinology clinic.

SEARCH STRATEGY

Data and recommendations in this chapter are taken from the ARIA 2008 update and 2010 revision, and may be updated by a Medline search using the keywords: allergic rhinitis, allergic rhinosinusitis and allergic rhinoconjunctivitis linked with aetiology, presentation, epidemiology, prevalence, allergen avoidance, treatment, immunotherapy, children, pregnancy and surgery.

INTRODUCTION

Allergic rhinitis is characterized by inflammatory changes in the nasal mucosa caused by exposure to inhaled allergens. It is a common disease, affecting between 0.8 and 39.7% of the world population¹ (depending on location) with prevalence in Western Europe of 23%. It causes significant disability and is often poorly managed. There may be co-morbidities with other organs being involved, commonly the eyes causing allergic conjunctivitis and the lungs with allergic asthma. Indeed, these diseases are increasingly considered to be a single entity, with a spectrum of respiratory allergic response, termed the unified allergic airway. They have a common epidemiology, pathophysiology, and in many cases, treatment approach.

Allergic rhinitis and allergic rhinoconjunctivitis are caused by an inflammatory response to an allergen to which the patient has already been exposed. In this abnormal response the individual has produced allergen specific immunoglobulin E (IgE) which binds to mast cell surface receptors. Subsequent allergen exposure causes this receptor/IgE complex to trigger mast cell degranulation with the release of preformed mediators. This inflammatory mediator release includes not only histamine, but also other granule contents (serine proteases, heparin), and newly synthesized eicosanoid mediators (leukotriene C4, prostaglandin D2, thromboxane and PAF).

For further details please see [Chapter 14](#), 'Allergy: basic mechanisms and tests'.

These inflammatory mediators cause the classic symptoms of allergic rhinitis: nerve irritation causing sneezing and itching, loss of mucosal integrity causing rhinorrhoea and vascular engorgement causing block. Histamine drives the majority of acute nasal symptoms such as sneezing and itching with leukotrienes and prostaglandins being involved in longer term symptoms such as block.

DEFINITION

Rhinitis is defined clinically as having two or more symptoms of anterior or posterior rhinorrhoea, sneezing, nasal blockage and/or itching of the nose during two or more consecutive days for more than one hour on most days.²

Allergic rhinitis is diagnosed when these symptoms are caused by allergen exposure leading to an IgE mediated reaction. Allergic rhinitis is subdivided into intermittent (IAR) or persistent (PER) disease and the severity into mild or moderate/severe ([Figure 91.1](#)).

These definitions are not interchangeable with the terms seasonal and perennial and were introduced to relate the patient's symptoms, rather than an allergen, to a diagnosis.⁴ In one large study of people with allergic

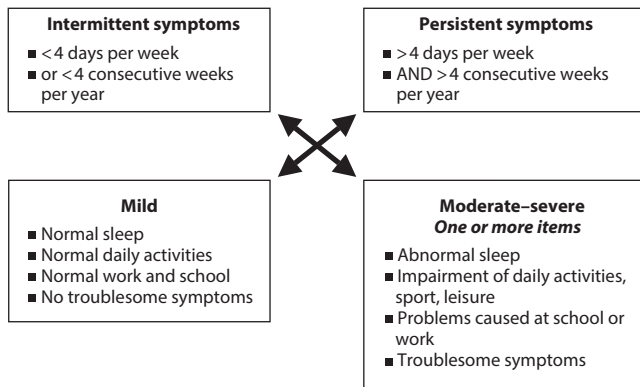

Figure 91.1 Classification of allergic rhinitis. Reproduced with permission.³

rhinitis, 10% were classified as having mild intermittent rhinitis, 14% mild persistent rhinitis, 17% moderate/severe intermittent rhinitis and 59% moderate/severe persistent rhinitis; therefore approximately 75% of patients will be diagnosed as having a persistent rhinitis and 25% intermittent.⁵ Whether the disease is classified as mild or moderate/severe depends on the effect on the patient's social life^{6,7} work/school^{8–10} and sleep.¹¹ Sleep disturbance is common in patients with moderate/severe allergic rhinitis¹² and may lead to daytime sleepiness.¹³ This is also linked to problems with learning at school¹⁴ and examination success in children¹⁵ and time off work and loss of productivity in adults.¹⁶

Patients with non-allergic rhinitis may have similar symptoms¹⁷ which are discussed in other chapters – infectious rhinitis, occupational rhinitis, drug-induced

rhinitis, hormonal rhinitis, irritant rhinitis, tobacco mucositis, persistent non-allergic rhinitis with eosinophilia (NARES) and idiopathic (vasomotor) rhinitis. The diagnosis of an allergic rhinitis is made by correlating the allergic symptoms and history with diagnostic tests demonstrating allergen-specific IgE, whether by skin prick testing or by measuring specific IgE levels in the blood (RAST).

PREVALENCE

The prevalence of allergic rhinitis varies widely around the world. The International Study on Asthma and Allergy in Childhood (ISAAC 1)¹ and its follow-up (ISAAC 3)¹⁸ showed the prevalence of rhinoconjunctivitis to vary between 0.8% and 39.7% in different populations (Figure 91.2).

Countries with a low prevalence of asthma (<5%) such as Indonesia, Romania and Greece had a low prevalence of allergic rhinitis. Conversely, countries with a high prevalence of asthma (>30%) such as the United Kingdom, Australia and New Zealand had a high prevalence of rhinitis (15–20%).

There has been a steep increase in the prevalence of allergic rhinitis over the last 40 years,^{19, 20} though this may now be slowing.²¹ The reasons for this increase are uncertain. Children who live on farms and have contact with livestock are less likely to develop allergic rhinitis than their urban peers^{22, 23} suggesting a possible protective effect of microbial exposure. Larger family size, more frequent infections and unhygienic contact may all be protective – the hygiene hypothesis.²⁴ This suggests

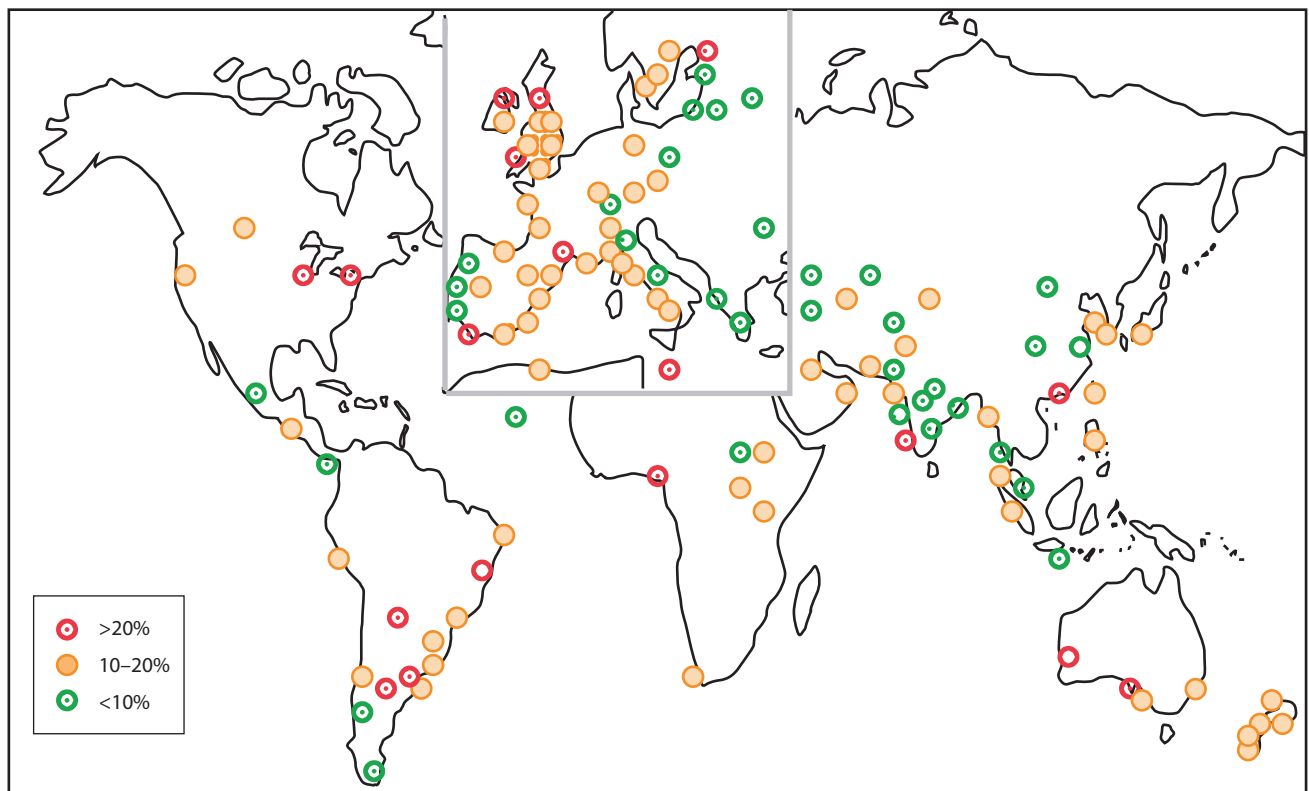

Figure 91.2 Prevalence of allergic rhinitis worldwide, 13–14 year olds. Reproduced with permission.¹

that reduced exposure to infective agents reduces the Th1 response and leads to an overdrive of the Th2 immune response leading to excessive production of IgE and consequent atopy. There are however some uncertainties about this concept.²⁵ Chronic parasitic disease (for example with worms) is also protective, possibly because of the production of blocking antibodies (IgG4).²⁶ Eradication of worm infestation increases skin reactivity to aeroallergens.²⁷

All these reasons suggest that an urbanized, Western lifestyle promotes the development of allergic disease. The link with helminth infection may also point the way to future treatment options.

NATURAL HISTORY

Genetic factors are certainly involved in the aetiology of allergic rhinitis. Having parents who are atopic may increase the risk of a child having an allergic disease by 3–6 times.²⁸ Exposure to an allergen is also required before sensitivity develops therefore environmental factors are also important. Pollen-induced allergic rhinitis is uncommon before the age of 2 years suggesting that exposure over two seasons is required for sensitization.²⁹ The ‘atopic march’³⁰ in children refers to the sequential development of allergic diseases, often starting in infants with atopic eczema then the development of allergic rhinitis and finally allergic asthma.³¹ Several studies have shown that adult-onset asthma is more likely to occur in patients with allergic rhinitis than in those without, usually increasing the risk by a factor of three,³² though whether allergic rhinitis is an earlier manifestation of allergic disease in patients who will go on to develop asthma or whether the nasal disease itself causes asthma is unclear. Remission of symptoms may occur over time. One study showed that although the overall prevalence of allergic rhinitis increased from 12.4% in 1992 to 15% in 2000 in keeping with the worldwide increase, 23.1% of patients who had allergic rhinitis in 1992 no longer had symptoms in 2000.³³ Symptoms of rhinitis generally become less severe with age and skin prick testing shows less reactivity in the elderly.³⁴

KEY POINTS

- Allergic rhinitis is an IgE mediated disease
- In Western societies it is common (>20%)
- It is often associated with other allergic diseases such as allergic conjunctivitis and asthma
- It may have significant negative effects on sleep, work and study
- Patients with allergic parents are more likely to be allergic
- Lack of helminth infection may be important in development of disease
- Allergic disease is often less severe in the elderly

PRESENTATION

Most patients will be referred from general practice with two or more symptoms of anterior or posterior rhinorrhoea,

sneezing, nasal blockage and/or itching of the nose. Young children may simply present with block. Other complaints such as itchy eyes, pharyngeal itch, hearing loss due to otitis media with effusion, atopic eczema, asthma, loss of smell, chronic cough, snoring, fatigue, sore throat and halitosis may occur.^{35, 36} Unilateral symptoms, mucopurulent rhinorrhoea, thick post-nasal discharge, epistaxis, pain and anosmia are not usually associated with allergic rhinitis and should prompt further investigation.

The history is crucial. When symptoms started, how long they last and when they occur will allow determination of likely long-term atopy, whether the problem is persistent or intermittent and the possible allergens. Ask direct questions regarding symptoms suggestive of asthma such as wheeze or cough. A family history of atopy is important as it makes the diagnosis of allergy more likely.

Symptoms of rhinitis, conjunctivitis, cough and wheeze during the summer months suggest grass pollen sensitivity; waking with a blocked nose might be linked to house dust mites in the bed. The main presenting symptoms and their severity should be determined. Does the nasal block cause problems with sleep or work?

Ask about the character of the nasal discharge. A coloured discharge suggests infection whereas the discharge is usually clear in allergy. Does the block switch from side to side? This is common in patients with mucosal inflammation and less likely with anatomical abnormalities alone such as septal deviation.

More direct questions should be asked regarding endocrine problems that may cause rhinitis (hypothyroidism) and medication (the combined oral contraceptive pill may cause congestion). Specific questions may be helpful in patients with seasonal symptoms. Tree pollen allergy (birch particularly) may be associated with oral allergy syndrome which causes swelling or tingling of the lips when eating uncooked fruits and vegetables such as potatoes, carrots, cherries, celery, apples, pears, plums, peaches, parsnip, kiwi, hazelnuts and apricots and is found in approximately half the patients with birch pollen sensitivity.³⁷ It may also be reported with other pollen sensitivities.

EXAMINATION

A general examination of the patient may reveal other signs of atopic disease such as eczema or allergic conjunctivitis and sometimes an allergic crease may be seen on the patient’s nose.

Examination of the nose should always be performed, if only to exclude causes other than allergy. Anterior rhinoscopy will allow an assessment to be made of the colour and state of the nasal mucosa and to see whether it is swollen and causing obstruction. It may be oedematous, blue or pale in colour and covered in thin mucus, but this is not always the case. In children a blocked nose with normal nasal mucosa may suggest adenoid enlargement. Endoscopic examination will allow polyps and other nasal disease to be excluded. In severe or atypical presentations (especially in the presence of cartilage or mucosal loss,

cosmetic changes, systemic illness or refractory bleeding) exclusion of other inflammatory or neoplastic diseases is important.

A history suggesting asthma such as wheeze or night-time cough may necessitate examination of the chest or referral to a respiratory physician.

DIAGNOSIS

For many patients, a clear history that fits with allergic rhinitis and a corresponding nasal examination will allow a diagnosis to be made confidently, though in specialist practice skin prick tests will normally be carried out as part of the standard workup. If there is diagnostic uncertainty, or if the consequences of a possible allergy are important (such as a pet allergy), then allergy testing should be performed. This will normally be either a skin prick test (SPT)³⁸ or measurement of specific IgE in the blood (often referred to as radioallergosorbent testing or RAST³⁹ (see [Chapter 14](#)).

Skin prick testing is usually the preferred option as it allows the patient to see the results directly and gives time for patient education about avoidance measures if required.

The method of skin prick testing involves the use of a small lancet to introduce an allergen into the skin. If the patient is sensitized to the allergen then IgE sensitized mast cells will degranulate and cause a wheal and flare reaction in the skin. Negative (saline) and positive (histamine) controls are also used to rule out dermatographism and non-reactivity respectively. If the negative control shows a reaction or the positive control shows no reaction then blood IgE levels should be measured. If an oral antihistamine has been taken in the preceding 7–10 days then the positive control may not react. A positive reaction is noted by a wheal size 2 mm or greater than the negative control. In the United Kingdom the main four allergens that should be tested for are grass pollen, house dust mite, cat and dog but the prevalence of sensitivities varies around the world with cockroach sensitivity common in tropical countries. Patients with particular exposure can have various other allergens tested depending on their history (for example exposure to horses or moulds). It should be noted that a positive skin test shows atopy but it does not necessarily mean that the patient has a clinically relevant reaction to that allergen. The reaction has to be correlated with the patient's symptoms. Approximately 25% of adults have a positive reaction on skin prick testing but only 10–15% are symptomatic (though some patients with positive tests will go on to develop allergic disease in the future).⁴⁰

RAST testing is usually reserved for patients who require a diagnosis but where SPTs are unavailable or inappropriate. A blood sample is taken and radio- or enzyme-labelled anti-IgE is added to the serum. A positive result is shown by an IgE level of 0.35 kU/l or greater. As for SPTs, a positive result may not necessarily be clinically relevant.

Nasal allergen challenge is the gold standard of allergy diagnosis but it is infrequently required or available. It may be useful where the history is suggestive of

a particular allergen being responsible for symptoms but the skin prick tests are negative. An allergen is applied to the nasal mucosa, or the patient exposed to an airborne allergen, and subjective measurements made (symptom scores) as well as objective measurements (sneeze count, peak nasal inspiratory flow, rhinomanometry, pulmonary peak flow, etc.).⁴¹ This method of testing can also be used in patients suspected of having salicylate intolerance using lysine aspirin applied to the nose and is a possible substitute for an oral salicylate challenge. Nasal challenge testing is complex and has the risk of inducing anaphylaxis and is therefore used only in specialist centres.

Various other methods of determining sensitivity are also described including the measurement of inflammatory mediators such as histamine, PGD₂, leukotrienes, kinins and tryptase in blood or nasal secretions, nasal cytology and histology and measurement of nitric oxide in exhaled air.⁴² None of these methods are generally used in clinical practice.

Symptoms of asthma may indicate the need for respiratory assessment with pulmonary function tests and reversibility with a bronchodilator.

KEY POINTS

- The history and symptoms are crucial in diagnosis.
- The timing of symptoms will often lead to diagnosing the allergy.
- Nasal examination is mainly to exclude other causes.
- In severe or atypical presentations (especially in the presence of cartilage or mucosal loss, cosmetic changes, systemic illness or refractory bleeding) exclusion of other inflammatory or neoplastic diseases is important.
- Ask about asthma symptoms (wheeze and cough).
- Skin prick testing is useful particularly in persistent allergic rhinitis where the cause may not be clear.

TREATMENT

- The prevention of allergic rhinitis
- Methods of reducing allergen exposure
- Pharmacological treatment of allergic rhinitis (see also [Chapter 28](#))
- Immunotherapy for allergic rhinitis
- Surgical treatment
- Complementary therapies

The prevention of allergic rhinitis

Various areas have been examined to determine if sensitization can be reduced in infancy – no definite triggers have been found but recommendations have been made on the available evidence. It has been advised that children should breastfeed for at least the first three months after birth,⁴³ that there is no benefit in having a reduced antigen diet for the mother in pregnancy and during lactation⁴⁴ and that parents should not smoke in pregnancy or near children, although no definite link with allergy has been found.⁴⁵ There was also limited evidence of benefit in reducing exposure to house dust mite but no benefit in not exposing children to furry pets.⁴⁶

REDUCING ALLERGEN EXPOSURE

As the clinical effects of allergic rhinitis are caused by allergens it would seem logical that reduced exposure would benefit symptoms. The major allergens to be found indoors are house dust mite, cat, dog and other furry animals, cockroach and moulds. Outdoors the main allergens are airborne pollens which vary during the year and depend on local conditions. In Europe tree pollen is found during the spring, grass and weed pollens during the summer and various mould spores during the summer and autumn. In North America ragweed sensitivity is a common problem but this is not found in Europe. Tropical areas will have less seasonal variation.

METHODS TO ACHIEVE ALLERGEN REDUCTION

House dust mite allergen reduction aims to reduce the amount of mite allergens in the home:

- Wash bedding regularly (every 1–2 weeks) at 55–60°C to kill mites (washing with cold water removes 90% of mite allergens; washing at 55–60°C kills mites)
- Wash pillows and duvets in hot water (55–60°C) and encase pillows and mattresses with protective coverings that have a pore size of 6 µm or less
- Sufficient ventilation of dwellings to decrease humidity; aim to reduce indoor relative humidity to below 50% and avoid damp housing conditions.

Reproduced with permission of the WHO.⁴⁷

ADDITIONAL STRATEGIES

- Use a good quality vacuum cleaner (if possible, one fitted with a HEPA filter)
- Use a damp duster when dusting and cleaning surfaces
- Replace wall to wall carpets with linoleum or wooden floors which can be wiped clean
- Remove/reduce curtains and soft furnishings in the bedroom
- Replace fabric-covered seating with leather or vinyl
- Remove soft toys from the bedroom; wash them at 55–60°C or freeze them (in a kitchen deep-freezer) to kill house dust mites
- Exposure of mattresses, rugs and carpets to direct strong sunlight (for more than 3 hours) kills mites and can be used in appropriate regions.

Pollen avoidance provides mechanical barriers to pollen contact.

- Keep windows closed at peak pollen times
- Wear glasses or sunglasses to help prevent pollens entering the eyes
- Consider wearing a mask over nose and mouth to prevent inhalation of pollens at peak time
- Use air-conditioning where possible
- Install car pollen filters where possible

Pet allergen avoidance reduces the amount of pet allergen indoors.

- If possible, find another home for the pet and do not introduce new animals into the home. If the pet is not removed from the home then:
 - Exclude pets from bedrooms and if possible keep pets outdoors
 - Vacuum carpets, mattresses and upholstery regularly
 - Change clothes before going to school or work if you have had contact with any animal (e.g. horse/cat/dog).

Cockroach allergen avoidance involves removing the cockroaches, eliminating the places and conditions in which they can live and removing all allergens.

- Eradicate cockroaches with appropriate insecticidal bait
- Seal cracks in floors and ceilings
- Enclose all food
- Do not store waste in the home
- Scrub floors with water and detergent to remove allergens.

Mould allergen avoidance aims to prevent mould from growing and mould spores from becoming airborne during mould removal.

- Use dehumidifiers in the home if relative humidity is consistently high (above 50%)
- Ensure heating, ventilation or air-conditioning systems are properly maintained
- Use 5% ammonia solution to remove mould from bathrooms and other contaminated surfaces
- Replace carpets with hard flooring and replace wallpaper with paint
- Repair indoor water damage immediately.

Unfortunately despite these measures it is very difficult to achieve significant allergen reduction or elimination and clinical benefit from these strategies has been limited. For example a study looking at the results of using impermeable covers on mattresses and pillows demonstrated a reduction in dust mite allergen to 30% of the initial level, but found no evidence of clinical benefit.⁴⁸

Table 91.1⁴⁹ summarizes the evidence of efficacy for some of these measures. Although the evidence base for recommending allergen reduction is poor it may nevertheless benefit some patients and a trial of avoidance may be useful.

Food allergy

It is very unusual for food allergy to cause isolated nasal symptoms, although the nose may be involved in more generalized systemic reactions. Foods such as peanuts, nuts, shellfish, fish and fruits such as strawberry may be involved. Milk and egg allergy is more common in younger children but usually resolves by 4–6 years old.

TABLE 91.1 Effect on allergen levels and evidence of clinical benefit

Measure	Evidence of effect on allergen levels	Evidence of clinical benefit
House dust mites		
Encase bedding in impermeable covers	Some	None (adults): evidence A Some (children): evidence B
Wash bedding on a hot cycle (55–60 °C)	Some	None: evidence A
Replace carpets with hard flooring	Some	None: evidence A
Acaricides and/or tannic acid	Weak	None: evidence A
Minimize objects that accumulate dust	None	None: evidence B
Vacuum cleaners with integral HEPA filter and double-thickness bags	Weak	None: evidence B
Remove, hot wash or freeze soft toys	None	None: evidence B
Pets		
Remove cat/dog from the home	Weak	None: evidence B
Keep pet from main living areas/bedrooms	Weak	None: evidence B
HEPA-filter air cleaners	Some	None: evidence B
Wash pet	Weak	None: evidence B
Replace carpets with hard flooring	None	None: evidence B
Vacuum cleaners with integral HEPA filter and double-thickness bags	None	None: evidence B

Reproduced with permission.⁴⁹

Skin prick testing or IgE levels can confirm a true allergy but may give false positive results, therefore should be targeted at specific allergens rather than having a screening role. Avoidance of allergenic foods may be difficult (particularly in the case of peanut allergen which may be found in many processed foods) and suitable substitutes must be found to avoid dietary insufficiency and consequent malnutrition.

True food allergy should not be confused with oral allergy syndrome where there is cross-reactivity with a pollen allergen and which is relatively common.

Pharmacological treatment of allergic rhinitis

The basic summary of recommendations for treatment according to the ARIA guidelines⁵⁰ are shown in [Figure 91.3](#).

The effects of the various medications used are summarized in [Table 91.2](#).

The most widely used and effective medications to treat allergic rhinitis are oral or topical antihistamines and topical nasal steroids.

It should be stressed that these medications aim to achieve improved symptom control and are not a cure for allergy. They generally need to be taken for as long as there is allergen exposure causing symptoms. Symptom control is better for patients with intermittent allergic rhinitis if they start treatment prior to exposure to the allergen to which they are sensitized. For example, patients with grass pollen allergy should be advised to start treatment a month before the pollen season starts to try to avoid the

development of symptoms and nasal inflammation and to stop treatment at the end of the season.

In keeping with the idea of the unified allergic airway, treatment for asthma may also be required, whether this be long-term or to manage wheeze only during the peak pollen season (peak seasonal wheeze). Treatment of the nose with topical steroids reduces asthma symptoms⁵¹ and treatment of the lungs may reduce nasal symptoms⁵² therefore symptom control will be better if both nose and lungs are assessed and treated together in symptomatic patients.

ANTIHISTAMINES

The symptoms of running, sneezing and nasal and eye itching are histamine driven and antihistamines are the first-line treatment for these symptoms in patients who have no problem with nasal obstruction. They have little effect on nasal blockage.⁵³ The older first-generation antihistamines (chlorphenamine, diphenhydramine) are rarely used now due to their sedative effects, though ketotifen may still have a role with some additional effect as a mast cell stabilizer. Second generation oral antihistamines such as loratadine and cetirizine are non-sedating, safe for long-term use and can be used for children. They have a rapid onset of action (usually less than an hour) and will give symptom reduction on a once daily dosing. Antihistamines give better symptomatic control when used regularly rather than on an as required basis.⁵⁴ Topical antihistamines (for example azelastine) may be used intranasally to achieve rapid symptom control and can be combined with a topical nasal steroid. It has the disadvantages of having a bitter taste that some patients

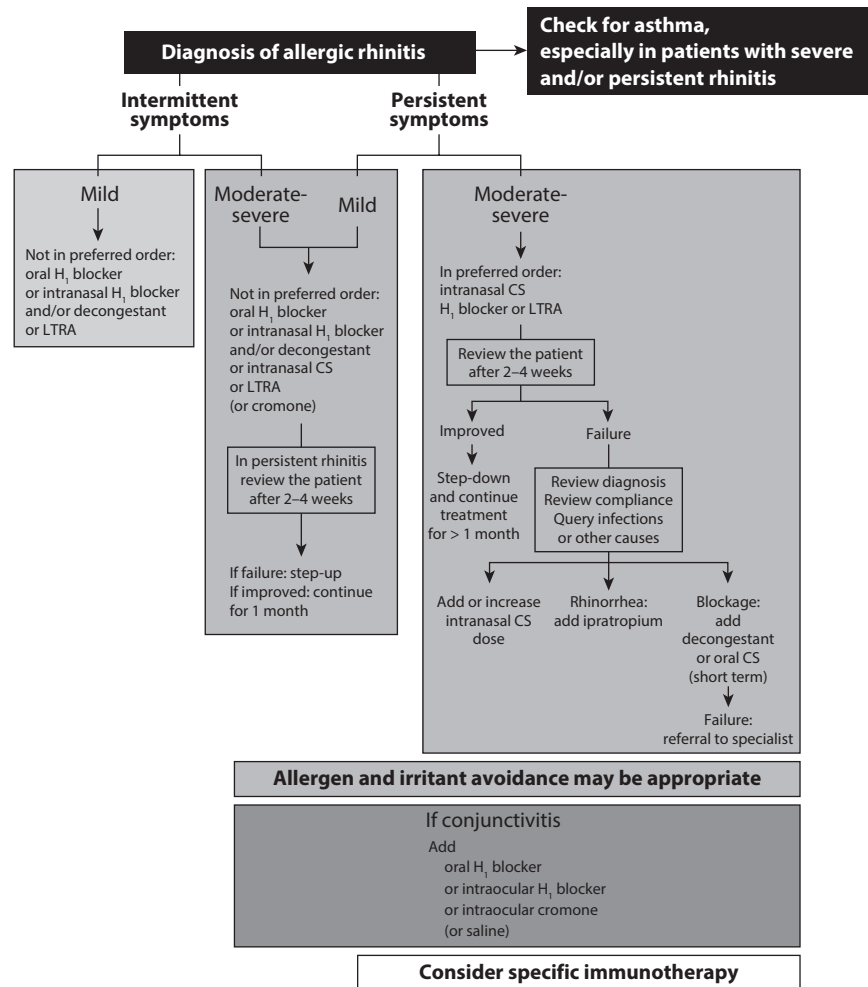

Figure 91.3 Allergic rhinitis management (algorithm of the ARIA update recommendations 2008). Reproduced with permission.⁵⁰

TABLE 91.2 Pharmacological treatments and their effects in allergic rhinitis

	Itch/sneezing	Discharge	Blockage	Impaired smell
Sodium cromoglicate	+	+	+/-	-
Oral antihistamines	+++	++	+/-	-
Ipratropium bromide	-	+++	-	-

Topical corticosteroids	+++	+++	++	+
Oral corticosteroids	+++	+++	+++	++
Antileukotrienes	-	++	+	+/-

dislike and needs twice daily dosing. Azelastine eyedrops may also be useful in reducing ocular symptoms.

Antihistamines alone may control symptoms adequately in some patients though many will require the addition of a topical nasal steroid.

INTRANASAL GLUCOCORTICOSTEROIDS

Glucocorticosteroids are the most effective treatment for allergic rhinoconjunctivitis.⁵⁵ Topical use in the form of a spray or drops is preferred to oral use to reduce side effects, although occasionally oral steroids may be useful.

Intra-nasal application allows a high concentration of the active drug to be delivered to the nasal mucosa with minimal systemic absorption. The drugs reduce all symptoms of allergic rhinitis and ocular symptoms and are the first-line treatment of choice in patients who complain of nasal block.⁵⁶ As steroids have an effect on the production of pro-inflammatory mediators within the cell nucleus their effect is slow to occur and long lasting. Most steroids will not have an appreciable effect on symptoms for several hours or days and it can take two weeks for full benefit to be noticed. Patients should be warned of this as some will give up on treatment if it does not work rapidly.

Side effects of intra-nasal steroids are few but include epistaxis. This may be caused by incorrect use of the spray delivery system causing trauma as there is no evidence of nasal mucosal atrophy even with long-term use.⁵⁷ The systemic bioavailability of these drugs is low. Minor growth retardation has been noted in children treated with intra-nasal beclometasone⁵⁸ but this has not been shown with fluticasone⁵⁹ or mometasone.⁶⁰ These drugs are generally relatively cheap and in many countries can be bought without prescription.

SYSTEMIC GLUCOCORTICOSTEROIDS

Oral steroids may occasionally be useful in patients with severe symptoms to allow reduction of mucosal swelling and subsequent use of topical medication or to cover a short period when symptom control is particularly bad. Prednisolone 20–40 mg/day is normally sufficient⁶¹ but oral steroids may cause serious side effects so their use should be considered carefully and length of treatment be kept as short as possible. For this reason depot injectable steroids, while effective at symptom control, are not recommended as once injected their effects cannot be stopped.⁶²

LEUKOTRIENE RECEPTOR ANTAGONISTS (LTRAS)

Cysteinyl leukotrienes are a family of eicosanoid inflammatory mediators (LTC₄, LTD₄ and LTE₄) produced in leukocytes, mast cells, eosinophils, basophils and macrophages by the oxidation of arachidonic acid by the enzyme arachidonate 5-lipoxygenase. Their effects are to cause bronchoconstriction, increase vascular permeability and attract inflammatory cells and as such are involved in the processes underlying asthma and allergic rhinitis.⁶³ In the UK montelukast (a leukotriene receptor antagonist) is licensed for the treatment of allergic rhinitis associated with asthma. In studies it was found to be as effective as loratadine in reducing nasal symptoms but less effective than a topical nasal steroid.⁶⁴ Combined use of cetirizine and montelukast was shown not to improve symptom control above each drug individually in one study⁶⁵ but to be more effective when combined in another.⁶⁶ There is a significant variation in responsiveness to LTRAs and a closely monitored trial of treatment may be useful in some patients. It now has a place in the updated ARIA treatment guidelines (Figure 91.3).

SODIUM CROMOGLICATE

Sodium cromoglicate nasal spray has modest effects on rhinitis symptoms but must be used four times daily, which limits compliance.⁶⁷ It has no side effects and can be used on young children.⁴ Cromoglicate eye drops can be effective against ocular itching.⁶⁸

DECONGESTANTS

Topical (e.g. xylometazoline) and systemic decongestants (e.g. pseudoephedrine) are available and have a place in allergic rhinitis management. The topical decongestants

are more effective and have a more rapid onset of action. They reduce nasal obstruction and may allow access of a topical steroid into an otherwise obstructed nose. The disadvantage is of rebound vasodilation when their use is stopped leading to a worsening of symptoms and of rhinitis medicamentosa with longer term use. A maximum length of treatment of 7–10 days therefore is advised. Systemic decongestants may also have side effects such as insomnia, tachycardia and tremor.⁴

IPRATROPIUM

Topical ipratropium bromide spray is effective at controlling watery rhinorrhoea and can be a useful addition to a topical steroid if rhinorrhoea is not being well controlled.⁶⁹ Side effects are infrequent but include prostatic symptoms and worsening of glaucoma.⁴

NASAL DOUCHING

Saline nasal douches may help with symptom control⁷⁰ and can physically remove an allergen from the nasal mucosa. If pollen levels are high regular douching may be of benefit.

Immunotherapy

Immunotherapy (sometimes called desensitization) is a method of inducing tolerance to an allergen and therefore reducing unwanted symptoms. It can reduce the symptoms of allergic rhinitis, offer long-lasting reduction of symptoms (even when treatment has stopped) and can prevent the progression of allergic disease.⁷¹ It involves repeated exposure of the patient to the allergen usually, but not always, with a gradual increase in allergen dose. It can be given subcutaneously by injection (SCIT) or sublingually in drops or tablets (SLIT). Studies have shown similar efficacy for SCIT and SLIT.⁷² It is effective in reducing symptoms in adults and older children⁷¹ though the results are less clear for children under five.⁷³ There are several guidelines regarding the selection of patients and treatment protocols, one of which is published by the British Society for Allergy and Clinical Immunology.⁷⁴

Immunotherapy use in the UK is limited but it is widely used elsewhere. Patients considered are those who have severe symptoms but whose response to standard medical treatment has been unsatisfactory, or those patients who have unacceptable side effects from their medication.

This group may be larger than generally supposed with up to 40% of patients in UK general practice stating that symptom control of their rhinitis was poor.⁷⁵ The diagnosis of an IgE mediated response should be confirmed by skin prick tests or measurement of IgE levels before treatment and correlated with the patient's history to ensure the correct allergen is used. The main allergens used in Europe are for the main causes of allergic rhinitis – house dust mite, grass pollen, cat, dog and tree pollen. These extracts are all available in standardized doses. Treatment is usually continued over a 3-year period to achieve a long lasting tolerance after treatment has stopped.⁷⁶

Recent exposure of the nose to allergen may lead to asymptomatic eosinophil infiltration and a pro-inflammatory mucosal environment – a concept known as priming. Such changes are likely to be reflected in the bone marrow also, with an increased production of allergy-associated cellular and biochemical mediators which are effective systemically. This can cause a patient who has specific IgE to an allergen but no clinical allergy to be ‘primed’ and who will subsequently react clinically to an allergen to which they would not normally react.⁷⁷ For example a patient with IgE to dog and grass pollen may not normally have an allergic response to either but if exposed to dog will then show an allergic response to grass pollen later in the season. This explains why immunotherapy treatment for one allergen may have a beneficial effect for others.

EFFICACY

With good patient selection immunotherapy can be very effective. In a study of patients with grass pollen sensitivity treated with SCIT, over the peak pollen season mean symptom and medication scores were 32% and 41% lower respectively than those in a placebo group,⁷⁸ and these results or better have been replicated in many other studies.⁷⁹ Immunotherapy for older children with allergic rhinitis also reduces the risk of developing allergic asthma later in life⁸⁰ and of developing new allergies.⁸¹

PROCEDURE AND SIDE EFFECTS

With SCIT there is usually an uposing phase of between 2 and 4 months when the dose of allergen is gradually increased to the maintenance dose. This maintenance dose is then injected every 4–6 weeks for a 3-year period. SLIT may be uposed or, in some treatment protocols, the patient starts with the maximum dose and continues with this daily for 3 years. Giving the patient a product to which they are known to be sensitized carries the risk of side effects. These are usually transient redness and itching around an injection site, or oral itching, and can be reduced by pre-treatment with an oral antihistamine. Very occasionally patients may suffer a generalized reaction such as urticaria, bronchoconstriction or anaphylaxis and resuscitation facilities with adrenaline must be available.⁷¹ Almost all reactions will occur within 30 minutes of treatment therefore patients should be observed for an hour after injection. SLIT should be taken under medical supervision for the first dose but can then be taken by the patient at home if they do not react severely.

ANTI-IgE ANTIBODY (OMALIZUMAB)

Omalizumab is a monoclonal antibody that binds to circulating IgE preventing it from binding to mast cells and causing degranulation.⁸² Omalizumab reduces all nasal symptoms and improves asthma control⁸³ but has the risk of causing anaphylaxis and is expensive. It is administered by monthly injection. Currently it is recommended only for patients with severe allergic asthma with or without rhinitis symptoms.

Surgery

Surgery cannot cure allergy but can give relief of nasal blockage if other methods fail. Reduction of submucosal fibrotic tissue on the inferior turbinates that has developed due to long-standing inflammatory changes may improve the airway and allow access for topical nasal steroids.⁸⁴ If the nose remains congested even after the application of a decongestant in clinic then surgery should be considered as the mucosal swelling may be fixed. Polypoidal mucosa may also be found in some patients with severe allergic rhinitis and occasionally this needs to be removed.

Complementary treatments

Trials of homeopathy, acupuncture and herbal remedies have not shown any evidence of beneficial effect in allergic rhinitis⁸⁵ but many patients use them and are satisfied with the results.

KEY POINTS

- Although allergen avoidance seems logical there is minimal evidence of beneficial effect.
- Food allergies do not present with isolated allergic rhinitis.
- Antihistamines and topical nasal steroids are the main treatments for allergic rhinitis.
- Antihistamines work better if used regularly rather than on demand.
- Leukotriene receptor antagonists may be useful.
- Immunotherapy is highly effective but access to treatment is limited.
- Reduction surgery to the inferior turbinates may be of use occasionally.

CHILDREN WITH RHINITIS

Allergic rhinitis is the most prevalent allergic disease in children⁸⁶ and can have significant effects on the child's quality of life. It may exacerbate other allergic disease such as asthma.⁸⁷ Younger children may get frequent episodes of acute infective rhinitis in a year and it can be difficult to differentiate these from allergy. If the episodes last more than 2 weeks and are associated with other allergic symptoms such as itching then allergy should be considered. In children with nasal obstruction but healthy nasal mucosa and clear anterior nares then adenoidal hypertrophy may be present.⁸⁸

Skin prick testing may be performed on young children, though some will not tolerate it. It can be done on the skin of the back rather than the forearm if the child is afraid of the lancet.

The treatment algorithm is similar to that for adults but it may be more difficult to get a child to use a nasal spray. As many of these children also have asthma, however, they may be used to using an inhaler. Oral non-sedating antihistamines are the standard first-line treatment but a trial of a leukotriene receptor antagonist should also be considered if a nasal spray is not tolerated or if the steroid load is excessive. Fluticasone (from 4 years old)

and mometasone and triamcinolone (from 6 years old) have low systemic bioavailability and are the steroids of choice.⁸⁹ As with adults depot steroids are not recommended. Growth should be monitored if the child is already using steroids (such as an inhaled steroid for asthma or steroid creams for eczema) although there is no evidence of an effect on the hypothalamic-pituitary-adrenal axis with normal doses.⁹⁰ Beclometasone has been associated with growth retardation and is not recommended for children.⁵⁸ SCIT is generally not recommended for children under 5 years, though SLIT may be used increasingly in the future. Its efficacy in young children is, however, still uncertain.^{73, 91}

PREGNANCY

Rhinitis of pregnancy is relatively common and probably caused by high levels of oestrogen. It may occur in women without any past history of rhinitis, allergic or otherwise. Symptoms of allergic rhinitis may also be exacerbated during pregnancy, probably by the same cause. Although topical nasal steroids with low bioavailability are relatively safe, hypertonic saline douches or occasional use of topical decongestants may be preferable. The condition is self-limiting and resolves rapidly following childbirth.

BEST CLINICAL PRACTICE

- ✓ Advice to reduce allergen exposure in high-risk families has not been shown to be effective in reducing prevalence of allergy.
- ✓ Avoidance of parental smoking during pregnancy and childhood is probably important, though evidence is lacking.
- ✓ Breastfeeding is recommended.
- ✓ Although allergen avoidance is desirable, it is frequently expensive, time-consuming, impracticable or, in the case of pollens, not feasible.
- ✓ Recent trials and a meta-analysis have failed to demonstrate efficacy of house dust mite avoidance or reduction methods in adult patients with persistent rhinitis and asthma.
- ✓ Patients with allergic rhinitis and/or asthma who are sensitive to cats and dogs should be advised to remove the animals, not replace them, or at a minimum keep them out of the bedroom.
- ✓ Food allergy almost never causes isolated nasal symptoms.
- ✓ Antihistamines all rapidly relieve itching and sneezing but have minimal effect on block.
- ✓ Antihistamines appear to be more effective if used regularly.
- ✓ Topical glucocorticoids are the most effective treatment for rhinitis, especially if started prior to allergen exposure.
- ✓ There is no difference in efficacy between the various topical glucocorticoid preparations, but fluticasone and mometasone have the lowest systemic bioavailability and therefore should be considered in paediatric practice or patients having inhaled or cutaneous steroids.
- ✓ Specific immunotherapy is highly effective and may prevent development of future allergic disease.

FUTURE RESEARCH

- Should allergen avoidance methods be used by parents to prevent the development of allergy in children? What effect does this have?
- Should occupational allergen avoidance methods be used?
- Should patients with allergic rhinitis and/or conjunctivitis use antihistamines, glucocorticosteroids, antileukotrienes, cromones, decongestants or ipratropium bromide? What is the relative effect of these medications? Can decongestants be used long term if used with a nasal steroid? For what period and how regularly should they be used?
- Should allergen specific immunotherapy be used in patients with allergic rhinitis? What is the effect of subcutaneous and sublingual specific immunotherapy?
- Do complementary and alternative treatments for allergic rhinitis have an effect?
- Should medications for allergic rhinitis be used in patients with concomitant asthma for the treatment of symptoms of asthma?
- What is the role of helminths in the development of allergic disease?

KEY POINTS

- Allergic rhinitis is best considered in the context of the unified allergic airway, or even as a systemic disease.
- Diagnosis is based on the symptomatic presentation, exposure and evidence of allergen sensitization.
- The disease has a strong association with asthma and an underestimated prevalence, cost and impact on quality of life.
- The mainstay of contemporary treatment are avoidance of allergen, oral or topical antihistamines and topical corticosteroids, but immunotherapy has a re-emerging role.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline and Embase searches using the keywords: rhinitis, vasomotor rhinitis, non-allergic rhinitis, NANIPER, occupational rhinitis, drug-induced rhinitis, NARES, drug therapy and surgery.

INTRODUCTION

Although rhinitis is a cause of widespread morbidity, medical treatment costs, reduced work productivity and lost school days, the disease is often trivialized. Non-infectious rhinitis can broadly be subdivided into two subclasses, allergic and non-allergic rhinitis, depending predominantly on whether or not an allergic aetiology is implicated. Whilst allergic rhinitis has been extensively investigated and the underlying mechanisms are relatively well understood, there is comparatively little information on non-allergic rhinitis. The term 'non-allergic rhinitis' is commonly applied to a diagnosis of any nasal condition in which the symptoms are identical to those seen in allergic rhinitis but an allergic aetiology has been excluded. These non-allergic aetiological entities can broadly be classified as:

- idiopathic rhinitis (also referred to as vasomotor rhinitis, or non-allergic non-infectious perennial rhinitis (NANIPER));
- non-allergic occupational rhinitis;
- hormonal rhinitis;
- drug-induced rhinitis; and
- other forms (non-allergic rhinitis with eosinophilia syndrome (NARES), rhinitis due to physical and chemical factors, food-induced rhinitis, emotion-induced rhinitis, atrophic rhinitis).^{1, 2}

Unlike allergic rhinitis there are no specific diagnostic tests for non-allergic rhinitis, and diagnosis is made on

the basis of rhinitis symptoms in the absence of identifiable allergy (by allergy testing), structural abnormality, immune deficiency, sinus disease or other causes.

Ninety-five percent of normal subjects without rhinitis complaints have been shown to sneeze up to four times a day and to blow their noses up to four times a day, as an average over 2 weeks.³ This would suggest that five or more sneezes and/or nose blowing per day may possibly be indicative of nasal disease. Whilst it is difficult to readily diagnose non-allergic rhinitis, it has been suggested that in patients with perennial non-allergic rhinitis this condition persists for greater than 9 months each year and produces two or more symptoms, including hypersecretion, blockage, sneezing and post-nasal drip.

Although there are some studies of the prevalence of non-allergic rhinitis amongst the rhinitic population, large variations (ranging from around 20 to 50%) have been reported,^{4, 5} presumably due to difficulties in definition and diagnosis of the disease. It is evident that the incidence of positive skin tests to inhalant allergens is far greater than the incidence of rhinitis symptoms in large cross-sectional epidemiological studies. This also implies that rhinitis symptoms in a patient with a positive skin test are not necessarily caused by the allergen, suggesting that the contribution of non-allergic rhinitis to the total number of rhinitis patients may be substantially greater than hitherto estimated. A survey of nearly 1000 rhinitis patients seen in 18 allergy clinics in the USA showed that 23% of the patients had pure non-allergic rhinitis and, importantly, 34% of the patients were diagnosed with

'mixed' rhinitis (a combination of allergic and non-allergic rhinitis),^{6, 7} a group not considered in the other studies. Furthermore, both non-allergic and mixed rhinitis occur more frequently in adults than in children, may be more common in females and are more likely to be perennial than seasonal. More recently, the survey was extended to include more than 22 000 practitioners, each of whom contributed ten patients with rhinitis to the survey. The interim results of the survey indicated that as many as 70% of these patients have mixed rhinitis, with only 9% having the non-allergic rhinitis component alone.

PATHOPHYSIOLOGICAL CONSIDERATIONS

Non-allergic rhinitis, allergic rhinitis and post-infectious rhinitis have nasal hyper-reactivity to various stimuli (for example odours, position, temperature, histamine, etc.) in common, which consequently does not allow differentiation between allergic and non-allergic causes. Unlike patients from some subgroups of non-allergic rhinitis (particularly drug-induced, hormone-induced and NARES) and patients with allergic rhinitis for whom the aetiology is well defined, the aetiology and pathophysiology for the majority of patients with non-allergic non-infectious rhinitis are largely unknown. Although the term 'vasomotor' implies increased neuronal efferent traffic to the blood vessels supplying the nasal mucosa, this has never been proved.¹ Some mechanistic studies have suggested that the functional abnormality in NANIPER may be associated with an imbalance between the sympathetic and parasympathetic nervous systems, which leads to an imbalance in neuronal control of the end organs in the nose.⁸ Indeed, nasal provocation with capsaicin, which specifically stimulates afferent nerve fibres, has been shown to result in a dose-dependent leukocyte influx, albumin leakage and glandular secretion in patients with allergic rhinitis⁹ and to be efficacious in the treatment of NANIPER.¹⁰ However, reports on the underlying mechanisms are conflicting. Whilst some studies have suggested that capsaicin induces neurogenic inflammation in patients with allergic rhinitis, possibly as a consequence of abnormal nociceptor function, this has been shown not to be the case in NANIPER.¹¹ Forced expiration through the nose has been found to significantly increase nasal airway resistance, but not mucous production or sneezing, within the first minute in NANIPER patients and not in non-rhinitic controls, suggesting that mechanical stimulation may also be an important mechanism in NANIPER patients.¹² However, in view of the fact that sympathetic stimulation leads to vasoconstriction and parasympathetic stimulation leads to nasal congestion, it is likely that the imbalance is biased towards parasympathetic stimulation since rhinorrhoea is the predominant complaint in this condition.⁸

Review of the limited data available for idiopathic rhinitis, which comprises the largest group of patients with non-allergic rhinitis, has indicated that several pathologic mechanisms, including non-IgE-mediated inflammatory responses, C-fibre stimulation, parasympathetic

hyper-reactivity and/or sympathetic hyporeactivity, and glandular hyper-reactivity, might play a role in these patients.¹³ However, it is not clear whether these mechanisms operate separately or in combination in the same patient, and whether these mechanisms may be caused by different aetiological entities.

Some attempts have been made to develop diagnostic tools for this condition. Assessment of skin reactivity to a variety of vasomotor agents, including Papaverine, Methacholine, Histamine and Compound 48/40, has demonstrated that the frequency of pathological skin reactivity to Papaverine, but not the other three agents, is significantly increased in patients with perennial non-allergic rhinitis, compared with healthy subjects.¹⁴ This suggests that Papaverine-induced skin reactivity may be a useful diagnostic tool for non-allergic rhinitis. A dose-response study has shown that histamine-induced total nasal resistance follows a model exponential curve, suggesting that it may be possible to classify non-specific nasal hyper-reactivity in allergic and non-allergic subjects as a function of the regression b coefficient of the empirical equation used in reactivity classes.¹⁵ Methacholine tests may be able to differentiate idiopathic rhinitis subjects from controls, but only in those suffering from rhinorrhoea as the main symptom. Recently, cold dry air (CDA) challenge has been suggested to differentiate best between controls and idiopathic rhinitis patients.¹³ However, none of these tests is suitable to differentiate the non-allergic idiopathic from other forms of rhinitis, nor has any been demonstrated to be superior to a simple case history.

TYPES OF NON-ALLERGIC RHINITIS

Idiopathic rhinitis

Idiopathic rhinitis is characterized primarily by symptoms of nasal blockage, rhinorrhoea and sneezing, although the prevalence of sneezing, conjunctival symptoms and pruritus is lower than that in allergic rhinitis. Although the subjects have traditionally been classified as either 'runners' (those with predominantly rhinorrhoea) or 'blockers' (those with predominantly nasal congestion and blockage), many patients suffer from more than one type of these symptoms, therefore making it difficult to subdivide the patients into these groups. The aetiology is unknown in most cases and the disease is thought to be triggered mainly by irritants and changes in atmospheric conditions.¹⁶ Among patients with chronic symptoms, the percentage with a non-allergic aetiology increases progressively with age and reaches >60% beyond the age of 50 years, therefore suggesting that functional abnormality in this condition may be associated with the ageing process in the nasal mucosa.¹⁶

Non-allergic occupational rhinitis

Occupational rhinitis, as the term implies, may be defined as rhinitis caused by exposure to airborne agents present in the work place. These agents elicit predominantly sneezing, nasal discharge and/or blockage and may act via

both immunologic (IgE-mediated) and non-immunologic mechanisms. The non-immunologic triggers are often irritant or toxic small molecular weight compounds such as aldehydes, isocyanates, aircraft fuel and jet stream exhaust, solvents, etc.,^{1, 8, 17} or may be physical (long-term exposure to cold air). Whilst the specific mechanisms underlying the effects of these irritants and toxic agents have not been fully elucidated, it is possible that damage and/or stimulation of the epithelial cells and neurons by the irritants may lead to proinflammatory mediators and neuromediators, which may predispose the nasal mucosa to inflammation and infection, subsequently resulting in the symptoms of rhinitis. Indeed, a study investigating the effect of airborne exposure to the non-allergenic microbial agents endotoxin and beta(1,3)-glucan in compost workers has reported that concentrations of total cells (predominantly neutrophils), myeloperoxidase (MPO), IL-8, nitric oxide (NO) and albumin were significantly higher in compost workers than in controls.¹⁸ Similarly, occupational exposure to vanadium pentoxide, a constituent of fuel oil ash and a known respiratory irritant, has been shown to significantly increase the number of polymorphonuclear cells in nasal lavage of boilermakers.¹⁹

HORMONAL RHINITIS

Hormonal rhinitis is often associated with pregnancy in particular, although puberty is also known to induce the symptoms of rhinitis.^{1, 8} A large multicentre study has indicated that the cumulative incidence of pregnancy rhinitis was 22%, and in women who were smokers this was significantly increased with a relative risk enhancement of 69%.²⁰ Neither asthma nor rhinitis were, apparently, risk factors for pregnancy rhinitis. In contrast, only 2% of patients with non-allergic rhinitis may be afflicted by rhinitis due to hypothyroidism or acromegaly.²¹

Oestrogens cause vascular engorgement, not only in the female genital tract, but also in the nose, leading to nasal obstruction and/or nasal hypersecretion. Beta-oestradiol and progesterone have been shown to increase the expression of histamine H₁ receptors on human nasal epithelial cells and mucosal microvascular endothelial cells,²² and to induce eosinophil migration and/or degranulation, in marked contrast to testosterone, which decreases eosinophil activation and viability.²³ Compared with pregnancy rhinitis, the evidence linking hypothyroidism with nasal pathology is sparse, and the reported increase in nasal secretion associated with thyroid disease is anecdotal.¹

DRUG-INDUCED RHINITIS

Several commonly employed medications, such as aspirin, other non-steroidal antiinflammatory drugs (NSAIDs), beta-blockers, angiotensin-converting enzyme (ACE) inhibitors, methyl dopa, oral contraceptives, psychotropic agents and nasal topical decongestants (Oxymetazoline, Naphazoline, Xylometazoline) may induce symptoms of rhinitis when they are administered either topically or

systemically. The symptoms may be either predictable, as would be the case for known side effects of particular drugs, or unpredictable, based on individual hypersensitivity to certain drugs, in particular aspirin, which commonly exacerbates rhinitis and asthma. However, intolerance to aspirin and/or NSAIDs predominantly produces rhinorrhoea, which may be either isolated or part of a complex involving hyperplastic rhinosinusitis, nasal polyps and asthma.¹ In contrast, intolerance to ACE inhibitors, methyl dopa or oral contraceptives, which is less common than aspirin intolerance, leads predominantly to nasal blockage.¹ Whilst persistent overuse of the topical nasal vasoconstrictors also leads to nasal decongestion by a mechanism involving a rebound effect following withdrawal of these drugs, excessive use of these agents may also lead to nasal hyper-reactivity and hypertrophy of the nasal mucosa, a condition known as 'rhinitis medicamentosa'.^{1, 8}

OTHER FORMS OF RHINITIS

NARES

The term NARES was originally introduced by Mullarkey and colleagues, who characterized the condition on the basis of a presence of greater than 20% eosinophils in nasal smears of symptomatic patients with perennial sneezing attacks, a profuse watery rhinorrhoea, nasal pruritis, incomplete nasal obstruction and occasional loss of smell.^{1, 4, 7, 8} In addition to these symptoms, a marked feature of the disease is the lack of evidence of allergy, as indicated by negative skin prick tests and/or absence of serum IgE antibodies to specific allergens.

The prevalence of NARES has been shown to range between 13 and 33% in patients with non-allergic rhinitis.^{21, 24} Although the specific aetiology of NARES is not clear, in view of the features shared by this syndrome and the triad (nasal polyposis, intrinsic asthma and intolerance to aspirin) and because NARES patients frequently develop nasal polyps and asthma later on in life, it has been suggested that NARES may be an early expression of the triad.²⁴ Indeed, in approximately 50% of NARES patients without a history of respiratory symptoms, bronchial responsiveness is associated with an increase in the number of sputum eosinophils, but not with an increase in the number of nasal eosinophils.²⁵ Some investigators have suggested that NARES is a variant of vasomotor rhinitis, and referred to the condition as 'perennial intrinsic rhinitis'.

Rhinitis due to physical and chemical factors

Nasal symptoms similar to those of rhinitis can be induced by physical and chemical factors in individuals with sensitized nasal mucous membranes.² Cold, dry air has been shown to lead to a condition known as skier's nose, in which rhinorrhoea features prominently. Exposure to chemicals, particularly air pollutants derived from cigarette smoke and liquid petroleum fuels, have also been

shown to directly exacerbate symptoms of rhinitis in non-allergic individuals,² although their effects have generally been extensively investigated and well documented in the lower airways of allergic individuals.²⁶ Little information is available on the acute or chronic effects of air pollutants on the nasal mucosa.

Food-induced rhinitis

Few studies have documented that certain foods and alcoholic beverages can induce non-allergic rhinitis, although the underlying mechanisms are largely unknown. Hot and spicy foods, in particular, which contain capsaicin, lead to a watery rhinorrhoea termed 'gustatory rhinitis', probably as a result of the capsaicin stimulating the sensory nerves to release neuropeptides and tachykinins.^{1, 2} In contrast, alcoholic beverages are thought to induce symptoms as a result of vasodilation. Dyes and preservatives, as well as sulphites, appear to play a role in a very few cases, whereas some foods may contain clinically relevant concentrations of histamine or other biogenic amines.

Emotionally induced rhinitis

Although not studied extensively, emotional factors such as stress and sexual arousal have been documented to affect the nose, likely as a result of autonomic stimulation.^{2, 27} In patients suffering from post-coital rhinitis, anxiety appears to be a predominant feature, which leads to worsening of their disease.²⁷

Atrophic rhinitis

Primary atrophic rhinitis is a condition that occurs predominantly in women and is characterized by progressive atrophy of the nasal mucosa and underlying bone of the turbinates.^{1, 2} This leads to the formation of thick crusts, which leave a constant foul smell (ozaena) in the nose.^{1, 2} Furthermore, the nasal cavities are enlarged and there is the sensation of nasal congestion. Although the precise aetiology of this condition is not clear, it has been suggested that this may be a result of infection with *Klebsiella ozaenae* and other bacteria. However, primary atrophic rhinitis is distinct from secondary atrophic rhinitis, which develops directly as a result of granulomatous nasal infections, chronic rhinosinusitis, excessive nasal surgery, trauma and irradiation.

Differential diagnosis

Allergic rhinitis is the major disease to differentiate from non-allergic rhinitis and may be excluded by appropriate allergy tests. However, the possibility of a local IgE production within the nasal mucosa may account for some cases where skin prick tests or IgE antibodies to common allergens are not positive. Several other conditions, including polyps, sinusitis, congenital and acquired anatomical abnormalities (e.g. nasal septal deviation, adenoid hypertrophy, hypertrophy of nasal turbinates, choanal atresia), benign and malignant tumours, granulomas, ciliary

defects and cerebrospinal rhinorrhoea,^{1, 2} are known to mimic symptoms of non-allergic non-infectious rhinitis and therefore have to be excluded by careful examination in order to make the correct diagnosis. Anatomical nasal abnormalities block the flow of nasal secretions and lead to rhinorrhoea, post-nasal drip and nasal blockage. In children, congenital choanal atresia can lead to reduced nasal airflow, resulting in nasal blockage. Tumours are not very common in the nasal passages, but when established and growing rapidly they often lead to unilateral nasal obstruction, bleeding and pain. Rhinorrhoea and nasal congestion, in the absence of pruritis, are also characteristic features of nasal mastocytosis, an extremely rare condition, in which eosinophils are absent and tests for IgE-mediated disease are negative.

Diagnosis as a step-wise approach

In daily clinical practice, the diagnosis of non-allergic rhinitis and its subgroups is mainly based on a thorough case history, followed by the step-wise exclusion of possible differential diagnoses, as follows.

If the case history is suggestive of clinically relevant non-infectious rhinitis:

- check possible stimuli, severity and duration of disease;
- check drug use (systemic and topical), exposure at work place, hormonal status (pregnancy, hypothyroidism, acromegaly) and involvement of other organs (asthma, hormonal status);
- exclude other nasal disease (rigid nasal endoscopy);
- exclude allergy: skin prick test, serum IgE-antibodies to the most frequent inhalant allergens, and ultimately nasal provocation testing in selected cases;
- exclude chronic rhinosinusitis (nasoscopy +/- computed tomography (CT) scan);
- perform nasal cytology (eosinophilia), and if shown to be positive then perform oral Aspirin challenge.

Therapy for non-allergic perennial rhinitis

First, an evaluation of the severity of the disease should be performed to confirm the need for therapy, in connection with counselling on how to avoid non-specific stimuli. In case of drug-induced, food-induced or occupational rhinitis, specific avoidance measures are employed as first-line therapy.

Several treatments (pharmaceutical, non-conventional and surgery) have been employed for idiopathic non-allergic rhinitis.²⁸ Intra-nasal anticholinergics (Ipratropium Bromide) may be useful in patients with nasal secretion as the predominant symptom, whereas nasal decongestants should be avoided or limited to 10 days. Topical steroids and antihistamines are the two main classes of drugs employed, of which only Fluticasone Propionate, Budesonide, Beclomethasone and Azelastine, respectively, have been approved by the Food and Drug Administration (FDA). Azelastine nasal spray has been

found to be more effective than placebo for control of rhinorrhoea, post-nasal drip, sneezing and nasal congestion in most patients, although its effect on nasal congestion was rather marginal.²⁹ The efficacy of intra-nasal steroids in patients with vasomotor rhinitis has been inconsistent. Furthermore, whilst the topical nasal steroids are more frequently used for treatment of more severe symptoms, they are mostly useful in patients in whom an inflammatory pathogenesis is a prominent feature of their disease, for example NARES. Recent evidence suggests that in patients who do not respond to treatment with nasal steroids, treatment with non-conventional therapies such as silver nitrate, botulin toxin and particularly intra-nasal capsaicin may be beneficial. Studies in patients suffering from NANIPER have demonstrated that intra-nasal capsaicin leads to a significant and long-term reduction in clinical VAS scores, compared with placebo.¹⁰ In another study, treatment once daily for 5 weeks with intranasal capsaicin was also shown to significantly improve all symptoms and produce a larger vascular response throughout a 6-month follow-up period in patients suffering from severe chronic non-allergic rhinitis with nasal vasoconstrictor abuse.³⁰ In cases where nasal obstruction is resistant to medical treatment and if the inferior turbinate is hyperplastic, surgical intervention to reduce the size of the turbinate by various procedures has been shown to be useful. Endoscopic trans-nasal vidian neurectomies have also been performed by excision, diathermy and cryotherapy, and have produced results with varying degrees and duration of success.³¹⁻³³

Recent interest in intranasal capsaicin prompted a Cochrane Review that included 302 patients with idiopathic non-allergic rhinitis.³⁴ Whilst the quality was judged to be low to moderate there was sufficient evidence that

capsaicin was superior to both placebo and Budesonide. Studies were of variable follow-up ranging from 4 to 38 weeks. Given the limited treatment options for non-allergic rhinitis and good safety profile³⁵ Capsaicin represents a reasonable therapeutic choice.

Small scale non-powered studies have shown therapeutic potential for intra-nasal Botulinum toxin for non-allergic rhinitis.³⁶⁻³⁸ Symptoms of nasal obstruction, discharge, sneezing and itching all improved, though the duration of improvement was limited to 2-3 months.

CONCLUSION

Despite increasing evidence for the various forms of non-allergic rhinitis, many of these conditions are often underrated and trivialized, primarily due to the paucity of information on the causative factors, the underlying mechanisms and/or the absence of specific diagnostic tests. Furthermore, there are differences in opinion amongst clinicians and researchers regarding classification of disease and in conditions such as occupational rhinitis, in particular, the situation is further compounded as a consequence of legal and financial compensatory implications, for both employers and employees alike. To date, no specific diagnostic test is available, and clinical diagnosis is based on case history and exclusion of other disease. Despite these difficulties, however, recent evidence suggests that relevant diagnostic tools and specific information regarding the mechanisms underlying some of these conditions is more forthcoming and should therefore lead to a better overall understanding and management of these conditions in the future.

BEST CLINICAL PRACTICE

- ✓ Wherever possible, the treatment should take into account the aforementioned subgroups of non-allergic perennial rhinitis.
- ✓ In idiopathic rhinitis, antihistamines and topical steroids are the two main classes of drugs for treatment. Topical steroids are to be preferred if an inflammatory pathogenesis is suggested.
- ✓ Intra-nasal capsaicin is supported by a better evidence base than intra-nasal Botulinum toxin but both treatments remain outside widespread clinical use.
- ✓ Surgery is an option in patients with persistent nasal obstruction not improved by medication.

FUTURE RESEARCH

- There is a marked lack of diagnostic tools/procedures for determining each type of these conditions.
- There is a marked lack of controlled trials for determining diagnosis.
- Epidemiological studies on prevalence of different types of non-allergic rhinitis are required.
- Research on mechanisms underlying these conditions is needed.

KEY POINTS

- Approximately half of rhinitis patients may suffer from non-allergic rhinitis.
- There are no specific diagnostic tests for non-allergic rhinitis.
- A thorough case history is the best diagnostic tool available and should focus on drug intake, work exposure and hormonal status to subdivide the condition into subgroups.
- As the symptoms are quite non-specific, the differential diagnoses have to be excluded.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search and an Embase search using the key words: rhinitis, occupational rhinitis, rhinitis and occupation, air pollutants and occupational, occupational disease, occupational accident, occupational allergy, occupational exposure, occupational hazard, occupational health, occupational medicine, occupational safety, work environment, industrial medicine, industry, industry and industrial phenomena, work and disability.

INTRODUCTION

Occupational rhinitis (OR) is an inflammatory disease of the nose, which is characterized by intermittent or persistent symptoms (i.e. nasal congestion, sneezing, rhinorrhoea, itching), and/or variable nasal airflow limitation and/or hypersecretion arising out of causes and conditions attributable to a particular work environment and not to stimuli encountered outside the workplace.¹ Symptoms usually manifest in weekdays and abate during weekends and holidays. When exposure has been prolonged the condition may become irreversible and symptoms persist.^{2,3} OR frequently coexists with asthma and conjunctivitis, and it has been documented that occupational rhinitis precedes the development of occupational asthma especially when high molecular weight compounds (HMW) are involved (see below).^{1,3,4} Occupational rhinitis is commoner than occupational asthma and most reports show that it tends to occur two to four times more frequently.^{1,3,5}

The prevalence of occupational rhinitis is unknown. Studies have dealt primarily with occupational asthma with less work on rhinitis. It has been estimated that 2–5% of all patients with asthma in the United States have work-induced asthma.¹ It is possible that the incidence of occupational rhinitis is underestimated due to failure to diagnose and because, unlike asthma, it is not

a life-threatening condition. Workers may be reluctant to report symptoms for this reason as well as for fear of job loss, loss of seniority, or fear of repercussions from co-workers.¹ A variety of cross-sectional studies of populations from diverse occupations exist but, because of the different methodologies used, interpretation of data is difficult. Furthermore, data from epidemiological studies are lacking. Information from the Finnish Institute of Health showed that 20% of all cases of rhinitis were occupational in origin.⁷ The same study also showed that the number of cases more than doubled between 1987 and 1991. Another study, utilizing the Finnish Register, showed that the incidence of occupational rhinitis is higher in men than women (60% and 40% respectively). Also a gender difference exists for the age at which occupational rhinitis develops. Men have the highest incidence at the age range of 25–29 years, after which the incidence gradually declines. In women, the incidence of occupational rhinitis gradually increases and peaks between 40 and 44 years of age.⁴ It has been suggested that this difference is related to the fact that men and women are engaged in different jobs and hence exposed to different kinds of causative agents.⁸

More than 200 chemicals and organic dusts have been implicated as a cause of occupational rhinitis and asthma.¹ The pathological effects of these are either due to an allergic reaction or irritation of the nasal mucosa. Well-documented causative agents include laboratory animals

such as rats, mice and guinea pigs, grains (bakers), storage mite (agricultural workers), wood dust, particularly hard wood such as western red cedar (furniture manufacturers), guar gum (workers in the food processing and carpet industry), *Bacillus subtilis* enzymes (detergent manufacturing workers), persulphate salts (hairdressers), latex and chemicals such as acid anhydrides, isocyanates, platinum salts, glues and solvents.^{1,3,6} Symptoms may develop after a latency period of 2 months to 18 years in the case of allergic occupational rhinitis.^{1,6} This observation does not apply to irritant occupational rhinitis which can develop on immediate exposure.

RISK FACTORS

Risk factors for developing occupational rhinitis include exposure (intensity and duration), atopy and smoking.⁶ Most reports on exposure have focused on intensity, and associations have been confirmed in laboratory animal workers, wool textile mill workers and bakery workers amongst others.³ Duration of exposure has seldom been studied. Other studies have shown an association between atopy and specific sensitization to high molecular weight agents in grain elevators, fish and seafood workers, bakers, workers exposed to latex, coffee and others. Although smoking is known to induce the release of inflammatory mediators and to cause mucosal changes, its impact on occupational rhinitis is yet to be shown. The current evidence on this matter is still inconclusive as some studies show higher risk of occupational rhinitis in smokers and some do not.^{3,6,9}

PATHOGENESIS

The nose is the first portal of entry to the respiratory tract and is exposed to a constant stream of air. Materials that accompany the air stream tend to impact on the mucus surface as a function of their aerodynamic equivalent diameter (AED).¹⁰ Approximately 80% of those that have an AED of more than 9 µm, 50% of those with 2–9 µm AED and 40% of material with less than 2 µm stick to the nasal wall. Highly soluble materials such as ammonia, sulphur dioxide, and formaldehyde also deposit in the upper airway. Smaller particles and less water-soluble gases generally pass to the lower airways.⁸ According to the nature of the offending agent, occupational rhinitis may be allergic or irritant.

Allergic occupational rhinitis

Allergic occupational particles may trigger an IgE-mediated (Type 1) immune response. A late-phase response may also develop 4–6 hours after the initial reaction.⁸ The causative agents are classified into high molecular weight compounds (HMWC), such as animal and vegetable proteins, and low molecular weight compounds (LMWC), such as isocyanates and anhydrides. IgE dependant mechanisms, that can be assessed through skin prick test and specific IgE levels have been demonstrated with most high molecular weight

compounds (HMWC).^{3,8} Low molecular weight compounds (LMWC) can also produce specific IgE antibodies by acting as a hapten to form hapten-protein conjugate. However, an IgE-mediated mechanism has been elicited only rarely with LMWC. **Table 93.1** shows a number of HMWC and **Table 93.2** shows LMWC implicated in allergic occupational rhinitis with the related occupations.^{1,3,6}

Irritant occupational rhinitis

Non-allergic, irritant chemicals may trigger the release of substance P and other inflammatory mediators from sensory C-fibres after binding to chemoreceptors on their surface.^{11,12} This sequence, known as neurogenic inflammation, leads to vasodilatation, oedema, and other manifestations of inflammation. The patients complain of burning, stinging or painful sensation in the nasal passages in addition to nasal congestion and rhinorrhoea.¹ Delayed response does not occur in cases of irritant rhinitis.⁸ Existing evidence shows the release of substance P in the nose with exposures to nicotine, capsaicin, ether, and formaldehyde. Chronic irritant rhinitis requires protracted exposure to one or more irritating chemicals. However, in reactive upper airways dysfunction syndrome (RUDS) rhinitis results from an acute exposure to high concentrations of a respiratory irritant, and persists after the exposure.¹² **Table 93.3** shows a number of agents implicated in irritant occupational rhinitis with the related occupations.^{1,6}

Corrosive reactions may also occur due to excessive concentrations of irritating and soluble chemical gases. Substances implicated in causing corrosion are ammonia, hypochloric acid, vinyl chloride, organic sulphur containing compounds, acrylamide, cyanide, nitriles and organophosphoside compounds.¹ Disorders of olfaction may occur a result of rhinitis or as a direct effect of irritants on the olfactory receptors and their central connections.¹³ Anosmia and hyposmia have been reported after single high-dose exposure to sulphuric acid, hydrogen selenide, phosphorus oxychloride and a mixture of pepper and cresol.⁸ Other case reports of olfactory disorders present workers chronically exposed to low levels of chemicals such as benzene, benzol, cadmium, carbon disulphide, ethyl acetate, formaldehyde, hydrazine, menthol, solvents, and oil of peppermint.^{8,14} However, olfactory disorders in occupational rhinitis are otherwise under-investigated.

Similar to other patients with allergic and non-allergic rhinitis, patients with occupational rhinitis may manifest nasal hyperreactivity to non-specific environmental agents such as changes in temperature and humidity, exposure to tobacco smoke and strong odours.¹ The prevalence of this entity is, however, unknown.

HIGH RISK OCCUPATIONS

Data from the Finnish Register of Occupational Diseases identified furriers, who are exposed to different kinds of animal epithelium, as the highest risk group for developing occupational rhinitis. Livestock breeders and bakers were the occupations following in rank.⁴ Other commonly

TABLE 93.1 High molecular weight compounds (HMWC) causing allergic occupational rhinitis

High molecular weight compounds	Occupation
Animal proteins (rats, mice, guinea pigs, rabbits, hamsters)	Laboratory animal workers, pet shop owners, veterinarians, farmers
Other animal derived allergens (pig)	Swine confinement workers
Grain dust	Grain elevators
Flour, alpha amylase	Bakery workers
<i>Bacillus subtilis</i>	Detergent workers
Enzymes (papain, trypsin, pancreatic extracts, lactase)	Pharmaceuticals
Wool	Wool textile workers
Insects (locust, fruit fly)	Laboratory workers
Arthropods	Laboratory workers
Mites (storage, red spider)	Bakers, farmers, grain elevators, food processors
Mould spores	Librarians
Latex	Healthcare workers
Guar gum/vegetable gum	Food processors, carpet workers, printing
Green coffee bean	Coffee production
Tea	Tea workers
Dried fruits	Dried fruit workers
Tobacco leaf	Tobacco workers
Cayenne peppers	Hot pepper workers
Pollens	Gardeners, greenhouse workers
Sunflower pollen	Bakers, agricultural workers
Soybean dust	Farmers, food processors
Saffron flower	Saffron workers
Cocoa	Packers
Garlic	Food workers
Milk proteins (alpha Lactalbumin, casein)	Chocolate manufacturing, tannery
Fish, prawn, crab	Food processors
Bird proteins	Poultry breeders, farmers
Raw poultry	Food processors
Cow dander	Dairy farms

TABLE 93.2 Low molecular weight compounds (LMWC) causing allergic occupational rhinitis

Low molecular weight compounds	Occupation
Diisocyanates (toluene diisocyanates, diphenyl-methan diisocyanates)	Painters, urethane mould workers
Anhydrides (trimellitic anhydride, methyl tetrahydrophthalic anhydride, pyromellitic anhydride)	Epoxy resin production, plastics, electric condenser workers, chemical workers
Wood dust (western red cedar, several other woods)	Furniture making, carpentry
Colophony	Electronics, welders
Metals (platinum, nickel, chromium)	Platinum refinery, metal processing or plating
Drugs (psyllium, senna, spiramycin)	Healthcare workers, bulk laxatives factory workers, pharmaceuticals
Chemicals (reactive dyes, carmine, polyamide, polyester, para-amide)	Reactive dye product producers, synthetic fibre workers
Cotton	Farmers, cotton mill workers
Persulphates	Persulphage product manufacturers, hairdressers
Solvents and organic dust	Shoe manufacturing
Azo dyes	Textile dyeing
Chlorine	Pulp and paper production

TABLE 93.3 Causative agents of irritant occupational rhinitis

Irritant substance	Occupation
Ammonia, nitrogen dioxide, hydrogen sulphide	Agricultural workers
Smoke	Firefighters
Cooking vapour	Food service workers
Glutaraldehyde, formaldehyde	Healthcare workers
Inorganic acid vapours	Laboratory workers
Sulphur dioxide	Power plant, oil refinery workers
Solvent vapours	Printers, painters
Zinc chloride smoke	Military personnel
Chloride, chlorine dioxide, hydrogen sulphide	Pulp mill workers
Oxides of nitrogen, ozone, diesel exhaust	Traffic wardens, lorry drivers, railroad workers
Asphalt vapours, polycyclic aromatic hydrocarbons	Roofers, pavers
Metallic oxide fumes	Welders
Talc	Pharmaceutical workers, cosmetic manufacturers

reported occupations include farmers, food-processing workers, wood workers, detergents manufacturers, animal laboratory workers, hairdressers and healthcare workers.

Bakers

A large number of cross-sectional studies show that work-related symptoms of rhinitis and sensitization are common among bakery workers. Work-related rhinitis has been shown in 18% to 29% of workers and specific sensitization in 10% to 38%.³ The offending agents are wheat and cereal flours, cereal amylases, fungal amylases, storage mites contaminating wheat flour and others such as baking additives.

Farmers

The prevalence of occupational rhinitis in farmers is unknown. However, a variety of agricultural exposures have been associated with rhinitis. These include grain farming and handling, livestock breeding, feed manufacture and handling, dairy farming, tea farming, cotton, flax, and hemp processing and organophosphorous pesticides.¹⁵ Storage mites, present in storage hay have been described as a cause of barn allergy. A number of reports on grain elevator workers showed prevalence of sensitization in 9% to 28%.³

Food processing workers

It has been suggested that the food industry accounts for the largest number of cases of occupational rhinitis.³ Cases of occupational rhinitis due to guar gum are well documented. It is obtained from the seeds of the tree *Cyamopsis tetragonoloba*, and used as a food additive as well as a laxative and a colour fixing agent in the carpet industry. The prevalence of symptoms in workers is, however, less well documented. Symptoms related

to other plant-related allergens such as soybean, coffee bean, garlic, cinnamon and hot peppers have also been reported.¹ Occupational rhinitis has also been correlated to fish and seafood proteins. Prevalence of symptoms of 5% to 25% in fish factory workers has been reported.³

Wood manufacturers

Hard woods, often of tropical origin, are well-known factors in causing work-related symptoms. Plicatic acid, found in western red cedar, has been suggested as the causative agent of rhinitis in carpenters and furniture manufacturing workers.^{3, 16} Symptom prevalence figures are less well documented. Oak, beech and pine have also been implicated.¹⁶ Soft woods, used in joiner shops, have been less reported than hard woods in relation to rhinitis.¹⁶

Detergent manufacturers

Biological enzymes are used extensively in the detergent industry as well as pharmaceutical and food industries. *Bacillus subtilis* enzymes and lactase have been commonly implicated in occupational rhinitis.^{1, 3, 6} Prevalence rates of occupational rhinitis from 7% to 16% have been reported in workers. Specific sensitization ranged from 22% to 52%.³

Animal laboratory workers

Laboratory workers are one of the groups most commonly affected with occupational rhinitis.¹ It has been suggested that proteins from virtually any mammalian species may induce an allergic response in human beings.¹ Rats are the most commonly implicated but mice, guinea pigs, rabbits and hamsters are also known to cause occupational rhinitis.^{1, 3} Immunological substances implicated include saliva, urine, dander and serum. Previous reports demonstrate symptom prevalence of 10% to 33% and specific

IgE antibodies to animal protein in 6% to 46% of workers. Recent evidence suggests a trend towards a progressive decline in the prevalence, which may be due to the reduction of exposure since the early 1980s.^{3, 17}

Healthcare workers

Concern has been raised about latex allergy in healthcare workers and patients due to the extensive use of latex gloves. Rubber latex is a naturally occurring cytoplasmic exudate obtained from the tree *Hevea brasiliensis*.¹⁸ It is used extensively in the manufacture of surgical gloves and other medical devices (drains, bag and valve masks, mouth gags and bandages are some examples).¹⁹ Aerosolized particles of latex proteins are carried in the cornstarch used to powder the gloves and may remain airborne for hours.^{19, 20} Significant quantities of airborne latex have been measured in areas using powdered latex gloves.²⁰ These proteins have been implicated in causing rhinitis, asthma and anaphylaxis.^{18–20} Exposed personnel may also develop contact dermatitis as a reaction to the chemical accelerators and preservatives that are added to latex to improve its physical property.¹⁹ Anaphylaxis most often affects patients during open surgery due to mucosal absorption, and has been reported in those who have had multiple surgical procedures and in patients with spina bifida.¹⁸ However, anaphylactic reactions were also reported during gloving and inhaling latex in the workplace.¹⁸ Healthcare workers with regular latex exposure have been reported to have symptom prevalence rates of 3% to 17%.²¹ Specific skin tests have been shown to be positive in 5% to 20% in contrast to prevalence in the general population of less than 1%.¹⁸

Other substances that may cause occupational rhinitis in healthcare workers include formaldehyde and drugs such as psyllium, senna and spiramycin.³ Formaldehyde is also used widely in industry in addition to its use as a sterilizing agent in medicine. It is toxic at high doses and can induce irritant reaction. It is also been suggested that it can act as a hapten and cause an IgE mediated reaction.²²

Other occupations

Workers reported to have occupational rhinitis in other occupations have been referred to in [Tables 93.1–93.3](#).

EFFECTS OF AIR POLLUTION

In the first half of the 20th century dramatic episodes of severe pollution, caused by sulphur dioxide (SO₂) derived from coal combustion, occurred in the Western world. Regulations to decrease the use of coal in homes and industry were set and other fuels like petrol and gas substituted coal. The by-products of petrol consumption in transport and industry, however, have replaced the decline of coal-associated pollution. Exhaust fumes consist of oxides of nitrogen, namely nitric oxide (NO) and nitric dioxide (NO₂), ozone (O₃), particulate matter (PM) and volatile organic compounds (VOCs).²³ Much of the research done

on pollution has been on its effects on the lower airway. However, epidemiological studies suggest an association between pollution and rhinitis.⁹ Laboratory studies have shown that exposures to NO_x, O₃ and diesel exhaust particles result in the release of inflammatory mediators in the nasal mucosa.²⁴ A link between high levels of environmental pollutants and increased prevalence of allergy has also been suggested.⁹ Whether this would have an impact on allergic occupational rhinitis remains to be examined.

Certain occupations such as traffic wardens, railroad workers and lorry drivers may be exposed to high levels of pollution that result in high prevalence of symptoms of rhinitis.²⁵

SICK BUILDING SYNDROME

Sick building syndrome (SBS) is described as the high prevalence of eye, nose and throat irritation, fatigue and headache among office workers temporally associated with time at work and characterized by an absence of abnormal physical findings and laboratory results.⁸ It is a diagnosis of exclusion as multiple causative agents have been implicated. More than 300 volatile organic compounds (VOCs) were identified as indoor pollutants causing SBS. They originate from building materials, combustion fumes, cleaning compounds, paints and stains in addition to tobacco smoke. It has been suggested that workers in buildings with mechanical ventilation and air conditioning have a higher risk of SBS symptoms than workers in naturally ventilated buildings.^{26, 27}

DIAGNOSIS

Diagnosing occupational rhinitis can be difficult. A combination of history, examination and investigation will aid the diagnosis. Nasal provocation test (NPT) with the suspected agent is particularly central to secure the diagnosis.

History

The patients present with a variable number of symptoms including nasal obstruction, anterior rhinorrhoea, post-nasal discharge, crusting, disturbed sense of smell and taste and epistaxis.² A detailed history of the patient's complaint in addition to occupational history is essential to aid the diagnosis. Development of symptoms during the working week with improvement at weekends and holidays provide the clue for diagnosis. However, history in itself is not sufficient for diagnosis and could be feigned by workers claiming compensation. The history can be further compounded by the presence of symptoms of rhinitis due to atopy in allergic patients. In patients with protracted exposure, the symptoms may continue during absence from work further complicating matters.¹ The difference in presentation between allergic and irritant occupational rhinitis should be also borne in mind. In allergic patients, rhinitis may take longer to develop

and may be manifested by a delayed response a few hours after exposure. On the other hand, patients with irritant rhinitis may develop the symptoms instantly on exposure and do not have a delayed response.¹ A history of eye, throat, skin and chest symptoms should be elicited. It is important to enquire about smoking and drug history including over-the-counter decongestants, substance abuse and other drugs known to cause nasal symptoms such as aspirin, alpha-blockers, beta-blockers, antidepressants and ACE inhibitors. Enquiries should be made on history of atopy in the patient and first-degree relatives.^{1,2} An enquiry about problems of the sense of smell and taste should also be made.

A detailed occupational history includes the patient's account of a typical working day, the nature of chemicals, duration and intensity of daily exposure and use of protective masks.⁸ A substance information sheet or an engineer's report may also be required particularly in medico-legal cases. Other work factors such as type and efficiency of ventilation, history of accidents and spills, and effects on co-workers should also be considered.^{2,6} A site visit has been recommended if the history of work conditions is unhelpful.¹

Examination

The physical findings in occupational rhinitis are non-specific. Nasal examination should include description of mucosal changes, nature of secretions, crusting, epistaxis, ulceration and perforation. These are particularly important in medico-legal cases.¹ Crusting and epistaxis are commoner in irritant rhinitis. Eye inspection for conjunctivitis and oral cavity/oropharynx examination for ulceration should also be done. Chest examination for signs of asthma is important as well as inspection for dermatitis, which occurs in latex allergy.

Investigations

The skin prick test is useful in allergic occupational rhinitis for most HMW and some LMW agents. It is also helpful in diagnosing suspected atopy. However, sensitization to an occupational agent is not sufficient to diagnose occupational rhinitis, because it only indicates an immunological response and not necessarily a clinical syndrome.³ Skin prick tests have been used extensively in cross-sectional studies to assess sensitization to a specific agent. Sensitivity and specificity have been evaluated with differing results.³ Measuring serum specific IgE has also been used in a number of studies. The sensitivity and specificity is probably less than that of the skin prick test but a combination of both tests may enhance sensitivity and specificity.¹

A secure diagnosis cannot be made without a nasal provocation test (NPT).^{1,6} This is more conclusive when performed in controlled conditions in the laboratory with known agents. Carefully graded exposure to increasing doses of the suspected agent in specialized ventilated environmental chambers is the best method. Difficulties arise

when dealing with unknown or multiple agents.³ On these occasions a workplace provocation test may be an option.^{1,3} Unfortunately, no standardized method for nasal provocation is yet recommended and the test is time consuming. The test must be accompanied by an objective measure of the nasal response such as acoustic rhinometry or rhinomanometry.^{4,28} Nasal inspiratory flow rate measurement (NIPF) is also useful with nasal provocation. It can be also used by the patient to measure fluctuations of the nasal airway during the working week.³ Other measures such as collecting nasal lavage for analysis of cells and inflammatory markers and brush biopsies have been used with nasal provocation. They are generally more suitable for research situations and have been used extensively in various trials.³ Exhaled nitric oxide measurement has also been used in clinical trials but not in routine clinical practice.²⁹

When an olfactory disorder is suspected and in medico-legal cases, olfaction should be tested using one of the commercially available tests such the University of Pennsylvania Smell Identification Test (UPSIT).²

MANAGEMENT

The best management approach for occupational rhinitis is prevention. In established cases avoidance methods should be instituted and medical therapy may be tried. Immunotherapy may have a part to play in treating severe cases of allergic occupational rhinitis.

Prevention

Primary prevention in the workplace may be effective and should always be considered.¹ Environmental control measures are undertaken by recognizing potentially sensitizing allergens and controlling the point source of any mucosal irritant. Enclosing previously open operations and automating hand operations should be considered. Masks, gloves and protective clothing should be used and ventilation improved.^{1,6} It has been suggested that applicants for high-risk jobs should be screened for atopy by history taking and skin prick test. However, this has not been shown to be efficient, particularly when the marker of susceptibility (e.g. atopy) is prevalent in the general population.¹

In workers with established diagnosis certain avoidance measures may be effective. For example, laboratory workers who become sensitive to rats generally react to rat urinary protein rather than epithelium. It has been suggested that it may be possible for them to perform surgery on rats, if the cage containing the rats – which is soaked with urine – is kept out of the laboratory. In healthcare workers sensitive to latex the use of powder-free gloves by all co-workers has been shown to reduce symptoms and allow allergic patients to continue their work.¹⁸ Non-latex gloves are available and may be used as an alternative for sensitive individuals. In some occupations where preventive measures are ineffective, relocation of the worker or even changing jobs may be recommended.

Medical therapy

Medical therapy of occupational rhinitis is similar to that of non-occupational allergic rhinitis and should be instituted according to evidence-based guidelines.³⁰ Antihistamines, sodium cromoglycate, topical corticosteroids, anticholinergic spray and saline douches have all been used.^{1, 6} Systemic steroids have also been suggested in severe cases. Treatment may be most effective in allergic occupational rhinitis.¹ However, no studies on the efficacy of these medications in occupational rhinitis are available at present. The choice of agent is often based on trial and error according to efficacy and frequency of side effects. Sedating antihistamines affect work productivity adversely and second-generation antihistamines are preferred. Patients may use them regularly when they

have chronic symptoms or periodically before an expected exposure to an allergen.¹

Immunotherapy

Studies have reported some improvement in symptoms during immunotherapy with purified rodent proteins, wheat flour extracts, and natural rubber latex.³¹ Fear of severe reactions with continued exposure to the offending antigen at the same time of the administration of immunotherapy have precluded its use.¹ Furthermore, many of the offending antigens are not available for treatment. However, where alternative jobs are not a consideration, the risks of treatment should be balanced against the benefits.¹

FUTURE RESEARCH

- ▶ Epidemiological studies are required to detect incidence and prevalence in various populations.
- ▶ Longitudinal studies should be conducted to document the natural history of the condition.
- ▶ The impact of occupational rhinitis on the quality of life of affected workers needs to be studied.
- ▶ Characterization of the clinical features and pathophysiology of non-allergic occupational rhinitis.
- ▶ More studies of the role of atopy and smoking in the development of occupational rhinitis are needed.
- ▶ The agreed diagnostic test, nasal provocation, should be standardized and other tests such as exhaled nitric oxide measurements should be further investigated.
- ▶ Randomized controlled trials should be designed to identify the best possible therapy.

KEY POINTS

- The prevalence of occupational rhinitis in the general population is still unknown.
- Occupational rhinitis is either allergic or irritant.
- Occupational rhinitis frequently coexists with asthma and conjunctivitis.
- Exposure, atopy and smoking are risk factors.
- History of work-related symptoms with improvement in weekends and holidays is typical.
- Nasal provocation is the main diagnostic test.
- Prevention is the best approach.
- Medical therapy is similar to that for other types of rhinitis.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: rhinosinusitis, rhinitis, sinusitis, classification and differential diagnosis and by reference to the European position paper on rhinosinusitis and nasal polyps.

RHINOSINUSITIS AND RHINITIS DEFINITIONS

The European position paper on rhinosinusitis and nasal polyps (EPOS) has now defined rhinosinusitis as a diagnosis made on clinical grounds based on the presence of characteristic symptoms, combined with objective evidence of mucosal inflammation (**Table 94.1**).¹

This has been widely accepted internationally, although alternative classifications and guidelines have been produced, such as by the American Academy of Otorhinolaryngologists/Head & Neck Surgeons (AAOHNHF) Rhinosinusitis Task Force Committee.² The most recent international guidelines have supported the EPOS definition, confirming the need for objective evidence to confirm the symptom profile (ICORS).³ The defining symptoms and signs listed in the EPOS 2012 document apply to both adults and children and can be further qualified in terms of severity by use of a visual analogue score for the question ‘how troublesome are your symptoms of rhinosinusitis?’ (**Table 94.2**). In practice, the severity is often defined by individual responses on Patient Reported Outcome Measures (PROMs) such as the SNOT-22 with recent consensus statements considering minimum scores for surgical candidates.⁴

Rhinosinusitis can then be further defined as acute or chronic based on duration of symptoms: acute being less than 12 weeks duration and chronic being greater.^{1,5} Within acute rhinosinusitis (ARS), further distinctions can be made on a timeline basis such that a common cold

TABLE 94.1 Clinical definition of rhinosinusitis

Diagnostic criteria for rhinosinusitis	Symptoms should be correlated by either endoscopic and/or radiological findings
Primary symptoms (requires at least one to be present, but if both present it is sufficient to make diagnosis on the basis of symptoms)	Nasal blockage/obstruction/congestion Nasal discharge (anterior/posterior)
Additional symptoms (may also be present and at least one is needed if only one of the primary symptoms is present)	Facial pain/pressure Olfactory dysfunction Hyposmia/anosmia
Duration	>10 days, <3 months = acute >3 months = chronic
Endoscopy (<i>any of these</i>)	Nasal polyps Mucopurulent discharge (middle meatus) Oedema/mucosal obstruction in middle meatus
CT scan findings (<i>as well as or instead of endoscopic findings</i>)	Mucosal changes within the ostiomeatal complex and/or sinuses

TABLE 92.2 Visual Analogue Scores (VAS) for rhinosinusitis symptoms

Severity	VAS scale (10 cm line)
Mild	0/1
Moderate	4/0d
Severe	8/eve

BOX 94.1 Additional symptoms or signs for acute bacterial rhinosinusitis¹**At least three of the following should be present:**

- Discoloured discharge (unilateral predominance)
- Severe local pain (unilateral predominance)
- Fever (>38°C)
- Elevated ESR/CRP
- 'Double-sickening' – deterioration after initial milder phase of illness

(acute viral rhinosinusitis) will last for less than 10 days and acute post-viral rhinosinusitis will last between 100 days and 12 weeks in duration. ARS is considered to be bacterial (ABRS) if at least three of the symptoms in **Box 94.1** exist.¹

For a diagnosis of recurrent acute rhinosinusitis, there must be symptom-free episodes between the clinical events. Chronic rhinosinusitis (CRS) is phenotypically divided into those cases with polyps (CRSwNPs) and those without (CRSsNPs) based on endoscopic findings. This division has also been broadly based up the pathophysiological themes within these two main subgroups which is discussed further below. Allergic fungal rhinosinusitis (AFRS)^{6–8} is a smaller subgroup, believed to represent 10% of those with CRSwNPs, and is discussed in **Chapter 96**. A proportion of patients with CRSwNPs also fall into a unique subset, characterized by coexistent asthma and aspirin sensitivity known as Samter's triad or aspirin exacerbated respiratory disease (AERD).⁸ AERD is believed to account for approximately 15% of CRSwNPs, classically manifest by severe nasal and/or respiratory symptoms following ingestion of salicylates, and there may be considerable overlap with AFRS-like cases.⁹

Finally, in all cases of CRS, some patients may experience acute exacerbations with worsening of symptoms for short periods, which may be triggered by viral URTIs.

Despite all the above definitions, there remain areas of uncertainty as not all patients adhere to the diagnostic symptoms and in primary care settings, diagnosis is often based on symptoms alone as the equipment to perform suitable nasal examinations is lacking. Rhinosinusitis should be distinguishable from rhinitis but inevitably there will be overlap. Rhinitis can broadly be categorized into allergic

and non-allergic types, with the former now defined as persistent or intermittent according to the WHO committee Allergic Rhinitis In Asthma (ARIA) (**Figure 94.1**).^{10, 11} Rhinitis is defined as the presence of at least two of the following: nasal blockage, rhinorrhoea (clear), sneezing or itching. Other varieties of rhinitis is discussed further in **Chapters 91–93**. Clinicians need to also be mindful that systemic diseases can manifest themselves in the nose, as is discussed further below.

EPIDEMIOLOGY AND SOCIOECONOMIC IMPACT

ARS is a very common condition and based on the current literature, prevalence rates vary from 6 to 15% with a prevalence of recurrent ARS estimated at 0.035%.¹ In a 3-year case-control study of the Dutch population, van Gageldonk-Lafeber estimated that annually, 900 000 individual patients consulted their primary care physician for acute respiratory tract infection.¹² This high volume of patients then receives a variable response from medical practitioners in terms of treatment.^{13–15} Given that the proportion of bacterial causes amongst all ARS is believed to be as little as 0.5–2.0%,¹⁶ this results in over-prescribing of antibiotics as found by a Danish study, where diagnostic certainty was found to be 70% based on symptoms and limited examination and where penicillin V was the preferred agent of choice.¹⁷ German healthcare data over 1 year showed that 6.3 million separate diagnoses of ARS were made and in conjunction with this 8.5 million prescriptions were provided.¹⁸

CRS represents a significant disease burden worldwide, affecting at least 11% of the population¹⁹ and consequently carrying with it a substantial economic burden to healthcare systems, to patients and to the economy from loss of productivity in the workplace.^{18, 19} In fact 'sinusitis' was cited as one of the top ten most costly physical health conditions to American businesses in 1999,²⁰ as it has an increasing incidence in middle age with a significant socio-economic impact and impairment of quality of life.^{21, 22} As a disease entity in the UK its prevalence is greater than ischaemic heart disease (3.7%), diabetes (4%), chronic obstructive pulmonary disease (1.5%), heart failure (<1%) and stroke (<1%) and equivalent to that of peripheral vascular disease, arthritis and back pain, several of which have been shown to have a lesser impact on patients' quality of life than CRS.²³ Patients with CRS also have a 5–17% prevalence of asthma as shown by a recent European study. This figure is higher in secondary care cohorts.^{22, 25}

In the EPOS 2012 document stated: 'The overview of the currently available literature illustrates the paucity of accurate information on the epidemiology of CRSsNPs and CRSwNPs, especially in European countries, and highlights the need for large-scale epidemiologic research exploring their prevalence and incidence.'¹ A recent UK study has shown that CRS affects the social spectrum equally and that poor socioeconomic status does not

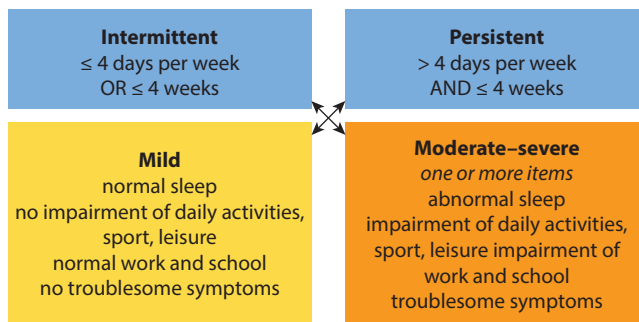

Figure 94.1 ARIA classification.⁹

appear to be a risk factor for CRS,²² but there remains a need for larger scale studies that may also examine the natural history of the disease.

There are about 2.7 million outpatient consultations for ENT disorders per year in England and Wales and sinonasal disease is thought to account for at least 120,000 visits per year.²⁶ Failure of medical treatment usually leads to an operation being offered with over 40,000 nose and sinus operations performed per year in England and Wales;²⁶ based on current tariffs this is an estimated £30 million spent each year. Furthermore, in patients who undergo surgery, the UK Sinonasal audit revealed a surgical revision rate of up to 20% within 5 years²⁷ and also a ten to fifteen fold variation in surgical practice around the UK;²⁸ the cost of this revision surgery is estimated at £15 million per year.²⁵

There are no published estimates of cost of healthcare and productivity losses for patients with CRS in the UK. Previous findings from the USA estimate that patients with CRS spend more than \$500 each year on healthcare and miss an average of 5.67 workdays per year versus 3.74 days per year for patients without CRS,²⁹ suggesting a significant disease burden on both the healthcare system and on individuals that is equal to or exceeds that for diseases that are thought to be more serious. An earlier study found that the overall yearly economic cost was \$1500 per patient³⁰ and that estimated healthcare expenditures attributable to CRS and common comorbidities were close to \$5.78 billion in 1996 excluding out-of-pocket expenditures or time off work for patients. Bringing this up to date, yearly estimated costs for CRS in the USA now exceed \$60 billion.^{31, 32} Another USA study concluded that the direct costs associated with CRS are higher than the background costs due to increased clinic visits and prescriptions, as well as significant productivity losses.³³ Surgical treatment for CRS certainly appears to influence drug costs,^{34, 35} but this may depend on the level of intervention. There is also increasing evidence that earlier surgical intervention may reduce the prevalence of late onset asthma.³⁶

DIAGNOSTIC AIDS

As stated above, EPOS 2012 has included the need for endoscopic or radiological findings to confirm the evidence from a patient's history and the flow diagrams within the EPOS document can be used to guide clinicians as to when to implement the latter. Thus rigid nasal endoscopy and CT scanning of the sinuses are at the present time the gold standard investigations for CRS. Endoscopy allows the clinician to assess the nose for the presence of polyps, mucopus discharge or middle meatal oedema. Furthermore the endoscope can be used to accurately sample any mucopus for microbiological analysis.³⁷ In cases of suspected allergic or eosinophilic fungal/mucinous rhinosinusitis, a fungal smear and culture should be requested, although diagnostic yield from such samples can be hugely variable depending on local laboratory resources and techniques.³³ CT scanning should be considered mandatory for all cases where surgical intervention is planned.²⁸

There are a number of adjuncts beyond endoscopy, radiology and microbiology that may aid diagnosis or perhaps the differential diagnosis, although they may also give more specific information about the aetiology or presence of concurrent disease and predict response to treatment.

These include:³⁸

- Allergy testing – skin prick testing or RAST
- Nasal brushings for cytology
- Nasal biopsy for exclusion of neoplasia, to look for granulomas/vasculitides or to examine for evidence of eosinophilia and fungal hyphae
- Blood tests – full blood count (serum eosinophilia), ANCA (Wegener's granulomatosis), ACE (sarcoidosis)
- Olfactory testing:
 - Psychophysical (threshold (quantitative) and discrimination/identification (qualitative))
 - Olfactory event-related potentials (OERPs) (objective)
- Physiological testing
 - Peak inspiratory nasal flow
 - Rhinomanometry
 - Acoustic rhinometry
 - Mucociliary clearance (saccharin test)
- Ciliary function testing
 - Ciliary beat frequency
 - Ciliary beat pattern analysis
 - Electron microscopy
- Patient reported outcome measures/symptom scores – these include the Sinonasal Outcome Text (SNOT),³⁹ Rhinosinusitis Outcome Measure (RSOM-31),⁴⁰ Chronic Sinusitis Survey (CSS),⁴¹ and other validated questionnaires.

ACUTE RHINOSINUSITIS

ARS is a very common condition that is predominantly managed in primary care and hence rarely seen by hospital specialists unless complications occur. As stated above, the primary cause of ARS is viruses³⁴ and only 0.5–2.0% of patients are believed to develop ABRS. Current EPOS guidelines for primary care therefore suggest the use of symptomatic relief, nasal douching and decongestants with consideration given to the use of topical steroids depending on severity. Cases with the features listed in **Box 94.1** or where duration has been greater than 10 days are more likely to benefit from antibiotics. Predisposing factors to ARS include anatomical factors (e.g. Haller/intra-orbital ethmoid cells, conchae bullosa), allergy, smoking and poor mental health. Whilst there is evidence in some of these factors to support the contrary, both anatomical and allergy factors have a reasonable weight of evidence in the literature.¹

The viruses most commonly implicated in ARS include rhinoviruses (50%), influenza and parainfluenza viruses, adenovirus, respiratory syncytial virus and enterovirus.⁴² If bacteria do become implicated the organisms most commonly seen are *S. pneumoniae* (27%), *H. influenzae* (44%), *M. catarrhalis* (14%) with other organisms sometimes seen including *S. pyogenes* and *S. aureus*. The proportion of

these organisms has changed in recent years with vaccination schemes.⁴³ Pathophysiological mechanisms relating to viral agents include cell invasion of the respiratory epithelium leading to inflammatory changes including mechanical changes, epithelial damage and activation of humoral and cellular defences. In bacterial cases, this is largely a superinfection following an initial viral insult where epithelial disruption has already occurred and there has been an associated decrease in ciliated cells and increase in goblet cells which eventually cause sinus ostial obstruction. The accumulating mucus causes an initial increase in the intra-sinus pressure followed quickly by negative pressure due to the lack of ventilation. This then sets up a vicious cycle of further congestion, mucus retention, impaired gas exchange and pH balance and largely prevents clearance of inflammatory products and debris leading to an ideal medium for bacteria to flourish.

TABLE 94.3 Complications of ABRS

Orbital	Intra-cranial	Osseous
Pre-septal cellulitis	Subdural empyema	Pott's puffy tumour (subperiosteal abscess of frontal sinus)
Orbital cellulitis	Meningitis/encephalitis	Maxillary osteomyelitis (in infancy)
Subperiosteal abscess	Intra-cerebral abscess	
Orbital abscess	Epidural abscess	
	Superior sagittal sinus thrombosis	
Cavernous sinus thrombosis		

Most cases will be self-limiting with complications of ARS exceedingly rare; an estimated 2–4 cases per million of the population per year. This was perhaps thought to be due to the high rate of antibiotic use but there is evidence to suggest that in cases where complications have occurred, this has not been prevented by prior use of oral antibiotics.⁴⁴ Complications of ARS can be subdivided into orbital (60–75%), intra-cranial (15–20%) and osseous (5–10%) (Table 94.3). In orbital cellulitis, 90% are secondary to ABRS. A national survey in the UK found 78 cases of complications relating to ABRS over a 1-year period.⁴⁴ A review of the literature on complications shows that the mortality rate varies between 2 and 19%.

CHRONIC RHINOSINUSITIS

Please refer to Figure 94.2.

At the present time CRS is largely subcategorized into cases with polyps (CRSwNPs) and cases without polyps (CRSsNPs). The clinical definition has been outlined above but relates to a heterogeneous group of patients that fall loosely within one of these two subgroups.¹ The reason for this coarse subcategorization is the apparent themes within the pathophysiology of these two groups. CRSwNPs is characterized by an intense oedematous stroma in the sinonasal epithelium, with albumin deposition, pseudocyst formation and subepithelial/perivascular inflammatory cell infiltration. It appears to be associated with a typical T-helper 2 cell (TH₂) skewed eosinophilic inflammation, with high interleukin (IL-5) and eosinophil cationic protein (ECP) concentrations in the polyps. By comparison, CRSsNPs is characterized by fibrosis, basement membrane thickening, goblet cell hyperplasia, subepithelial oedema,

Figure 94.2 Aetiological mechanisms proposed for CRS.

and mononuclear cell infiltration. It exhibits a T-helper 1 cell (TH₁) milieu, with increased levels of interferon gamma (IFN- γ) in inflamed sinus mucosa and low ECP/myeloperoxidase ratios.⁴⁵ This basic division into the two subgroups does however represent a gross oversimplification of a heterogeneous disease. These categories can therefore be further divided as discussed below (Tables 94.4 and 94.7). The various aetiological mechanisms that have been proposed for CRS are summarized in Figure 94.2.

Polypoidal chronic rhinosinusitis

It is important that ‘nasal polyposis’ is not considered a diagnosis, merely a description of a pathological endpoint of sinonasal disease, hence why the term chronic rhinosinusitis with nasal polyposis is used to denote the most common manifestation of polyps; other examples of nasal polyps will include antrochoanal polyps and reactive polyps such as may be seen around other inflammatory focus such as a fungal ball or inverted papilloma. The clinician finding nasal polyps inside the nose should always ask why they have formed, although the answer may not always be readily apparent. The classifications below provide a useful framework around which to base the potential aetiology of nasal polyps.

LOCALIZED NASAL POLYPOSIS (CRSWNPS – LOCALIZED)

Please refer to Figure 94.3. A unilateral nasal polyp should always be viewed with suspicion, especially in older patients and in anyone exposed to wood dust. It may represent a benign entity such as an antro-choanal polyp or be part of a tumour such as an inverted papilloma or sinonasal malignancy. A unilateral polyp may occur as a result of a prior inflammatory event, predisposing to sinus ostia obstruction, hypoxia and subsequent bacterial infection. Microbiology sampling in clinic should be performed if appropriate but computed tomography and biopsy of the polyp are indicated in order to decide on the medical and surgical treatment strategy to pursue. Caution should be advised with performing a biopsy of

any polyp that arises superiorly within the nose, or from the back of the nose in a juvenile male patient.

DIFFUSE NASAL POLYPOSIS (CRSwNP – DIFFUSE)

A number of recognized mechanisms appear to have a role in polyp formation, although this is by no means fully understood and there may well be crossover between them. These include bacterial (super-antigen response), fungal sensitization, and atopy. These may be associated with biofilm formation or frank eosinophilia, both exacerbating and propagating the inflammatory process. When severe bilateral nasal polyposis is present with aspirin sensitivity and asthma, the possibility of AERD and hence salicylate desensitization therapy should be considered. CT scanning will further elucidate a pansinus opacification typical of AFRS/AERD (Figure 94.4), (double density signs) or show less marked disease consistent with atopy and superantigen cases. In cases of suspected AFRS/AERD, thick granular

Figure 94.3 (a) Radiological and (b) endoscopic appearance of an antro-choanal polyp.

TABLE 94.4 Classification for the finding of nasal polyps

Polypoid CRS		
Localized	Reactive polyp(s)	Inflammatory
		Neoplastic
Diffuse (CRSwNPs)	Host	Anatomical e.g. poor OMC function, aspirin sensitivity (AERD)
		Atopy
	External agent	Staphylococcus superantigen
	Combined host/external agent interaction	Allergic fungal rhinosinusitis and its related derivatives
Systemic	Cystic fibrosis, Churg/EMRSexternal	

Figure 94.4 Pan-sinus opacification consistent with AFRS and AERD cases.

(eosinophilic) mucin will usually be found at initial presentation, during surgery or sometimes in the post-operative period. Less viscous mucus will perhaps suggest bacterial superantigen aetiology.

Bacterial superantigens, fungal antigens and allergic allergens have all been suggested as mechanisms driving T-cell activation, IgE and IL5 production resulting in subsequent tissue eosinophilia. Lack of consistency in studies suggests that each of these pathogens cannot be solely responsible, and the pathogenesis is likely to represent a multifactorial interaction. Also Asian studies have identified a predominantly TH₁ cell and TH₁₇ pattern within polyp tissue⁴⁶ and in cystic fibrosis, patients exhibit a neutrophilia.⁴⁵ These observations highlight the apparently heterogenous nature of biochemical pathways that ultimately result in the clinical phenotype of CRSwNPs.

Furthermore some cases show polyps confined to the OMC on CT scanning indicating poor OMC function perhaps with narrowing features such as Haller cells. All cases should have appropriate mucus samples sent for routine and/or fungal cultures with fungal smears in the latter case. Both gram positive and negative bacteria have been cultured from the nasal cavity of CRSwNPs patients, the latter of which are rarely cultured from healthy subjects.⁴⁷⁻⁴⁹ However, it is uncertain as to whether identification of a specific bacterium represents infection, or simply colonization. Data on biofilms in CRSwNPs is lacking but some recent evidence suggests up to 75% of cases may elicit biofilm,⁵⁰ clearly further evidence is needed to confirm this.

The super-antigen hypothesis proposes that non-invasive *S. aureus* in the nasal mucosa of CRS patients secretes exotoxins, which produce a localized eosinophilic inflammatory response as studies have shown exotoxin, specific super-antigen IgE, eosinophils and markers of eosinophilic inflammation are higher in cases of CRSwNPs compared to CRSsNPs.^{51, 52} To counter this hypothesis is the evidence that there are differing levels of *S. aureus*

Figure 94.5 CRSwNPs with marked osteitis.

(65%), superantigen-specific IgE (50%) and T-cell changes (33%)^{53, 54} suggesting that the superantigens may have a role in some cases of CRSwNPs patients, but not all. Tissue eosinophilia can be a useful marker of severity and may help predict severity in these patients.⁵⁵

Much of the evidence around fungal hypotheses is muddied by the difficulties in proving fungal organisms are present and with studies that do not carefully select cases more likely to represent fungal aetiology leading to the conclusion that fungi are mere bystanders and antifungals do not work.⁵⁶ Studies have demonstrated a high frequency of both fungi and eosinophilic mucin in CRS patients compared to control subjects suggesting a unique, T-cell driven hypersensitivity to fungi, independent of IgE mediated/atopic pathways.⁵⁷ This is supported with evidence that peripheral blood mononuclear cells and eosinophils of CRS patients react to *Alternaria* fungal extracts, in contrast to controls.⁴⁷ However a T-cell receptor mediated hypersensitivity response to fungal antigen has yet to be definitively elucidated and it is possible that a non-specific protease-based reaction to *Alternaria* is occurring.

The role and significance of osteitis in CRS is currently unclear, although may explain why some cases are resistant to standard oral treatment regimens. In CRSwNPs, osteitis may act as a marker of severity and has been shown to occur significantly more often in revision cases^{58, 59} (Figure 94.5).

NASAL POLYPOSIS SECONDARY TO SYSTEMIC DISEASE

Two main systemic conditions should be considered in the presence of diffuse nasal polyposis: Churg-Strauss Syndrome (CSS) and cystic fibrosis (CF). Up to 76% of CSS cases demonstrate nasal polyps and ANCA positivity should alert the clinician to the underlying vasculitis characterized by necrotizing inflammation of the vessel wall, particularly of small arteries, arterioles, capillaries and venules.⁶⁰ Although newborn screening for CF will pick up most cases, any doubt in a child presenting with diffuse nasal polyposis in conjunction with total opacification of the sinuses as well as hypoplastic

sinuses (typically frontal and sphenoid), should be followed up with a sweat test. Nasal endoscopy demonstrates polyp formation in up to 45% of adults with cystic fibrosis (CF), although most will show radiological evidence of disease.⁶¹ Polyps from children with CF have a significantly lower eosinophil count than patients with 'typical' adult onset CRSwNPs.⁶² However, there have also been studies to demonstrate significant overlap in eosinophil concentrations between groups.⁶³ Absent mucociliary clearance exhibited in primary ciliary dyskinesia results in recurrent bacterial infections and CRSwNPs in approximately 40% of patients.⁶⁴

NON-POLYPOIDAL CHRONIC RHINOSINUSITIS (CRSsNPs)

It is worth noting here that some cases of CRSsNPs may be classified as CRSwNPs due to polypoid change around obstructed sinus ostia, rather than representing more diffuse polyps seen in other cases of CRSwNPs. Careful consideration of the relevant treatment paradigms should therefore be given in conjunction with relevant radiological findings. However, it is also likely, given the insidious nature of CRS, that some cases appear as CRSsNPs at first presentation but eventually develop nasal polyposis.

Localized CRSsNP (isolated sinus disease and odontogenic disease)

Anatomical variation may predispose a patient to isolated inflammation in only one of the sinuses (Figure 94.6) as a post-obstructive phenomenon.

Infundibular opacification has been shown to be associated with maxillary sinus disease in approximately three-quarters of cases in a series of 100 prospectively evaluated CT scans,⁶⁵ suggesting that anatomic variants such as infra-orbital ethmoid cells, concha bullosa, and narrow nasal cavity secondary to deviated nasal septum correlated with mucosal thickening, particularly in the maxillary sinus (Figure 94.7).

Figure 94.6 Localized CRSsNPs.

Preceding events may include an allergic or viral exacerbation, leading to obstruction of the sinus ostia, with secondary bacterial infection. Depending on the attachment of the uncinate process, some cases may also involve the frontal and anterior ethmoid sinuses on that same side and endoscopy typically reveals a bulging uncinate process where the infection appears to be 'walled-off' in the anterior sinuses. Microbiology sampling of mucopus should be performed in conjunction with surgical drainage and aeration as medical therapy typically fails but these patients tend not to need any sustained post-operative medical treatment. In approximately 10% of these cases the cause will be odontogenic.⁶⁶ Therefore, all unilateral cases should include an oral examination and a careful review of the maxillary sinus floor on the CT scan to look for signs of an oro-antral fistula.⁶⁷ Involvement of oral maxillofacial colleagues will be beneficial at an early stage where odontogenic aetiology is suspected to enable optimization of management.⁶⁸

DIFFUSE NON-POLYPOIDAL CRSsNP

CRSsNPs is histologically characterized by fibrosis, goblet cell hyperplasia, basement membrane thickening, subepithelial oedema and mononuclear cell infiltration (Figure 94.8).

It accounts for about 45% of the cases seen in secondary care²² but presents a lower surgical burden than CRSwNPs.^{25, 55} Remodelling is a dynamic process in both health and disease that balances extra-cellular matrix (ECM) production and degradation, which is regulated by diverse mediators among which TGF- β takes a central role. Indeed, the up-regulation of the TGF- β signalling pathway in patients with CRSsNP and its down-regulation in patients with CRSwNPs on the protein level are reflected by oedema formation and a lack of collagen production in patients with CRSwNPs and excessive collagen deposition associated with

Figure 94.7 Infundibular disease due to anatomical narrowing.

Figure 94.8 Coronal CT image demonstrating diffuse pansinusitis and mucosal thickening, indicative of severe CRSsNPs.

fibrosis in patients with CRSsNPs.⁵⁶ CRSsNPs is also distinct from CRSwNPs immunologically, characterized by a TH₁ milieu with increased levels of IFN- γ in the inflamed sinus mucosa and low ECP/myeloperoxidase ratios.

Much like CRSwNPs, bacterial colonization of the paranasal sinuses in CRSsNPs has a similarly uncertain significance.⁶⁹ While identifiable bacteria are comparable between the two subtypes,^{47–49, 69, 70} *S. aureus* colonization appears to be more statistically significant in patients with CRSwNPs (63.6%) compared to controls, which is not apparent in CRSsNPs patients (27.3%),⁵² however, the organism is identified as the most common pathogen in CRS patients as a whole, especially post-operatively.⁷¹ This former observation has thus largely rejected the superantigen hypothesis in CRSsNPs. Conversely, reports on biofilms are more abundant in CRSsNPs patients, with detection rates ranging from 28.6 to 100%.^{72–76} Multiple bacterial species have been identified, including *P. aeruginosa*, *S. aureus*, *S. pneumoniae*, *H. influenzae* and *M. catarrhalis*. Again, their overall relevance in the context of disease pathogenesis remains incompletely defined, but biofilms are thought to be at least partially responsible for a subset of recalcitrant CRSsNPs cases. The same can be said for the clinical significance of fungal pathogens isolated from CRSsNPs patients.

The significance of OMC obstruction in the context of CRSsNP is more clear-cut than the polypoidal variant. In the latter, OMC obstruction may be a ‘barometer’ of overall disease burden, in that increasing Lund-Mackay scoring is associated with OMC involvement overall.⁷⁷

SYSTEMIC CONDITIONS CAUSING RHINOSINUSITIS

The systemic conditions likely to manifest with nasal polyps have been discussed above in the section on CRSwNPs. This section will therefore focus on other systemic conditions that give rise to CRS or should perhaps be considered as a differential diagnosis for CRS.^{78,79} Granulomatous diseases

to consider include granulomatosis with polyangiitis (GPA) formerly known as Wegener’s Granulomatosis and sarcoidosis.⁸⁰ Clues to the diagnosis may be derived from blood tests including Anti-nuclear cytoplasmic antibody (ANCA) and angiotensin converting enzyme (ACE) which if elevated may need corroboration with tissue biopsy and other imaging. These conditions typically manifest with intranasal crusting and the former can be locally destructive with erosion of sinus lamellae and septal cartilage, the latter giving rise to a characteristic saddle-nose deformity. Ciliary dyskinesias represent another group of disorders that will manifest with rhinosinusitis.⁸¹ Primary ciliary dyskinesia is often associated with situs inversus and known in this circumstance as Kartagener’s syndrome. Patients often present in adolescence and may have a prior history of otitis media with effusion; they may also suffer with bronchiectasis.⁸² Ciliary dyskinesias will show delayed mucociliary clearance times and require investigation at specialist centres, of which there are three in the UK.⁸³ Clear rhinorrhoea, especially unilaterally, should always prompt investigation for a CSF leak, initiated by collecting nasal fluid to test for β -2 transferrin. Tumours will typically present with unilateral symptoms such as blockage or bleeding but inverted papillomas may sometimes be found amongst bilateral CRSwNPs, hence it is important to send material for histology during any surgery to remove polyps, especially the first time, if there is any index of suspicion. Tumours may also present when they cause secondary infection by sinus ostial occlusion.

Rhinosinusitis may also be a presenting or secondary feature of patients with immunodeficiencies (e.g. HIV⁸⁴) or who are immunocompromised by systemic treatment for other disorders (e.g. receiving immunosuppressive drugs for organ transplantation). In those cases, patients require endoscopic retrieval of mucopus where possible, as unusual organisms may be found.⁸⁵ Immunodeficiency should always be considered a possibility in patients who appear not to respond to standard medical and surgical care for CRS^{86, 87} and in cases of recurrent ARS. Common variable immune deficiency (CVID), selective IgA deficiency, IgG subclass deficiency, and specific antibody deficiency are all possible immunodeficiencies that can be detected in cases of CRS.⁸⁸ Refractory cases of CRS have been shown to have low IgG in 18%, low IgA in 17% and low IgM in 5%⁸⁹ with both IgA and IgG deficiencies postulated as potential contributory factors for patients failing medical therapy for CRS.⁹⁰ In children, where a higher index of suspicion accompanies the onset of CRS, IgG₃ subclass deficiency has been reported in association with the presence of nasal polyposis.⁹¹ Another study looking at 245 CRS patients failing prolonged antibiotic therapy found that about 8% had an IgG deficiency⁹² with IgG₃ deficiency being implicated as the most common Ig deficiency in the wider group of patients with CRS⁹³ and IgG₂ in cases of recurrent ARS.⁹⁴ Certainly there is a role for screening for immunodeficiency in CRS patients refractory to standard treatment.^{88, 95}

A list of differential diagnosis and key diagnostic features is found in [Table 94.5](#). This is by no means exhaustive but does provide a guide to other conditions that should be considered.

TABLE 94.5 Systemic conditions causing rhinosinusitis or possible differential diagnosis

Congenital	Cystic fibrosis	Abnormal sweat test CFTR gene mutation on chromosome 7
	Primary ciliary dyskinesia	Abnormal mucociliary clearance and cilia ultrastructure
	Primary immunodeficiencies (CVID, SCID, hypo/dys-gammaglobulinaemias)	Low/absent antibodies
Infectious/inflammatory	HIV	Positive ELISA for HIV
	Sarcoidosis	Elevated ACE CXR signs (hilar lymphadenopathy)
	Tuberculosis	Acid-fast bacilli Mantoux test positive
	Granulomatosis with polyangiitis (Wegener's)	cANCA positive Leukocytoclastic vasculitis on biopsy
	Eosinophilic granulomatosis with polyangiitis (Churg-Strauss Syndrome)	pANCA positive
Neoplastic	Haematological malignancies	Abnormal FBC/bone marrow
	Sinonasal malignancies	Biopsy positive Radiological changes
Iatrogenic	Atrophic rhinitis	Excessive crusting following radical nasal surgery
	Chemotherapy/immunosuppression	Relevant drug history
Metabolic	Malnutrition	Low BMI

FUTURE RESEARCH

- ▶ The EPOS paper¹ and more recently the European Forum for Research and Education in Allergy and Airway Disease (EUFOREA)⁹⁶ have carefully detailed where future research efforts need to be directed and hence the tables below summarize this.
- ▶ There is clearly much work to be done, above all, in understanding the complexities of this heterogeneous disease and perhaps in the future separating patients out into distinct groups based on cytokine profiling, allowing personalized medical treatment for individual patients.⁹⁷
- ▶ Through the characterization of CRS phenotype subsets, well-defined endotype groups should become distinguishable.
- ▶ Continual identification of specific disease subgroups, genetic changes and biomarkers as directed by good epidemiological studies will be valuable undertakings for future research, particularly in the context of implementing novel treatment strategies and the overall prognosis of the condition.

BOX 94.2 EPOS 2012 Aetiological Research Priorities**Future research should consider the role of:**

- Socioeconomic status
- Severity staging with respect to QoL
- Prognostic symptoms in primary care
- Endotyping and phenotyping – including how to assess this and the impact upon management and outcomes
- Osteitis (long-term study and RCT of treatment options)
- Purulence in assessing response to treatment
- Childhood events, smoking and AR as risk factors
- Psychological, neurological, GORD risk factors
- Genetic profiling on susceptibility to disease and therapeutic response
- CRSsNPs pathophysiology

Future research should further investigate:

- Olfactory disorders, headache, facial pain
- The development of new classifications based on endotypes and phenotypes
- Better understanding of inflammatory pathways including TGF- β , T-cells, dendritic cells, microbiomes and search for new and clinically applicable biomarkers
- The pathogenesis of 'allergic' fungal rhinosinusitis and AERD.
- Understanding of the link between CRSwNPs and lower airway disease.
- The natural history of CRS and epidemiology studies.

BOX 94.3 EPOS¹ and EUFOREA⁹⁶ research priorities for CRS management

- Improve professional education and efficient dissemination of evidence-based guidelines to optimize outcomes and reduce referral rates to secondary care.
- Conduct a large prospective placebo controlled study of long-term antibiotic treatment in a well-defined CRS population, exploring effects on the patient's quality of life, immune system, microbiota of the airway as well as the health economic impact.
- Seek better local therapies for immunomodulation.
- Conduct an RCT on oral steroids versus surgery on the long-term outcomes of CRSwNPs.
- Conduct an RCT studying the effects of oral corticosteroids on olfactory function in CRSwNP.
- Conduct multicentre RCTs on surgery versus no treatment for patients with CRSwNPs to establish the natural course of disease.
- Conduct RCTs on minimal versus more extensive endoscopic sinus surgery.
- Investigate the effect of early surgical intervention on CRSwNPs to see if it alters the course of the disease.
- Better tools for the diagnosis and differential diagnosis of facial pain in assessment of rhinosinusitis symptoms and examination in CRS.
- To establish whether treatment of CRS affects outcomes of comorbid lower airways disease (eg asthma, COPD)
- To undertake further RCTs studying the effects of surgery and medical treatment on the lower airways (lung function/QoL/symptoms) in CRSwNP and concomitant asthma.
- Demonstrate whether the relative frequency of different symptoms and signs in CRSwNPs and CRSsNPs predict a differential response to different therapies.
- Cost effectiveness of biological treatment versus surgery.
- Socioeconomic impact of implementation of phenotyping and endotyping into care pathways.

KEY POINTS

- Rhinosinusitis is a common disease with CRS affecting an estimated 10% of the population worldwide.
- Most ARS is not bacterial and requires symptomatic relief only.
- CRS is a heterogeneous disease with differing phenotypes and endotypes; the latter have yet to be clearly determined.
- CRS presents a significant burden on healthcare resources but guidelines exist for its medical and surgical management.
- Where other clues are present, consideration must be given to other systemic causes for sinonasal disease.
- Due to the relative paucity of evidence, more clinical trials are needed to determine the most effective treatment strategies for the various forms of CRS.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: nasal polyps, chronic rhinosinusitis with nasal polyps, cystic fibrosis, asthma, aspirin exacerbated respiratory disease, eosinophilic granulomatosis with polyangiitis, Young's syndrome, intranasal corticosteroids, systemic corticosteroids and endoscopic sinus surgery.

INTRODUCTION

Nasal polyps represent the end stage local manifestation of chronic inflammatory disease of the sinonasal tract. The condition is a distinct subgroup of chronic rhinosinusitis, chronic rhinosinusitis with polyps (CRSwNP). Despite the prevalence of polyps, the long history of recognition and extensive research and literature, their aetiology remains elusive and poorly understood. In the last few decades numerous studies have tried to determine the exact pathogenesis of this disease and although many have shown factors thought to be related and associated, none have come to a definitive conclusion about causation. CRSwNP can significantly affect quality of life, and places significant financial burden on society, directly as a result of outpatient appointments, prescriptions, investigations and hospitalization, and indirectly as a result of missed work days and decreased productivity at work. Despite adequate treatment CRSwNP runs a chronic and recurrent course. Nasal polyps continue to be a challenge for rhinologists treating patients with this chronic disease and for those searching for a cause.

Definition

Nasal polyps are best thought of as 'chronic rhinosinusitis with nasal polyps' (CRSwNP), and European guidelines define these conditions clinically as:

- inflammation of the nose and paranasal sinuses associated with two or more symptoms, one of which should be nasal blockage/obstruction/congestion or nasal discharge:
 - +/- facial pain/pressure
 - reduction or loss of smell

and either

- endoscopic evidence of
 - polyps and/or
 - mucopurulent discharge from the middle meatus or oedema, mucosal obstruction primarily in the middle meatus

and/or

- CT changes:
 - mucosal changes within the osteomeatal complex and/or sinuses¹

Morphologically nasal polyps are oedematous grape-like protrusions most often originating in the upper part of the nose around the osteomeatal complex on the lateral wall. The surface epithelium tends to be smooth and consists of pale translucent tissue which distinguishes them from the more vascular mucosa of the nasal cavity. Polyps can vary widely in size and should be considered a bilateral condition. Rare cases of unilateral polyps should only be diagnosed once all other more likely pathologies have been reliably excluded.

INCIDENCE AND PREVALANCE

The annual incidence of CRSwNP is between 1 and 20 per 1000 population.² This incidence declines after 60 years of age. In the normal population the prevalence is between 1 and 4% in adults and 0.1% in children. Nasal polyps are more common in males (2–4:1). There is no racial predilection. Certain systemic diseases, as mentioned below, carry a much higher incidence of nasal polyps.

CLINICAL PRESENTATION

Clinical presentation is variable and depends on the extent of polyp disease. Small polyps may not produce symptoms and may be identified incidentally during rhinoscopic examination, whilst larger polyps may cause significant symptoms. In general, patients with nasal polyps will present with various symptoms that have generally persisted over months to years, progressing from mild nasal congestion with a watery rhinorrhoea to a persistent nasal obstruction associated with hyposmia or anosmia, as well as a thicker post nasal discharge and very occasionally headaches. Epistaxis is not associated with benign polyps and may suggest a more serious pathology in the nasal cavities. Massive polyps or a single large polyp that obstructs the nasal cavities or nasopharynx can cause chronic mouth breathing and obstructive sleep symptoms. Rarely, proptosis, hypertelorism and diplopia can result from alterations in the craniofacial structure. Generally, because of their

slow-growing nature, massive polyposis does not cause neurological symptoms or pain, even if they extend into the intracranial cavity (Figure 95.1).

PATHOGENESIS

Polyps arise in the presence of inflammation that may be initiated by a number of factors, resulting in dysregulated interaction between the sinus epithelium and the lymphoid system.³ Histologically, they consist of loose connective tissue, inflammatory cells and fluid, and are usually covered by pseudostratified, columnar, ciliated epithelium (Figure 95.2). Polyps form when oedematous connective tissue stroma ruptures and herniates through the basement membrane.⁴

Despite a growing body of evidence that bacteria, fungi, allergens, and superantigens play a prominent role in the pathophysiology of nasal polyps the exact cause remains unknown.

In the last decade, research has revealed unique cytokine and cellular inflammatory profiles that may contribute

Figure 95.1 Coronal CT image showing complete opacification of sinuses secondary to nasal polyps.

Figure 95.2 Photomicrographs of a simple inflammatory nasal polyp (magnifications of X250 and X400).

to nasal polyps. Approximately 80% of nasal polyps in Western countries are characterized by a robust T-helper 2 response, eosinophilic infiltration^{5,6} decreased T regulatory function,⁶ and an abundance of IL-5 cytokine.^{7,8}

Allergy

It is not yet completely clear whether there is an increased risk for the development of nasal polyps in allergic patients, and the evidence in the literature is conflicting. Only 0.4–4.5% of patients with allergic rhinitis have nasal polyps,^{9–11} which is similar to the normal population. However, nasal polyps have been shown in 25.6% of patients with allergy compared to 3.9% in a control population.¹² The prevalence of allergy in patients with nasal polyps has been shown to vary from 10%¹³ to 64%.¹⁴ Elevated levels of immunoglobulin E (IgE) and positive skin tests to inhalant allergens have been determined in the majority of patients with nasal polyps^{10,15} and association has been found between levels of both total and specific IgE and eosinophilic infiltration in nasal polyps. In patients with nasal polyps however the total serum IgE levels are only partially correlated to local tissue IgE levels and local eosinophilic inflammation.¹⁶ The highly increased local tissue IgE levels in nasal polyps are often polyclonal and independent of total serum IgE levels or allergy skin prick test responses¹⁷ and it has recently been demonstrated that mucosal polyclonal IgE is functional by inducing mast cell degranulation independent of serum IgE levels.¹⁸

Bacteria

A link between bacterial colonization and nasal polyps has been postulated, but remains unproven. Examination of microbial organisms in the nasal cavity has revealed the presence of a diverse flora, consisting mostly of aerobic and anaerobic bacteria. These include gram-negative organisms such as *Moraxella catarrhalis*, *Haemophilus influenzae*, *Prevotella* species, *Enterobacter* species, and *Pseudomonas* species.^{19,20} Gram-positive organisms include streptococci, coagulase-negative staphylococci, and *Staphylococcus aureus*.²¹ It is believed that the main species involved in the exacerbation of nasal polyps is *Staphylococcus aureus* which harbours genes coding for enterotoxins.^{16,22–25}

In one study, 42.5% of *Staphylococcus aureus* strains isolated from nasal polyp patients and controls harboured at least one classic enterotoxin gene.²⁶ The secreted toxins coded for by these genes behave as superantigens, which, unlike conventional antigens, do not need processing.^{23–28} Superantigens induce the activation of numerous T-cell clones and a massive secretion of cytokines, and therefore have the ability to activate as much as 20% of the body's T cells, compared with only 0.001–0.0001% for regular antigens.^{29,30} In CRSwNP this is characterized by an increased eosinophilic inflammation and formation of IgE antibodies.³¹ The formation of bacterial biofilms on the sinus mucosa has also been suggested to be responsible for chronic rhinosinusitis.^{32,33} Biofilms are bacteria enclosed within a self-developed matrix of polysaccharides which

renders the bacteria inaccessible to antimicrobial agents. Clinically, cases of nasal polyps with the presence of biofilms may be associated with a more severe form of the disease and worse postoperative outcome.^{34,35}

ASSOCIATED DISEASES

The prevalence of CRSwNP is around 7% in patients with asthma, compared to 4% of the general population,³⁶ and increases to 30–60% in patients with aspirin exacerbated respiratory disease (AERD).³⁷ Chronic inflammation and allergic fungal sinusitis have also been considered to be potential risk factors for nasal polyps, and the association between genetic variations and chronic rhinosinusitis suggests that genetic polymorphisms could be related to nasal polyps development.^{38,39}

Asthma

The link between the upper and lower airways has been reported since the beginning of 1800s, with both being lined by the same pseudostratified ciliated columnar epithelium. In patients with nasal polyps 30–71% have been shown to have asthma,^{10,40} and there is a direct association between asthma severity and the presence of nasal polyps.⁴¹ Of patients with late-onset asthma, 10–15% develop nasal polyps, with patients generally developing asthma first, then polyps within 9–13 years. This occurs faster in patients with aspirin-induced asthma, about 2 years from the onset of symptoms.⁴² Asthma and nasal polyps share the same basic features of eosinophilia, mucus cell hyperplasia, oedema, thickened basal membrane and increased pro-inflammatory mediators, for example cysteine leukotrienes.^{43–45}

The relationship between upper and lower airway pathology is further corroborated by the improvement in lower airway disease that is observed when nasal polyps are effectively treated.⁴⁶

Aspirin-exacerbated respiratory disease (AERD, *Samter's Triad*)

The combination of bronchial asthma, nasal polyposis and aspirin sensitivity is also well described in the otolaryngology literature. It was first described by Wimal in 1922 and then formally recognized as a triad of clinical manifestations by *Samter* et al. in 1967.⁴⁷ Its prevalence is reported to be as high as 0.3% in the general population and between 5 and 10% of the adult asthmatic population.⁴⁸ The prevalence of patients with nasal polyps, asthma and aspirin sensitivity increases over 40 years of age, and these patients are normally non-atopic. The currently accepted pathophysiology behind aspirin sensitivity syndrome lies in the inhibition of cycle-oxygenase in the arachidonic acid pathway. By blocking cycle-oxygenase, the arachidonic acid is shunted into lipoxygenase and there is an increased production of leukotrienes. The subsequent decreased prostaglandin E2 leads to mast cell instability with release of histamine. The combination of increased histamine

release and increased leukotriene causes increased vascular permeability, leakage from the vascular system and oedema. It is thought that this cycle of inflammation and oedema results in the formation of polyps.⁴⁹ The nasal polyps associated with AERD/*Samter's* Triad are often very extensive, with significantly higher radiological CT scores than non-AERD patients with nasal polyps.⁴⁸ They can be difficult to treat and have a higher rate of recurrence. One cohort study of 549 patients with nasal polyposis found the polyp-free rates at 5 years following FESS for failed medical treatment to be 84% for control patients, 55% for patients with asthma and 10% for patients with AERD. At 10 years these rates dropped to 78% and 45% for the control patients and the patients with asthma. 100% of those with AERD had already recurred.⁵⁰

Allergic fungal rhinosinusitis

Allergic fungal rhinosinusitis (AFRS) was first reported in 1976.⁵¹ It is a type 1 hypersensitivity reaction to fungal antigens in which patients usually present with unilateral or bilateral nasal polyps. Approximately 80% of patients with fungal sinusitis have nasal polyps.³⁶ Theories on pathogenesis include hypersensitivity and T-cell mediated reactions as well as a humoral immune response. Treatment is largely surgical, with a strong role for oral corticosteroids and an emerging role for immunotherapy. Antifungals, both systemic and topical, currently have a limited role in treatment, although this area needs further study.⁵² In 1994, Bent and Kuhn published their diagnostic criteria centred on the histologic, radiographic, and immunologic characteristics of the disease (**Table 95.1**).⁵³ Patients must meet all the major criteria for diagnosis, while the minor criteria serve to support the diagnosis and describe individual patients but are not used to make a diagnosis. The major criteria include a history of type I hypersensitivity by history, skin testing, or *in vitro* testing; nasal polyposis; characteristic computed tomography (CT) scan findings with soft tissue differential densities; the presence of eosinophilic mucin without fungal invasion into the sinus tissue; and a positive fungal stain of sinus contents removed at the time of surgery. The minor criteria include a history of asthma, unilateral predominance of disease, radiographic evidence of bone erosion, fungal cultures, presence of Charcot-Leyden crystals in surgical specimens, and serum eosinophilia. A wide variety of fungi have been isolated from the sinuses of patients with

chronic rhinosinusitis and as fungal detection techniques improve, so does the sensitivity to detect them, with some studies demonstrating fungal presence in almost 100% of patients, both controls and CRS patients.⁵⁴ Therefore the only features that appear to be unique to AFRS are type 1 hypersensitivity and the characteristic CT findings.

Cystic fibrosis

Cystic fibrosis (CF) is an autosomal recessive disorder caused by mutations of a gene on chromosome 7. The gene prevalence is approximately 1:25 in the Caucasian population and it currently affects 9000 people in the UK.⁵⁵ CF patients have thick, tenacious mucus secondary to a mutation in the CF transmembrane conductance regulator chloride channel that affects mucociliary transport.⁵⁶ Although the majority of CF patients do not report sino-nasal symptoms, CRS is prevalent,⁵⁷ with nasal polyps present in up to 86% of patients.⁵⁸ In CF CRS, inflammation is neutrophil driven with IL-8 being the primary cytokine.^{59, 60} Sinus cultures typically grow *Staphylococcus aureus* or *Pseudomonas aeruginosa*.^{61, 62} Examination of CF patients with nasal polyps usually reveals bilateral polyposis with thick rhinorrhoea and facial deformities such as hypertelorism.⁶³ In addition to nasal polyps, CT scan findings include hypoplasia of the frontal or sphenoid sinuses as well as demineralization and medial displacement of the uncinate process.^{59, 64–67}

Mucocele formation is not uncommon in CF, and therefore the presence of mucoceles in a child should raise suspicion for CF.^{68, 69}

Primary ciliary dyskinesia

Primary ciliary dyskinesia (PCD) is a rare autosomal recessive disease in which abnormal or absent beating of cilia hinders normal mucociliary clearance. The commonest presentations are in the upper and/or lower respiratory tracts, with mucus retention and recurrent infection leading to nasal polyposis and/or bronchiectasis.⁷⁰ Kartagener's syndrome is a clinical variant of PCD and is a triad of chronic sinusitis, bronchiectasis and situs inversus. Twenty-seven per cent of patients with Kartagener's syndrome have nasal polyps (**Figure 95.3**).³⁶

Young's syndrome

Young's syndrome is a rare disease consisting of three components: obstructive azoospermia, bronchiectasis and sinus disease. Although it is a recognized cause of male infertility and is well known in the field of infertility,⁷¹ the exact nature and natural history of the sinus disease component is not widely understood. The prevalence of Young's syndrome remains unknown. In the 1980s, the syndrome was reported to affect one in 500 males and was described as being more common than cystic fibrosis.⁷² However, in the last 20 years only a handful of case reports have been published on this syndrome.^{73–75} A reduction in the use of mercury in Europe and the USA has been cited as a potential reason for this decline. Mercury exposure in

TABLE 95.1 Bent and Kuhn Classification of Allergic fungal rhinosinusitis⁵³

Major	Minor
Type I Hypersensitivity	Asthma
Nasal polyposis	Unilateral disease

childhood is likely to be the only aetiological factor identifiable in Young's syndrome, with a history of mercury intoxication seen in 10% of Young's syndrome patients in one series.⁷⁶ Mercury inhibits enzymes containing sulphhydryl by reacting with thiols to form mercaptides. Mercaptides are thought to inhibit glycolysis, which is necessary for the normal function and energy supply of sperm and cilia.⁷⁷

EGPA (Churg Strauss)

Previously known as Churg Strauss syndrome, this entity has now been recognized by the 2012 revised nomenclature for vasculitides as eosinophilic granulomatosis with Polyangiitis (EGPA). It is a systemic small-vessel vasculitis associated with asthma and eosinophilia, and is traditionally described to evolve through a prodromic, allergic phase characterized by asthma and rhinosinusitis, an eosinophilic phase hallmarked by peripheral eosinophilia and organ involvement, and a vasculitic phase with clinical manifestations due to small-vessel vasculitis.⁷⁸ These phases partially overlap and may not appear in such a defined order, although asthma and rhinosinusitis only rarely arise after the vasculitic manifestations.⁷⁹ Criteria for classification from the American College of Rheumatology⁸⁰ consist of the following:

- asthma
- eosinophilia of >10% in peripheral blood
- paranasal sinusitis
- pulmonary infiltrates, sometimes transient

Figure 95.4 Chest radiograph showing pulmonary infiltrates.

- histologic evidence of vasculitis with extravascular eosinophils
- mononeuritis multiplex or polyneuropathy
- if ≥ 4 criteria are present, sensitivity is 85%, and specificity is 99.7%.

The typical case that should raise suspicion of EGPA is that of a patient with adult-onset asthma and a history of rhinosinusitis, who develops pronounced eosinophilia and lung infiltrates. Eosinophilia may occur in straightforward asthmatic patients but is usually mild (<10%); likewise, lung infiltrates due to bronchial plugging by mucus and superimposed infection may complicate asthma, but they are uncommon. Nasal polyps affect approximately 50% of patients with EGPA and consistently recur after surgery in patients not receiving immunosuppressive therapy (Figure 95.4).⁸¹

Genetics

Despite many previous attempts to explain disease pathogenesis, the exact genetic mechanisms underlying the development of nasal polyps remain unclear. Suggestion for a potential genetic basis to nasal polyps is afforded by degree of inheritability suggested from family and twin studies as well as the existence of chronic rhinosinusitis and nasal polyps in simple mendelian diseases. Associations between chronic rhinosinusitis and polymorphisms in over 30 genes have been published, however, studies of monozygotic twins have not shown both siblings to always develop polyps, indicating that environmental factors are also likely to play a role in the development of nasal polyps.⁸²⁻⁸⁵

DIAGNOSIS

Anterior rhinoscopy is the first step to diagnosis, but is inadequate alone and cannot exclude polyps. Rod Lens nasendoscopy after topical decongestant is needed for

diagnosis, as well as identifying discharge, crusting or scarring secondary to previous surgery. Plain sinus radiographs are insensitive^{86–88} and should not be used to diagnose polyps. CT scanning with coronal sections is the investigation of choice for assessing the extent of the disease and detailing the anatomy before surgery.^{89–91} Magnetic resonance imaging may be helpful to differentiate from tumour, or if intracranial extension of disease is suspected. History for features of systemic disease should be taken, including lower airway symptoms, and tests for factors associated with nasal polyps can be performed. The effects of treatment on nasal obstruction and polyp masses can be documented objectively via nasal inspiratory peak flow,⁹² rhinomanometry,⁹³ acoustic rhinometry,⁹⁴ olfactory tests and symptom scoring (Figure 95.5).⁹⁵

CLASSIFICATION

Endoscopic and CT-based staging systems are used to determine the extent of disease within the nose and sinuses, and facilitate both medical communication and evaluation of therapeutic responses. The clinical staging system and endoscopic scoring systems are based on the assumption that the polyp grows from the middle meatus down towards the floor of the nose (Table 95.2).^{96, 97} The radiological staging system includes all sinuses and the osteomeatal complex bilaterally. Various radiological staging systems have been described. The Lund–Mackay system gives a score of 0–2 depending on the absence, partial or complete opacification of each sinus system and of the osteomeatal complex on computed tomography scanning. A maximum score of 12 per side can be achieved (Table 95.3).⁹⁸ The Lund–Mackay score increases with increasing grade of polyposis.

Figure 95.5 Endoscopic view of a nasal polyp.

MANAGEMENT

Treatment aims to eliminate symptoms and nasal polyps, re-establish nasal breathing and olfaction, prevent recurrence and improve patients' quality of life. Treatment can be divided into medical and surgical.

Medical

All patients should have a trial of medical therapy first, unless histology is required. Medical treatment consists mainly of topical and systemic corticosteroids, which are thought to affect eosinophil function directly by reducing both eosinophil viability and activation,⁹⁹ and indirectly by reducing the secretion of haemotactic cytokines by nasal mucosa and polyp epithelial cells.¹⁰⁰ Intranasal corticosteroids (INCS) have been shown to be more effective than placebo at improving nasal airflow, reducing polyp size and decreasing rate of recurrence.¹ The effect on sense of smell is poor when compared to systemic steroids, which may be due to the sprays being unable to reach the olfactory mucosa because of oedema. Nasal drops are more effective than sprays and have a significant positive effect on sense of smell, however, they are relatively potent topical steroids, and may be used initially, although not for longer than 2 months at one time unless under specialist supervision, or for longer than 4 months in one

TABLE 95.2 Endoscopic staging of nasal polyps

Polyp	0 = absence of polyp 1 = polyps in middle meatus only 2 = beyond middle meatus
Oedema	0 = absent 1 = mild 2 = severe
Discharge	0 = no discharge 1 = clear, thin discharge 2 = thick, purulent discharge
Scarring	0 = absent 1 = mild 2 = severe
Crusting	0 = absent 1 = mild 2 = severe

TABLE 95.3 Radiological staging of CRS

Paranasal sinuses	Right	Left
Maxillary 0,1,2		
Anterior ethmoid 0,1,2		
Posterior ethmoid 0,1,2		
Sphenoid 0,1,2		
Osteomeatal complex 0*, 2*		
Total points to each side		

0 = no abnormalities, 1 = partial opacification, 2 = complete opacification

0* = not occluded, 2* = occluded

12-month period, as they can be absorbed systemically. Larger polyps may require systemic corticosteroids,¹⁰¹ for example prednisolone 0.5 mg/kg each morning for 5–10 days. Maintenance therapy with topical corticosteroid spray is recommended as these may have lower bioavailability than drops and are less likely to be administered incorrectly.

It is recommended that patients are started on sprays, drops or systemic steroids depending on their initial presentation and examination findings. On review, a decision can be made whether to continue with medical treatment, request further investigations or consider surgical intervention.¹ Antihistamines only help if allergy is present,¹⁰² and leukotriene inhibitors may help patients with coexisting asthma and/or aspirin sensitivity.^{103–105}

Common side effects of intranasal corticosteroids include local irritation and epistaxis. Potential adverse events related to the administration of intranasal corticosteroids are effects on growth, ocular effects, effects on bone and effects on the hypothalamic pituitary-adrenal axis. Cases of adrenal suppression and Cushing's syndrome from systemic absorption have been reported, but are rare.¹⁰⁶ Measurement of salivary cortisol is a useful, non-invasive and economical test for monitoring patients using intranasal corticosteroids.¹⁰⁷ There is evidence that a 3-month course of a macrolide antibiotic can help nasal polyps.¹⁰⁸ Macrolides have been shown to increase mucociliary transport, reduce goblet cell secretion and cause accelerated apoptosis of neutrophils, all of which would reduce the symptoms of chronic inflammation. However, acute cardiac toxicity is an increasingly recognized potential adverse effect of antimicrobial drug treatment and several agents of the macrolide class of antibiotics are known to interfere with the delayed rectifier potassium current, which results in accumulation of potassium ions in cardiac myocytes and thereby delays cardiac repolarization. Evident on an electrocardiogram as a prolongation of the QT interval, this mechanism is thought to underlie an increase in the risk of torsade de pointes, a potentially fatal arrhythmia, with macrolides. A recently published large cohort study has found a significantly increased risk of cardiac death associated with clarithromycin. No increased risk was seen with roxithromycin.¹⁰⁹ Nasal douching provides symptomatic benefit, and should be used with sterilized or distilled water to avoid contamination.

Surgical

Surgical management is considered for patients who have failed to respond to maximal medical treatment and for those with complications.

Functional endoscopic sinus surgery aims to improve sinus ventilation and drainage as well as removing polyps. The extent of surgery varies with the extent of disease, the surgeon's individual practice and available technology. Functional endoscopic sinus surgery has been used for many years to treat sino-nasal conditions and permits a better view of the surgical field, allowing more precise clearance of the inflammatory change than

conventional surgery. It may be associated with fewer complications and lower recurrence rates.^{110, 111}

Patients being treated for polyp disease derive the greatest benefit from functional endoscopic sinus surgery, and those whose main preoperative symptom is nasal obstruction or headache report higher benefit. Coexistent asthma, allergic rhinitis or aspirin intolerance does not decrease the benefit of sinus surgery in patients with polyps.

Postoperatively, patients should be treated with nasal douching and intranasal or systemic corticosteroids, and compliance with this treatment will influence the long term efficacy of surgery. There is good evidence that postoperative use of topical nasal steroids reduce the rate of polyp recurrence.¹¹²

SUMMARY

Nasal polyps are a chronic disease of the upper respiratory tract that form as an end result of severe inflammation in the nose and paranasal sinuses and are considered to be a subgroup of chronic rhinosinusitis. Although not life-threatening, they can cause severe symptoms with a significant impact on quality of life. Nasal polyps arise in patients with chronic inflammation resulting from many different pathologies and why certain patients develop polyps remains unknown. Extensive research has resulted in a greater understanding of this disease, with evidence that bacteria, fungi, allergens, and superantigens play a prominent role in the pathophysiology of nasal polyps. However the exact cause remains elusive. The annual incidence of nasal polyps is between 1 and 20 per 1000 population. Certain systemic diseases are associated with a much higher incidence of CRSwNP with a prevalence of around 7% in patients with asthma and up to 30–60% in patients with aspirin exacerbated respiratory disease.

Anterior rhinoscopy is the first step to diagnosis, but cannot exclude polyps. Rigid nasendoscopy after is required for diagnosis. CT scanning with coronal sections is the investigation of choice for assessing the extent of the disease and detailing the anatomy before surgery.

A combined treatment strategy involving both medical and surgical management is recommended for long-term control because of the chronic and recurrent nature of the disease, with treatment aiming to eliminate nasal polyps and rhinitic symptoms, re-establish nasal breathing and olfaction, prevent recurrence and improve patients' quality of life. Medical treatment consists mainly of intranasal

BEST CLINICAL PRACTICE

- ✓ Initial medical treatment with topical intranasal corticosteroids
- ✓ Clinical review allows adjustment of medical therapy, planning of further investigations and reduces need for surgery
- ✓ Consider surgery in patients who have failed to respond to maximal medical therapy
- ✓ Unilateral nasal polyps are tumours until proved otherwise

and systemic corticosteroids, thought to affect eosinophil function by reducing both eosinophil viability and activation, and by reducing the secretion of chemotactic cytokines. This improves nasal airflow, reduces polyp size and

decreases the rate of recurrence. Surgical management should be reserved for patients who have failed to respond to maximal medical treatment.

KEY POINTS

- Nasal polyps can cause severe symptoms and can have a significant impact on quality of life.
- Although known to be associated with chronic inflammation the exact aetiology remains elusive.
- Nasal polyps are associated with many chronic conditions including asthma, aspirin exacerbated respiratory disease and cystic fibrosis.
- Nasal polyps can be easily diagnosed with anterior rhinoscopy and nasendoscopy.
- Combined medical and surgical treatment is recommended for long-term control of symptoms.
- Unilateral nasal polyps should be treated as suspected malignancy until biopsy proves otherwise.

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed and Medline search using the following keywords: fungal rhinosinusitis, fungal ball, mycetoma, allergic fungal rhinosinusitis, invasive fungal rhinosinusitis.

INTRODUCTION

Fungal rhinosinusitis (FRS) can be categorized into two broad groups; invasive and non-invasive.¹ This is based on the presence or absence of fungus in the tissue (mucosa, blood vessel or bone) respectively.²

NON-INVASIVE FRS

SAPROPHYTIC FUNGAL INFECTION

Saprophytic fungal infection refers to visible fungal colonization of mucus crusts seen within the nose and paranasal sinuses on nasoendoscopy (Figure 96.1).^{3, 4} These patients are usually asymptomatic or may present with a foul smelling odour.² The proposed mechanism is dysfunction in mucociliary transportation from surgery leading to crust formation. The crust then acts as a platform for growth of fungal spores.³ It has been suggested that saprophytic fungal infections may be precursors to fungal balls if left untreated.³ Endoscopic cleaning of the infected crust with or without continued self-irrigation with saline is usually the only treatment required.³

Figure 96.1 Saprophytic fungal infection where visible fungus is seen growing on mucosal crust.

FUNGAL BALL

A fungal ball is a dense accumulation of extramucosal fungal hyphae, usually within one sinus, most commonly the maxillary sinus.² Although the most common organism in a fungal ball is *Aspergillus*, the cultures are often negative and other fungal species have also been identified.² Fungal balls are seen more commonly in immunocompetent, middle-aged and elderly females, often with a history of previous dental procedure, especially dental fillings.²

The diagnosis of fungal ball is based on the following features: radiological findings of sinus opacification often with areas of hyperattenuation, cheesy or clay-like debris within the sinus (Figure 96.2a and 96.2b), accumulation of fungal hyphae without evidence of tissue fungal invasion seen microscopically, non-specific chronic inflammation of the sinus and the absence of eosinophil predominance, granuloma or allergic mucin.¹

Figure 96.2(a–b) (a) Image guidance system (IGS) CT images of a left maxillary sinus fungal ball showing areas of hyperattenuation. (b) A centrally located calcification within a completely opacified left maxillary sinus from a fungal ball. The calcification is due to metabolic deposits of calcium within the fungal concretions.

The management involves a wide opening of the involved sinus and complete removal of the fungal debris. Examination of the involved sinuses with angled scopes is crucial to ensure complete surgical extirpation. Subsequent regular surveillance in the clinic is necessary. Oral or topical antifungals are not necessary.

FUNGUS-RELATED EOSINOPHILIC FRS INCLUDING ALLERGIC FUNGAL RHINOSINUSITIS (AFRS)

Introduction

AFRS is a non-invasive fungal sinusitis resulting from an allergic and immunologic response to the presence of extramucosal fungal hyphae in the sinuses. It was first recognized as an upper airway manifestation of allergic bronchopulmonary aspergillosis (ABPA) in the 1970s.⁵ Although *Aspergillus* was the presumed pathogen in the first few early case series, subsequent case series showed that dematiaceous fungi such as *Bipolaris*, *Curvularis* and *Alternaria* were more common.⁶

Epidemiology

The prevalence of FRS amongst chronic rhinosinusitis (CRS) patients who undergo surgery is between 12 and 47%.^{7, 8} Of this, AFRS is the most common form, accounting for between 56 and 72% of patients with FRS.^{7, 8} The typical AFRS patients are young immunocompetent adults.⁹ The mean age at presentation is between 21 and 33 years old.¹⁰ There is a higher male to female ratio of between 1.5 and 2.6 to 1.¹⁰ Wise et al. found that AFRS patients also have a lower socioeconomic status and a higher African American ratio compared to CRS patients.¹⁰

Pathophysiology

Although it has been over 30 years since AFRS was first described, the underlying pathophysiology remains unknown and controversial. A number of popular theories have evolved. Manning et al. proposed a mechanism derived from the ABPA model.¹¹ Based on studies demonstrating raised fungal-specific IgE antibodies and IgG antibodies in AFRS patients, it is believed that an atopic host exposed to fungi resulted in antigenic stimulation by a combination of Gell and Coombs type I and type III hypersensitivity.^{11, 12}

While the immunologic theory proposed by Manning et al. is supported in the literature, it fails to explain the unilateral or asymmetric nature of AFRS, the persistence of a raised IgE level after prolonged fungal immunotherapy and the failure of a rise in specific IgG levels resulting from the formation of IgG-blocking antibodies following fungal immunotherapy.¹³ An alternative theory was later proposed by Panikou et al.¹⁴ Their landmark but non-peer-reviewed paper stated that fungi were present in

the nasal secretions of 96% (202 patients) of consecutive CRS patients and 100% (14 patients) of healthy volunteers with no sinus disease. Elevated total and specific IgE levels were not prevalent amongst the AFRS patients and not significantly different to that of the control group. Hence, they rejected the role of an IgE-mediated reaction in the pathogenesis of AFRS. Rather, eosinophilic chemotaxis in response to extramucosal fungi was the hallmark of the inflammatory reaction in AFRS. The term **eosinophilic fungal rhinosinusitis** (EFRS) was introduced. Similarly, the term **eosinophilic mucin** was suggested as a replacement for **allergic mucin** to emphasize the importance of eosinophils in the pathophysiology of AFRS. However, the eosinophilic theory does not explain the triggering factor for eosinophil chemotaxis.

In 2000, Ferguson performed a literature review and concluded that there may be two different disease processes in play: allergic and non-allergic fungal rhinosinusitis.¹⁵ The term **eosinophilic mucin rhinosinusitis** (EMRS) was used to describe non-allergic fungal sinusitis. These patients were felt to have histological features similar to AFRS but without the presence of fungus. The underlying mechanism was believed to be a systemic dysregulation of immunologic controls resulting in upper and lower airway eosinophilia. By recognizing EMRS and AFRS as two separate entities with a similar phenotypic endpoint, the treatment strategies for these patients can be formulated according to their pathogenesis. Antifungal agents and fungal immunotherapy should theoretically benefit only AFRS and not EMRS patients.¹⁵

Diagnostic criteria

In 1994, Bent and Kuhn described a diagnostic criteria for AFRS based on 15 consecutive AFRS patients.¹⁶ They found 11 important clinical features, 5 of which were present in all 15 patients. These 5 features were termed major criteria and the remaining 6 features as minor criteria. All 5 major criteria were necessary to define AFRS while the minor criteria were considered supporting features (Box 96.1). These criteria set the benchmark for diagnosis of AFRS for many years with minor variations proposed over the years.

There exists a subgroup of patients who do not meet all five major criteria but behave like AFRS patients and respond to AFRS treatment strategies (previously known as **atypical AFRS**). We have therefore adopted the Bent

BOX 96.1 Bent and Kuhn Diagnostic Criteria for AFRS

Major criteria	Minor criteria
<ul style="list-style-type: none"> Evidence of type I IgE-mediated hypersensitivity Nasal polyposis Characteristic CT findings Eosinophilic mucus Positive fungal smear 	<ul style="list-style-type: none"> Asthma Unilateral predominance Radiographic bone erosion Fungal culture Charcot-Leyden crystals Serum eosinophilia

BOX 96.2 St Paul's Sinus Center Diagnostic Criteria for AFRS

Major criteria

- Immunocompetent patient
- Presence of nasal polyposis
- Characteristic CT findings
- Presence of allergic mucin
- Positive fungal cultures or the presence of fungal hyphae on fungal staining

and Kuhn criteria with minor modifications to be more inclusive. An elevated IgE level is not always present in all AFRS patients and may fluctuate within the normal range as the disease stage changes.^{9, 17} We currently utilize the following five major criteria to diagnose patients with AFRS (Box 96.2).

Clinical presentation

Although there are no pathognomonic symptoms for AFRS, clinical suspicion should be high when one encounters a young patient with uni- or bi-lateral nasal polyposis with thick, sticky yellow/green mucus, characteristic double density sign on CT and who responds to oral steroids. Often, the symptoms are subtle and similar to that of chronic sinusitis with nasal polyposis.¹⁸ On nasoendoscopy, inspissated thick yellow or brown peanut-butter like mucus may be seen among the polyps (Figure 96.3a–c).

Investigation

IMMUNOLOGIC TEST

Patients with AFRS have an elevated IgE level. In a long term follow-up of AFRS patients by Marple et al. the total IgE levels were found to be between 50 and >1000 IU/ml. The average total IgE level was about 550 IU/mL. Because of the wide range of total serum IgE levels in AFRS patients, it is not useful as a screening tool.¹⁹ However, total serum IgE level may be useful in monitoring clinical activity in the management of AFRS.¹⁷ An *in-vivo* (skin prick) or *in-vitro* (RAST) test can be utilized to demonstrate fungal specific IgE as a diagnostic criteria for AFRS.^{20, 21}

IMAGING – COMPUTED TOMOGRAPHY (CT) AND MAGNETIC RESONANT IMAGING (MRI) SCANS

AFRS patients have typical features that are present on an unenhanced CT and enhanced MRI scans of the paranasal sinuses (Box 96.3).^{22, 23}

CT without contrast is the imaging of choice in suspect patients. The focal or diffuse areas of hyperintensity seen on CT are due to calcium and manganese deposits in the necrotic debris of the fungus and allergic mucin.²² This results in a 'double density' or rail-track sign, (Figure 96.4). The optimum setting in the bone protocol

Figure 96.3(a-c) Clinical appearance of AFRS. (a) Nasoendoscopic picture of the left nasal cavity of an AFRS patient with allergic mucin covering a nasal polyp. (b) Allergic mucin is being suctioned out from the left sphenoid sinus. (c) Gross appearance of allergic mucin.

BOX 96.3 Characteristic findings of AFRS on CT and MRI scans of the paranasal sinuses

CT features	MRI features
<ul style="list-style-type: none"> • Heterogenous signal intensities within the paranasal sinuses filled with allergic mucin ('double density sign') • Expansion of the paranasal sinuses/nasal cavity • Unilateral or asymmetric disease load • Bony erosion 	<ul style="list-style-type: none"> • T1 weighted images – central areas of hypointensity with peripheral enhancement • T2 weighted images – central areas of hypointensity or signal void with peripheral enhancement

Figure 96.4 IGS CT images of a patient with extensive AFRS. There is a large erosion of the left skull base with intra-cranial extension as well as erosion of the left lamina papyracea. There is complete opacification of all sinuses with heterogeneity in signal intensity that is most obvious in the left maxillary sinus ('double density' sign).

Figure 96.5(a-c) Radiographic imaging of a patient with chronic invasive fungal rhinosinusitis with fungal concretions in the left maxillary sinus. (a) Coronal cut of a CT scan showed complete opacification of the left maxillary sinus with areas of hyperattenuation, suggestive of fungal concretions. (b & c) Coronal cut of a T1-weighted MRI (b) and T2-weighted image (c) of the same patient showing a signal void (asterisk) from the fungal concretions in the left maxillary sinus. The signal void is due to heavy metals (iron, magnesium and manganese) within the fungal concretions.

to accentuate this sign is a window width of ~2000 House unit (HU) and centred at ~-250/-200.²⁴

MRI of the paranasal sinus with intra-venous gadolinium contrast can be considered when the diagnosis of AFRS is uncertain or if there are concerns with rare intra-cranial or intra-orbital complications. The protein content and viscosity of the secretion will determine the signal intensity seen on MRI. In fungal infections, the consistency of the secretion usually results in a low intensity on T1 and a much lower intensity to signal void on T2 (Figure 96.5a–c).²² This is due to higher concentration of iron and manganese as well as calcium deposits within the fungal concretions.²³

HISTOLOGY

The hallmark of AFRS is the presence of allergic mucin. Grossly, it is thick, tenacious and highly viscous in consistency.¹⁸ Hence, the terms ‘peanut butter’ and ‘axle-grease’ are often used to describe the characteristic appearance of the mucus. Histologically, allergic mucin consists of an eosinophilic mucin with necrotic eosinophils, inflammatory cells, Charcot-Leyden crystals (the by-product of eosinophil) and fungal hyphae (Figure 96.6a).²⁵ As fungal hyphae are infrequent and scattered within allergic mucin, their detection is difficult unless specific stains with a silver stain such as Grocott’s or Gomori’s methamine silver (GMS) stain are performed (Figure 96.6b).¹⁸

FUNGAL CULTURE

A positive fungal culture provides supporting evidence in the diagnosis of AFRS. However, its absence does not exclude the diagnosis of AFRS. The presence of a positive fungal culture in AFRS patients ranged from 49 to 100%,

depending on the culture method used.^{6, 12, 14, 26, 27} In our institution, positive fungal cultures were obtained in 64% of AFRS patients using a modified Mayo Clinic fungal culture technique. Likewise, a positive fungal culture does not confirm the diagnosis of AFRS. The histological identification of allergic mucin is still the most reliable marker for the diagnosis of AFRS.¹⁸

Management

Once a diagnosis of AFRS has been established, patients are enrolled into a committed long-term management program with regular and long-term follow-up considered critical to the success of the treatment. A combination of surgery with a comprehensive post-operative medical regimen to keep the disease under control is almost always required.²⁸

SURGICAL TREATMENT

Unlike the management of classical CRS, surgery is usually the first line treatment in the management of AFRS. Meticulous and complete endoscopic sinus surgery is the gold standard for the surgical extirpation of polypoid disease and allergic mucin in an attempt to restore ventilation and drainage of the sinuses.⁹ Removal of allergic mucin and fungal debris eliminates the antigenic factor that incites the disease in an atopic host. Surgery also provides wide access for surveillance, clinical debridement and application of topical medication. In our center, functional endoscopic sinus surgery (FESS) for AFRS patients is routinely carried out with image-guidance system (IGS). We feel that the use of IGS allows complete removal of diseased cells in the sinuses and minimizes the risk of complications from distorted anatomy.

Figure 96.6(a–b) Histology of allergic mucin and fungal hyphae. (a) H&E stain of allergic mucin showing eosinophils (black arrows), eosinophil aggregate (yellow asterisk) and Charcot-Leyden crystals (blue arrow) on a mucinous background. **(b)** Fungal hyphae (black arrows) with 45° branching and septation typical of *Aspergillus* sp. ENDOSCOPIC STAGING OF MUCOSAL DISEASE POST-SURGERY

Regular follow-up and accurate documentation of the sinonasal mucosa of AFRS patients after surgery is critical to monitor disease status and response to adjunctive medical treatments. Kupferberg et al. devised a 4-stage system for endoscopic follow-up in these patients post-surgery (Table 96.1).³⁰ However, the Kupferberg staging system

TABLE 96.1 Kupferberg post-operative endoscopic staging system for AFRS

Stage	Endoscopic finding
I	Normal mucosa
II	Mucosal oedema/allergic mucin
III	Polypoid oedema/allergic mucin
IV	Sinus polyps and fungal debris

lacks sensitivity, often resulting in patients remaining in the same endoscopic stage despite having improved symptomatically and endoscopically. In 2010, Philpott et al. introduced a new endoscopic staging system for AFRS. The Philpott-Javer system³⁰ is a validated mucosal staging system that was derived from modifications made to the Kupferberg system. Such a system is much more sensitive and allows for much better tracking of disease control post-operatively (Figure 96.7).

Medical treatment

SYSTEMIC MEDICATIONS

I. Corticosteroids

Oral steroids are useful in the perioperative period of patients with AFRS. In the pre-operative period, a short course of corticosteroids reduce intra-operative bleeding

Sinus Cavity	Right	Mucin	Left	Mucin
Olfactory cleft	0-9	1	0-9	1
Frontal	0-9	1	0-9	1
Ethmoid	0-9	1	0-9	1
Maxillary	0-9	1	0-9	1
Sphenoid	0-9	1	0-9	1
Total	50		50	
Bilateral total	100			

Grading	State of Mucosa
0	No oedema
1-3	Mucosal oedema (mild/moderate/severe)
4-6	Polypoid oedema (mild/moderate/severe)
7-9	Frank polyps (mild/moderate/severe)

Figure 96.7 A clinic poster for the Philpott-Javer endoscopic staging system for AFRS.

and size of the polyps.¹³ In a prospective comparative study by Landsberg et al, AFRS patients who received oral steroids pre-operatively showed greater radiologic and endoscopic improvement compared to CRSwNP patients.³¹

In the post-operative period, the corticosteroids regimen was initially derived from the protocol used in treatment of ABPA.³² In a 4-year follow-up study of 11 AFRS patients by Kuhn and Javer, a reduction in IgE and mucosal disease post-operatively were seen in patients who were on steroids. They found that in order to prevent recurrence, a minimum of 6 months of normal sinus mucosa while on steroids is necessary before steroids can be slowly discontinued.¹⁷ A 6-month post-operative regimen of tapering corticosteroid therapy was proposed by Kuhn and Javer, including the use of high-dose intranasal corticosteroids.²⁹

Systemic steroids, although beneficial in the perioperative period, are not without adverse side effects. Although long-term oral corticosteroid may be necessary in some patients, its use should be judicious and limited to short courses in the perioperative period and in acute exacerbations of AFRS to suppress growth of recurrent polyps.³³

II. Antifungals

Oral antifungals are considered a viable treatment option for patients with recalcitrant AFRS. They are also used as a steroid-sparing medication, allowing some patients to be weaned off from long-term oral corticosteroid therapy.³⁴ Early reports by Bent and Kuhn on the efficacy of oral antifungals in AFRS patients showed mixed to poor results.³⁵ However, subsequent retrospective case series showed that oral itraconazole (200–400 mg daily) has potential benefits as a steroid sparing alternative and in prolonging time to disease recurrence.^{34, 36, 37} Oral itraconazole is associated with risk of elevated liver enzymes, congestive heart failure, nausea, rash, headache, malaise, fatigue and oedema (Janseen Pharmaceutica, Beerse, Belgium). Asymptomatic transaminitis is not uncommon (4–19%)^{34, 36} and cessation of treatment is usually sufficient for the elevated liver enzymes to revert back to normal. It appears that a subset of AFRS patients seem to respond to antifungals. Future RCTs are needed to identify the ideal candidate and to assess the efficacy, safety and optimal dosage and regime for oral antifungals in the treatment of AFRS.

TOPICAL MEDICATION

I. Corticosteroid

Topical corticosteroids are used as standard treatment for patients with AFRS. They are most effective in the post-operative period when open sinus cavities and middle meati allow access to the paranasal sinuses. The benefit of topical over systemic steroid lies in the ability of topical steroid to achieve the highest drug concentration in the target tissue (sinonasal mucosa) without the undesirable systemic side effects.³⁸ Although studies on the efficacy of intra-nasal steroids in AFRS patients are lacking, their benefits have been well established in CRS patients with nasal polyposis.³⁹ An evidence-based review with

recommendations based on Grade A evidence by Rudmik et al. provided a strong recommendation for the use of standard topical nasal steroids for the management of CRS.⁴⁰ Standard topical nasal steroids are metered-dose topical steroid solutions that have been approved for use in the nasal cavity by the U.S. Food and Drug Administration (FDA). These include metered-dose nasal sprays such as mometasone furoate, fluticasone propionate, fluticasone furoate, budesonide, beclomethasone dipropionate monohydrate, ciclesonide, flumisolide and triamcinolone acetate.⁴⁰

The use of budesonide administered as drops, atomized sprays or through low volume saline rinses have gained popularity in the treatment of AFRS patients. These are ‘non-standard’ topical nasal steroids and are not FDA approved for application in the nasal cavity. Other ‘off-label’ non-standard topical steroids that have been used in the sinonasal cavity include low-volume solutions such as intra-nasal dexamethasone ophthalmic drops (0.1%), prednisolone ophthalmic drops (1%) and ciprofloxacin/dexamethasone otic drops (0.3/0.15).⁴⁰ Non-standard topical nasals steroids have the advantage of delivering higher volume and/or high concentration of steroids into the sinonasal cavity. In the treatment of post-operative refractory CRS patients, topical budesonide (Pulmicort Respules) via the Mucosal Atomization Device (MAD; Wolfe-Tory Medical, Salt Lake City, UT) resulted in improvements in both physician and patient global assessments and also reduction in the use of oral prednisolone (Figure 96.8).⁴¹

Figure 96.8 Pulmicort nebulizer and the MAD syringe.

The main concern of non-standard topical nasal steroids sprays is systemic absorption resulting in unwanted systemic side effects. In post-surgical CRS patients, Sachanandani et al. demonstrated that budesonide nasal irrigation (2.5 mg of budesonide diluted in 5 ml of normal saline in each nasal cavity) for 30 days improved clinical symptoms of CRS without hypothalamic-pituitary-adrenal (HPA) axis suppression.⁴² A prospective study was conducted in our centre to determine if application of high dose budesonide (1 mg of Pulmicort Respules twice a day) via the MAD over 2 months causes HPA suppression and results in an increase in plasma cortisol and detection of plasma budesonide. The result of the ten patients subjected to high dose budesonide delivered via the MAD did not show any evidence of HPA suppression nor any elevation of plasma cortisol or presence of plasma budesonide.⁴³ Hence, the use of topical budesonide delivered via the MAD looks promising as an effective and safe adjunct in the treatment of AFRS.

At our centre, AFRS patients are instructed to use budesonide rinses (2 ml of 0.5 mg/ml Pulmicort Respules in every 60 ml of normal saline) in the immediate post-operative period. After 3 weeks post-operatively, the budesonide is delivered through a MAD (1 ml in each nostril). Patients are taught to apply the spray in the Mygind position (Figure 96.9). We favour the Mygind position as it is supported by our recently completed study on post-FESS cadaveric heads. Our study showed superior distribution of fluorescein within the ethmoid and frontal sinuses and the frontal recess when the head was placed in the lateral-head-back (LHB) position compared to the vertex-to-floor (VTF).⁴⁴

Figure 96.9 Application of Pulmicort through the MAD in the Mygind position.

II. Antifungals

In CRS, topical antifungals have been deemed ineffective in a number of meta-analyses and systemic reviews.^{40, 45–48} As AFRS is a different disease entity resulting from an immunologic hyperreaction to extramucosal fungus,^{11, 12} topical antifungals should hypothetically reduce the immunologic reaction of an atopic host by decreasing the antigenic load. In a RCT of 50 AFRS patients by Khalil et al.,

the fluconazole nasal spray arm had the best recurrence rate (10%) followed by combined oral itraconazole and topical fluconazole (14.3%), fluconazole nasal irrigation (28.6%), oral itraconazole alone (66.7%) and control (75%).⁴⁹ Although results from this RCT appeared promising, larger RCTs will be required to establish the role of topical antifungals in the management of AFRS.

III. Immunotherapy (IT)

In ABPA, IT has been avoided due to the possibility of an immune complex-mediated reaction developing from the IgG produced by IT.⁵⁰ As opposed to ABPA, the fungal antigenic stimulus can be removed surgically in AFRS patients. Surgical removal of fungal debris and allergic mucin in AFRS patients has also been shown to decrease allergen-specific IgE levels for fungal antigen.¹¹ Hence, it can be argued that fungal IT after surgery may potentially provide benefit rather than harm in the management of AFRS.⁵⁰

A literature review by Hall and deShazo in 2012 revealed ten studies on fungal IT in AFRS patients.⁵⁰ In most studies, there were improvements in clinical outcomes. No major systemic reactions, nor evidence of worsening of disease in patients treated with fungal IT were reported. The only side effects reported were minor local reaction. Although the results of fungal IT appeared promising, the lack of RCT warrants better-designed research to establish the efficacy and safety of fungal IT in the treatment of AFRS.

Adjunctive treatment

MANUKA HONEY

Manuka (*Leptospermum scoparium*) honey from New Zealand is the most therapeutically potent honey.⁵¹ It has been shown to be active against a broad spectrum of gram-positive and gram-negative bacteria.⁵² The principal active ingredient responsible for the antibacterial property in Manuka honey is methylglyoxal (MGO).⁵³ MGO is present in Manuka honey at a concentration of up to 100-fold that of conventional honey.⁵³ In an *in vitro* study by Alandejani et al., Manuka honey at a concentration of 33% v/v was shown to be effective in eradicating methicillin-susceptible *Staphylococcus aureus* (MSSA), methicillin-resistant *Staphylococcus aureus* (MRSA) and *Pseudomonas aeruginosa* (PA) biofilms.⁵⁴ In fact, conditions that rapidly induced antibiotic resistance did not cause bacterial resistance to honey.⁵⁵

At St Paul's Sinus Centre, our early experience with Manuka honey irrigation (Figure 96.10) in AFRS patients refractory to surgery and post-operative oral and intranasal steroids showed a partial response to Manuka honey with 21% of patients showing mucosal improvement after treatment with Manuka honey irrigation in one nostril.⁵⁶ It appears that there is a subgroup of AFRS patients who do respond well to Manuka honey irrigation. In our recently completed RCT (unpublished) comparing post-FESS patients treated with either Manuka honey or saline solution for 3 months, we found a cytokine signature of up-regulated interleukin (IL)-1b, IL-4, IL-6 and

Figure 96.10 Manuka honey preparation and the power rinse bottle for sinus irrigation.

IL-12 in the sinonasal mucosa of patients who responded to Manuka honey treatment. This preliminary result looks promising and larger studies to confirm the result of this study will be warranted.

Future treatment strategy

ANTI-IMMUNOGLOBULIN E (IGE) THERAPY

Omalizumab (Xolair) is a humanized monoclonal anti-IgE antibody that has been used as an adjuvant treatment in severe atopic asthma, allergic rhinitis and CRS with nasal polyposis.^{57, 58} In the only randomized double-blind placebo-controlled trial on omalizumab therapy on nasal polyps and asthma patients, Gevaert et al. demonstrated that there was significant improvement in total nasal endoscopic polyp scores, CT findings, airway symptoms and quality of life scores after 16 weeks of omalizumab treatment.⁵⁹ These improvements were seen irrespective of the presence of allergy. Omalizumab therapy has also been shown to be effective in ABPA patients.⁶⁰ Given the pathophysiological similarity between ABPA and AFRS, the use of omalizumab in AFRS patients should be explored. At our centre, seven patients with refractory AFRS and raised IgE levels with moderate or severe asthma underwent subcutaneous omalizumab injections (mean number of injections = 7.57; mean dosage = 287 mg; mean follow-up period = 9.7 months). They had improved sinonasal symptoms and endoscopic scores and were less dependent on corticosteroid and antifungal treatments.⁶¹ We are excited about the outcome of this study which we hope will pave the way for a double blind RCT to determine the efficacy of this drug.

INVASIVE FRS

ACUTE (FULMINANT) INVASIVE FRS

Acute or fulminant invasive FRS is a life-threatening disease present usually in immunocompromised patients with impaired neutrophilic response. These patients include those with uncontrolled diabetes mellitus, acquired immunodeficiency syndrome (AIDS), iatrogenic immunosuppression, organ transplantation and haematological malignancies.⁶² This condition is characterized by the presence of hyphal invasion of sinus tissue and a time course of less than 4 weeks.^{3, 4} Histological features include mycotic infiltration of blood vessels, vasculitis with thrombosis, tissue infarction, haemorrhage and acute neutrophilic infiltrate.¹ *Aspergillus* species and the fungi in the order of mucorales (e.g. *Rhizopus*, *Rhizomucor* and *Mucor*) are the most commonly implicated species.¹

The inability to mount a host response to invasive fungal disease in immunocompromised patients can make the diagnosis of this disease entity difficult, especially in the early stages.⁶³ Although common reported clinical symptoms include fever, cough, crusting of the nasal mucosa, epistaxis and headaches,¹ a high index of suspicion of this disease entity should be present in any immunosuppressed patients with localizing sinonasal symptoms. Often, fever of unknown origin that has failed to respond to 48 hours of broad-spectrum intravenous antibiotics may be the initial presenting symptom.⁶⁴

In the early stages, nasoendoscopic findings may be as subtle as the presenting symptoms. Alteration in mucosal appearance such as a discoloration, granulation and ulceration are the most consistent physical findings.⁶⁵ There are no pathognomonic features for invasive FRS on imaging and a CT scan is the initial radiologic investigation of choice (Figure 96.11). Compared to AFRS, invasive FRS tends to have more focal bony erosions, lacks expansion of the sinuses, has more limited sinus disease and has more disease outside of the sinuses than within when there is intra-orbital or intra-cranial extension.²³

Without early treatment, rapid progression of disease with 50–80% mortality rates from intra-orbital and intra-cranial complications have been reported.⁶⁴ Improvement of the host immune response is paramount for survival. Surgery is necessary to halt or slow progression of the disease (allowing time for bone marrow recovery), to reduce fungal load and to provide a tissue culture.⁶⁴

Prior to definitive identification of the causative fungi, empirical treatment with intravenous amphotericin B, a broad-spectrum antifungal agent, has been recommended.⁶⁶ Once a causative fungal species has been identified, the use of the triazoles (fluconazole, itraconazole and voriconazole) can be considered.^{63, 66} The triazoles are effective in the treatment of invasive FRS without the associated nephrotoxicity seen in standard amphotericin B.⁶⁶ However, the triazoles lack effectiveness against the *Mucorales* species and their presence should be ruled out before its use is considered.^{1, 63}

Figures 96.11 Intra-operative IGS images of the sphenoid sinus of a patient with invasive FRS. The fungal disease has eroded the inferoposterior wall of the sphenoid sinus (which is formed by a pneumatized clivus).

GRANULOMATOUS INVASIVE FRS

This disease entity is defined by invasive fungal infection lasting more than 12 weeks.⁴ It is usually of gradual onset and is seen more commonly in Sudan, India, Pakistan and Saudi Arabia.¹ The causative agent is almost exclusively *Aspergillus flavus*.¹ Patients are typically immunocompetent and the predominant clinical features include proptosis with an enlarging mass in the cheek, nose, paranasal sinus and orbit.^{1, 63} CT findings are not different to that of chronic invasive FRS although they have a tendency for multiple sinus involvement.⁶⁷ The distinguishing feature from chronic invasive FRS is histological findings of fungal tissue invasion and a granulomatous reaction with considerable fibrosis. This is evident from the presence of non-caseating granulomas with foreign body or Langerhans-type giant cells, occasional vasculitis and sparse hyphae.^{1, 4, 63} Treatment includes complete surgical removal and antifungal agents.

CHRONIC INVASIVE FRS

Chronic invasive FRS is a slowly destructive disease with a time-course of more than 12 weeks duration. Patients are usually immunocompetent or have subtle abnormalities in the immune system from diabetes mellitus, chronic low dose corticosteroid use and AIDS.^{4, 63} The most common fungi implicated is *Aspergillus fumigatus*.⁴ The clinical picture of chronic invasive FRS is similar to that of granulomatous invasive FRS. The ethmoid and sphenoid sinuses are most commonly involved.⁴ On histology, chronic invasive FRS demonstrates invasion of fungi into the sinonasal mucosa with a dense accumulation of fungal hyphae, occasional vascular invasion, and chronic or sparse inflammatory reaction.^{1, 4} There is no difference in the prognosis or the management of both chronic invasive and granulomatous invasive FRS.⁴ For the occasional patients with invasive FRS with a time line between 4 and 12 weeks, the term subacute invasive FRS has been recommended.⁴

CONCLUSION

In summary, FRS is an uncommon but important part of the disease spectrum of CRS. Although there are certain clues from clinical and radiological findings, histology is key

in distinguishing the different subtypes of FRS. Obtaining the correct diagnosis is crucial as each disease entity differs in the optimal management strategy. Antifungal agents are usually not required in the management of non-invasive FRS but are part of the first line treatment in invasive FRS.

BEST CLINICAL PRACTICE

- ✓ In the management of AFRS, endoscopic sinus surgery is required to decrease antigenic stimulation from the fungus; drain and ventilate the paranasal sinuses; and provide access to the surgeon for clinical surveillance, debridement and application of topical medication.
- ✓ Post-operative oral steroids and standard topical nasal steroids are recommended to maintain a healthy sinus cavity in the medical management of AFRS.
- ✓ Non-standard topical nasal steroid (e.g. budesonide), oral antifungals and immunotherapy are options in cases of refractory AFRS.

FUTURE RESEARCH

- ▶ There is insufficient evidence for the use of topical antifungals in the management of AFRS or invasive FR and more research in this area is required
- ▶ Omalizumab therapy may be a potential treatment option for the management of refractory AFS. The safety and effectiveness of this treatment modality should be explored in randomized controlled trials

KEY POINTS

- FR is categorized into non-invasive and invasive groups depending on the absence or presence of fungus within the sinonasal tissue respectively.
- AFRS is the most common type of FR.
- In medically fit patients with FR, endoscopic sinus surgery is indicated to remove fungal load and ventilate the involved paranasal sinuses.
- Intravenous antifungal agents and reversal of the immunocompromised status of the host are paramount in the management of invasive FR.

SEARCH STRATEGY

The author consulted the suite of Cochrane reviews on chronic rhinosinusitis (www.cochrane.org/news/suite-cochrane-reviews-chronic-rhinosinusitis) to underpin the recommendations in this chapter.

MEDICAL MANAGEMENT OF ACUTE RHINOSINUSITIS

INTRODUCTION

Acute rhinosinusitis is common, affecting 6–15% of the population each year. The vast majority of cases are viral, with bacterial infection estimated in less than 2% of cases; however there is significant overlap, with viral infection triggering inflammatory changes that facilitate secondary bacterial infection. Most cases resolve spontaneously within 10 days, and the incidence of complications is very low. Medical treatment may be antimicrobial or anti-inflammatory, with an aim of reducing the infective and inflammatory load to both reduce the severity and duration of illness, to prevent recurrence and complications, or reducing symptom severity alone.

REDUCTION OF INFECTIVE LOAD

Inappropriate antibiotic use is a significant threat to public health in terms of increasing resistance, yet antibiotics are prescribed in over 80% of outpatient visits in the United States for acute rhinosinusitis (ARS),⁵ and ARS is the fifth most common indication for antibiotic treatment.

Although the majority of ARS is viral, antibiotics are often both expected by patients and prescribed by physicians.^{1–4}

The majority of studies and meta-analyses have shown little benefit from antibiotics in most patients with ARS.^{5–8} The most recent systematic review, published by the Cochrane Collaboration in 2012, included 10 trials with a total of 2450 adult participants.⁹ Irrespective of antibiotic usage, 47% of participants were cured after one week and 71% after 14 days. Five more participants per 100 had shortened time to cure between 7 and 14 days if they received antibiotics instead of placebo (number needed to treat = 18). Purulent secretion resolved faster with antibiotics (odds ratio (OR) 1.58 (95% CI 1.13 to 2.22)), (NNT = 11, three trials). However, 27% of the participants who received antibiotics and 15% of those who received placebo experienced adverse events (OR 2.10) (number needed to treat to harm NNT_H = 8, seven trials). Therefore, while there was a small beneficial clinical effect with antibiotics, there was also an increased risk of adverse effect.

While there are limitations with the evidence (there is often marked heterogeneity of patients, different diagnostic criteria applied, and most studies conducted in subspecialty clinics, rather than primary care), current evidence supports restricting antibiotic usage in uncomplicated ARS.

DIFFERENTIATING BACTERIAL FROM VIRAL ARS

If those with bacterial infection can be identified, a more selective approach to antibiotic prescribing may be applied. The gold-standard for confirmation is a positive bacterial culture from a maxillary sinus aspirate. However, this requires specialist care, and incurs patient morbidity. Endoscopically guided middle-meatal cultures have been shown to have good specificity but lower sensitivity when compared with direct aspiration. Symptomatic selection alone is unreliable, unilateral facial pain and nasal purulence have a positive predictive value of 40% and 50% only for positive bacterial culture. When a combination of 3 out of 4 of nasal purulence, purulence in the post-nasal space, high fever (>39°C) and raised ESR are used, specificity may be increased to 80%.

Choice of antibiotic if indicated

Where a decision to treat with antibiotics has been made, due to the presence of complications or in severe infection, the choice can be based on culture results, or local resistance to common classes. A Cochrane review comparing different classes of antibiotics found no significant difference between penicillins or non-penicillins (cephalosporins, macrolides) or between non-penicillins and amoxicillin-clavulate. Prolonged courses (10–14 days) do not significantly increase cure rates, thus a short course of narrow-spectrum agents may reduce the risk of increasing antibiotic resistance.

Role of treatment in preventing complications

The incidence of complications of ARS is low. Of those cases of complicated ARS reported to a UK audit, 50% had received antecedent antibiotic treatment. When comparing the prevalence of complicated ARS in countries with widely differing rates of antibiotic prescribing, there seems to be little difference; in the Netherlands, with the lowest rates of antibiotic usage, the prevalence is reported at 3 per million population per annum while in the US it is 2.7–4.3 per million. Thus antibiotic usage does not seem to prevent the development of complications.

Reduction of inflammation

Studies of topical glucocorticoids have demonstrated some benefit for the relief of symptoms in both viral and bacterial ARS. A meta-analysis of three studies, with ARS diagnosed by symptoms and confirmed by radiologic or endoscopic studies, found that adult participants receiving INCS were more likely to have resolution or improvement of symptoms than those receiving placebo (73% versus 66.4%; risk ratio (RR) 1.11).¹⁰ Higher doses of INCS had a stronger effect on improvement or complete relief of symptoms. When used as an adjunct to antibiotic therapy in the

treatment of ABRS, a meta-analysis of placebo-controlled trials suggests that 15 patients would need to be treated with intra-nasal glucocorticoids to improve clinical symptoms in one patient.¹¹ As the risk of adverse events with short-term usage INCS is low, INCS can be recommended in ARS.

Similarly, meta-analysis supports a role for systemic steroid treatment as adjunctive treatment.¹² Four RCTs with a total of 1008 adult participants met our inclusion criteria. Acute sinusitis was defined clinically in all studies, with radiological confirmation in three. All participants received oral antibiotics and were assigned to either oral corticosteroids or the control (placebo in three trials and non-steroidal anti-inflammatory drugs in one). In all trials, participants treated with oral corticosteroids were more likely to have short-term resolution or improvement of symptoms than those receiving the control treatment: at Days 3 to 7, risk ratio (RR) 1.4; risk difference (RD) 20% and at Days 4 to 10 or 12, RR 1.3, RD 18%. An analysis of the three trials with placebo as a control treatment showed similar results but with a lesser effect size: Days 3 to 6: RR 1.2, RD 12% and Days 4 to 10 or 12: RR 1.1, RD 10%.

Symptomatic improvement

There is limited evidence to suggest that nasal decongestants may have a small beneficial clinical effect in reducing nasal congestion, but not overall duration of ARS.

There is little evidence that saline therapies assist in symptom relief. Low-volume saline sprays may assist in mucus and crusting but there is evidence that high-volume irrigations are poorly tolerated in the setting of acute inflammation and are currently not recommended.¹³ A randomized study comparing hypertonic with isotonic saline found no difference between groups in terms of severity or duration of symptoms, but higher adverse events (local discomfort) associated with hypertonic saline.

Medical management in complicated ARS

The management of complications of ARS will often require surgical intervention to address the complication itself, but will also require ongoing medical management to treat the underlying sinus infection. Where possible, choice of antibiotic should be culture directed, and are usually be given intravenously, followed by an oral course on discharge. There are no randomized trials of the medical management of complicated ARS; however, in many published case series, decongestants are given. There is little evidence regarding the use of systemic steroids in such cases, but they are often given to reduce cerebral oedema associated with intra-cranial complications, and are likely to be more beneficial than detrimental.

Prevention of ARS

There is a growing body of evidence identifying allergic rhinitis as a predisposing factor for ARS. It would be reasonable to assume that optimal medical management of

AR may reduce the risk of ARS, but there are no studies to confirm or refute this. A recent systematic review found only a weak association between laryngeal reflux and ARS. Therefore, there does not appear to be any role for antireflux medication. One study has evaluated the benefit of INCS at the onset of symptoms of a common cold in reducing the risk of developing post-viral rhinosinusitis, and found no benefit.

MEDICAL MANAGEMENT OF CHRONIC RHINOSINUSITIS

INTRODUCTION

‘The treatment of chronic rhinosinusitis is primarily medical, with surgery reserved for those who fail a trial of maximal medical therapy’, is a commonly quoted approach in the management of CRS. However, what maximal medical therapy entails, and how to define those who fail to respond is perhaps more controversial than it may appear. This chapter hopes to address this and summarize current evidence.

OVERVIEW OF THE PATHOPHYSIOLOGY OF CRS

Chronic rhinosinusitis is a heterogenous group of several phenotypes, and is likely to represent the end-point of multiple aetiologies, rather than a single disease process. In some cases, sinonasal disease is a manifestation of systemic disease; examples include vasculitides, cystic fibrosis, sarcoidosis and ciliary motility disorders. Medical treatment in these groups is usually directed at systemic disease management, where possible. CRS may also occur as a direct result of focal abnormalities; a foreign body, fungal ball, odontogenic infection or very rarely, an anatomical obstruction. Medical management plays no significant role in first-line management in this group, and treatment is usually surgical correction of the focal abnormality. Medical treatment may be required to facilitate normalization of the sinonasal mucosa post-operatively. These groups of *secondary* CRS will not be considered further in this section.

Primary CRS refers to the vast majority of patients that present to otolaryngologists with unexplained inflammation of the upper airway. It is common to find lower airway disease as part of a broader respiratory condition but not as a result of systemic disease. In these patients, with *primary* CRS, there is an interaction of intrinsic mucosal inflammation, local microbial community and mucociliary dysfunction, with each factor being of varying importance in individual patients.¹⁴ Considerations of these three factors will help direct medical therapy in these patients; the aim will be to reduce inflammation, reduce bacterial load and optimize ciliary function by removing mucus. Chronic rhinosinusitis may be subcategorized by the endoscopic assessment of the middle meatus, if necessary after

decongestant; polyps presenting to the middle meatus or nasal cavity is defined as *CRS with polyps* (CRSwNP), *CRS sine (without) polyps* (CRSSNP) is used when no polyps are visible on endoscopy, accepting that there may be polypoid change within the sinuses. While there is increasing recognition that CRSwNP and CRSSNP are opposing ends of a spectrum, there remains overlap between the conditions, and many studies to date have not separated according to phenotype. It is acknowledged that there is a move away from phenotyping the disease, and greater endotyping of the mucosal condition is anticipated.^{15–16} Greater distinction occurs when separating the eosinophil dominated (or Th2 skewed) CRS group. This better defines the inflammatory process and often referred to as eosinophilic CRS (eCRS). However, little distinction occurs in routine clinical practice beyond phenotype. Therefore this review will combine both groups, but will highlight where medical therapies differ in efficacy.

TREATMENT TARGETING INTRINSIC MUCOSAL INFLAMMATION

Mucosal inflammation is the defining feature of CRS; it may be intrinsic, as in those with asthma and aspirin sensitivity, or occur as a result of local infection or environmental exposure. Glucocorticoids have formed the mainstay of medical therapy for CRS, while long-term macrolides, doxycycline and other novel approaches also target the inflammatory pathway.

Intra-nasal corticosteroids

There are many studies supporting the role of topical corticosteroids. For CRSwNP, 40 studies (3624 patients) met the inclusion criteria for a recent Cochrane review.¹⁷ The primary outcomes were sino-nasal symptoms, polyp size and polyp recurrence after surgery. When compared to placebo, topical corticosteroids improved overall symptom scores (standardized mean difference (SMD) -0.46 ; $P < 0.00001$; seven trials, $n = 445$) and had a higher proportion of patients whose symptoms improved (responders) (risk ratio (RR) 1.71, $P = 0.0002$; four trials, $n = 234$). Topical corticosteroids also decreased the polyp score (SMD -0.73 ; $P < 0.00001$; three trials, $n = 237$) and had a greater proportion of patients with a reduction in polyp size (responders) (RR 2.09; $P < 0.00001$; eight trials, $n = 785$) when compared to placebo. Topical corticosteroids also prevented polyp recurrence after surgery (RR 0.59; $P = 0.0004$; six trials, $n = 437$). However, there is a significant amount of heterogeneity in the included studies. Some of these showed very little or no benefit. Subgroup analyses by sinus surgery status helps to explain this heterogeneity, revealing a greater benefit in reduction of polyp score when topical steroid was administered in patient groups who had undergone previous sinus surgery (SMD -1.19) compared to patients who had never had surgery (SMD -0.13 ; $P < 0.00001$). There was no

difference between groups in terms of adverse events. In CRSsNP, the number of studies available smaller, and the risk of bias greater, but a beneficial effect for INCS is found; ten studies (590 patients) met the inclusion criteria for meta-analysis.¹⁸ The primary outcome was sino-nasal symptoms. When compared to placebo, topical steroid improved symptom scores (SMD -0.37 ; $P = 0.002$; five trials, $n = 286$) and had a greater proportion of responders (risk ratio 1.69; $P = 0.002$; four trials, $n = 263$). Even with a limited number of studies, heterogeneity was present and subgroup analyses of patients who had received sinus surgery versus those who had not was not significant ($P = 0.35$). However, only the sinus surgery group had a positive effect on meta-analysis. Subgroup analyses by topical delivery method revealed more benefit when steroid was administered directly to the sinuses than with simple nasal delivery ($P = 0.04$). There were no differences between groups for quality of life and adverse events.

Intra-nasal corticosteroids have an excellent safety profile, with the systemic bioavailability for second-generation compounds (mometasone and fluticasone) less than 1%.¹² There is a low incidence of adverse events, with nasal irritation and epistaxis the most common, and are safe for long-term use. Studies show no evidence of nasal mucosal atrophy with long-term use,¹⁹ or growth retardation in the paediatric population.²⁰ Patient education regarding delivery techniques and the need for compliance is essential (Figure 97.1).

In summary, INCS are beneficial in CRSwNP and CRSsNP, and the risk of adverse events low. However, the effect size is often very small and penetration into

previously unoperated sinuses is limited, and there may be a greater response to topical therapy after surgery, utilizing direct delivery to the sinuses.

Systemic corticosteroids

In contrast, there is a relative paucity of comparative data for the efficacy of systemic corticosteroids. In CRSsNP, there are no RCTs, or studies evaluating systemic steroids alone: instead all case series supporting the use of systemic steroids combine therapy with antibiotics and INCS, and are at best level 4 or 5.²¹⁻²² In CRSwNP, three trials (166 patients) were suitable for inclusion in systematic review,²³ and showed a short-term benefit of a short (2- to 4-week) course of oral steroids of variable doses and duration when compared to placebo. There was an objective reduction of polyp size and a subjective improvement of nasal symptoms and quality of life. There was no report of significant adverse effects of treatment with a short course of steroids. Therefore, for short periods, when the risk of adverse event is small, systemic steroids can be recommended for the treatment of CRSwNP. There are no studies to inform us as to the optimum interval between repeated courses of systemic steroids, and use should be weighed up against potential adverse events and discussed with individual patients. However, deriving a plan from best evidence may suggest that a course should last at least as long as the life-span of a tissue eosinophil, have a total or maximal dose below that reported in most case series of serious adverse event from systemic steroid and be infrequent enough to protect against long-term risks of osteoporosis and posterior subcapsular cataract formation. This is further discussed later in this chapter.

Immunomodulatory antibiotics

Long-term macrolide antibiotics are used for their anti-inflammatory effects, based on their efficacy in lower airways disease. They target markers including IL-8, IL-4, IFN γ and TNF α , and have a predominant effect on neutrophil-mediated inflammation. Open label studies have demonstrated improvement in symptoms. There are two prospective randomized controlled trials, one published after a Cochrane review on the topic. The first study included only CRSsNP and showed a significant effect of roxithromycin on symptom scores and IL-8 levels, with greater efficacy in patients with normal IgE levels. A subsequent study has found no effect; however this study included both CRSwNP and CRSsNP, and therefore it is likely that this study included more patients with elevated IgE than the first.²⁴

Long-term use of macrolide antibiotics is associated with increasing levels of macrolide resistance, and gastrointestinal side effects are relatively common. Therefore use should be directed at those patients most likely to benefit (i.e. CRSsNP, normal IgE levels), and further studies are required.²⁵

Doxycycline has been investigated for a potential anti-inflammatory role. In a PCRCT, a 20-day course of doxycycline was shown to reduce levels of myeloperoxidase,

Figure 97.1 Correct application for nasal drops. (a) Head back position. (b) Head down position.

eosinophil cationic protein, matrix metalloproteinase-9 in CRSwNP patients, and had a moderate and sustained effect on polyp size over a 12-week period.²⁶ The clinical impact of this effect, while present at 90 days, is likely to be of minimal clinical benefit. The difference between corticosteroid and the doxycycline was dramatic, but simple withdrawal of the corticosteroid at 20 days prevents sustained benefit. Doxycycline may be an adjunct in the eCRS subgroup while macrolides may assist in the non-eCRS patient.

Leukotriene receptor antagonists

Montelukast, a leukotriene receptor antagonist has been investigated in studies primarily as an adjunct to steroid treatment inpatients with CRSwNP and asthma. There is one positive single-blinded placebo controlled cross-over study with methodological problems, that shows benefit over placebo, while three other randomized trials were negative for change in polyp scores, although there were some benefits on some symptoms including sneezing and facial pain.²⁷ Most studies found greater benefit in patients with associated nasal allergy. There is the definite possibility of leukotriene receptor antagonists assisting with concomitant allergic rhinitis symptom control in these patients and may be the mechanism of effect as many of these patients have both conditions. This is also the basis of some benefit seen and reported by studies on immunotherapy and CRS.²⁸

Novel immunoregulation

Direct targeting of the inflammatory pathway is possible using monoclonal antibodies. In two recent small PCRCTs, omalizumab (anti-IgE) has been shown to significantly reduce both symptom scores and polyp size,²⁹ and mepolizumab (anti-IL-5) has a significant effect on polyp size.³⁰ High cost, risk of anaphylaxis and need for subcutaneous injection are limiting factors in widespread application of such treatments at present. Many other anticytokine and antichemokine agents have been trialled in asthma and lower airway disease.³¹ The respiratory epithelium is likely to co-ordinate the inflammatory process in eCRS with many mediators enacting a pro-inflammatory response.³² It is highly likely that 'downstream' inhibition of a single agent may be suboptimal as redundancy of inflammatory pathways is present, and while one may be inhibited, others may persist. This is likely to explain why some of these medications have an effect but are not a panacea of treatment.

Aspirin desensitization

Aspirin sensitivity is usually associated with nasal polyposis and asthma (Samter's triad). Patients often have extensive polyposis, with high rates of recurrence after both medical and surgical treatment. Immune tolerance may be achieved and maintained by regular administration of aspirin, either orally or intra-nasally.

Tolerance is achieved by giving incrementally increasing dosages of oral aspirin until several hundred milligrams

per day are tolerated. Used in this fashion, there is evidence of significant improvement in many parameters affecting both nose and chest, and has been found to be beneficial in patients with Samter's triad,³³⁻³⁴ but comes with a significant risk of gastrointestinal side effects. More recently, doses as low as 100 mg have been used, and a placebo controlled randomized trial has shown a reduction in polyp recurrence in trial patients.³⁵ In the event of polyp recurrence requiring surgical intervention, oral aspirin is normally discontinued, and therefore desensitization must be repeated.

Lysine aspirin, a soluble form, is used for diagnosis of aspirin sensitivity by nasal or bronchial challenge and topical nasal desensitization. In a double-blind, placebo-controlled crossover study, topical lysine aspirin was associated with a reduction on cysteinyl leukotriene receptors, however, there was no significant clinical effect.³⁶

TREATMENT AIMED AT REDUCING MICROBIAL LOAD

Treatment aimed at reducing microbial load or eradicating pathogens from the sinuses assumes that these play a role in causing or propagating CRS. Bacteria may play a role in acute infective exacerbations. Bacterial capsules and exotoxin may trigger an inflammatory response, while superantigens (predominantly Staphylococcal) and fungi may induce eosinophilic inflammation. The organisms isolated from patients with CRS differ from those in ARS, with *Staphylococcus aureus*, *S. epidermidis*, and anaerobic and Gram-negative bacteria predominating. Some, such as *S. epidermidis* are likely to be innocent colonizers. Polymicrobia is common. *S. aureus* may be isolated in up to 50% of CRSwNP, and MRSA is being increasingly grown, with more than 40% *S. aureus* cultures in the US now resistant to methicillin. Anaerobes are identified in 14–93% cultures, and may be involved in acute exacerbations.

Culture directed short-term antibiotics may be of use during acute exacerbations of CRS, but there are no studies evaluating effect on short courses on long-term symptom control. Long-term macrolides are discussed above, and are used predominantly for an anti-inflammatory effect.

Doxycycline has been compared with oral steroids in a placebo-controlled RCT in CRSwNP, and was found to have a moderate, but more sustained effect when compared with methylprednisolone. While doxycycline reduced post-nasal drip, it had no effect on nasal congestion, anosmia or rhinorrhea. Therefore it may be considered as an adjunct in treatment of CRSwNP but needs further evaluation.

While topical antibiotics have been shown to reduce bacterial colonization in animal studies, there is no evidence in the current literature that topical antibiotics are beneficial in the treatment of CRS. There have been three placebo-controlled RCTs, two in patients without previous surgery, one in difficult to treat CRS.³⁷ In all three there was no additional benefit of topical antibiotic compared to the placebo arm of nasal irrigation alone.

Even more recent trials of mupirocin, as an antistaphylococcal, delivered post-surgically in large volume irrigation, demonstrated little effect on patient outcomes. They are not therefore currently recommended.

Biofilms, both bacterial and fungal, have been demonstrated within the sinuses of patients with CRS, and their presence is associated with more severe disease and recalcitrance to surgical therapy. Systemic antibiotics are relatively ineffective against biofilms; topical antibiotics and surfactants may be more beneficial, but are likely to penetrate the sinuses only after surgery, and therefore will play a limited role in the treatment of the pre-operative patient with CRS.

The role of antifungal agents in the treatment of CRS has caused much controversy since the Mayo clinic made a patent application for the topical application of antifungals in patients with CRS in the late 1990s. However, the encouraging results of open label studies have not been repeated in randomized trials. A Cochrane meta-analysis identified 5 PCRCTs evaluating topical treatment, and one comparing systemic treatment with placebo.³⁸ Symptomatic response rates were better, and adverse event rate was lower in the placebo arm in all studies. These studies were conducted on groups of patients with CRSwNP (2), CRSsNP (1), and a mixed group of both (2 without previous surgery, 1 with). Therefore in any of these patients there is no evidence to support the use of antifungals. There are no randomized trials assessing antifungal agents in the treatment of selected patients with allergic fungal sinusitis, except for one PCRCT demonstrating reduced recurrence rates up to 9 months after surgery in patients treated with topical fluconazole when compared with itraconazole of placebo.³⁹

TREATMENT AIMED AT IMPROVEMENT IN MUCOCILIARY CLEARANCE

Normal mucociliary clearance is dependent upon both ciliary function and the mucus blanket. Saline irrigation can improve mucociliary clearance by the removal

of mucus, infected crusts and pro-inflammatory agents. Eight studies were eligible for inclusion in a Cochrane meta-analysis in 2007,⁴⁰ which demonstrated benefit from saline irrigation both when used as sole modality treatment and as an adjunct, albeit less efficacious than intranasal steroid. Large volume irrigation appears to have a greater impact on mucus management than simple sprays on RCT.⁴¹ A subsequent RCT published in 2012 found hypertonic saline irrigations and saline spray alone had a comparable response rate to patients treated with hypertonic saline irrigation and INCS.⁴² Studies directly comparing isotonic and hypertonic saline have not reported symptomatic outcomes, but suggest some benefit of hypertonic saline in terms of radiological improvement, at the cost of higher rates of local adverse effects. One small cross-over randomized trial demonstrated greater effectiveness of saline irrigation with xylitol compared with saline alone.⁴³

As irrigation is generally well tolerated, it can be recommended for use in patients with CRS. As with other topical treatments, patients should be instructed on correct techniques for irrigation (**Figure 97.2**).

Mucoactive agents

Amphiphatic molecules possess the ability to be soluble in both water and organic solutions. They form the basis of surfactants. This effects both the solution and remaining molecular load behaviour at air–surface interfaces.⁴⁴ Pulmonary surfactant greatly improves the efficiency of mucociliary clearance by reducing adhesiveness of mucus to the respiratory epithelium. Acute respiratory distress of the newborn is the case example of the requirement of such agents in respiratory function. Surfactants can have both mucoactive properties and antimicrobial properties. Chemical surfactants can interfere with microbial cell membrane permeability and cause membrane disruption. These agents are often classified as cationic, anionic or zwitterioninc (possessing non-adjacent positive and negative charges) based on the charge of the hydrophilic domain present in these molecules. Cationic surfactants possess the most antimicrobial properties but are also the most irritating.⁴⁵

Figure 97.2 Technique for nasal irrigation.

Commercial agents such as detergents, soil wetting agents, paints, antifogging solutions and ski wax are all examples of surfactants. The combination of PEG-80 sorbitan laurate, cocamidopropyl betaine and sodium trideceth sulfate (Johnson & Johnson Baby Shampoo®) has been shown to have both antibiofilm forming properties at 1% solution and clinical efficacy in managing refractory CRS patients.⁴⁵ Surfactants may not be a direct therapy for aggressive polypoid mucosal change that is dominated by inflammatory Th2 response but they are useful for treating crusting, thick mucus and chronic bacterial mucosal colonization.

Delivery of medical therapy

Cadaveric studies have documented poor penetration of topical therapies into the sinuses, particularly the frontal and sphenoid sinuses.⁴⁶ ESS can improve delivery, but only if ostial enlargement and the extent of surgery are sufficient to do so; the minimum ostial size is 4 mm to achieve maxillary sinus penetration, and retention of the uncinate in minimally invasive techniques is likely to act as a barrier to penetration.⁴⁷ Therefore, in the pre-operative state, topical therapies reach only the nasal cavity, potentially treating nasal polyps, oedema at the ostiomeatal complex and any associated turbinate hypertrophy. In order to treat the sinus mucosa, systemic therapy must be employed. In the post-operative state, topical therapy plays a greater role in managing disease control. Studies in humans support the data from these studies with less than 0.1% of solution making the maxillary sinus.⁴⁸

The delivery device is important, with aerosol sprays achieving poor penetration beyond the anterior third of the nose. The most effective delivery devices are the positive pressure, high-volume irrigation bottles or Neti pots, which can penetrate all sinuses in a post-operative patient following wide sinus surgery or frontosphenoidectomy (Figure 97.3).⁴⁹

Figure 97.3 Combining local topical corticosteroid into a delivery device (such as an irrigation bottle with a volume > 100ml) makes an enormous difference to the distribution of local therapy. When combined with a wide post-surgical cavity, the ability to control the sinus mucosa is vastly different than simple nasal sprays and without prior surgery. This shift in transitioning a patient from relying on systemic medication to delivery treatment to the sinuses to a local-based therapy has dramatically changed the outcomes for patients with chronic conditions.

ASSESSMENT OF THE RESPONSE TO MEDICAL TREATMENT

As the aim of treatment for CRS is to reduce the symptom load and impact on quality of life, these subjective symptoms need to be quantified to allow repeated measures in order to evaluate response to therapy. There are several validated disease specific quality of life measures for use in CRS. Knowledge of scores in the normal population and the minimum clinically important difference facilitates detecting improvement (Table 97.1). Alternatively a VAS scale may be used.

Response to treatment should be considered as relief of the symptoms of CRS to the point that they are no longer present or bothersome.¹³ If this is maintained, with or without ongoing medical therapy, then disease can be considered as controlled. This concept of disease control is well defined for asthma, but has been largely neglected in CRS until the recent EPOS guideline (Table 97.2); however, the proposed table needs to be data driven. Recent publication has suggested a refinement of this to focus on nasal obstruction, endoscopic evidence of oedema and mucus production and systemic medication use as either corticosteroid or antibiotics.⁵⁰ A proposed NOSE system was proposed (Nasal Obstruction, Systemic Medication, Endoscopy).

Control of disease is both to prevent infective exacerbations and control baseline symptoms. 'Normal' mucosa on endoscopy is the reference point but even this is not associated with 'no' nasal symptoms as many will have rhinitis reactions to account for some disease burden.

Usually 4–8 weeks should be allowed before considering treatment to have failed in patients with established CRS. If there has been improvement but incomplete resolution, a further period of ongoing medical treatment is recommended, although this is rarely with systemic corticosteroids. Persistent evidence on either endoscopy or CT of active mucosal inflammation is associated with

a high rate of relapse even in the asymptomatic patient (Figure 97.4).⁵¹ Where patients are asymptomatic, treatment can be withdrawn in the presence of normal endoscopy and or CT. Where endoscopy remains abnormal, the patient should continue with saline irrigation and intranasal corticosteroid and counselled on the potential need for future therapy.

Where there has been no response, the history and examination findings should be reviewed to ensure both the correct diagnosis, and to exclude symptom amplifiers that may be less amenable to standard treatment – for example, coexisting depression may lead to higher levels of symptoms for a given disease burden. Secondary CRS should be considered, and assessment of the full respiratory system undertaken, including testing for secondary eosinophilic disorders, vasculatides and immunodeficiencies where appropriate. Smoking cessation should be strongly encouraged. If there is no response, and surgical treatment is being considered, a CT scan should be performed, even with positive endoscopy, as an aid to surgery and exclusion of other diagnoses (fungal ball, AFS, neoplasia) if not already performed.

Any patient with unilateral polypoid disease, where there is a suspicion of malignancy, the presence of associated neurological or orbital symptoms or atypical features should not be considered for a trial of maximum medical therapy. They require urgent radiological imaging, followed by surgery and histological examination where indicated.

WHEN DOES A MEDICAL THERAPY ONLY APPROACH FAIL?

The question of when to be more aggressive in therapy for CRS is a common question. The dictum of a trial of conservative medical therapy before surgery in every case is false. Both fungal ball and AFS are examples where initial surgery is required. Especially in CRSwNP, there is little basis to the concept of either medical or surgical treatment alone, as combined therapy is critical to control disease.⁵² Thus, what is being achieved from intervening surgically? There will be CRSsNP patients in whom the mucosal oedema, basement membrane thickening and fibrosis are causing ostial occlusions, which cannot be resolved medically and are leading to persistent disease. However, this concept is not true for CRSwNP, eCRS or eosinophilic subtypes.^{53,54} Simply operating to ‘unblock’ or ‘ventilate’ the sinus is not an endpoint supported by evidence. Access for topical therapies is critical as a goal of surgery for CRS patients, and thus allows a patient to switch from relying on systemic therapies to local treatments.⁵²

Failure is defined by patient-focused outcomes rather than evidence of mucosal inflammation. Those patients who have a high symptom burden despite treatment, or go on to have infective exacerbations, are failures. The benefits of repeated courses of systemic treatment need to be weighed against the risk of adverse events. We would consider the need for more than two courses of systemic treatment per year indications that medical-only treatment has failed. Greater frequency may expose patients to deleterious effects of systemic corticosteroid use.⁵⁵ Each course is recommended for 14–21 days as this best equates to the lifespan of a tissue eosinophil.⁵⁶ An accumulative dose less than 290–1000 mg is recommended, with a maximum of 30–40 mg daily, as this is the range in which significant complications and medicolegal complaints occurred.⁵⁷ Those patients that fail to derive sufficient benefit from pre-surgical medical treatment and fulfil the diagnostic criteria for CRS, in whom an alternative diagnosis is not found, and who have confirmation of mucosal disease on CT, should be considered for surgery.

Patients with complete nasal obstruction due to nasal polyps, where there has been no reduction in size following initial medical treatment, are unlikely to be able to achieve access to topical treatment. In the van Zele study,²⁶ symptomatic improvement was maximal shortly after completing prednisolone, and the benefit had significantly waned by 12 weeks. It may be worth considering surgical intervention at an earlier point in such patients.

MEDICAL TREATMENT POST-SURGERY

Allowing a transition to effective local or topical therapy is a critical role for surgical intervention. With this aim, surgery is often complete, wide and designed to remodel the paranasal sinus to a common cavity that can be managed. Hypersecretory mucus can be easily removed and anti-inflammatory therapy effectively delivered.⁵² This is especially true for CRSwNP, where local ostial obstruction is unlikely to play a major role in the perpetuation of the disease process.^{53, 54}

Although nasal polyps or the presence of asthma might identify these inflammatory patients, they are still often missed. A structured histopathology of sinus tissue using defined criteria for eosinophilic CRS or greater than 10 eosinophils per high power field (>10 per hpf) will reveal

an additional 20% of CRSsNP to be classified as eCRS (Figures 97.5, 97.6).⁵⁸ The diagnosis of eCRS has prognostic implications. eCRS is associated with greater clinical and radiological severity,^{58, 59} higher risk of asthma⁵⁹ and higher risk of polyp recurrence when compared to non-eCRS.⁶⁰ Serum eosinophilia, while associated with eCRS and predictive of asthma,⁵⁹ is not predictive of the localized inflammatory processes⁶¹ and was less sensitive for eCRS.⁵⁸ Surgery provides an ideal opportunity to make this disease distinction.

Corticosteroid irrigations are the mainstay of topical anti-inflammatory therapy post-ESS.^{52–62} They are delivered in large-volume positive pressure saline irrigations. These treatments are often mislabelled as ‘high dose’ or ‘high concentration’ but neither of these is true. The delivered steroid dose is mostly in a more diluted form than

Figure 97.5 (a) Tissue eosinophilia is a marker of more severe disease and generally corticosteroid sensitive. (b) Significant subepithelial fibrosis is a feature of long-term tissue remodelling and likely portends a poor prognosis similar to studies on tissue remodelling and in asthma.

Chronic Rhinosinusitis Histopathology Report	
Tissue	
Overall degree of inflammation	Absent / mild / moderate / severe
Eosinophil count	<10 / 10–100 / >100 per hpf
Neutrophil infiltrate	Absent / focal / < 20 / > 20 per hpf
Inflammatory predominance	Lymphocytic / lymphoplasmocytic / lymphohistiocytic / neutrophilic / eosinophilic / other
Basement membrane thickening	<7.5 μm / 7.15–15 μm / >15 μm
Sub-epithelial oedema	Absent / mild / moderate / severe
Hyperplastic / papillary change	Absent / present
Mucosal ulceration	Absent / present
Squamous metaplasia	Absent / present
Fibrosis	Absent / partial / extensive
Mucin	
Fungal elements	Absent / present
Charcot-Leyden Crystals	Absent / present
Eosinophil aggregates	Absent / present

Figure 97.6 An example of routine efforts to improve histopathologic profiling in CRS during routine clinical care. The structured outline provides simple information on eosinophilic inflammatory activity, eosinophil activation (aggregates and Charcot-Leyden crystals), neutrophilic infiltrate and tissue remodelling (squamous metaplasia, fibrosis and basement thickening). Simple algorithms such as corticosteroids for eosinophilic disease and potential macrolide therapy for neutrophilic predominant patients are possible with just a little pathologic assessment.

simple sprays and the total residual delivered is usually less than 5% making the exposure to the patient less than simple spray therapy.⁶³ They are effective since they actually deliver the pharmaceutical to the sinus mucosa. Studies have shown no effect on serum cortisol,⁶⁴ urinary cortisol or the adrenocorticotropin hormone stimulation test.⁶⁵

SUMMARY

Medical therapy is the mainstay of management for rhinosinusitis.

KEY POINTS

- Medical therapy should have a 3-way goal of reducing inflammatory load, normalizing microbial community and restoration of mucociliary function.
- Medical therapy to the paranasal sinus is primarily via the systemic route in the unoperated patient.
- Systemic corticosteroid is effective, but use is usually limited to 2 courses a year, of 2–3 weeks duration and often less than 30–40mg maximal daily dose as a reducing course.
- There is little evidence of ostial obstruction as a cause of CRSwNP or the eosinophilic subgroup.
- Surgery, while potentially curative for some, is more commonly utilized to enable long-term local or topical therapy to control disease.
- Corticosteroid irrigations are a common effective delivery mechanism in the post-surgical patient. Their use is similar to that of a prophylactic inhaler for asthma patients.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the following keywords: rhinosinusitis, sinusitis and surgery, restricted to English language and abstract publication. A secondary literature review of reference lists from keynote papers and relevant book chapters was also undertaken.

INTRODUCTION

As the mucosa of the paranasal sinuses are in direct continuity with that of the nasal cavity, the term ‘rhinosinusitis’ has now been recognized as the correct description of a disease defined as: ‘inflammation of the nose and the paranasal sinuses characterized by two or more symptoms, one of which should be either nasal blockage/obstruction/congestion or nasal discharge (anterior/posterior nasal drip): +/- facial pain/pressure +/- reduction or sense of smell’.¹

Rhinosinusitis of less than 12 weeks with complete resolution of symptoms is termed acute rhinosinusitis (ARS) with chronic rhinosinusitis (CRS) developing at or after 12 weeks of symptoms without complete resolution.¹

There are many exacerbating factors, which can cause or influence the severity of rhinosinusitis. These include (but are not restricted to): asthma, aspirin exacerbated respiratory disease (AERD), cystic fibrosis and immunodeficiency.¹⁻⁴

A comprehensive history of surgery for the management of rhinosinusitis is beyond the scope of this chapter; however, it is fair to say that the advent of antibiotics and the rigid endoscope have both completely revolutionized the indications and surgical techniques for operative management of rhinosinusitis.⁵

The aetiological causes of both ARS and CRS remain controversial, incompletely understood and subject to continued speculation.⁶ It is becoming increasingly

apparent that surgical indications and techniques for the management of rhinosinusitis depend, to a greater or lesser degree, on the belief by the individual surgeon or local surgical community in these various aetiological theories. For example, in countries where osteo-meatal complex (OMC) obstruction is seen as paramount for disease causation, simple middle meatal antrostomy and anterior ethmoidectomy (‘mini-FESS’) may be considered as standard of care; whereas, in countries where surgery is predominantly seen as optimizing the environment for the application of topical medical therapies, a more complete fronto-spheno-ethmoidectomy (‘full-house FESS’) is deemed as a more appropriate primary procedure.^{7, 8}

With new technological developments, minimally invasive options such as balloon sinus dilatation are now available⁹ and yet at the other end of the spectrum, extensive ‘nasalization’ of all the paranasal sinuses is now possible using high powered drills, haemostatic agents and computer navigation systems.¹⁰

In this chapter, we will examine the literature surrounding this complex area and attempt to present it in an evidence-based manner.

DIAGNOSIS

The diagnosis of both ARS and CRS depends on an accurate history and clinical examination of the patient. Whilst nasal endoscopy and CT scanning are critical in confirming the diagnosis, these are usually only available

through an ENT specialist or allergist. CRS is subdivided into disease with nasal polyps (CRSwNP) and without (CRSsNP).¹ Bilateral nasal polyps are required for a diagnosis of CRSwNP.¹ It can further be subdivided by histological phenotypes such as eosinophilic or neutrophilic CRS, which is now recognized to influence both the medical (both pre- and post-operative) and surgical management of the patient.¹¹

In the specialist setting, rigid nasal endoscopy can be used to visualize the osteo-meatal complex in patients. It can also aid the collection of sinus secretions for microbiological analysis.¹ Whilst the presence of pus, erythema and oedema can be valuable positive findings, endoscopic findings remain extremely subjective and there is little evidence they alter outcomes.^{1, 12-14}

Radiology

Due to the poor resolution, high false positive and false negative results, plain sinus x-rays are no longer recommended for the investigation of either ARS or CRS.¹ The advance in CT scanning technology has meant it is now possible for high resolution CT images to be rapidly obtained with a very small radiation dose. CT scans should ideally be reconstructed into three planes (coronal, axial and para-sagittal).¹⁵ The use of laptop-based computer programs such as OsiriX, and the routine availability of images on CD-ROM, has now made further manipulation of CT images possible on an individual patient basis.¹⁶

SURGICAL OPTIONS

Indications for surgery

ACUTE RHINOSINUSITIS

Medical management remains the mainstay for ARS with antibiotic therapy being reserved for patients with severe disease, especially with the presence of high fever or severe (unilateral) facial pain.¹ In rare cases, ARS may progress to complications involving the orbit, the cranium or frontal bone. Where sub-periosteal and intra-orbital abscess, epidural or subdural abscesses, meningitis and/or intra-cranial sinus thrombosis, surgical options may then enter the management algorithm.¹⁷ A good principle is that where the ARS complication is managed medically (e.g. meningitis), the ARS may be managed medically as well; whereas when a complication is to be managed surgically (e.g. orbital or intra-cranial abscess, Pott's puffy tumour), then simultaneous surgical drainage of the affected sinuses should be considered.¹⁸

CHRONIC RHINOSINUSITIS

There is a huge amount of evidence on the medical management of CRSwNP and also CRSsNP.¹⁹ Well produced guidelines such as the EPOS2012 document¹ have concluded that topical steroids and nasal irrigation should be tried by primary care physicians for at least 4 weeks before considering a referral to an ENT specialist. If the diagnosis is clinically confirmed and maximal medical therapy

has not improved symptoms, a CT scan is then indicated. The CT findings not only enable assessment of the presence of residual disease that could be addressed by surgery but also provide the surgeon with the ability to recognize the presence of anatomical risk factors for the development of CRS and to facilitate surgical planning. There are multiple factors which need to be considered before a decision to undertake surgery is reached;²⁰ these include i) patient factors; such as general cardio-respiratory health, anticoagulation treatment and social factors, ii) facility factors; such as access to (and the availability of) appropriately trained personnel and acceptable equipment levels for the type of surgery being considered and iii) economic factors; which include cost both to the individual and to the relevant healthcare system.

Appropriate informed consent must be obtained from all patients when considering surgery and this consent must include an honest discussion of the natural history of their condition,²¹ the risks and sequelae of surgical complications,²² the potential for recurrent disease,²³ the usual need for ongoing medical management and always the option of continuing non-surgical management.²⁴

SURGICAL PROCEDURES

Anaesthesia for sinus surgery

Although it is entirely possible to do most forms of endoscopic sinus surgery under local anaesthetic, it is common practice for patients to have a general anaesthetic in many Western countries.^{1, 25} Whilst the use of laryngeal mask anaesthesia has not yet been universally accepted, it is the authors' view that, unless there are significant increased risks of laryngeal soiling (significant laryngopharyngeal reflux, obesity or other medical factors), laryngeal mask anaesthesia is generally preferred over endotracheal intubation.²⁶ The use of volatile inhalation agents has declined and with the increasing availability of short acting opiates such as Remifentanyl, many surgeons prefer total intravenous anaesthesia (TIVA). With TIVA there is a very small but real risk of awake anaesthesia and therefore the use of bispectral index (BIS) monitoring is recommended to avoid this potentially serious medicolegal complication. The evidence regarding TIVA and an improved surgical field remains controversial.²⁷ Whilst some authors claim that there is significant benefit from TIVA,²⁸ the use of sevoflurane (at low concentration only) and remifentanyl combined probably provides just as good a surgical field and avoids the need for BIS monitoring. Mean arterial blood pressure (MAP) is determined by the following equation: $MAP = \text{heart rate (HR)} \times \text{stroke volume (SV)} \times \text{systemic vascular resistance (SVR)}$. In order to optimize the surgical field, hypotensive anaesthesia is desirable. Our evidence-based recommendation is to maintain a systolic MAP of approximately 90 mmHg, which is best achieved by maintaining the HR at approximately 60 beats per minute.^{25, 27, 28} Volatile agents, which achieve hypotension by reducing SVR, can paradoxically cause a deterioration of the surgical field due to vasodilatation of the nasal microvasculature. Further discussion

on anaesthesia for sinus surgery can be found in several good review articles.^{25, 29, 30}

Surgical position

There is good evidence that the surgical field is optimized by placing the patient in the reverse Trendelenberg position.³¹ Many surgeons remain concerned about the effect of head elevation and its potential reduction in cerebral blood flow (CBF) and oxygenation. Whilst physiological studies have confirmed that CBF does vary with head elevation, the cerebral perfusion pressure remains constant at elevations of between 0 and 30°.³¹

Intranasal preparation

There is evidence that transpalatal injection of the greater palatine canal decreases intra-operative blood loss during sinus surgery³² but despite the evidence, the technique has failed to break through it into routine clinical practice. This may be due to the fact that whilst head elevation has been demonstrated to produce a 38.3% reduction in nasal blood flow, injection of the greater palatine canal only produces a reduction of 4.7%.^{31, 32}

Topical decongestion in the form of cocaine and adrenaline, +/- sodium bicarbonate ('Moffat's solution') soaked on neuro-patties, ribbon gauze or pledgets remains most commonly used³³ although a randomized controlled trial has shown that the use of co-phenylcaine (ENT Technologies, Victoria, Australia) which is a combination of lignocaine 5% and phenylephrine 0.5%, is just as effective.³⁴ There are many legal restrictions on the use of cocaine and in many countries it is simply not possible for ENT surgeons to use cocaine and other alternatives are therefore required. Oxymetazoline alone is utilized in many centres with effective results.³⁵ Local anaesthetic infiltration of the middle turbinate, nasal septum and frontal process of the maxilla is then commonly performed. 1–2mls of 1% lignocaine with 1 in 80000 adrenaline is typically utilized.³⁵ It is always important to be aware of the total dose of cocaine, lignocaine or other local anaesthetics that are given both topically and intra-mucosally. Toxic reactions from overdose have been reported and the use of adrenaline will frequently cause a rise in heart rate with a corresponding temporary deterioration in the operative field (which may be greater than the gained benefit of the vasoconstrictor effect). Rather than immediately proceeding to surgery, it is therefore preferable to allow a period of time for topical and injected vasoconstrictors to establish their local effect, whilst allowing their systemic effect to dissipate.

Functional endoscopic sinus surgery (FESS) for rhinosinusitis

GENERAL PRINCIPLES

Recent CT scans of the patient's sinuses are mandatory and should be available to the surgeon throughout the operation.³⁶ If scans are available in traditional x-ray film

format, these can be placed on a mobile viewing box adjacent to the surgeon. It is increasingly common for images to be provided in electronic format (DICOM-viewers). In this case, a large plasma screen TV or monitor can be placed adjacent to the surgeon and multiple images displayed on the screen simultaneously. It is important that a member of the theatre team is computer skilled to change the displayed images, if required. It is difficult for a surgeon to remember the multiple anatomical nuances of each individual patient and without the presence of images during surgery, increased complications may occur. If intra-operative image navigation is available, some surgeons regard this as an adequate replacement for the above but it is the personal preference of the authors to have standard images available at all times, in case of equipment failure or poor registration of the image navigation system.

EYE PREPARATION

Traditionally, the eyes have been left open with lubrication but many surgeons now accept limited or even complete taping of the eye, still allowing rapid access to the globe but providing for better corneal protection. There have been several medicolegal cases whereby corneal abrasions have resulted in successful lawsuits.³⁷

SURGICAL TECHNIQUES^{36, 38}

i) Uncinectomy

The free edge of the boomerang-shaped uncinate process can be identified in most cases by the use of a Freer's elevator. The use of a sickle knife on the interior portion of the uncinate is to be discouraged as orbital penetration can easily occur.³⁷ Either adult or paediatric back-biting forceps are readily available which allow for safer uncinete incision (**Figure 98.1**).

Superiorly on the uncinate process, the orbit is relatively more protected by the hard bone of the frontal process of the maxilla.³⁶ A sickle knife can be used safely in this area although a back-biter remains an acceptable alternative. The uncinate process can then be removed using

Figure 98.1 A paediatric back-biting forcep is used to perform the inferior uncinete incision.

Figure 98.2 Dissecting out the bone of the horizontal process of the uncinate.

angled through-biting forceps or can be dislocated forward using a double right-angled ball probe and then cautiously removed with the microdebrider or through-biting forceps. Any rough edges can be removed using a 2 mm Kerrison's punch.³⁸ It is always important to then address the horizontal part of the uncinate which extends inferior to the natural ostium of the maxillary sinus. The bone of the horizontal portion can be dissected free from the mucosa (Figure 98.2) and the natural ostium can simply be stretched open with an angled probe or sucker, without removing any mucosa. For more advanced disease (or in revision cases), it may be necessary to remove mucosa to create a large middle meatal antrostomy.

ii) Removal of the ethmoidal bulla

The natural ostium of the ethmoidal bulla sits postero-medial to the anterior face. The ostium can be located by several methods; a double right angled ball probe or 45° antral curette can then be used to fracture the anterior face forwards (Figure 98.3). A microdebrider can then be used to remove the bulla, aiming for complete removal

Figure 98.3 A double right-angle ball probe is inserted into the natural ostium of the bulla ethmoidalis (medial) then the anterior face is fractured anteriorly.

of partitions between the lamina papyracea and the middle turbinate. When removing the bulla superiorly, it is important to recognize the location of the anterior ethmoidal artery. Although commonly located in the suprabullar recess, on rare occasions, the artery can sit within the anterior wall of the bulla and be damaged by inadvertent use of the microdebrider in this area. If present, other anterior ethmoidal cells can be removed in a similar manner. The use of through-biting instruments is preferred to standard Blakesley-Wells forceps as the latter can tear mucosa and leave exposed bone in the final sinus cavity.

iii) Posterior ethmoidectomy

The ground lamella of the middle turbinate defines the junction between the anterior and posterior ethmoid sinuses. After reference to the CT scan, the ground lamella should be perforated in the infero-medial quadrant. This avoids inadvertent injury to the skull base or lamina papyracea. Once the posterior ethmoid is opened, the roof of the maxillary sinus can be used as a guide to the superior limit of dissection within the posterior ethmoid. Anatomical studies have shown that the antral roof will always be below the skull base and allow for safe passage to the sphenoid sinus.^{38, 39} A microdebrider, Kerrison's punch or through-biting instruments can be used to remove the partitions between the posterior ethmoid cells. Care should be taken in the posterior ethmoid as the optic nerve may traverse through an Onodi cell and the surgeon should always be aware of their exact surgical location at all times.

iv) Sphenoidotomy

The natural sphenoid ostium is located in the sphenoidal recess, medial to the superior turbinate and at the height of the antral roof. It is not always possible to pass an endoscope medial to the superior turbinate to identify the ostium and part of the middle turbinate can be resected with a back-biting forceps, entering the superior meatus and locating the forward projection of the superior turbinate from within the posterior ethmoid cavity. The inferior third of the superior turbinate can then be resected in order to gain access to the sphenoidal recess. If the sphenoid ostium can still not be located using this method, an artificial opening to the sphenoid can be made through the posterior ethmoid and then extended medially to incorporate the natural sphenoid ostium. Again, if accessing the sphenoid through the posterior ethmoid cavity, perforating the ground lamella of the superior turbinate should always be done in the infero-medial portion to avoid accidental injury to the skullbase.

v) Frontal sinus surgery

The Agger nasi cell is key to all approaches to the frontal recess.³⁶ In a small percentage of patients it may be absent but it is a good landmark in the vast majority of cases. Using a Kerrison's punch in the axilla of the middle turbinate (Figure 98.4), the anterior portion of the Agger nasi can be removed.³⁸

Figure 98.4 A 2 mm 450 forward-angled Kerrison's punch is used to raise the axilla of the middle turbinate and improve access to the Agger nasi and the frontal recess.

Figure 98.5 Exposure of the frontal recess by removing the posterior wall and roof of the Agger nasi cell.

Curettes and angled instruments can then be used to remove the posterior wall and roof of the Agger nasi to expose the frontal recess (Figure 98.5).

Although mucosal flaps have been advocated for this approach,³⁶ the authors no longer regularly utilize axillary flaps as adhesions can easily be prevented using other methods and regular post-operative review. Once the Agger nasi has been removed, any remaining fronto-ethmoidal cells can be removed using through-biting instruments, curettes or angled microdebrider blades. Care must be taken to avoid a circumferential injury to the mucosa in this area as this will undoubtedly result in stenosis of the frontal recess and recurrent frontal sinusitis. When dissecting the frontal recess, the position of the anterior ethmoidal artery needs to be identified and maintained in the surgeon's mind at all times. Any inter-sinus septal cells or supraorbital ethmoid cells may also need to be addressed and these generally require the use of angled endoscopes and curved microdebrider blades. Advanced frontal instrumentation such as a giraffe forceps or 3.5 mm Hosemann punch (Figure 98.6) may greatly facilitate surgery in this area.³⁸

POST-OPERATIVE MANAGEMENT

It is critical to see patients regularly in the immediate post-operative period. Although surgeons routinely perform debridement of the sinus cavity in several countries, there is controversy as to whether this is absolutely necessary. Randomized controlled trials have shown no difference in outcomes between patients who receive regular toilet of their sinus cavities versus those that do not.⁴⁰

Most surgeons routinely use high volume saline irrigations to clean the nose of mucopus, blood clot and other tissue.¹ Although the choice of solution is largely an individual one, a recent randomized controlled trial demonstrated improved outcomes using Ringer's lactate solution, when compared to either isotonic or hypotonic saline solution.⁴¹ However, the cost of pre-made irrigation sachets needs to be offset against any potential benefit. There is no evidence that the use of prophylactic

Figure 98.6 Use of a Hosemann punch to facilitate removal of Kuhn cells in the frontal recess. It is critical to avoid circumferential mucosal injury in this location.

post-operative antibiotics improves outcomes following routine endoscopic sinus surgery.¹ If mucopus is found at the time of surgery, a swab should be taken and targeted antibiotic treatment should then be prescribed. Institutional guidelines may now prevent the surgeons from prescribing routine prophylactic antibiotics unless infection is identified at the time of surgery. In the case of severe disease (and usually in most cases of CRSwNP) a 10 day course of oral Prednisolone can be given. It is the authors' practice to use 25 mg prednisolone daily for 10 days without tapering. However, individual surgeons will have their own preferred steroid regimens. It is important to remember that eosinophils can last up to 3 weeks in the tissues and if there is extensive eosinophilic disease (usually in the case of CRSwNP), it may be logical to use an extended course of steroids for 3 weeks or longer.³⁸ In this case, the steroid dose will need to be tapered off to avoid an Addisonian crisis. It is the authors' practice to see patients 7–10 days following surgery then weekly if there are any concerns or fortnightly if not. At 6 weeks, one would expect the sinus cavity to be fully healed and at that

stage, routine nasal steroids and less frequent irrigations can be continued until review at 3 months. It is important to emphasize to patients with severe disease that they may need to be on topical steroid sprays or irrigations for some time (and in some cases, e.g. eosinophilic CRS, for an indefinite period) to prevent recurrence of their nasal polyps.

SURGICAL COMPLICATIONS

In the hands of experienced clinicians, reported complications are rare. Analysis of the literature reveals a range of significant complications between 0.3 and 22.4% (median 7.0%).²² Although the majority of these are minor and do not result in any adverse outcome to the patient, damage to the orbit or skull-base can be severe and result in significant morbidity and mortality. Excessive bleeding and poor visualization of the operative field is associated with an increase in complication rates. When a bloody field is encountered, if this cannot be controlled, it is always safer to abandon the procedure and plan elective second stage surgery. Continuing with surgery without proper visualization can result in a catastrophic outcome. A recent meta-analysis from Australia has demonstrated that the use of intra-operative image guidance does significantly reduce the incidence of complications.⁴² Such equipment however is costly and in the UK and Australia, surgeons would not routinely use intra-operative image guidance for primary, uncomplicated sinus surgery.

Avoiding complications

A proper pre-operative history will identify if the patient is taking significant medication (e.g. warfarin, clopidogrel or aspirin). There are many other drugs and homeopathic preparations that can also effect bleeding. NSAID's, fish oil and vitamin preparations are amongst those often missed. Correct interpretation of the CT scans will alert the surgeon to any presence of any high risk anatomical features which might increase the chance of damage to the orbit or cribriform plate. Dehiscence of the lamina papyracea, angulation of the vertical lamella of the cribriform plate and congenital defects in the skull base and over the carotid artery can all be identified pre-operatively.

HAEMORRHAGE

Knowledge of the anatomical location of the major branches of the sphenopalatine artery and anterior ethmoidal artery will prevent injury in the first instance. Aggressive resection of the horizontal part of the middle turbinate and extending the sphenoid ostium inferiorly will damage two of the major branches of the SPA. Identification and avoidance of the anterior ethmoidal artery should be performed in all cases where the bulla is elevated up to the skull base or the frontal recess is dissected. Small bleeding vessels can usually be controlled with topical vasoconstrictors (1 in 80000 adrenaline, with or without cocaine). Larger vessels can be controlled

with dedicated suction bipolar diathermy. Caution must be used if monopolar diathermy is considered as heat dissipation can damage surrounding structures, including the optic nerve.⁴³ In cases of diffuse mucosal bleeding, topical haemostats such as Surgiflo or Floseal can be utilized to good effect. Very rarely, formal ligation of the SPA³⁶ or exploration of the orbit for clipping of the anterior ethmoidal artery may be required. Direct bipolar diathermy of the anterior ethmoid artery is rarely required and may be problematical, owing to the presence of varying degrees of bone thickness over the artery.

ORBITAL INJURY

The orbit can be damaged with the first incision of a sickle knife through the inferior portion of the uncinat process (Figure 98.7). Other high risks areas are when performing a middle meatal antrostomy where there is a long thin infundibulum. If orbital fat is exposed, it is essential that the surgeon recognizes this immediately. No repair of the defect is usually necessary and the eye should be routinely checked to identify any intra-orbital haemorrhage. Any proptosis should be regarded as significant and decompression of the orbit by removing the lamina papyracea and incising the orbital periosteum may be required, with or without a lateral canthotomy and/or cantholysis.³⁶

If a surgeon fails to recognize they have exposed orbital fat and continues manipulation in this area, damage to the medial rectus or other ocular muscle can occur. The use of the microdebrider has been associated with an increased risk of damage to the medial rectus muscle. If damage to the ocular muscles is suspected, an ophthalmological opinion should be obtained although there is usually little that can be done to repair a transected muscle and late oculoplastic surgery may never restore normal movement to the damaged eye.³⁷

OPTIC NERVE INJURY

The optic nerve can be damaged due to intra-orbital haematoma (see above) or direct injury from within the

Figure 98.7 An orbital haematoma caused by a breach of the lamina papyracea during sinus surgery.

posterior ethmoid or sphenoid. It is most at risk if the optic nerve is on a mesentery within an Onodi cell. If injury to the optic nerve is suspected during a surgical procedure, steroids should be given and an urgent ophthalmological consultation should be obtained as soon as possible.

CSF LEAK

If the skull base is damaged during sinus surgery, a CSF leak can be created (Figure 98.8). The estimated prevalence of this is 0.5% of sinus surgical cases.³⁷ The area at greatest risk is surrounding the vertical lamella of the cribriform plate. If this lamella is at an angle (rather than vertical) it is more easily damaged, especially with angled instruments or microdebrider blades. Again, a bloody surgical field increases the risks of CSF leak.

Often a CSF leak can be identified immediately and can be repaired without any long-term morbidity to the patient. Repair of CSF leaks has been covered elsewhere in this book but options include fat plugs, artificial materials or homografts with or without covering mucosal grafts. The use of fibrin glue has greatly facilitated the closure of CSF leaks.

CAROTID ARTERY INJURY

The internal carotid artery can be damaged during sphenoid surgery, especially if there is a bony dehiscence over the artery. Pre-operative identification of such a dehiscence will reduce the chance of such complications arising. A carotid injury can be catastrophic and devastating. It can be extremely difficult to manage due to the high volume of exuding blood, which will obscure the operative field. The anaesthetist must commence immediate haemostatic resuscitation and the sphenoid packed. Although direct carotid artery repair (with either a J-suture or muscle pack) has been advocated,⁴⁴ placement of an endovascular stent is an effective alternate treatment option.

Figure 98.8 Iatrogenic CSF leak caused by damage to the skull base during FESS.

EVIDENCE BASED SURGERY FOR CHRONIC RHINOSINUSITIS

Whilst most surgeons would feel that sinus surgery benefits the vast majority of their patients, critical analysis of the literature reveals that this is not always the case. Owing to the phenomenon of cognitive dissonance,⁴⁵ surgeons will always be reminded of their successes and psychologically repress their failures. There have been few randomized controlled trials (RCT) looking at surgery for chronic rhinosinusitis. The Cochrane collaboration continues to update its analysis of evidence behind surgery for CRS and have only found six RCT's in this area and excluded three of them.⁴⁶ One trial compared twelve patients undergoing endoscopic middle meatal antrostomy with seventeen patients undergoing inferior meatal antrostomy. The trial showed no difference between the groups but was poorly powered and poorly designed.⁴⁷ A second study looked at patients undergoing FESS versus antibiotics and again found no difference between the two groups.⁴⁸ The third and best study randomized ninety patients to medical treatment (long-term antibiotics, intra-nasal corticosteroids and saline irrigations) or FESS. Whilst both treatments had significant benefit to the patients, there was no significant difference between the medical and surgical arm.⁴⁹

In patients with CRSwNP, thirty-one patients were randomized to receive FESS on one side after oral and topical steroids. Whilst surgery provided additional benefit in some patient symptom scores, there was no difference in post-operative smell between the two groups.⁵⁰ The RCT evidence does demonstrate more benefit for patients with CRSwNP than CRSsNP.⁵¹ Other non-RCT data provides more support for surgery, especially in patients who have failed medical management.⁵¹ The Royal College of Surgeons of England performed the national comparative audit of surgery for nasal polyposis and chronic rhinosinusitis in 2000. This audit looked at over 3000 patients and found that patients with CRSwNP did better following surgery than patients with CRSsNP. Three point six percent had revision surgery within 12 months and 11.8% within 36 months.⁵² A 5-year follow-up study published in 2009⁵³ revealed that 19% of patients had undergone revision sinus surgery during a 5-year post-operative period. Revision rate was 21% in patients with CRSwNP compared to 15% with CRSsNP.

Recently, studies have evaluated the implications of tissue eosinophilia on post-operative outcome. Eosinophilic CRS has been shown to be of greater clinical severity as well as having a higher recurrence of disease following surgery.⁵⁴ One recent study also showed that 'full-house' FESS with post-operative steroid irrigations significantly reduces the risk of recurrence in CRSwNP.⁵⁵

Whilst several clinical factors have been shown to decrease baseline quality of life (QOL) scores (including; asthma, ASA status, depression, and female gender), few of these factors appear to correlate with

poorer outcomes post-operatively.⁵⁶ Asthma and ASA status have been demonstrated to influence clinical outcome post-ESS.⁵⁷ One trial showed that patients with asthma or higher ASA generally had worse endoscopy scores post-operatively but showed greater symptom improvement than those without asthma.⁵⁸ Depression, whilst having no effect on objective measures, demonstrated greater degrees of improvement on QOL scores.⁵⁹ Patients who had undergone previous FESS had worse post-operative endoscopy scores although their degree of symptom improvement was similar to that seen in primary surgical patients.⁶⁰ Although contrary to established conceptions, neither smoking nor allergy has been shown to affect post-surgical outcomes following FESS.

These QOL studies have been reviewed well in several published articles.⁶⁰

In conclusion, although there is little RCT evidence to demonstrate the benefit of FESS over medical treatment, there is a large amount of level 2 and level 3 data demonstrating that FESS is safe and produces significant symptom and QOL improvement for patients with both CRSwNP and CRSsNP.

Balloon sinuplasty

Balloon dilatation of either the maxillary, frontal and/or the sphenoid sinus ostia is an alternative technique that is increasingly being performed, especially in North America. It is a highly controversial topic and yet there is a large amount of evidence that balloon dilatation can maintain patency of the sinus ostia with 80.5% patency at 6 months, 85.1% at 1 year and 91.6% at 2 years.⁶¹ However, cadaveric studies have shown that, when the maxillary sinus 'ostium' is dilated, the true ostium may be missed and a false ostium created in the posterior fontanelle. These findings have been confirmed by a clinical study performed in Austria.⁹ There are significant health care costs with the disposable balloons used for most sinus dilatations, although reusable balloons are now entering the marketplace, which should reduce costs in the future. Small RCTs have shown balloon dilatation to be non-inferior to FESS⁶² and a non-randomized trial has shown balloon dilatation to produce lower sinonasal outcome test (SNOT-20) scores compared to conventional FESS at three months.⁶³ Larger and more robust trials are certainly required to establish which patients should be treated with this new treatment modality and at what stage during their disease progression.⁶⁴

RHINOSINUSITIS IN CHILDREN

The management of children with rhinosinusitis remains controversial. There is a large body of evidence to support the use of adenoidectomy alone as a first-line treatment and to reserve any form of endoscopic sinus surgery for rare and resistant cases.¹ In a meta-analysis and systematic review of adenoidectomy in paediatric CRS, 50–80% of children with CRS improved following

adenoidectomy alone.⁶⁵ Whilst there does not appear to be any evidence that endoscopic sinus surgery produces any deleterious effects on mid-facial growth, it is widely accepted that conservative treatment should be pursued with all medical management options exhausted before surgery is considered in this patient age group.¹ There may be a role for surgery in patients with cystic fibrosis and immune deficiencies to provide better access for topical irrigations and medications to control their disease although fortunately, such cases remain in the minority treated by most paediatric rhinologists.

CONCLUSIONS

The advent of endoscopic sinus surgery has largely replaced external approaches to the sinuses with some exceptions relating to disease involving the lateral frontal sinus or pre-maxilla. Outcomes of FESS surgery in patients with CRSwNP and CRSsNP remain excellent where medical management has failed, however there is little evidence for endoscopic sinus surgery over medical management as a primary treatment. When significant extra-sinus complications are associated with ARS, and surgical intervention is indicated, most cases can be managed endoscopically. It should always be remembered that FESS does carry a risk of significant and severe complications and rare mortality. Good patient selection, meticulous operative technique and post-operative care remain critical to optimize patient outcomes.

FUTURE RESEARCH

- ▶ Better evidence about the best treatment regimes for 'maximal medical therapy' prior to consideration of FESS is required.
- ▶ The relative benefits of aggressive 'full-house' FESS versus conservative 'mini-FESS' need to be ascertained.
- ▶ Balloon sinus dilatation remains an intervention where further clinical trials would clarify its role in current management algorithms.
- ▶ More research is necessary to provide an adequate evidence-basis for post-FESS medical management regimes.

KEY POINTS

- FESS is an effective technique for patients with both CRSwNP and CRSsNP when medical management has failed.
- Revision rates for FESS are generally between 10–20% over a 5-year period, more so in patients with CRSwNP.
- Good pre-operative planning, surgical technique and post-operative follow-up have been demonstrated to produce optimal outcomes.
- FESS has been demonstrated to improve the effective medical management of patients with eosinophilic CRS.
- CRS remains a mucosal disease and ongoing medical management is typically required to prevent recurrent symptoms despite adequate FESS.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search (as well as PubMed) using the following keywords: frontal sinus, Draf, Lothrop, frontal sinus drill out, osteoplastic flap, osteoma focusing on anatomy, diagnosis, outcomes, management and surgical strategy. The evidence in this chapter is mainly levels 3/4 with some level 2 evidence. The clinical recommendations are predominantly B and C.

INTRODUCTION

The frontal sinus is arguably the most complex of the paranasal sinuses. It demonstrates great variability in size and septation and is rarely symmetrical. In up to 5% of the population this sinus is absent or rudimentary.¹

ANATOMY

An overview of the anatomy of the paranasal sinuses is covered in [Chapter 87](#). This section refers specifically to the complex anatomy of the frontal recess and frontal sinus.

The frontal sinus ostium drains into an hourglass shaped space termed the frontal recess. Previously, this was incorrectly termed the frontonasal duct but it is not a tubular structure. The frontal recess is a three-dimensional space which communicates with the ethmoidal infundibulum within the middle meatus. In essence the ventilation and drainage of both the maxillary and frontal sinuses pass through narrow complex clefts and spaces before they reach the middle meatus. These clefts and spaces are part of the anterior ethmoid air cells. A normal healthy frontal sinus is therefore dependent on the health of the anterior ethmoids.

Only in the frontal sinus is mucus actively transported inwardly. This is along the frontal intersinus septum, laterally along the roof and back medially along the floor. Less than 60% exits the sinus in any given circuit. Hence, there is a significant recirculation of mucus.²

THE FRONTAL RECESS

The frontal recess is bound anteriorly by the agger nasi and the frontal process of the maxilla, the frontal beak. The thickness of the frontal beak depends on the pneumatization of the agger nasi and the presence of frontoethmoidal cells. In general, but not invariably, the greater the number of cells and pneumatization present the smaller the beak and the wider the frontal ostium.³ The medial border of the frontal recess is the superior attachment of the middle turbinate, the lateral lamella of the cribriform plate, the height and angle of which can vary considerably. The lateral and posterior boundaries are formed by the lamina papyracea and the upward continuation of the anterior face of the bulla, respectively. If the bulla lamella is absent superiorly, a suprabulla space will communicate directly with the frontal recess. In this situation the anterior ethmoidal artery is not protected by the bulla lamella and may be at risk during dissection of the frontal recess. The anterior ethmoidal artery, traversing the skull base

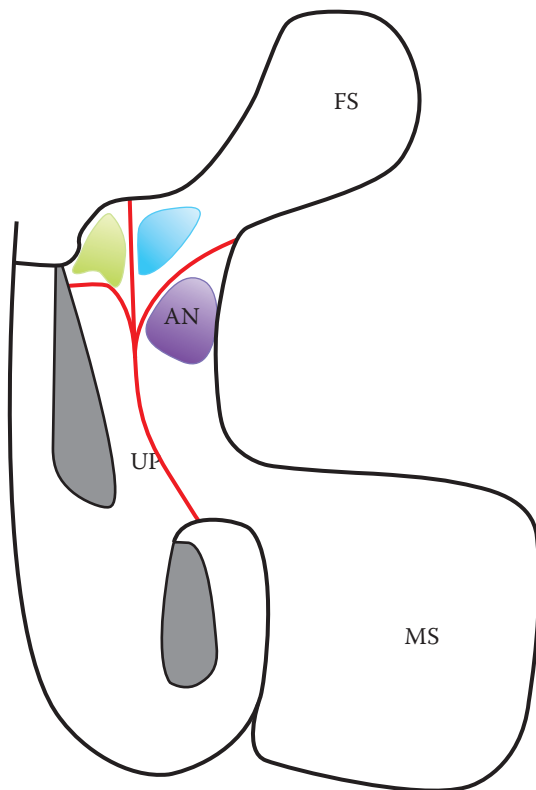

Figure 99.1 Attachments of the uncinete process (UP). Note the presence of frontal ethmoidal cells may alter the attachment of the uncinete process to the skull base, middle turbinate or a combination of these (AN, Agger nasi; FS, Frontal sinus; MS, Maxillary sinus).

from laterally posteriorly to medially anteriorly, is more likely to lie in a mesentery when the olfactory fossa depth is greater than 4 mm.⁴ Superiorly, the frontal recess communicates with the frontal sinus but posterior to this, the roof is formed by the fovea ethmoidalis.

Both the agger nasi and uncinete process are key structures in understanding the frontal recess. The agger nasi cell is present in over 90% of patients.⁵ The crescent shaped uncinete process attaches inferiorly to the inferior turbinate but superiorly it can attach to the lamina papyracea (33%), skull base (10%) or middle turbinate and a combination of these (57%) (Figure 99.1). When present, the medial, posterior and even superior walls of the agger nasi cell are often attached or intimately related to the superior aspect of the uncinete process (Figure 99.2).⁶

There are many complex anatomical variations within the frontal recess. Building a three-dimensional image of the various cells is crucial to understanding the anatomy and safe dissection in this area. This has been elegantly described by Wormald et al. in numerous articles and texts.^{3, 7, 8}

The simplest configuration within the frontal recess is the presence of an agger nasi cell only. In this instance the uncinete process, curving around the agger cell, would most likely attach directly to the lamina papyracea. Following an uncinectomy and viewed from below, the superior cut end of the uncinete resembles ‘a vertical bar’. Access to the frontal sinus is medial to the vertical bar.⁹

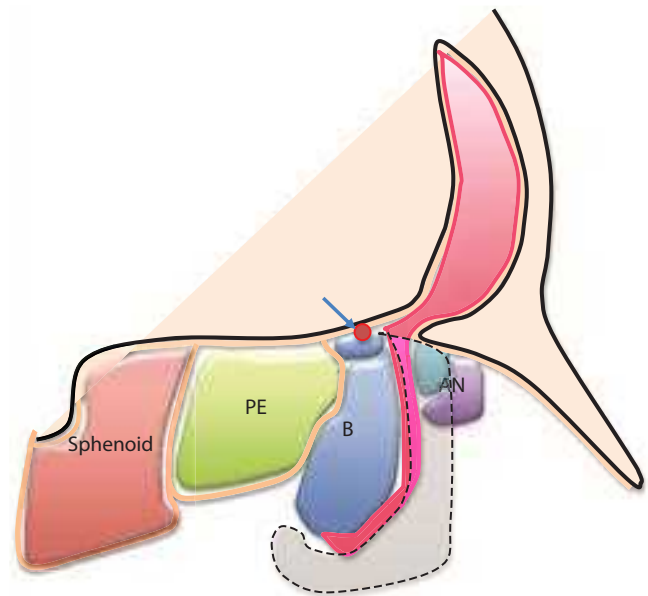

Figure 99.2 The lateral nasal wall. The uncinete process is outlined in a black dotted line. Note its relationship with the agger nasi (AN), B (bulla) and PE (posterior ethmoid). Arrow highlights the anterior ethmoidal artery.

Accessory cells in the frontal recess

The array of cells within the frontal recess can be complex and confusing. In an attempt to provide clarity, Bent and Kuhn proposed an early classification of these cells.¹⁰ This has since been modified.³ The most recent classification describes the various cells as anterior or posterior, and medial or lateral, with respect to the frontal recess.¹¹

Frontal ethmoidal cells are frequently present and classified 1 to 4 (Table 99.1). These are anterior ethmoidal cells that are in contact with the frontal process of the maxilla, the anterior limit of the frontal recess. They sit above the agger nasi cell and are described by their number and degree of extension into the frontal sinus. Recently, a more simplified classification has been proposed. The IFAC (International Frontal Sinus Anatomy Classification), primarily describes these accessory cells based on their location and relationship with the agger nasi and ethmoid bulla.¹² Anterior cells are termed supra agger cells and if extending into the frontal sinus are called supra agger frontal cells (SAF). Supra bulla cells are posterior cells and similarly if these extend into the frontal sinus are called supra bulla frontal (SBF) cells. When multiple or large they can obstruct ventilation of the frontal sinus (Figure 99.3). Being able to read the configuration of these cells, and how it affects the outflow tract is an important step in dissecting the frontal recess. In general, frontal ethmoidal cells tend to push the frontal sinus drainage pathway either posteriorly and/or medially (Figure 99.4).

In order to build a three-dimensional understanding of the frontal recess, CT images in the coronal, axial and parasagittal planes are required. In Figure 99.5 the coronal CT image depicts bilateral frontal cells (a). If one merely looked at image (b), the frontal ethmoidal cell on the left

TABLE 99.1 Classification of frontal sinus and recess cells

Cell type	Description	Significance	Best CT view
Anterior*			
Agger nasi	A cell that sits anterior to, or directly above to the origin of the middle turbinate	Push the drainage pathway of the frontal sinus medial, posterior or posteromedially	Coronal, Sagittal
Frontal ethmoidal	Anterior lateral ethmoid cells above the agger nasi cell (in contact with the frontal process of the maxilla)		
Type 1/SAC	Single cell above the agger nasi cell – supra agger cell (SAC)	Tend to push the drainage pathway posteriorly	
Type 2/SAC	Tier of cells above the agger nasi cell		
Type 3/SAFC	A frontal cell that pneumatizes into the frontal sinus – supra agger frontal cell (SAFC)		
Type 4/SAFC	A frontal cell that pneumatizes into the frontal sinus and extends by more than 50% of the vertical height of the sinus (Figure 99.6)	Removal of these cells will often require an extended frontal sinus procedure	
Posterior*			
Supra bulla	Cell above the bulla not pneumatizing into the frontal sinus	May contain the anterior ethmoid artery	Sagittal
Frontal bulla or supra bulla frontal cell (SBFC)	A cell pneumatizing forward from the bulla or suprabulla space. These ‘crawl’ along the skull base. Posterior wall of the cell is the skull base.	They tend to push the frontal sinus drainage pathway anteriorly	Coronal, Axial
Supraorbital ethmoid	Pneumatization of the orbital plate of the frontal bone. Posterior wall is the skull base	Give the impression that one has entered the frontal sinus. They open posterior and lateral to the frontal ostium. Associated with anterior ethmoid artery in a mesentery	
Medial*			
Intersinus or frontal septal	Cell based medially in the anterior ethmoid region or pneumatizing the interfrontal sinus septum	Tend to push the drainage pathway laterally	Coronal, Axial

* Refers to EPOS anatomical terminology classification.¹¹ Supra agger frontal cell (SAFC), based on the IAFAC (International Frontal Sinus Anatomy Classification), is an anterior lateral ethmoidal cell that extends into the frontal sinus (T3 cell) whereas a large SAFC can significantly pneumatize into the frontal sinus (T4 cell).¹²

Figure 99.3 Frontal ethmoidal cells. A type 1 or Supra Agger cell (SAC), a single cell sitting above the agger nasi (**a**). Multiple supra cells, but not entering the frontal sinus (**b**). Any cell extending beyond the floor of the frontal sinus (hashed line) is at least a type 3 cell or supra agger frontal cell (SAFC) (**c**). In (**d**) a cell extending beyond 50% of the height of the sinus (dotted line), is termed a type 4 cell or large SAFC.

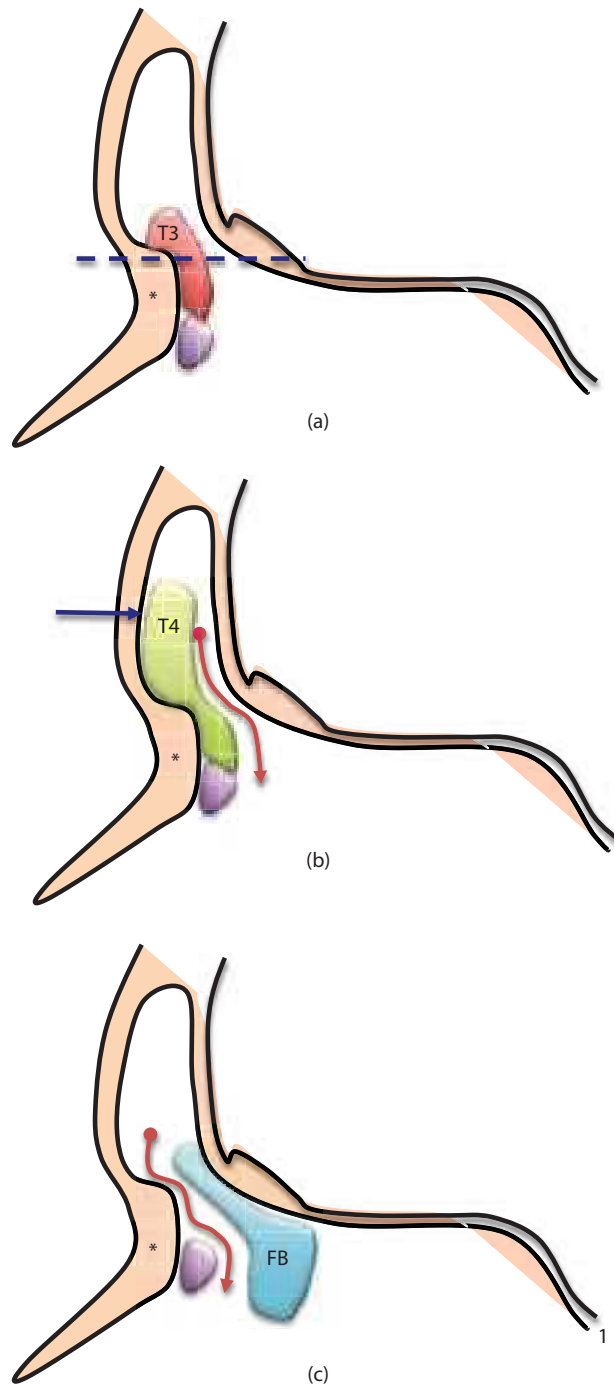

Figure 99.4 Parasagittal views. In (a), a type 3, or small supra agger frontal (SAF) cell pushes above the floor of the frontal sinus (dotted line). In (b) a type 4, or large supra agger frontal (SAF) cell extends above 50% of the height (solid arrow) of the frontal sinus. In (c) a frontal bulla (FB), or supra bulla frontal (SBF) cell pneumatizes forward from the bulla. It is not in contact with the frontal process of the maxilla or frontal beak (*). The red arrows indicate the drainage pathway of the frontal sinus, which is anterior to the frontal bulla cell and posterior to the frontal ethmoidal cell.

side would have been identified incorrectly as a type 1 cell sitting above the agger nasi cell. However, ‘walking’ forwards through the images one can identify the same cell

Figure 99.5 In the coronal CT scans (a) and (b), the frontal beak (FB), agger nasi cell (dotted arrow) and type 3 cell can be seen (*). Pneumatization of the orbital plate of the frontal bone, the supraorbital ethmoids (SOE), produces a curious ‘double lamina’ effect of the orbital roof. The anterior ethmoidal artery (solid arrow) is seen traversing the space in a mesentery (c). Axial image identifying the type 3 cell within the frontal sinus (d).

extending superiorly into the frontal sinus, thus making this a type 3 cell. The drainage pathway is best studied in the axial images, and in this case is medial to the type 3 cell (d). It is through these pathways that one can dissect the frontal recess and remove obstructing cells.

Type 4 cells are rarely isolated within the frontal sinus and usually pneumatize from the frontal recess. They can be extensive (Figure 99.6) and cause disease by direct obstruction of the outflow tract or be diseased themselves. In most instances, it is not possible to completely remove these cells via a standard frontal sinus approach and an extended procedure such as a modified endoscopic Lothrop may be required.

In approximately 65% of Caucasian patients, the orbital plate of the frontal bone can be extensively pneumatized, resulting in supraorbital ethmoid cells (SOEC) (Figure 99.5c). An ethnic variation does exist with the incidence being much lower in east Asia.¹³ SOEC can present a number of surgical challenges. Firstly, the anterior ethmoidal artery is more likely to be present in a mesentery and hence susceptible to injury.⁴ Secondly, a greater proportion of the orbit and skull base are exposed within the surgical field. Finally, it is easy to mistake the opening of the supraorbital cells as that of the frontal sinus. The former tends to open more posteriorly and laterally.

Cells can pneumatize forward from the bulla itself (frontal bulla cells) or above the bulla (suprabulla cells). These ‘crawl’ along the skull base and if large enough can push the frontal sinus drainage pathway anteriorly (Figure 99.4). Large frontal bulla cells can appear as isolated cells within the frontal sinus and be mistaken for a type 4 cell on a coronal CT scan image. They are readily

Figure 99.6 Extensive bilateral type 4 cells (a) coronal view and (b) parasagittal.

Figure 99.7 Frontal bulla cells. (a) CT image shows cells within the frontal sinus (*). These cells are present in the frontal recess and closely applied to the skull base (b). The parasagittal view confirms forward pneumatisation of the bulla (c). Note the mucosal thickening and frontal sinus drainage pathway anterior to the frontal bulla cells (d).

distinguished from frontal ethmoidal cells as they are not in contact with the frontal process of the maxilla or the frontal beak. Instead they hug the skull base and are best identified on the axial and parasagittal CT sections (Figure 99.7). On coronal CT images supraorbital ethmoid cells are found lateral to the frontal sinus, whereas frontal bulla cells are medially placed.

As the name indicates, frontal intersinus septal cells arise from the frontal sinus septum. These tend to push the drainage pathway laterally and ultimately drain into the frontal recess on that side (Figure 99.8). According to the most recent classification proposed by the EPOS (European position paper) group, an intersinus septal cell is therefore a medial frontoethmoidal cell.¹¹

Diagnosis

A carefully taken clinical history is indispensable. This is particularly important with frontal sinus symptoms

Figure 99.8 Interfrontal sinus septal cells (*). Drainage pathway (solid arrow).

where often a diagnosis of headache has been mislabelled as frontal sinusitis. Sinus headaches are uncommon. An excellent review on the subject by Jones explains that the vast majority of people presenting with symmetrical frontal headache have a tension type headache. Unilateral, episodic headaches are vascular in origin.¹⁴ The headache history is important to try and characterize the symptoms and exclude frontal sinusitis.

A history of facial trauma, previous sinonasal surgery and comorbidities such as asthma and aspirin sensitivity are relevant.

Most patients would undergo a full otorhinolaryngological examination. Rarely inspection of the forehead might reveal a swelling which may or may not be tender. Painful percussion is suggestive of acute frontal sinusitis or even osteomyelitis, so called Pott's puffy tumour. A painless swelling may indicate a mucocoele.

Endoscopy

Although anterior rhinoscopy is routinely performed, the accepted gold standard is nasal endoscopy. Traditionally, 4mm rigid endoscopes have been used to examine the nose. However, smaller 3mm endoscopes provide very similar optics and tend to be better tolerated by most patients. Narrower 2.7mm and 1.9mm endoscopes are available but compromise image quality and are less robust. Despite the use of narrow endoscopes, access to the middle meatus may be difficult. In patients who have had previous surgery an angled endoscope (30° or 45°) is useful in examining the frontal recess. In addition, a flexible nasendoscope can be navigated into the frontal sinus for inspection purposes.

Imaging

Plain sinus X-rays are inadequate for the routine diagnosis and management of frontal sinus disease. They are useful in providing a template of the frontal sinus when considering an osteoplastic flap procedure. The recommended view is an occipitofrontal sinus plain X-ray.

Ultrasonography is not routinely used for imaging of the paranasal sinuses. Scintigraphy is useful in diagnosing osteomyelitis of the frontal bone. It is helpful in assessing the extent of disease and for follow-up purposes.

COMPUTER ASSISTED TOMOGRAPHY (CT)

Clinical history and nasal endoscopy are essential in managing patients with frontal sinus symptoms but this must be complemented by imaging. CT is the first choice of radiological imaging for sinus disease and is essential for planning surgery. In pre-operative planning, coronal sinus images are most frequently used due to better correlation of radiological and clinical findings during surgery. However, studies have demonstrated that parasagittal views are very helpful in not only identifying the complex cells within the frontal sinus but also the drainage pathways.^{15, 16} Ideally, CT images should be available in coronal, axial and parasagittal planes. Although Zinreich et al.¹⁷ proposed a protocol for CT imaging of the sinuses, most institutions will have developed their own preferred technique. Current low dose spiral and multidetector CT scanners are able to acquire images quickly and reformat axial images into coronal and parasagittal planes. The need to acquire direct coronal images is no longer necessary and the effective dose of paranasal sinus CT can be reduced to the order of a chest radiograph.¹⁸ Advantages of axial scanning include improved patient comfort during scanning and avoidance of dental artifacts. Furthermore, raw data from thin section axial scanning can be used for intra-operative computer assisted navigation, if available. Excellent detail can be achieved with contiguous axial cuts of 0.6 mm thickness. A satisfactory compromise might be to use thin-collimation contiguous, 1 mm thickness axial slices. Scan should be reconstructed in the axial, coronal and sagittal planes using both soft-tissue and high resolution algorithm bone windows with a reconstruction thickness of 3 mm or less.¹⁹ The standard bone window/level settings range between 1500–2000/300 Hounsfield units (HU) and 450/50 HU for soft tissue windows. Many centres have access to picture archiving and communication systems (PACS), which allow the end user to easily alter the window settings. This is particularly helpful in fungal ball and chronic fungal sinus disease, where soft tissue window settings may demonstrate double densities associated with calcification and eosinophilic mucin, respectively.

MAGNETIC RESONANCE IMAGING (MRI)

MRI offers excellent soft tissue detail but no bony definition. It is very useful in differentiating tumour from retained secretions. Tumours tend to enhance with T1-weighted gadolinium enhanced scans while fluids do not. Mucus and secretions tend to avidly enhance on T2-weighted images. MRI is very helpful in assessing the dual interfaces between the nasal cavity, and the orbit and the intra-cranial cavity.²⁰ Enhancement of the lamina papyracea or dura may indicate tumour involvement. Indeed, dural thickening of greater than 2 mm, loss of the hypointense zone and nodular enhancement are highly predictive of dural invasion by malignancy.²¹ MRI is particularly useful in assessing patients with ongoing symptoms, who have previously undergone an osteoplastic flap with obliteration. The scans can helpfully distinguish mucocoele formation from fat necrosis and infection.^{22, 23}

It is recommended that in cases of unilateral sinus disease, both CT and MRI are routinely performed. The two imaging modalities are complementary in diagnosing tumours such as inverted papilloma and fungal disease. The characteristic appearances of fungal disease are an iso- or hypo-attenuated signal on T1-weighted images and a signal void on T2-weighted images.²⁴

CONGENITAL FRONTOBASAL MALFORMATIONS

Nasal dermoids, cysts and fistulae

Rarely, the frontal sinus can be involved in congenital abnormalities of the skull base. This may be secondary to craniofacial dysostosis or persistence of embryonic remnants. Congenital midline nasal lesions include nasal dermoids, encephaloceles and gliomas. The nasal dermoid is the least rare of these, and is an uncommon midline developmental anomaly. Unlike other craniofacial dermoids, these lesions can present as a cyst, a sinus or a fistula (Figure 99.9a) and may have an intra-cranial extension (Figure 99.9b).²⁵ The incidence is estimated at between 1:20,000 and 1:40,000 live births.²⁶ These fistulas may extend from the skin to the frontal bone, leading to pressure atrophy and narrowing of a frontal sinus if it is developed. Progressive enlargement of the nasal dermoid can cause local infection, meningitis and brain abscesses.

Typically, nasal dermoids present as a midline mass anywhere from the base of the columella, along the dorsum to the glabellar region. They are non-compressible and can discharge sebaceous material.²⁷

Pathogenesis

Sessions²⁵ was the first to coin the term *nasal dermal sinus cyst* to include all the lesions containing ectoderm and mesoderm located in the nose. Briefly, as the neuroectodermal tract recedes, dermal attachments can be drawn in along its course. As the dura mater recedes from the pre-nasal space it may pull nasal ectoderm upward and inward to form a sinus or a cyst.²⁸

Imaging

Imaging is a critical component in the evaluation of nasal dermoids given the associated risk of intra-cranial extension. CT and MRI provide complementary information. For CT, fine cut multiplanar, contrast enhanced imaging is optimal. On CT imaging, the presence of a widened foramen caecum and bifid crista galli do not necessarily indicate intra-cranial extension. However, a normal foramen caecum and crista galli rule out intra-cranial disease.²⁸

Surgery

The following principles are important when considering the ideal surgical approach: permit access to a midline cyst

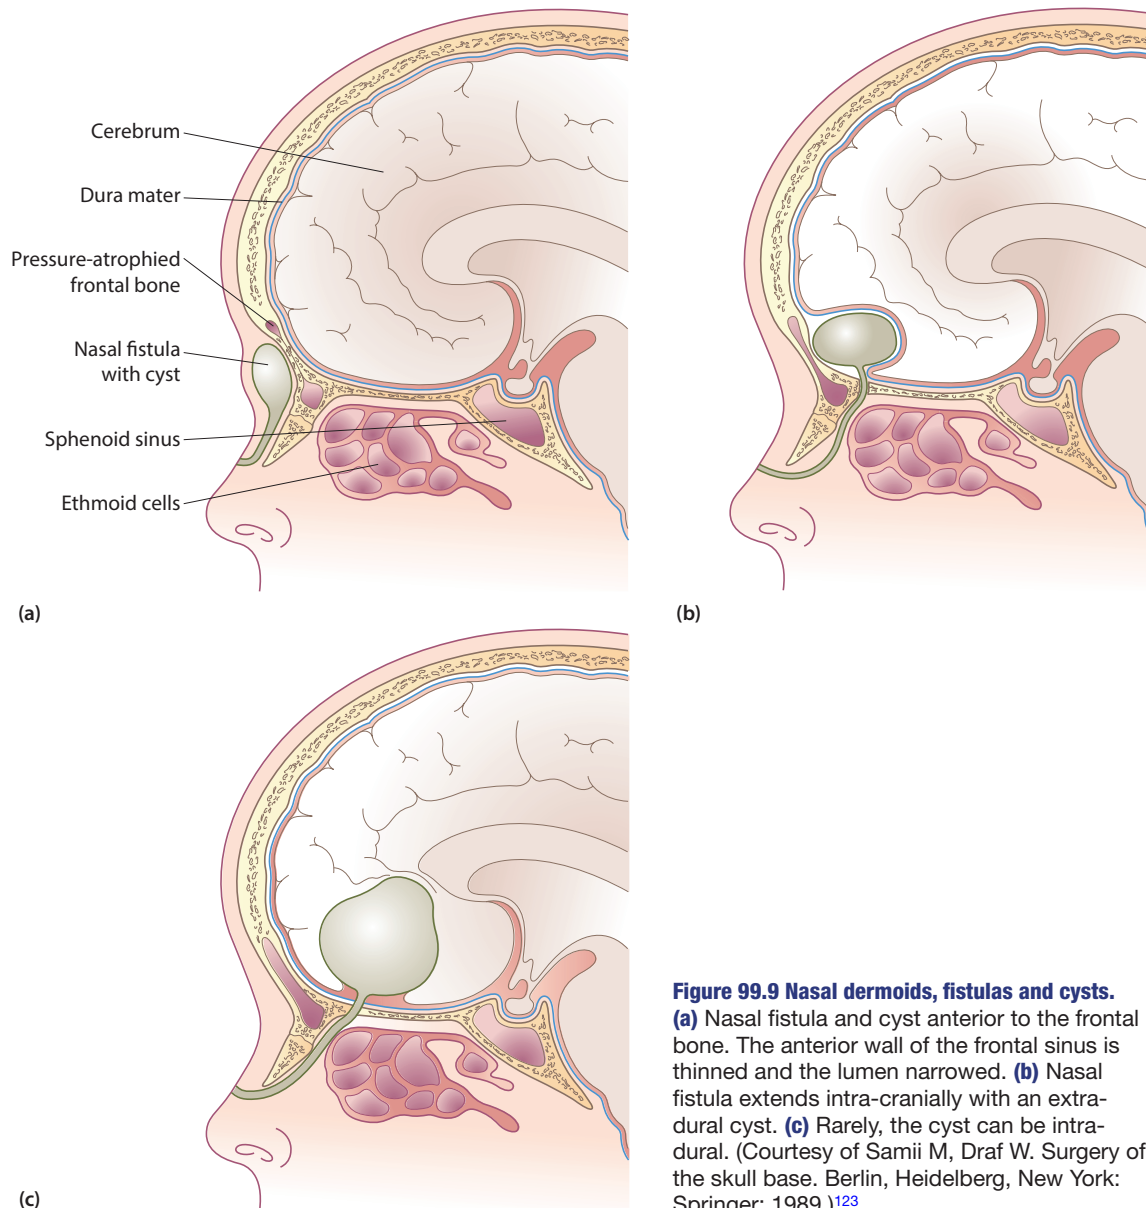

Figure 99.9 Nasal dermoids, fistulas and cysts.

(a) Nasal fistula and cyst anterior to the frontal bone. The anterior wall of the frontal sinus is thinned and the lumen narrowed. **(b)** Nasal fistula extends intra-cranially with an extra-dural cyst. **(c)** Rarely, the cyst can be intra-dural. (Courtesy of Samii M, Draf W. *Surgery of the skull base*. Berlin, Heidelberg, New York: Springer; 1989.)¹²³

and allow access for medial and lateral osteotomies; allow access to the skull base; facilitate reconstruction of any resulting nasal deformity and finally have a cosmetically acceptable scar.²⁷ The midline vertical approach is commonly used for extra-cranial lesions although some favour an external rhinoplasty approach for better cosmesis. The latter can be combined with a direct excision if necessary.²⁹ When there is evidence of intra-cranial extension, a combined approach with the neurosurgical team is recommended. Endoscope assisted excision of extra-cranial dermoids using bilateral intercartilagenous incisions have been described. Recent publications have suggested that it may be feasible to endoscopically access some intra-cranial dermoids.³⁰

Although the recurrences following surgery are low, they can occur many years later. Long-term follow-up is therefore essential.

INFLAMMATORY CONDITIONS OF THE FRONTAL SINUS

Acute frontal sinusitis

Acute rhinosinusitis (ARS) is sudden in onset and often follows an upper respiratory tract infection (URTI). It is defined as an increase in symptoms after 5 days or persistent symptoms after 10 days with less than 12 weeks duration. It is estimated that only 0.5% to 2% of viral URTI are complicated by bacterial infection, although the true incidence is unknown due to the difficulty in clinically distinguishing bacterial from viral infections. The prevalence rates for ARS vary from 6% to 12%.³¹

Acute frontal sinusitis occurs as part of a generalized acute rhinosinusitis. In most cases ARS resolves without complication or the need for antibiotic treatment.

Mild symptoms are effectively managed with intra-nasal corticosteroid monotherapy or in conjunction with antibiotics (see [Chapter 97](#), ‘Medical Therapy for Rhinosinusitis’). Although topical nasal decongestants are often used, there is little evidence to suggest any effect in relieving ostial oedema. However, they may provide symptomatic relief of nasal congestion. Isotonic and hypertonic saline nasal douches are effective in alleviating symptoms.³¹

Extranasal complications of acute frontal sinusitis are relatively rare in the current antibiotic era. Nonetheless, in some patients acute frontal sinusitis may become complicated. This is most commonly seen in young adolescent men.^{32, 33} The frontal sinus is the most common sinus associated with intra-cranial infection. Clinically, patients may present with a persistent severe headache, frontal or periorbital swelling, altered mental status or meningeal signs. The possible complications are outlined in [Table 99.2](#).

The general management of the complications of rhinosinusitis are discussed elsewhere (see [Chapter 101](#), ‘Complications of Rhinosinusitis’). If culture results are unavailable, antibiotic therapy should target the common organisms which include *H. Influenzae*, *S. pneumonia*, *S. pyogenes* and *alpha haemolytic streptococci*.³⁴ Despite antibiotic therapy, there is not an insignificant incidence of morbidity and occasionally mortality estimated between 5% and 15%.³⁵

CT is the imaging modality of choice. Multiplanar imaging of the brain, orbit and sinuses with contrast enhancement is necessary as the incidence of concomitant complications is significant. In one study, approximately 24% of patients aged 7 or older attending theatre for surgical intervention of an orbital complication also had an intra-cranial complication.³⁶ Evidence of intra-cranial or orbital involvement requires a multidisciplinary approach.

As mentioned above the surgical management is covered elsewhere. In brief, neurosurgical complications may require a craniotomy. Traditionally, the frontal sinus can be trephined and irrigated via a small infrafrow approach and the placement of a drain. An alternative approach has been described which involves performing a ‘mini’ frontal sinus trephine.³⁷ The disadvantage of this method is the difficulty in establishing irrigation via the small trephine port. Orbital abscesses not responding to maximal medical therapy require surgical drainage. A classical Lynch-Howarth approach is favoured.

Increasingly, orbital complications such as subperiosteal abscesses and acute complicated frontal sinusitis are being managed endoscopically. In the acutely infected state, dissection of the frontal recess can be very challenging and

requires a significant level of advanced endoscopic skills. However, the role of endoscopic frontal sinus surgery in the initial management of intra-cranial complications of sinusitis remains unclear. In a recent 6 year retrospective review of 23 patients, ESS did not appear to influence the need for neurosurgical intervention, even with lesions less than 1 cm.³⁸

Chronic frontal sinusitis

Although much work has improved our understanding, the aetiology and pathogenesis of chronic rhinosinusitis (CRS) is still described as multifactorial. The bacteriology of CRS differs from that of ARS with a higher prevalence of anaerobic organisms. Chronic rhinosinusitis with (CRS_{NP}) or without (CRS_{NP}) may cause obstruction of the frontal sinus outflow tract and lead to chronic frontal sinusitis. The current mainstay of treatment for CRS involves medical therapy.³¹ The majority of patients respond to a combination of antibiotics, nasal irrigations, intra-nasal and if necessary oral steroids therapy. The optimal management is discussed in [Chapter XX](#) (The management of CRS). However, despite maximal medical therapy some patients may have persistent symptoms. As in CRS, the diagnosis of frontal sinusitis is based on symptoms (frontal pressure or headache), clinical findings and CT imaging. In these patients, surgical intervention may be necessary. However, despite surgery a proportion of patients may continue to suffer with frontal sinus symptoms and develop recalcitrant chronic frontal sinus disease. This may be related to persistent disease or scarring and stenosis secondary to surgery.

The frontal recess is a complex space and anatomical variations, inflammation and scarring may play an important role in the aetiology of chronic frontal sinusitis. The relative contribution of each of these factors to chronic frontal sinusitis requiring surgical intervention has not been well quantified. A number of retrospective studies have examined the impact of accessory cells within the frontal recess and the development of frontal sinusitis. One study has reported that the presence of suprabulla cells, supraorbital ethmoid cells, frontal bulla cells and recessus terminalis was significantly associated with frontal sinusitis.³⁹ In another study, the prevalence of frontal sinus mucosal thickening was increased in patients with type 3 and 4 frontal ethmoidal cells.⁴⁰ Other studies suggest that although scarring, retained agger and frontal cells may contribute to anatomical obstruction, the ongoing mucosal inflammation is the most important factor leading to frontal sinusitis.^{41–44}

TABLE 99.2 Complications of acute frontal sinusitis

Local (frontal sinus)	Orbital	Intra-cranial
Mucocele Pyocele Osteomyelitis (Potts puffy tumour)	Orbital cellulitis (including subperiosteal, intra-orbital abscess)	Meningitis Epidural abscess Subdural empyema Intra-cerebral abscess Superior sagittal sinus thrombosis Cavernous sinus thrombosis

FRONTAL SINUS SURGERY

Despite advances in medical and surgical therapy, chronic frontal sinusitis remains a difficult disease to manage. Over the years, the surgical management of frontal sinus disease has evolved from open oblitative procedures to endoscopic mucosal sparing techniques. Although extensive and complex frontal sinus pathology can be managed endoscopically there remains a definitive role for open procedures such as the osteoplastic flap.

There are no simple guidelines for the management of chronic frontal sinusitis. Prior to considering any surgery it is wise to review the clinical history, imaging and indications. Underlying conditions such as diabetes, immune

disorders and aspirin exacerbated respiratory diseases need to be identified.⁴⁵

In the past, treatment of chronic frontal sinusitis was directed towards the sinus itself. However, contemporary management is based on the understanding that the problem most often involves the drainage pathway, the frontal recess rather than the sinus. The principles of surgery are to relieve obstruction that may lead to inflammatory changes. Mucosal preservation is important as mucosa regenerating over bare bone lacks effective cilia.⁴⁶

There is much debate regarding the philosophies of managing the frontal sinus in CRS. These range from minimal invasive sinus techniques (MIST) where following an uncinectomy transitional spaces are opened, to addressing an obstructed frontal recess irrespective of patient symptoms.^{7, 47} Most rhinologists would agree that the best surgical approach to the frontal sinus is a graduated one (Table 99.3).

Numerous descriptions and approaches to the frontal sinus have been described. Not only is this confusing but it makes it difficult to draw meaningful comparisons from the published literature. The most widely accepted classification is that described by Draf and his colleagues although this has waned in popularity, as it too can be open to interpretation.⁴⁸ The classification describes increasingly aggressive approaches to the frontal sinus. The general rule would be to choose the least invasive approach to achieve the desired outcome. In some cases, the least invasive may necessarily be quite extensive. The surgery needs to be tailored to the individual needs of each patient and depends on various factors such as previous surgery and extent of disease.

The choice of surgical procedure used to manage recurrent frontal sinus disease will depend on a number of factors outlined in Table 99.4. The surgeon needs to take into account the extent and completeness of the previous surgery, the anatomy of the frontal sinus and the overall burden of disease. An assessment of the surgical complexity based on the anatomy alone is available in Table 99.5.

In an attempt to better define the extent of surgery to the frontal recess and sinus, an international panel of

TABLE 99.3 Graduated approach to frontal sinus surgery

Graduated approach to frontal sinus surgery	
No exploration	No disease
Balloon sinuplasty	May have a role in certain situations with limited disease
Draf type I (frontal sinusotomy), ethmoidectomy*	Removing cells within the frontal recess, following an FESS
Draf type IIa and b*	Remove cells extending into the frontal sinus and resect bone between the lamina papyracea and middle turbinate (a) or nasal septum (b)
Draf type III, modified endoscopic Lothrop (MEL), Frontal sinus drillout*	Resection of the floor of the frontal sinus, superior nasal septum and interfrontal sinus septum
Osteoplastic flap + MEL Osteoplastic flap with obliteration	Above and below approach Removal of all mucosa within the sinus and obliteration with fat
Riedel's procedure	Removal of the anterior table of the frontal sinus
Cranialization	Removal of sinus mucosa and the posterior table of the frontal sinus

* A frontal sinus mini trephine may be used as an adjunct to these procedures.

TABLE 99.4 Factors influencing the surgical approach

	Considerations	Surgical options
Patient	Compliance issues and significant comorbidities	Simple FESS with minimal manipulation of the frontal recess
	Asthma, aspirin sensitivity	Comprehensive clearance of frontal recess If recurrent disease see below
Anatomy	Preserved landmarks, minimal previous surgery, no complex cells	Draf type I procedure
	Poor landmarks, osteoneogenesis, multiple revision procedures, thick frontal beak, complex frontal cells	Draf type (modified endoscopic Lothrop)
Pathology	Chronic frontal sinusitis with or without polyps. No previous surgery	Draf type I procedure
	Recurrent disease, ASA with polyps, eosinophilic mucin CRS, tumours, lateral mucoceles. Recalcitrant	Draf type (modified endoscopic Lothrop)
	Complicated frontal sinusitis with erosion of the posterior table, anterior table osteitis, tumours extending laterally	Draf III or an osteoplastic flap approach. Combined approach

TABLE 99.5 The International classification of complexity of frontal sinus surgery

	Wide AP diameter (≥10 mm)	Narrow AP diameter (9–6 mm)	Very narrow AP diameter (≤5mm)
Cells below ostium (AN, SAC, SBC)	Less complex (Grade 1)	Moderate complexity (Grade 2)	High complexity (Grade 3)
Cells encroaching into the ostium (SAFC, SBFC, SOEC, FSC)	Moderate complexity (Grade 2)	High complexity (Grade 3)	Highest complexity (Grade 4)
Cells extending significantly into the frontal sinus (SAFC, SBFC, SOEC, FSC)	High complexity (Grade 3)	Highest complexity (Grade 4)	Highest complexity (Grade 4)

AP refers to the frontal ostium anterior-posterior (AP) diameter as measured from the frontal beak to the skull base at its narrowest distance on the parasagittal CT scan. Classification of the cells is in accordance to the International Frontal Sinus Classification¹²: AN (Agger Nasi), FSC (frontal septal cell), SAC (supra agger cell), SAFC (supra agger frontal cell), SBC (supra bulla cell), SBFC (supra bulla frontal cell), SOEC (supra-orbital ethmoid cell). Data from Wormald PJ, Bassiouni A, Callejas CA, et al. The International Classification of the radiological Complexity (ICC) of frontal recess and frontal sinus. *Int Forum Allergy Rhinol.* 2016.¹²³

TABLE 99.6 Extent of frontal sinus surgery (EFSS). A comparison between the Draf frontal sinus surgery classification and a new proposed international classification of extent of frontal sinus surgery

Draf classification ¹²⁴	International classification of the extent of EFSS ¹²	Tissue/Bone removal
	0 – No bone or tissue removal. Balloon dilatation	No Tissue removal
Draf 1 – Ethmoidectomy and removal of cells below the frontal sinus	1 – Removal of cells in the frontal recess not directly obstructing the frontal ostium	Removal of cells
	2 – Removal of cells obstructing the ostium but not extending through the ostium	
Draf 2a – Enlargement of the frontal ostium between the lamina papyracea (LP) and the middle turbinate (MT)	3 – Removal of cells extending through the frontal ostium (no widening of the frontal ostium)	Removal of bone
	4 – Removal of cells extending through the frontal ostium with enlargement of the ostium (bone removal, usually frontal beak)	
Draf 2b – Enlargement of the frontal ostium from the LP and the nasal septum	5 – Enlargement of the frontal ostium from the LP to the nasal septum	
Draf 3 – Bilateral enlargement of the frontal ostia, resection of the superior nasal septum, floor of the frontal sinus and inter-sinus septum	6 – Bilateral enlargement of the frontal ostia into a common ostium, with resection of the superior nasal septum, inter-sinus septum and floor of the frontal sinus	

experts have proposed a new classification ([Table 99.6](#)). The aim is to standardize terminology and provide a framework which should allow better comparison of surgical outcomes.¹²

No frontal recess exploration

Unfortunately, it is not uncommon for frontal sinus obstruction to occur as a result of surgery.^{41, 43} In the absence of positive CT scan findings and clinical symptoms the frontal sinus or recess should not be explored. Unnecessary instrumentation in a healthy recess can result in mucosal injury and adhesion formation.⁴⁹

Balloon sinuplasty

Introduced in 2006, balloon sinuplasty is proposed to be a minimally invasive approach to the management of CRS involving the frontal sinus. The technique introduces a balloon over a guide wire, which may be illuminated, to confirm its position in the frontal sinus. Once in place, spanning the ostium, the balloon is dilated with a controlled inflation device. In theory, this gently enlarges

the ostium by effecting microfractures of the surrounding bone and compressing the soft tissue. Soft tissue injury is suggested to be minimal but the rate of synechia formation is reportedly at least equal to that seen with conventional endoscopic sinus surgery (ESS). Complications include inability to cannulate the sinus, and CSF leak.^{50, 51} Although it is a safe and well tolerated procedure, the evidence in support of its use as an alternative to standard ESS techniques is limited.^{31, 52, 53} In many instances balloon dilation is combined with ESS and is termed a hybrid procedure.

Draf type I (ethmoidectomy and frontal sinusotomy)

This is the commonest primary procedure performed for chronic frontal sinusitis and in many cases is sufficient.⁵⁴ As the least invasive procedure the aim is to clear obstructing disease inferior to the level of the frontal ostium – the frontal recess. The key step is performing a complete ethmoidectomy. This includes removal of any anterosuperior ethmoid cells, the agger nasi and uncinat process ([Figure 99.10](#)). This approach is best limited to when there

Figure 99.10 A Draf type I frontal sinusotomy with removal of the agger and anterior ethmoid cells in the frontal recess cells.

is only minor pathology in the frontal sinus. It may not be sufficient in cases where the patient suffers from significant nasal polyposis associated with aspirin intolerance and asthma.

Draf type II frontal sinusotomy

Where a more conservative surgical approach has failed an extended frontal sinus procedure may be required. In a Draf type II approach, cells extending into the frontal sinus are removed (Figure 99.11). If the frontal ostium is widened from the lamina papyracea to the middle turbinate this is called a type IIa approach. This may be possible by using a Kerrison or Hajek-Kofler punch. Extending this opening beyond the middle turbinate to the nasal septum is a type IIb approach. This involves removing the anterior end of the middle turbinate and drilling the floor of the sinus to the midline. The indications for a Draf type IIb are limited but may be used to address unilateral frontal ostium osteoneogenesis, inverted papilloma, osteomas or medially placed frontal mucoceles. A recent study has suggested using a Draf type IIb approach for addressing contralateral inaccessible frontal sinus disease. Although short-term patency was good, larger patient numbers and longer follow-up data are required before this can be recommended.⁵⁵

Draf type III (modified endoscopic lothrop)

Also known as a median drainage procedure or frontal sinus drill-out, the operation was first described by Lothrop in 1914 as an external procedure.⁵⁶ Draf described an intranasal microscopic approach while others described a similar endoscopic technique.^{57, 58} The modified endoscopic Lothrop procedure (MELP) has recently gained popularity as a minimally invasive alternative to frontal sinus obliteration. The possible indications for a MELP are highlighted in Table 99.7.

The procedure consists of creating a large common drainage pathway for the paired frontal sinuses by resecting the upper nasal septum, the frontal intersinus septum

Figure 99.11 The Draf type II, with removal of cells extending into the frontal sinus (a). The coronal CT highlights the extent of bone removal (b). Type IIa involves widening of the ostium from the lamina papyracea to the middle turbinate (blue line) and IIb extending this to the nasal septum (red line).

and the floor of both frontal sinuses (Figure 99.12). The procedure is technically demanding as useful landmarks are often absent and the operative field is narrow. A septectomy performed early allows the surgeon to work more freely in the narrow confines. The use of frontal mini trephines helps with early identification of the frontal ostium and hence the posterior limit of dissection. The use of computer assisted navigation may improve efficacy and safety but is no substitute for sound surgical training and anatomical knowledge.⁵⁹

Drilling commences from one frontal recess and proceeds across the midline to the contralateral recess. A small area of skin is often exposed bilaterally just above the axilla of the middle turbinate and demarcates the lateral extent of dissection. To obtain the maximum possible opening it is necessary to drill down the anterior projection of the skull base. In order to do this safely, it is helpful to identify the first olfactory neurons, which are found by peeling back the mucosa between the middle

turbinate and the nasal septum. The fibres can be seen to arise just posterior to a linear groove through a small bony opening. When this is performed on both sides the so-called 'frontal T' results (Figure 99.13). The long limb corresponds to the posterior aspect of the septectomy (the perpendicular plate of the ethmoid) and the horizontal limbs to the posterior margin of the frontal sinus floor resection. A summary of the essential steps of the procedure is outlined in Box 99.1.

In certain situations when access to the frontal sinus is blocked (osteoma or osteoneogenesis) or the anatomy is grossly distorted, one can use a midline approach. Rather than drilling from lateral to medial a transeptal approach

TABLE 99.7 Utility of the modified endoscopic Lothrop procedure (MELP)

Potential indications for a MELP	
Chronic frontal sinusitis	Refractory to previous endoscopic surgery
CRS with nasal polyps, asthma, aspirin exacerbated respiratory disease	Controversial, but may be indicated as a primary procedure
Allergic fungal disease	Includes eosinophilic mucin CRS, fungal sinusitis
Mucoceles	Large frontal mucoceles, even those extending beyond the mid-pupillary line ²²
Salvage osteoplastic flap	'unobliteration' of the frontal sinus ²³
Frontal osteoma	Grade I and II. Less suitable for grade III and IV with significant posterior table erosion and lateral extension ¹¹
Inverted papilloma	Extending into the frontal sinus. May require an accessory port in to the sinus ⁷²
Frontal sinus trauma	Closure of CSF leaks
Cranionasal resection	As part of a skull base resection for anterior cranial fossa tumours

can be used. This involves finding the 'frontal T' early and drilling immediately superiorly to enter the floor of the frontal sinus in the midline. This is relatively safe as one is drilling away from the skull base. Drilling then proceeds from medial to lateral in an 'inside to outside' fashion.

Complications of the MELP include injury to the skin and nasal bones, orbital injury, damage to the skull base and CSF leak.

Reasons for failure of frontal recess and sinus surgery

Despite careful pre-operative planning and maximum medical therapy, surgery in the frontal recess can fail. The commonest causes for failure include.

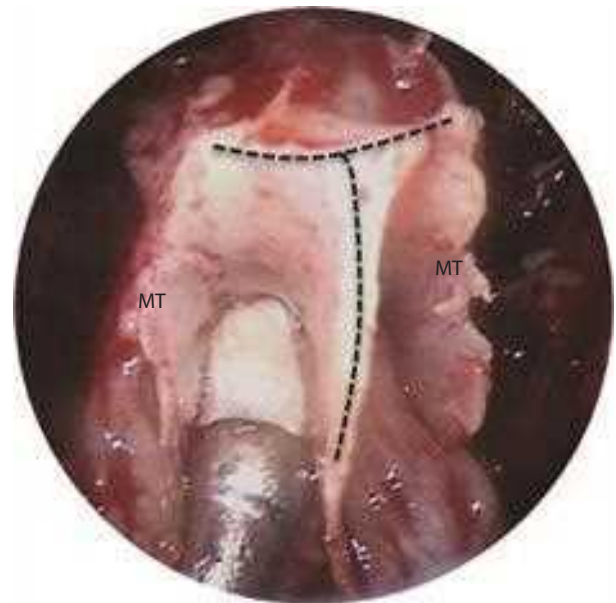

Figure 99.13 The 'frontal T'. An intra-operative view with the olive tip suction on the first olfactory neuron. The vertical limb of the dotted line is the posterior margin of the septectomy (perpendicular ethmoid plate). Horizontal limb is the posterior margin of the frontal ostium and joins the two amputated ends of the middle turbinate (MT).

Figure 99.12 The Draf type III or modified Lothrop. Note the widening of the frontal ostium from lamina to lamina (a), the reduction of the frontal intersinus septum (b) and the beak (c).

BOX 99.1 Summary of operative steps for the MELP**ESSENTIAL STEPS OF A MODIFIED ENDOSCOPIC LOTHROP (DRAF TYPE III) PROCEDURE**

- 1 Complete sphenoidectomy
- 2 Clear frontal recess and identify frontal ostium. Frontal mini trephines may be required. If no access consider midline, trans-septal approach
- 3 Create septal window. At least 2 x 2 cm. Posterior limit is anterior end of middle turbinate. Inferior limit, to allow visualization of contralateral middle turbinate axilla. Superiorly to the nasal vault
- 4 Trim anterior end of middle turbinate to skull base.
- 5 Dissect mucosa posteriorly between middle turbinate and nasal septum to identify first olfactory neuron
- 6 Drilling commences in an anterior, superior and lateral direction from the frontal ostium through the axilla of the middle turbinate. Small area of skin may be exposed laterally.
- 7 As drilling extends superiorly, it is easier to drill from the contralateral side via the septal window
- 8 Reduce frontal intersinus septum and frontal beak to join the two sides together
- 9 Try to preserve mucosa over posterior aspect of frontal ostium
- 10 Lower bone over anterior projection of the skull base to primary olfactory neuron

ONGOING MUCOSAL DISEASE

Persistent or recurrent nasal polyps frequently obstruct the sinuses. Patients with eosinophilic CRS presenting with polyps fare less well. Similarly patients with asthma and nasal polyps are likely to require revision surgery.⁶⁰

INCOMPLETE DISSECTION WITH RETAINED UNCINATE PROCESS AND RESIDUAL CELLS IN THE FRONTAL RECESS

This can impede drainage and exacerbate ongoing mucosal inflammation.^{40, 61}

LATERALIZATION OF THE MIDDLE TURBINATE

Whether partial resection of the middle turbinate predisposes to frontal sinusitis is unclear. However, the incidence of lateralized middle turbinates in revision surgery is high (36–78%).^{61, 62} The frontal sinus rescue procedure was described to address frontal recess stenosis secondary to middle turbinate lateralization. Mucosa is dissected from the turbinate and the stump trimmed back to the skull base. The medial mucosa is discarded and the lateral mucosa from the sinus is draped over the denuded stump.⁶³

SCARRING AND SYNECHIA

Meticulous attention to detail can help to minimize unnecessary trauma and subsequent scarring. However, synechia and scarring are very common findings in revision frontal sinus surgery but may not always be symptomatic.^{60, 62}

OSTEONEOGENESIS

Failure to preserve mucosa results in scarring and osteoneogenesis.⁶⁴ The incidence of osteoneogenesis is higher in patients that have undergone sinus surgery. It may occur secondary to a combination of factors such as persistent mucosal inflammation, ongoing infection and surgical trauma. The ongoing osteitis promotes mucosal inflammation and oedema and may contribute to frontal recess stenosis.⁶⁵

Outcomes for endoscopic frontal sinus surgery

Although trials providing high level of evidence are not available, there are a number of well organized prospective studies that have shown endoscopic sinus surgery (ESS) is safe and effective in managing patients with CRS (with and without polyps) when medical therapy has failed.³¹ The evidence of effectiveness for various frontal sinus procedures is less well documented.

Most studies define success as objective endoscopic evidence of frontal sinus patency. Subjectively however, despite a patent recess some patients will continue to complain of ongoing symptoms.⁶⁶ This mismatch between patient reported outcome measures and clinical or radiological findings poses a challenge in both selecting the ideal candidate for frontal sinus surgery and reporting results. A recent review of the literature has identified at best, level 3 evidence in support of the clinical efficacy of frontal sinus surgery, the main issues being the relative short follow-up periods and the different surgical techniques performed for various indications.⁶⁷ Early patency rates of 90% at 12 months, falling to 68% after 72 months, have been reported.⁶⁰ Others report a 90% patency rate in non-eosinophilic CRS, dropping to 85% in eosinophilic CRS, over an average follow-up period of 46 months.⁶⁸ A recent study with a shorter follow-up reported a high overall ostial patency rate of 92% with symptom resolution in 78% which was unaffected by asthma, EMCRS and smoking when assessed individually but additive when combined together.⁶⁹

There has been much comparison in the literature between the osteoplastic flap procedure (OPF) with obliteration and the MELP. The OPF with obliteration has a reported success rate as high as 93% at 8 years but is not without complications (see 'The osteoplastic flap procedure' below).⁷⁰ A systematic review and meta-analysis of the safety and efficacy of the MELP reports an overall patency rate of 95.9%. An overall failure rate of 13.9% is quoted with 80% of those failing undergoing a revision MELP and the remainder an osteoplastic frontal sinus obliteration.

The osteoplastic flap procedure

The OPF procedure was developed to manage chronic frontal sinus disease refractory to procedures such as the external frontoethmoidectomy, which were associated with high failure rates.⁷¹ Obliteration with fat was introduced later and popularized by Goodale and Montgomery. Although the OPF with fat obliteration is reported to be

the gold standard treatment with success rates over 90% it does have a long-term failure rate of up to 25%.⁷² In addition, it is associated with significant morbidity. These include CSF leaks, persistent forehead numbness, severe headaches without evidence of recurrent disease, frontal bossing, supraorbital neuralgia, mucocele formation, donor site complications after abdominal fat harvesting and difficulties with post-operative surveillance.^{70, 73, 74} In a graduated approach to frontal sinus surgery some might consider this the final step, as the frontal sinus is rendered non-functional. Others would argue that it is a safe and effective procedure in carefully selected patients.

Without question, the OPF approach offers unparalleled access to the frontal sinus and is indicated when wide exposure is necessary (Table 99.8). However, the role of frontal sinus obliteration for the surgical treatment of frontal sinus abnormalities is much more controversial.^{71, 75-77} In a large series, based in a tertiary setting performing over 700 frontal sinus procedures in a 3-year period, less than 2% of cases were managed by an OPF with obliteration.⁷⁸ In the current endoscopic era, the indications for obliteration are dwindling. The ability to tackle pathology from above via an OPF approach and simultaneously endoscopically restore ventilation from below has offered an alternative to obliteration. Traditionally, obliteration was suggested for fractures of the anterior table of the frontal sinus involving the outflow tract. Currently however, one might consider repairing the fracture, monitoring with imaging and perhaps endoscopically intervening at a later stage if necessary.⁷⁹

Without obliteration

An OPF can be performed through a number of approaches. Coronal, brow and mid forehead incisions have all been used to expose the anterior table of the

frontal sinus. Zigzag coronal incisions are better camouflaged in male pattern baldness. A combination of local anaesthesia (Lignocaine 1%), vasoconstrictors (adrenaline 1:1000), steroid (Adcortyl 5 mg) and Hylase (1,500iu) aid dissection and minimize bleeding. An incision is made down to the periosteum. Using a combination of blunt and sharp dissection the scalp flap is elevated to the supraorbital ridge and over the root of the nose. The flap is pulled caudally on both sides, leaving behind the periosteum and the bone, thus preserving the supraorbital and supratrochlear vascular nerve bundles. The next step is to precisely define the extent of frontal sinus pneumatization. Conventionally, a 6-foot Caldwell view (occipito-frontal view) X-ray was used as a template to mark out the margin of the frontal sinus. CT-generated frontal sinus templates are virtually identical to the Caldwell radiograph-derived templates and may obviate the need for additional imaging.⁸⁰ As an alternative, transillumination can be used to outline the extent of the sinus. When available, surgical navigation has been shown to be more accurate and may reduce the risk of inadvertent intra-cranial entry.⁸¹ Others have developed 3D models of the frontal sinus using pre-operative CT data from which an accurate template is produced (Figure 99.14).⁸²

The periosteum is incised 1.5 cm outside the frontal sinus margin (or template) and elevated to the margin of the sinus where an osteotomy is performed. An alternative is to entirely elevate the pericranium with the skin flap.⁸³ An oscillating saw angled at 30° towards the frontal sinus provides an opening with a large surface area for easier fixation of the bone lid. The bony incision is carried to the supraorbital ridge on both sides. When opening the frontal sinus bilaterally, the intersinus septum must be separated from the anterior frontal sinus wall with an angled chisel. The fracture and elevation of the bony lid is undertaken

TABLE 99.8 Relative indications for an osteoplastic flap procedure. (*) May consider frontal sinus obliteration

Possible scenarios	Pathology
Wide exposure of the frontal sinus necessary and endoscopically inaccessible anatomy	Large osteomas Inverted papilloma with significant lateral extension Malignant tumours Far lateral mucoceles in a well-pneumatized sinus
Failed endoscopic procedures for chronic frontal sinusitis	Where maximal medical therapy and MELPs have failed (*)
Extensive frontal bone osteomyelitis	Unresponsive to medical therapy and ESS
Extensive neo-osteogenesis of the frontal recess	May occur secondary to failed endoscopic sinus surgery, facial fractures, frontal bone osteomyelitis (*)
Diseased small underdeveloped sinuses	Anterior-posterior distance less than 8 mm making a MELP difficult (*)
Frontal sinus fractures	Anterior and posterior table fractures, CSF leaks and those involving the frontal sinus outflow tract

Figure 99.14 Marking out the osteotomy incision during an osteoplastic flap procedure. The template shown (*) was created from a 3D model and provides a guide for the bony osteotomy. Note the cute edge of the periosteum approximately 1.5 cm posterior to the incision site (dotted line) and the zigzag coronal skin incision (white arrow). (Courtesy of Mr A Sama.)

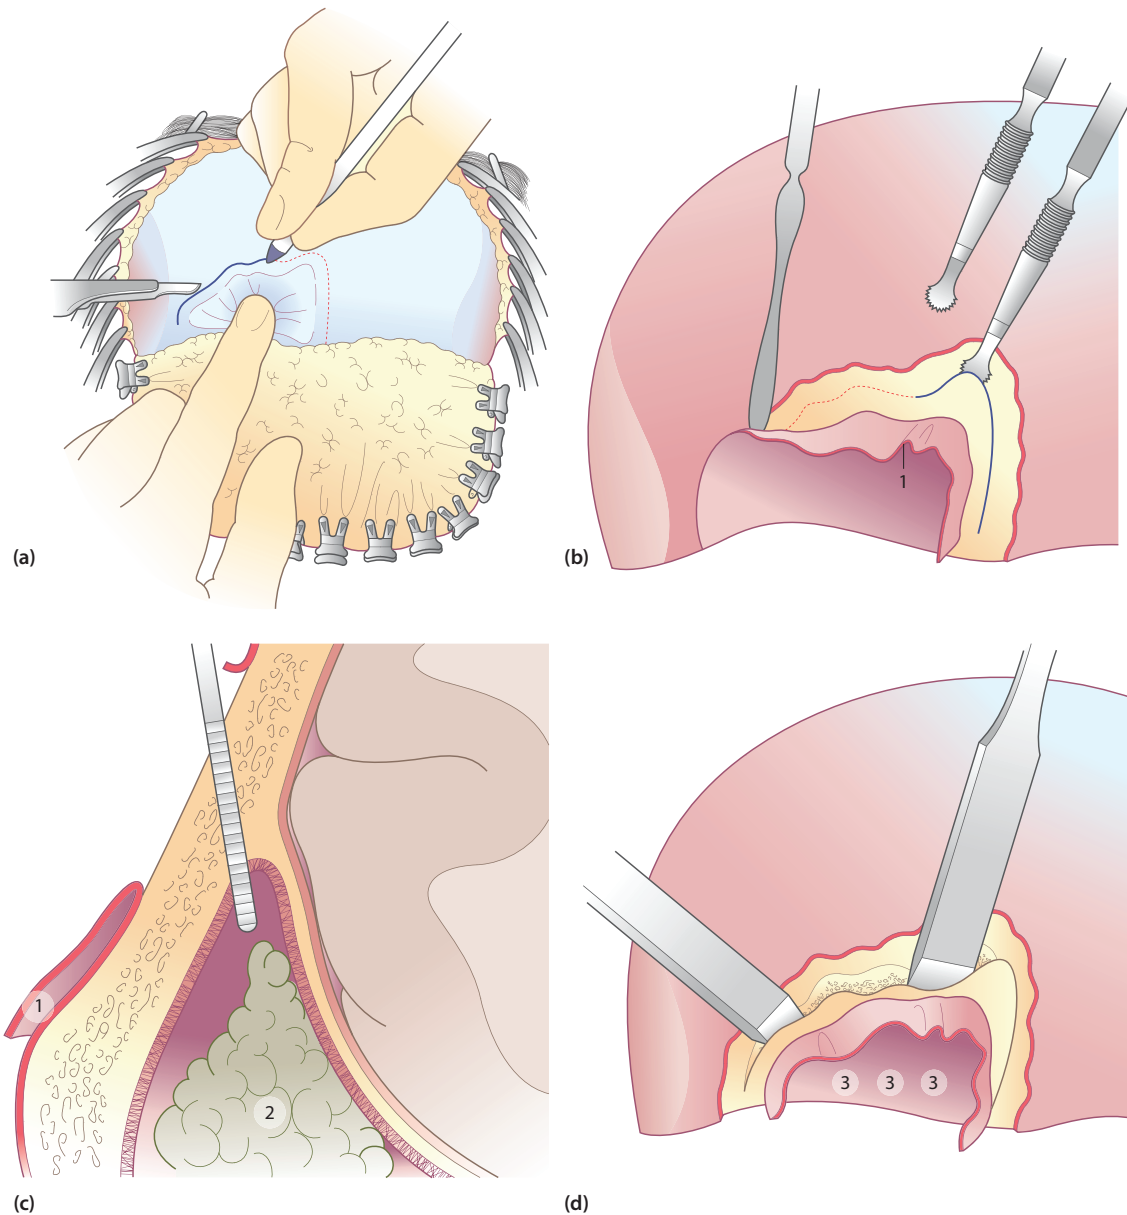

Figure 99.15 Technique of the osteoplastic frontal sinus operation. (a) The periosteal incision is marked approximately 1.5 cm outside the template. (b) The periosteum is elevated just beyond the osteotomy site. The bone flap is created with a drill/saw corresponding to the limits of the frontal sinus. (c) An oblique incision through the bone enlarges the area for replacement of the bony flap. (d) Elevation of the frontal sinus anterior wall with two broad chisels. This ends in a fracture of the frontal sinus floor just posteriorly of the supraorbital ridge. (1: periosteum, 2: pathology, 3: drill holes for fixation.) (Continued).

with a wide osteotome. Ideally the bone lid hinges on the periosteal flap, although in practice this is rarely possible. The pathology is now accessible (Figure 99.15).⁸⁴

On completion, the bone lid is replaced and the periosteum is sutured. Often the periosteum may not be intact and the bone lid will need securing with mini plates. The scalp wound is closed over a closed-suction drain.

With obliteration

If obliteration is being considered, its success depends on the complete removal of all mucous membrane elements. The use of a diamond burr on the inner cortex of the sinus helps to exenterate mucosal invaginations and promotes

neovascularization. The frontal ostium is plugged with fascia, or oxidized cellulose (Surgicell®, Ethicon, Inc., Somerville, NJ).⁴⁹ Obliteration is usually performed with fat harvested from the abdomen but alternatives include a vascularized pericranial flap, cancellous bone, muscle and alloplastic material. Monitoring the sinus post-obliteration is an issue. MRI is most useful but it can be difficult to distinguish fat necrosis from mucocele formation and recurrent disease.⁷⁵

Above and below approaches

Endonasal procedures may be combined with external procedures such as an osteoplastic flap or trephine

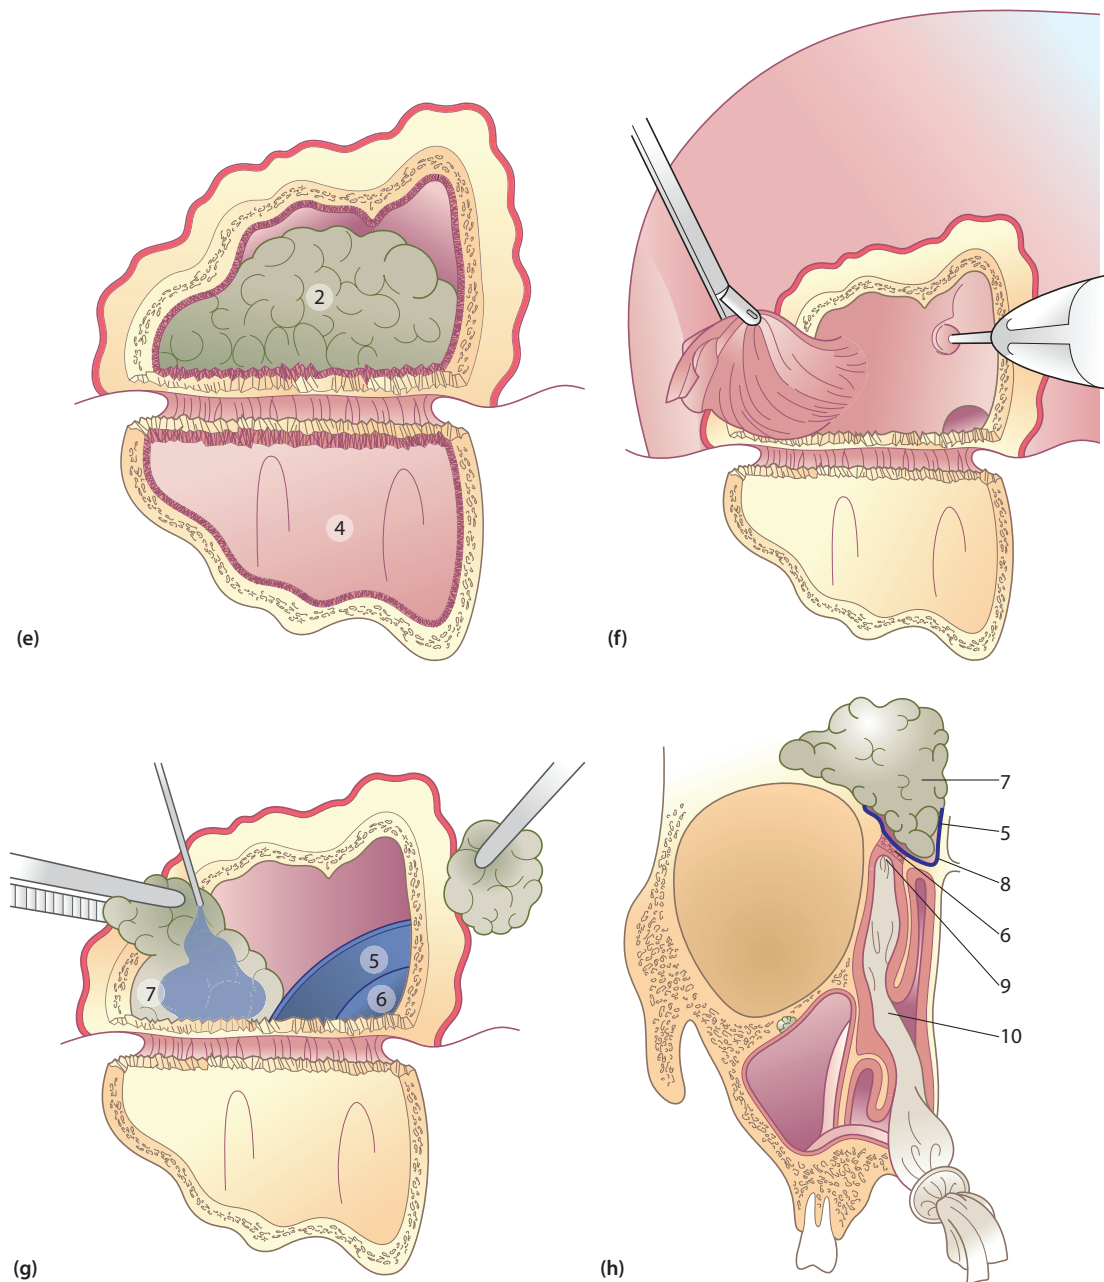

Figure 99.15 (Continued) Technique of the osteoplastic frontal sinus operation. (e) Appearances after down fracturing of anterior wall of frontal sinus. (f) The mucosa is completely removed and using the operation microscope, the internal table drilled with the burr. (g) After blockage of the ostium, frontal sinus drainage by inverting the mucosa, covering the cartilage with preserved fascia or galea-periosteum and fixing with fibrin glue, the frontal sinus is filled with pieces of fat. These are made to cohere with fibrin glue. Finally, the bony flap is replaced and closure of the wound begins. (h) Situation at the end of the operation: (1) Elevated galea-periosteum; (2) pathologically altered mucosa frontal sinus; (3) drill holes; (4) bony flap hinged on periosteum (anterior wall of the frontal sinus); (5) preserved fascia; (6) cartilage; (7) transplanted fat with fibrin glue; (8) fibrin glue; (9) resorbable sponge; (10) rubber finger packs. (Redrawn from Draf W. Surgical treatment of the inflammatory diseases of the paranasal sinuses: indication, surgical technique, risks, mismanagement, and complications, revision surgery (Reproduced with permission from *Die chirurgische Behandlung entzündlicher Erkrankungen der Nasennebenhöhlen: Indikation, Operationsverfahren, Gefahren, Fehler und Komplikationen, Revisionschirurgie*). *Arch Otorhinolaryngol* 1982; **235**: 133–205 (Kongressbericht 1982).

(see 'Frontal sinus trephination' below). This combined approach has meant that where some sinuses would have been obliterated in the past it may not be necessary to do so now. The approach may be used when pathology in the frontal sinus outflow tract cannot adequately or safely be addressed by an endonasal approach alone. A MELP can be combined with a frontal trephine or OPF

to remove tumours such as inverted papilloma with lateral attachments. The obvious advantage of this is to retain a functioning sinus that is endoscopically accessible and can be monitored by imaging. Medially based osteomas, neo-osteogenesis of the frontal recess, posterior table CSF leaks and encephaloceles can be managed by the 'above and below' approach.^{46, 75–78}

Frontal sinus trephination

Trephination of the frontal sinus is a procedure that is normally performed in cases of complicated acute frontal sinusitis not responding to medical management, but it can have a role in chronic frontal sinus disease.⁸⁵

In the acute setting, a small incision (1–1.5 cm) is made below the medial eyebrow and supraorbital rim down through the periosteum. The periosteum is elevated and a drill is used to make a small window at the junction of the floor and anterior wall of the frontal sinus. The sinus is irrigated and a drain placed *in situ*.

A modified frontal trephine technique, the mini trephine (Medtronic, Jacksonville), is useful during surgery for chronic frontal sinus disease. The landmarks are identified in **Figure 99.16**. The use of fluorescein stained saline to irrigate the trephine can aid in dissection of the frontal recess pathway. One must always aspirate prior to irrigation and be cautious when a dehiscence of the orbit is present. Indications include any situation where the frontal sinus outflow tract is difficult to detect, for irrigation of the sinus intra- and post-operatively and as an adjunct to more complex frontal sinus procedures. A pre-operative CT scan to define the depth and extent of pneumatization of the frontal sinus is essential. Complications such as intracranial penetration with CSF leak, periorbital trauma and incision related infection have been reported.^{86–88}

External frontoethmoidectomy

This historical procedure, which was associated with a high failure and complication rate, has been replaced by endoscopic approaches to the frontal sinus.⁸⁴ The operation was conceptually flawed as it was designed to remove

the bony support of the frontal recess. As a result scarring and fibrosis obstructed the outflow tract. It was performed via an external, slightly curved incision (Lynch) made halfway between the nasal dorsum and the medial canthus. The indications for a Lynch incision today are to externally access the anterior ethmoidal artery, in the drainage of periorbital abscesses and if extended superolaterally, to trephine the floor of the frontal sinus.

Cranialization of the frontal sinus

Frontal sinus cranialization for refractory chronic frontal sinusitis is rarely performed. Cranialization has a role in procedures requiring a craniotomy. Performed in conjunction with the neurosurgeons, the commonest indication is for extensive fractures of the frontal sinus, particularly the posterior table. Other indications include tumours and osteomyelitis.

Using a coronal incision a midfrontobasal craniotomy can be used.⁸⁹ The posterior wall and floor of the sinus are removed. Mucosa of the frontal sinus outflow tract is inverted into the nasal cavity and sealed with fascia or a strip of pericranium and fibrin glue. The success of the procedure relies on meticulous removal of the entire frontal sinus mucosa and drilling the sinus with a diamond burr. Dead space between the anterior wall and dura can be filled with fat or a vascularized pericranial flap.⁹⁰ Complications include dural injury with CSF leak, bone flap necrosis, frontal lobe trauma and intra-cranial mucocele formation.

Riedel's procedure

Riedel's procedure involves removing the floor, anterior wall of the frontal sinus and its entire mucosal lining.

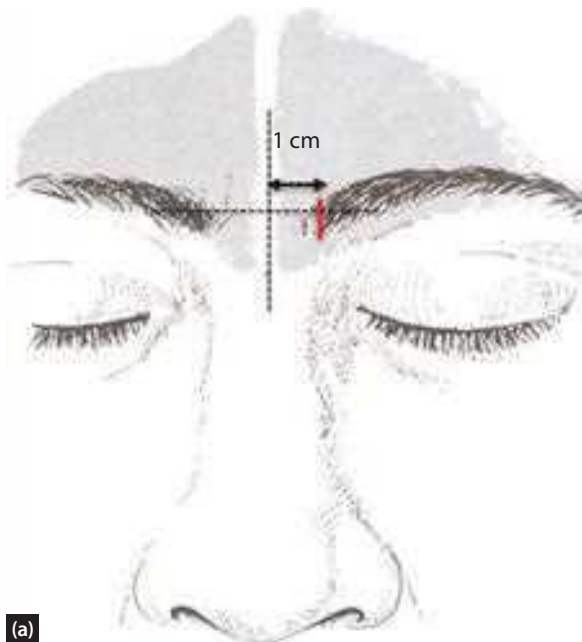

Figure 99.16 (a) Frontal mini-trephine landmarks. The incision can be hidden in the medial aspect of the eyebrow or if necessary in a vertical crease. However, given the possible anatomical variations, careful evaluation of the imaging is essential in every case to avoid inadvertent injury and to help select the safest distance from the midline for frontal sinus trephination.⁸⁷ **(b)** Fluorescein tinted saline is injected via the trephine during a MELP.

Although it is rarely performed, it does have a role in a small proportion of patients where frontal sinus drainage cannot be established and frontal sinus obliteration has failed. These include patients who have osteomyelitis or tumours involving the anterior wall of the frontal sinus. The main criticism of the procedure is the cosmetic defect, which can be reduced by chamfering the supraorbital ridge and smoothing out the margin of the sinus to a gentle curve. As the mucosa within the sinus is removed recurrent complications are uncommon.⁹¹

TUMOURS

Sixty percent of sinonasal tumours arise in the maxillary sinus, 20% arise in the nasal cavity, 5% in the ethmoid sinuses, and only 3% in the sphenoid and frontal sinuses. Fifty-five percent of sinonasal malignancies are carcinomas, squamous cell carcinomas being the commonest. Tumours of the ethmoid sinus and superior nasal vault are usually adenocarcinomas.⁹² As it is with chronic frontal sinus disease, tumours of the frontal sinus present a significant challenge in diagnosis and management. Although tumours originating within the frontal sinus are rare, extension into the sinus is not.

Imaging

The aim of imaging is to provide reliable information on the nature of the tumour (benign vs. malignant), map its extent and point of origin, and distinguish concomitant inflammatory reactions. MRI best achieves this. Multiparametric MRI imaging, using a combination of apparent diffusion coefficient and time-signal intensity curve techniques, may help differentiate benign and malignant sinonasal diseases.⁹³

CT is often requested as the initial investigation for sinonasal symptoms and it provides useful bony detail particularly in fibro-osseous lesions.

General principles of tumour surgery of the frontal sinus

Ideally, it is preferable to remove a frontal sinus tumour using the most minimally invasive technique. Tumour characteristics (benign or malignant), site, involvement of adjacent structures (dura and orbit), and local expertise determine the surgical approach. Management decisions should be made within a multidisciplinary team including head and neck surgeons and neurosurgery when appropriate. As with chronic frontal sinus disease a stepwise approach is recommended:

- Endonasal (including modified Lothrop procedures)
- Osteoplastic flap (bi-coronal incision, mid forehead, brow)
- Above and below (endoscopic and frontal craniotomy)
- Subcranial, subfrontal and transcranial.

The midfacial degloving approach provides excellent access to bony structures of the midface and posterior

parts of the anterior skull base but less satisfactory access to the frontal sinus. Generally, with OPF approaches for tumour removal, frontal sinus obliteration should be considered a contraindication given the inability to detect subsequent tumour recurrence.

Endoscopic considerations

When considering an endoscopic approach, experience in dealing with inflammatory diseases and endonasal duraplasty is mandatory. The endoscopic modified Lothrop procedure (MELP) provides excellent access to the frontal sinus when managing chronic frontal sinus disease but its utility in tumour disease has some limitations. In tumour surgery it is necessary not only to visualize the site of the lesion but also to instrument that area with curettes and drills. The degree of the frontal sinus pneumatization is an important factor. The better the pneumatization, the wider the radius of action of the instrument. The following general guidelines for operating on tumours of the frontal sinus are useful:

1. Lesions not extending beyond a sagittal plane through the lamina papyracea are accessible endoscopically. Lesions extending beyond this may be accessible depending on the anterior-posterior dimension of the floor of the frontal sinus and the intercanthal distance.⁹⁴
2. Tumours arising from the medial quarter of the orbital plate of the frontal sinus may be accessible via a MELP alone or with the aid of an external trephine. (Figure 99.17).
3. Lesions originating in the lower third of the posterior wall of the frontal sinus are usually accessible via an endoscopic approach.
4. In general, tumours arising from the anterior wall of the frontal sinus are difficult to access endoscopically.⁸⁴ Those arising low down may be accessible via a MELP.
5. A narrow anterior-posterior dimension of the floor of the frontal sinus (<10 mm) can limit endoscopic access and favour open or combined approaches.⁹⁵
6. Superior reach within the sinus may not be possible in well pneumatized sinuses.⁹⁶
7. The junction of the anterior and posterior wall in the most lateral part of the frontal sinus may be too narrow to admit a drill. Similarly, supraorbital ethmoid cells may limit lateral access for tumour removal.⁹⁷

BENIGN TUMOURS

Inverted papilloma

Inverted papilloma (IP) are relatively uncommon benign epithelial tumours of the nasal cavity. They are locally aggressive, have a tendency to recur and are associated with malignancy. Histologically, the tumour is characterized by epithelium inverting into the stroma with a distinct and intact basement membrane. Human papilloma virus has been implicated in the pathogenesis. Viral DNA has been found in the adjacent normal appearing

Figure 99.17 (a) Coronal CT demonstrating orbital zones. Zone 1: medial quarter of the orbit (yellow highlight); Zone 2: outer margin of Zone 1 to the midorbital point; Zone 3: laterally from midorbital point to halfway between the midorbital point and the lateral aspect of the orbit; Zone 4: the lateral-most quarter. (Modified with permission.)⁹⁷ (b) Parasagittal CT scan. Lesions which originate from the lower third (yellow area) of the posterior or anterior wall of the frontal sinus may be accessible endoscopically.⁸⁴ (c) Axial CT scan. The lateral junction of the anterior and posterior walls may be inaccessible due to their narrowness (red area).

tissue and may account for the associated recurrence rates although in many cases this is due to residual disease. The incidence of IP in normal bilateral nasal polyps is rare (<1%). As multiple sites within the paranasal sinus may be involved, localization of the origin is not always easy. The commonest sites of origin are the ethmoid region (48%), lateral nasal wall and maxillary sinus (28%) with the frontal sinus accounting for only 2.5%.⁹⁸ Bilateral frontal sinus involvement is not uncommon (16%).⁹⁹

Although CT is the primary mode of imaging, MRI is complementary and recommended. Particularly in the frontal sinus when tumour can obstruct the outflow tract, MRI is very useful in distinguishing mucus from papilloma. Focal hyperostosis on CT imaging is a common finding in patients with IP but may be helpful in identifying the site of origin.^{100, 101}

Surgical strategy

The success of surgery is dependent on defining the extent of disease, identifying the site of tumour origin and attachments and fully extirpating all affected tissue. This includes removal of the underlying mucoperiosteum and burring the bone. Within the frontal sinus, the narrow confines and proximity to the anterior skull base and orbit makes this a challenge. This is reflected by the higher recurrence rates (22%) than would be expected for endoscopic management of IP in other locations (3%).⁹⁹

The OPF procedure offers a wide exposure of the frontal sinus, and has traditionally been the preferred approach. The modified Lothrop procedure combined with angled instruments and endoscopes offers similar access and is a valid alternative.¹⁰² Generally, tumours originating medially or from the lower third of the posterior wall of the frontal sinus can be accessed by a frontal sinusotomy or Draf type II approach. Those arising laterally or along the anterior wall will require an extended endoscopic approach or an OPF. A summary of the suggested surgical strategy can be found in [Table 99.9](#).

Extended approaches such as a MELP can be augmented by an external trephine, which can provide an additional port for instruments or endoscopes. The relative accessibility is highlighted in [Figure 99.17](#).

TABLE 99.9 Suggested surgical strategy for frontal sinus inverted papilloma

Site of origin within the frontal sinus	Surgical approach options
Unifocal, attached to MW or lower AW/PW. Multifocal as above	Draf type IIa/b MELP
Unifocal or multifocal, attached to superior AW, superior PW or LW	OPF, MELP possibly with external trephine
Lateral to midpoint of orbit	OPF, MELP with external trephine

Anterior wall: AW; posterior wall: PW; medial wall: MW; lateral wall: LW; osteoplastic flap: OPF; endoscopic modified Lothrop procedure: MELP.¹⁰²

A recent systematic review suggests that more aggressive primary approaches may facilitate better disease control.⁹⁹ Patients should be followed up for a minimum of 3 years. Where tumour removal was performed via a MELP, direct surveillance can be performed. When this is not possible an MRI is recommended.¹⁰³

Fibro-osseous lesions

Fibrous dysplasia, ossifying fibroma and osteoma are a group of benign bony abnormalities that can affect the paranasal sinuses. They lie along a continuum from least to the most bony content.¹⁰⁴

OSTEOMAS

Osteomas are the most common benign tumour of the paranasal sinuses, with a prevalence of 3%. These slow growing tumours occur most often in the ethmoid followed by the frontal sinuses.¹⁰⁵ There are three main theories regarding the aetiology of osteomas: developmental, traumatic and infectious. The developmental theory suggests that reactivation of embryonic stem cells leads to uncontrolled bone formation. The traumatic and infectious theories propose an inflammatory process as the initiating factor for bony tumour formation.¹⁰³ Histologically 3 types are found: ivory or compact, mature or cancellous

and mixed. Their attachment may be broad based or occasionally via a stalk.

CT imaging is the investigation of choice with osteomas appearing as homogenous, dense, well-circumscribed lesions. MRI is recommended when extra sinus involvement is suspected.

Most osteomas are asymptomatic. The commonest reported clinical symptoms are headache or a sensation of pressure. However, these symptoms may be non-sinogenic and one must be cautious in attributing them to the presence of an osteoma.¹⁴

Surgical strategy

Small asymptomatic osteomas do not require surgery. Conservative management with watchful waiting and interval imaging is recommended.¹⁰⁶ The following guidelines are useful indicators for surgery:

- Symptomatic patients (chronic rhinosinusitis and mucocoeles secondary to obstruction, facial deformity, orbital or neurological complications)
- Tumours occupying more than 50% of the frontal sinus
- Continued growth on serial CT imaging
- Tumours obstructing the frontal recess
- Tumours extending outwith the paranasal sinuses (orbital and intra-cranial)

Surgical approaches can be classified as external, endoscopic or a combination of both (above and below). The osteoplastic flap approach with or without fat obliteration has been the gold standard as it provides excellent access and visualization (**Figure 99.18a–c**) but it is not without morbidity (see above). Recently, there has been a trend towards an entirely endoscopic approach such as a Draf IIb (**Figure 99.19a–c**) or modified endoscopic Lothrop procedure (MELP/Draf III).

When combined with an OPF procedure, the MELP aims to maintain long-term patency of the frontal neostium by avoiding obliteration. There is some debate as to the limits of the endoscopic approach. Some of these limitations are discussed above under 'Endoscopic considerations'. Other important factors include the extent

of intra-cranial extension, significant orbital involvement and erosion of the posterior or anterior wall of the frontal sinus.^{95, 107} A grading system for osteomas is outlined in **Table 99.10**. Conventionally mostly grade I and II tumours were removed endonasally. With the advances in endoscopic instrumentation and surgical skill, many grade III and grade IV can be managed endoscopically.^{108–110} Tumours extending beyond a vertical plane through the lamina papyracea are accessible endoscopically. However, access to tumours arising lateral to the midpoint of the orbit may be limited.⁹⁷ Tumours extending through the anterior table of the frontal sinus are best managed by an external approach. Although large osteomas filling the sinus may be managed endoscopically, the operative duration is likely to be much shorter via an open approach. Clearly, the surgical strategy needs to be based on the individual's anatomy. Variables such as the degree of frontal sinus pneumatization, interorbital width (distance between both lamina papyracea) and A-P dimension of the floor of the frontal sinus are important considerations in determining the most appropriate approach.^{94, 111}

Gardner's syndrome

The syndrome consists of a triad of multiple osteomas, colorectal polyps, skeletal abnormalities and supernumerary teeth. The disease is autosomal dominant and carries a 100% risk of malignant transformation of the colonic polyps by the age of 40. Patients usually present in their second decade with rectal bleeding, pain and diarrhoea. As early diagnosis is important, all patients presenting with frontal sinus osteomas should have a thorough systemic enquiry.¹⁰⁴

Fibrous dysplasia

Fibrous dysplasia (FD) is a slow growing, tumour-like lesion of bone. It occurs when normal cancellous bone is replaced by abnormal fibrous tissue. The fibrous tissue replaces the spongiosa and fills the medullary cavity with poorly calcified trabeculae (**Figure 99.20**). This genetic disease is a result of a mutation in the *GNAS1* gene located on chromosome 20q13, which normally codes for the alpha subunit of the stimulatory G-protein.^{112, 113}

Figure 99.18 Osteoplastic approach for the removal of a large frontal sinus osteoma. Elevation of the bone flap (**a**) and (**b**) reveals the osteoma (*) filling the left frontal sinus (**c**); the right frontal sinus outflow tract is indicated with a white arrow.

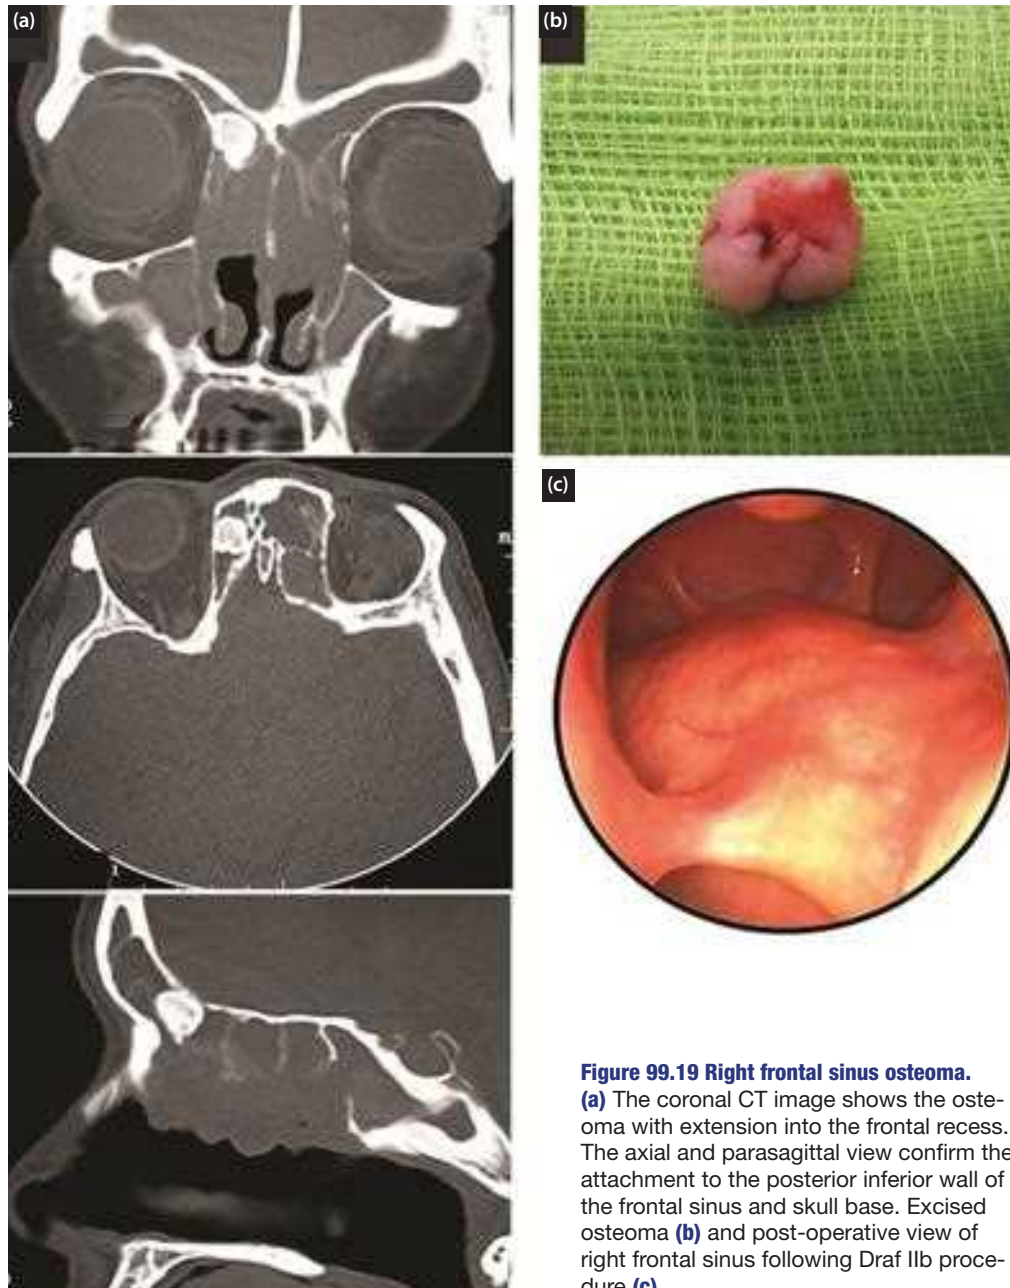

Figure 99.19 Right frontal sinus osteoma.

(a) The coronal CT image shows the osteoma with extension into the frontal recess. The axial and parasagittal view confirm the attachment to the posterior inferior wall of the frontal sinus and skull base. Excised osteoma (b) and post-operative view of right frontal sinus following Draf IIb procedure (c).

TABLE 99.10 Frontal sinus osteoma grading system. The grading system highlights three variables: The location of attachment of the base, the relationship of the lesion to a virtual sagittal plane through the lamina papyracea and the A-P width of the frontal recess

Grade	Description
I	Base of attachment is posterior–inferior along the frontal recess. Tumour is medial to a virtual sagittal plane through the lamina papyracea. Anterior–posterior diameter of the lesion is less than 75% of the anterior–posterior dimension of the frontal recess.
II	Base of attachment is posterior–inferior along the frontal recess. Tumour is medial to a virtual sagittal plane through the lamina papyracea. Anterior–posterior diameter of the lesion is greater than 75% of the anterior–posterior dimension of the frontal recess.
III	Base of attachment is anterior or superiorly located within the frontal sinus AND/OR Tumour extends lateral to a virtual sagittal plane through the lamina papyracea.
IV	Tumour fills the entire frontal sinus.

Figure 99.20 Extensive fibrous dysplasia (FD) involving the ethmoid and sphenoid sinus. The patient had previously undergone surgery for FD involving the left frontal sinus.

Most cases (75%) are diagnosed before the age of 30 and tend to stabilize after the patient reaches skeletal maturity.^{104, 114} Two forms are present:

- Monostotic (80%) – Craniofacial involvement occurs in up to 25% of cases with the maxilla and mandible most commonly affected. Although monostotic FD in the long bones does not cross the joint line, it can cross bony sutures in the maxillofacial skeleton.
- Polystotic (20%) – various areas of the skeleton can be affected with craniofacial involvement present in 40% to 50% of cases. Polystotic FD, endocrine hyperfunction (such as precocious puberty and/or hyperthyroidism) and café-au-lait spots are components of McCune-Albright syndrome. This rare condition primarily affects females.

FD has a low rate of malignant transformation occurring in 0.5% of polystotic forms and in 4% of lesions with McCune-Albright syndrome.

Patients with the monostotic form are frequently asymptomatic, often diagnosed incidentally. Polyostotic FD can present early with manifestations of bone pain and deformity. Both variants can lead to symptoms of vascular or neurological compression. Craniofacial disease can present as headaches or facial asymmetry. Sphenoid and frontal sinus FD may lead to optic nerve compression and mucocele formation respectively.

CT and MRI are helpful in establishing the diagnosis but if there is any doubt a biopsy is recommended. On CT imaging, lesions appear fairly homogenous with a 'ground glass' appearance. As the lesion scleroses, 'cotton wool' areas appear. MRI helps evaluate the soft tissue component and can distinguish it from other lesions such as meningiomas and bone cysts. FD tends to display an

intermediate signal on T1-weighted images and is hypointense on T2-weighted images.¹⁰⁴

Surgical strategy

Most studies recommend conservative management. Medical treatment is limited to symptomatic relief. Bisphosphonates are useful in reducing the incidence of fractures and bone pain. Asymptomatic patients with monostotic FD can be observed. Endoscopic sinus surgery can provide symptomatic relief by improving sinus drainage pathways.¹¹⁵ In more severe cases and those with cosmetic deformity, local controlled resection and recontouring may be feasible depending on symptoms and location. Paranasal sinus lesions causing sinusitis or optic nerve compression may be managed endoscopically, ideally with the aid of computer assisted navigation.^{84, 103} The rate of malignant transformation to an osteosarcoma is low, at 0.5%, but any painful, rapidly growing lesion should raise suspicion. There is no role for radiotherapy in treating FD.¹¹⁵

Ossifying fibroma

The nomenclature surrounding ossifying fibroma (OF) is diverse and confusing. Broadly, OF can be classified into 3 categories:¹¹⁶

1. Ossifying fibroma
2. Cemento-ossifying fibroma (COF)
3. Aggressive psammomatoid ossifying fibroma (APOF) or juvenile-aggressive OF.

These benign tumours can have differing biologic behaviour. Histologically, lesions consist of 2 main components: fibrous stroma and bone elements. APOF lesions consist of irregular bony spicules within a cellular fibrous stroma. Classically, this resembles cementum or calcified 'psammomatoid bodies'. COF lesions have similar histologic features with cementum-like material present throughout the lesion.

Clinically, lesions are often asymptomatic but can present with proptosis, diplopia, epiphora, facial swelling, nasal obstruction, epistaxis and headaches. Endoscopically they appear as smooth mucosally covered masses. This locally destructive tumour occurs most commonly in the facial skeleton affecting the mandible in 75% of cases. When arising outside the mandible, OFs appear to affect the ethmoid and maxillary sinuses most frequently. Similarly, APOFs most commonly affect the ethmoid sinus followed by the maxillary sinus, orbit and frontal sinus. Multiple sinus involvement is not uncommon. COF most commonly present in the maxillary and ethmoid sinus and rarely in the frontal and sphenoid sinus.¹¹⁶

All three variants display similar features on CT. Sharply circumscribed round lesions with an eggshell rim and central radiolucency are typical of OF. APOF and COF have a thicker bony rim and a central ground glass appearance. MRI features are similar to fibrous dysplasia with a low to intermediate signal on T1-weighted

imaging and variable intensity on T2-weighted imaging. An endoscopic biopsy may be required to confirm the diagnosis.

Treatment strategy

If OF is suspected on imaging, a biopsy is recommended to confirm the diagnosis. For paranasal sinus disease this may be achieved endoscopically. The role of biopsy is to exclude malignant pathology such as sarcoma. Ideally, treatment should be complete surgical excision but this is dependent on the site and symptoms. Evidence would suggest that a more conservative approach might be acceptable where there are little or no symptoms.^{115, 117} Surgical resection may be achieved by an endoscopic approach, with more extensive disease requiring a combined approach including craniofacial resection. Recurrence rates for APOF, COF and OF are low.^{103, 104, 117}

MALIGNANT TUMOURS INVOLVING THE FRONTAL SINUS

Primary malignant tumours of the frontal sinus are very rare. Squamous cell carcinoma is the commonest tumour, affecting the maxillary sinus in up to 30% and the frontal sinus in less than 1%. Other primary tumours include adenocarcinomas and non-epithelial malignancies such as lymphomas. Mostly the frontal sinus becomes involved by direct extension of tumour from adjacent sites. Metastasis of malignant tumours to the frontal sinus is rare. Along with tissue biopsies, CT and multiparametric MRI are helpful in establishing the diagnosis, extent of disease and in particular orbital and dural involvement.¹¹⁸

The comprehensive management of sinonasal malignancy is covered elsewhere in this book. However, the principles of surgery are twofold: complete resection of the tumour by the least invasive approach. It would appear that more important than 'en bloc' resection is to achieve negative tumour resection margins.¹⁰³

Malignant tumours of the nasal cavity and other paranasal sinuses, which have not led to major bone destruction and are just reaching the frontal sinus, may be operated on via the endonasal route.

More extensive tumours of this type, or primary malignant frontal sinus tumours, may be approached by the subcranial technique, according to Raveh et al.¹¹⁹ through a coronal incision, without shaving the hair, sometimes in combination with midfacial degloving, if the lower sinuses are involved. The subcranial approach also allows management of malignancies with skull base or even intradural involvement.

To summarize, there is a stepladder of three surgical techniques: (1) endonasal; (2) midfacial degloving; (3) subcranial approach,¹¹⁹ which has proved to be very efficient when dealing with malignant tumours of the nasal cavity and the paranasal sinuses, including the frontal sinus and the anterior skull base. The great advantage of all these approaches is the avoidance of visible scars, a fact

much appreciated by the patients. The lateral rhinotomy is generally reserved if exenteration of the orbit is needed simultaneously.

OTHER CONDITIONS

Frontal pneumosinus dilatans

Pneumosinus dilatans refers to an abnormally large aerated sinus. This uncommon condition can affect all the paranasal sinuses but has a predilection for the frontal sinus. When associated with the frontal sinus, aeration extends beyond the normal margin of the frontal bone. Characteristically, the walls of the sinus are of normal thickness and there is no evidence of erosion. It is unlike a pneumocele where the aerated sinus is associated with a thinning of its wall and this can be focal or generalized.¹²⁰

AETIOLOGY

A number of theories have been put forward but the pathophysiology remains poorly understood. These theories include: (a) mucocoele growth and spontaneous rupture, (b) a one-way valve mechanism, (c) hormonal influences affecting bone resorption and (d) congenital defects.¹²¹ The mechanism most favoured is that of a one-way valve.

CLINICAL FEATURES AND INVESTIGATIONS

The condition usually presents between the 2nd and 4th decade and has a male preponderance. Most patients are asymptomatic but bony expansion can result in frontal bossing. Less common pressure-related symptoms include diplopia, headache or intra-cranial symptoms.

Pneumosinus dilatans has been shown to be associated with a number of pathological conditions such as planum meningiomas, arachnoid cysts, fibrous dysplasia, acromegaly and prolonged cerebrospinal fluid shunting. Recently, an association with congenital polyosteotic fibrous dysplasia (McCune Albright syndrome) has been reported.¹²¹

CT imaging is the investigation of choice.

MANAGEMENT

It is important to address any pathology within the sinus or obstructing ventilation of the sinus. If this cannot be achieved endoscopically then an open approach may be required. In patients with functioning ostia the cosmetic deformity is the main issue. This can be corrected by direct, full thickness, resection of horizontal bone strips of the anterior wall of the sinus. Plating of the bone fragments is not required if the galea-periosteum remains attached.¹²²

BEST CLINICAL PRACTICE

- ✓ Trial of optimum medical therapy prior to any surgical intervention is important.
- ✓ Recording of outcome data is essential.
- ✓ Post-operative care should include regular saline douches and debridement as necessary.
- ✓ Mucosal preservation during surgery is important. The use of pedicled flaps in more extensive surgery such as the modified Lothrop aids healing and reduces post-operative crusting.
- ✓ The modified Lothrop procedure aims to provide maximal ventilation and facilitate removal of eosinophilic mucin and osteitic bone.
- ✓ Consider more extensive surgery in the following scenarios:
 - ✓ AERD is associated with higher incidence of frontal neo-ostium stenosis.
 - ✓ Asthma (associated with a higher rate of surgical revision).
 - ✓ CRSwNP revision rate higher.
 - ✓ Osteoneogenesis.
 - ✓ Greater burden of disease, Lund McKay score > 16.
 - ✓ Frontal ostium opening on anteroposterior dimension (sagittal CT view) < 4mm.

FUTURE RESEARCH

- Which patient groups might benefit from more extensive primary frontal sinus surgery?
- Method of targeted delivery of local steroid and antibiotic therapy within the frontal sinus.
- Effect of alternative therapies on chronic sinus disease.

KEY POINTS

- The anatomy of the frontal recess is variable and complex. A detailed knowledge of the anatomy is vital when operating within this area.
- One should approach this area with caution. Meticulous attention to detail and careful dissection is key.
- An *all or nothing* approach is suggested.
- It is important to address any disease in the frontal recess/sinus when managing patients with Chronic Rhinosinusitis. Failure of surgery can often be attributed to unaddressed disease within the frontal recess and sinus.
- Incomplete or inadequate surgery in the frontal recess can lead to iatrogenic disease and persistence of symptoms.
- The greater the disease burden as noted by the preoperative Lund-McKay (LM) CT score, the more extensive the surgery required.
- The incidence of more extensive frontal sinus surgery is higher in patients with Asthma and AERD (Aspirin exacerbated respiratory disease)
- Patients with frontal sinus disease may not have *specific* frontal sinus symptoms
- Headache as the predominant symptom without any other significant symptoms of sinusitis is unlikely to be sinogenic in origin.

SEARCH STRATEGY

A PubMed search was conducted to support the data in this chapter using the Medical Subject Headings (MeSH) paranasal, maxillary, frontal, ethmoid, sphenoid sinus and mucocele. The chapter will focus on the etiology and surgical management of mucoceles. The evidence in this chapter is mainly level 2b.

DEFINITION

A mucocele is an epithelium-lined mucus-filled sac within one of the paranasal sinuses with expansion of the sinus cavity and remodelling of the sinus walls. It forms secondary to obstruction of the outflow tract of the involved sinus together with an inflammatory process within the sinus.¹ It is lined by pseudostratified or low-columnar epithelium in contradistinction to a cyst that has a distinct separate membrane. Where bony erosion has taken place, the mucocele's epithelium is often fused with dura or orbital periosteum.

SITE OF DEVELOPMENT

The frontal, ethmoid, maxillary and sphenoid sinuses are involved in descending order of frequency (**Table 100.1**).² Frontal sinus mucoceles are probably more common because of the complex and narrow drainage pathway of the frontal sinus that is easily obstructed.²⁻³ Mucoceles can form in any other aerated structure such as a concha bullosa of the middle (**Figure 100.1**) or superior turbinate. Obstruction of the nasolacrimal duct can also cause a lacrimal sac mucocele/dacryocoele.

Figure 100.1 Mucocele within a concha bullosa.

TABLE 100.1 Aetiopathogenesis of mucoceles

Series	Number of cases	Prior sinus surgery	Prior trauma	Spontaneous	CRS without surgery	Tumours
Bockmühl et al. ²	255	66%	14%	17%	2%	1%
Devars du Mayne et al. ⁷	68	75%		15%	7%	
Khong et al. ⁵	28	86%	7%			
Nakanishi et al. ⁶	24	87.5%		12.5%		
Lund et al. ¹	48			92%	2%	

AETIOLOGY

Sinus surgery is now the leading cause (66–86%)^{4–6} of mucocele formation following surgery mostly for chronic sinusitis and nasal polyposis.^{2,7} The interval between surgery and subsequent mucocele formation can range between 1 and 19 years and depends on the location of the mucocele, with frontal and sphenoid mucoceles developing earlier than maxillary sinus mucoceles. Surgery in the region of the frontal recess during functional endoscopic sinus surgery can cause circumferential injury to the frontal sinus outflow tract with subsequent stenosis and mucocele formation. External fronto-ethmoidectomy/Lynch-Howarth operation is a leading cause of mucoceles because of loss of lateral bony support of the frontal recess which causes herniation of the periorbital tissue into the frontal sinus outflow tract. In a large series by Bockmühl et al, 78% of mucoceles following sinus surgery was associated with the Lynch-Howarth and/or Caldwell-Luc operations versus 1.5% after endonasal surgery.²

A significant incidence of mucoceles has been reported following endoscopic repair of skull-base fractures in children. In one study 50% of patients developed mucoceles after repair of skull-base defects with a middle turbinate overlay patch.⁸ Only 10–14% of mucoceles are secondary to trauma and 15–17% develop spontaneously; the mean interval between head injury and mucocele formation is 9 years.⁷ Any benign or malignant tumour can lead to mucocele formation but the incidence in the literature is low and ranges from 1% to 5% (Table 100.2).

PATHOGENESIS

It is thought that in order for a mucocele to form two factors are essential: an obstructed sinus outflow tract and an inflammatory process within the sinus. Osteolytic cytokine-IL-1 and tumour necrosis factor are present within the epithelial lining of mucoceles; it has been

postulated that this cytokine may be the responsible for the bony erosion in expanding mucoceles.¹

CLINICAL FEATURES

Bony erosion leads to expansion of the sac beyond the sinus cavity into the cranial cavity or orbit. Symptoms depend on the sinus involved. A visible mass is often seen on the forehead (Figure 100.2a and b), medial canthus or in the gingivobuccal sulcus or cheek. Ophthalmologic symptoms are more common than rhinological and neurological symptoms.⁹ The most common ophthalmologic complaints are periorbital swelling, pain and exophthalmos (Figure 100.3). Displacement of the orbital contents can lead to limited ocular mobility, visual disturbance and diplopia.^{4,9} Optic neuropathy has been reported in up to 18% of patients who present with ophthalmologic symptoms and is due to direct compression of the optic nerve in the posterior ethmoid and sphenoid sinuses.⁹ A mucocele within a concha bullosa may present with nasal obstruction and/or secondary sinusitis. Epiphora and a cystic swelling in the medial canthus suggest the presence of a dacryocoele.

Radiology

Computed tomography (CT) findings suggestive of a mucocele are a homogeneous, isodense lesion within an expanded sinus with bony remodelling of the sinus walls (Figures 100.2c and 3). Contrast enhancement only occurs with a pyocoele. A bony defect of the lamina papyracea and/or superomedial part of the orbital rim is often seen in fronto-ethmoidal mucoceles.¹⁰ The globe may be displaced laterally and/or inferiorly with evidence of proptosis on axial images. The sac can cause erosion of the posterior table of the frontal sinus and compression of the intracranial contents. It can be difficult to differentiate maxillary sinus mucoceles from other benign or malignant lesions.

TABLE 100.2 Site of involvement

Series	No. of mucoceles	Frontal	Fronto-ethmoidal	Ethmoid	Spheno-ethmoid	Sphenoid	Maxillary
Lee et al. ^{4,10}	82	45%		28%		18%	9%
Bockmühl et al. ²	290	43%	8%	14%		10%	25%
Har-El et al. ¹¹	108		61%	16%	6%	11%	6%

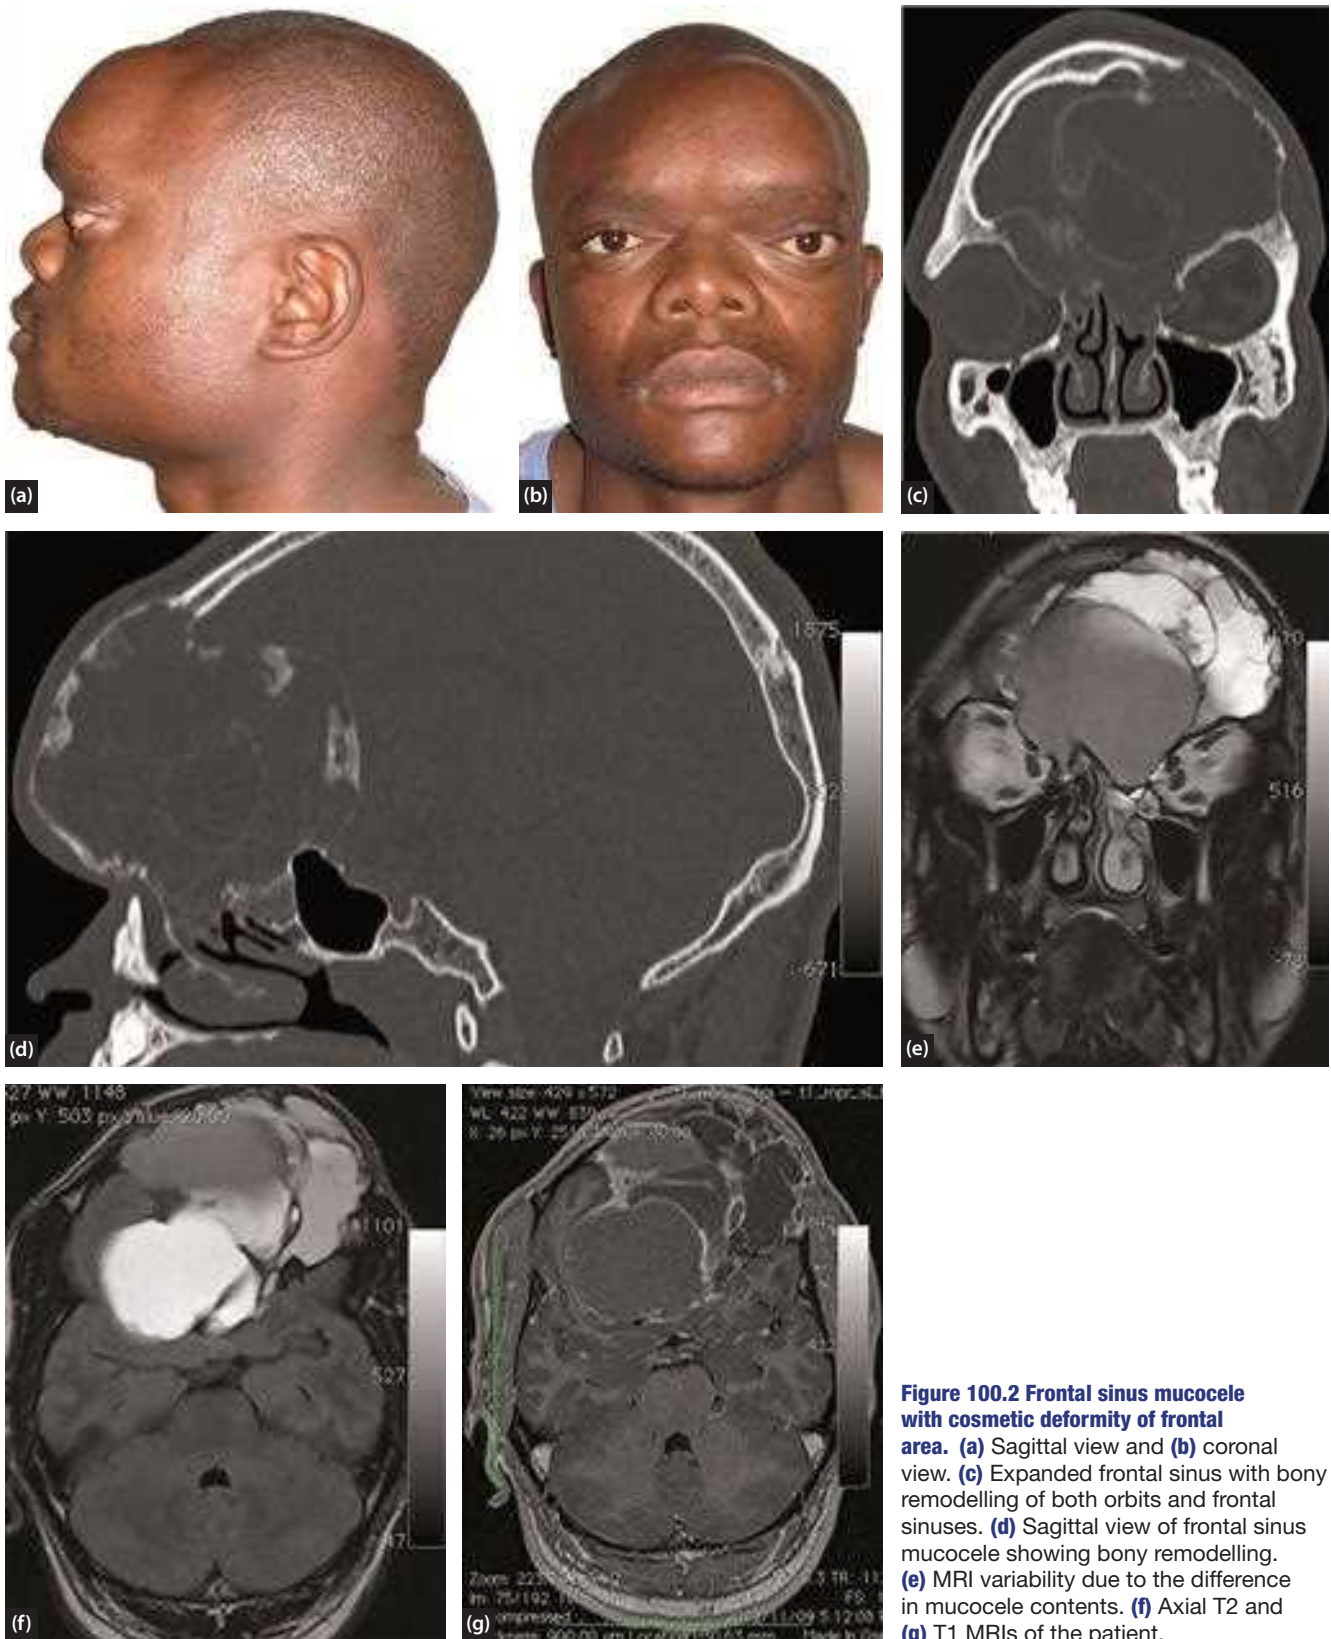

Figure 100.2 Frontal sinus mucocele with cosmetic deformity of frontal area. (a) Sagittal view and (b) coronal view. (c) Expanded frontal sinus with bony remodelling of both orbits and frontal sinuses. (d) Sagittal view of frontal sinus mucocele showing bony remodelling. (e) MRI variability due to the difference in mucocele contents. (f) Axial T2 and (g) T1 MRIs of the patient.

Magnetic resonance imaging (MRI) should be considered in cases of significant bony erosion of the posterior table of the frontal sinus or the orbital lamina papyracea, in order to delineate the mucocele from adjacent soft tissue e.g. cerebral tissue. It should also be recognized that MRI can be misleading

due to the variability of mucocele content (Figures 100.2e and 2f). Mucoceles generally have a high-water content and are hyperintense on T1; pyoceles have higher protein content and greater variability of signal intensity on both T1- and T2-weighted images (Figure 100.2e to 2g).

Figure 100.3 (a) Displacement of the left eye secondary to a frontal sinus mucocele. (b) Coronal CT scan of the patient.

Differential diagnosis

1. Benign or malignant tumours
2. Allergic fungal sinusitis/Other fungal disease
3. Cholesterol granuloma (rare).

SURGICAL MANAGEMENT

Treatment is to widely marsupialize the sac to provide permanent ventilation and sinus drainage and to relieve pressure on vital structures. Cosmetic deformities often settle with time as bony remodelling takes place.¹¹

Fronto-ethmoidal mucoceles

Wide marsupialization is essential whether by endoscopic and/or open technique. Endoscopic surgery with wide marsupialization/nasalization is the first line of treatment for simple mucoceles but a modified endoscopic Lothrop procedure (MELP) is often required for more complex frontal sinus mucoceles.^{5, 11} Good results have been reported with endoscopic techniques with recurrence rates ranging from 0 to 25%.^{7, 11} The MELP is especially useful where there is loss of lateral support in the frontal recess due to bony erosion/previous removal of the superior aspect of the lamina papyracea. Combined approaches are often required for laterally located mucoceles as thick bony septations might not allow for endoscopic techniques alone (Figure 100.3b). Whilst the Lynch-Howarth approach can be used to access laterally located frontal sinus mucoceles and to assist with the drilling down of bony septations, the approach is associated with risk of long-term frontal

outflow obstruction. An osteoplastic frontal flap in combination with a MELP may be required for those mucoceles lying far laterally in the frontal sinus. Transorbital neuro-endoscopic surgery (TONES) – and specifically the superior eyelid approach – allows for an alternative, less invasive approach to address pathology of the lateral frontal sinus. Stenting remains controversial; most authors do not advocate the use of stents to maintain patency except in smaller unilateral marsupializations.^{6, 11, 12} If a stent is placed, it is important that it is loose fitting to prevent circumferential pressure necrosis that could eventually lead to stenosis.

Obliteration of the frontal sinus has a high success rate (93%) but a major complication rate in excess of 20%.¹² A contraindication to frontal sinus obliteration is extensive erosion of the posterior table of the sinus due to the inability to remove the normal respiratory epithelium on dura.¹² Obliteration has, therefore, largely fallen out of favour.

Maxillary sinus mucoceles

It is important to allow for wide drainage of the maxillary sinus into the nasal cavity; a wide middle meatal antrostomy will usually suffice. A partial medial maxillectomy with preservation of the lacrimal system may be required to gain access to laterally located mucoceles.¹¹ The Caldwell-Luc approach is only offered in centres where endoscopic surgery is not an option.

Sphenoid sinus mucoceles

A wide sphenoidotomy and intra-nasal marsupialization are all that is required for sphenoid sinus mucoceles.

Figure 100.4 Homogeneous, isodense lesion within an expanded ethmoid sinus with bony remodelling of the sinus walls.

No attempt is made to remove the lateral sphenoid sinus mucosa as bony erosion places the internal carotid artery or optic nerve at risk of injury.

Other mucocoeles

Mucocoeles that have formed within a concha bullosa require resection of the lateral aspect of the concha bullosa. Dacryocoeles are managed by endoscopic dacryocystorhinostomy.

COMPLICATIONS

Great care needs to be taken when decompressing a large, tense frontal mucocoele that displaces the frontal lobe of the brain (Figure 100.2c and d) as sudden expansion of the cranial contents can disrupt the dural vessels and cause a subdural haematoma, or disrupt the dura and cause a cerebrospinal fluid (CSF) leak. Close post-operative monitoring is therefore essential in such patients. Because recurrence can occur decades later, long-term follow-up is required.

BEST CLINICAL PRACTICE

- ✓ CT is the imaging modality of choice and must be performed pre-operatively.
- ✓ Wide endoscopic marsupialization is the first line treatment for simple mucocoeles.
- ✓ MELP is a good alternative to obliteration procedures.
- ✓ Combined approaches may be required with laterally located frontal sinus mucocoeles.
- ✓ Long-term follow up is required to assess the need for further surgery to correct cosmetic deformities and to ensure patency of the marsupialized sac

FUTURE RESEARCH

- ▶ The pathogenesis of idiopathic mucocoeles needs to be further investigated to ascertain if factors exist that make certain people more susceptible to mucocoeles.
- ▶ Although cosmetic deformities can settle with time as bony remodelling takes place, no studies have been done to assess the long-term cosmetic outcome with marsupialization alone.

KEY POINTS

- Sinus surgery is now the leading cause of mucocoeles.
- Wide marsupialization is required for all mucocoeles.
- Bony remodelling can take place after surgery and cosmetic deformities will improve with time.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search along with BMJ evidence using the keywords: rhinosinusitis, complications, orbital cellulitis, intra-cranial, cavernous sinus thrombosis and Pott's puffy tumour.

DEFINITION

Complications of rhinosinusitis result from progression of acute or chronic infection beyond the paranasal sinuses, potentially causing significant morbidity from either local or distant spread.

EPIDEMIOLOGY

Epidemiological studies estimate an incidence of three complications from rhinosinusitis per million population per year; approximately one in every 12,000 acute rhinosinusitis episodes,¹ although this probably underestimates the disease burden. Most complications tend to occur in children and young adults, who typically experience six to eight upper respiratory infections per year.² Rhinosinusitis occurs in 5–10% of these infections³ with the majority of complications originating from frontal and ethmoid sinus infections. Complications of rhinosinusitis are more accentuated in children and adolescents because of their thinner, more porous bony septa and sinus walls, open suture lines and larger vascular foramina.

CLASSIFICATION

Complications of rhinosinusitis are generally classified as orbital, intra-cranial, bony or chronic.

Complications may be caused by either local progression or distant spread via the bloodstream. Local progression is typically through areas where the surrounding bone is thin such as the porous lamina papyracea, where there is a direct anatomical connection^{6,7} or through osteitic bone. Direct routes of spread occur through neurovascular foramina such as the infraorbital canal, or via the valveless diploic veins of Breschet of the frontal, ethmoid and sphenoid bones. The venous drainage of the sinus mucosa is via these diploic veins,⁸ which communicate with the dural venous plexus, the absence of valves facilitates retrograde spread of infection. Local complications of rhinosinusitis can be specific for the individual sinus groups and may best be discussed relating to their presumed anatomical sinus of origin. However, isolated sinus infections are rare and usually simultaneous infection is present in more than one sinus group.

Frontal

Anterior spread of acute frontal sinusitis through the outer table of the skull may cause a boggy subperiosteal abscess and osteomyelitis. This condition is commonly referred to as Pott's puffy tumour, following its description by Sir Percival Pott in 1760.⁹ Posterior spread of infection can cause acute intracranial complications such as subdural empyema, meningitis, cerebritis and intracranial abscess. Subdural empyema is the most common intracranial complication of sinusitis, and the most common cause of subdural empyema is frontal sinusitis.⁵ Spread of infection inferiorly can lead to orbital cellulitis.

Ethmoid

Orbital cellulitis is by far the most frequent acute complication of ethmoid sinusitis. It can vary in degree and severity and is typically graded with the Chandler classification.¹⁰ This clinically useful classification (Table 101.1 and Figure 101.2) also helps to guide the overall management of the patient although its lack of sensitivity and specificity means it has been superseded by the current availability of CT scanning. It is also important to note that orbital cellulitis can present at any stage of the Chandler classification and the disease does not necessarily progress in a chronological order i.e. a stage 2 can progress directly to stage 5 bypassing the steps in between and so on.

Maxillary

Isolated maxillary rhinosinusitis rarely gives rise to acute complications. Acute cheek swelling usually results from complications of dental disease, though there may be an associated secondary maxillary rhinosinusitis.

Sphenoid

Isolated sphenoid sinusitis is rare, but complications can result in meningitis¹² or cavernous sinus thrombosis by direct spread.¹³ In cavernous sinus thrombosis infection may spread through veins from the paranasal sinuses and orbit to the cavernous sinuses as thrombophlebitis or by septic emboli. Bacteria themselves are pro-thrombotic, the thrombus provides good conditions for growth and bacteria within the thrombus are shielded by the outer layers from antibiotics which they can later re-infect.¹⁴ In cases arising from acute sinusitis the sphenoid and ethmoid sinuses are the most common source.¹⁴ Intracranial complications can also occur following a skull base fracture through the sphenoid sinus.

CLINICAL PRESENTATION

Any of the complications described above may present with a good history or obvious signs of preceding rhinosinusitis. However, it is not uncommon for the rhinosinusitis itself to be 'occult' or asymptomatic. In children it is more likely that there will be no prior history of rhinosinusitis, with the complication often being the first presentation.

ORBITAL COMPLICATIONS

It is estimated that 3% of sinusitis cases will progress to orbital cellulitis⁷ with 60–85% of orbital cellulitis cases being secondary to sinusitis.^{15, 16} The remainder are caused by processes such as dacryocystitis or facial infection.¹⁶ In the pre-antibiotic era death or blindness occurred in up to 20% of patients.⁷

Figure 101.1 Right orbital cellulitis, Chandler classification stage 2; postseptal cellulitis. It is important to open the eyelids to fully examine the eye & vision. Here we see chemosis typical of orbital cellulitis, there was no visual defect, diplopia or relative afferent pupillary defect.

Figure 101.2 Various orbital complications on axial projection: **(a)** preseptal inflammation; **(b)** orbital cellulitis; **(c)** orbital cellulitis with subperiosteal (extra periosteal) abscess; **(d)** orbital cellulitis with intra-periosteal abscess; **(e)** cavernous sinus thrombosis. Red and yellow shading indicate inflammation/cellulitis, and green shading indicates pus. Redrawn from [11], with permission.

TABLE 101.1 Complications of rhinosinusitis, figures in brackets indicate relative frequency

Orbital ^[4]	Intracranial ^[5]	Bony	Chronic
Preseptal cellulitis (50%)	Sub dural empyema (38%)	Osteomyelitis & Pott's puffy tumour	Mucocele & pyocele
Postseptal cellulitis or orbital cellulitis without abscess (35%)	Intracranial abscess (30%)		
Subperiosteal abscess (15%)	Extradural abscess (23%)		
Orbital abscess (<1%)	Meningitis (2%)		
Cavernous sinus thrombosis	Cavernous or sagittal sinus thrombosis (2%)		

Figure 101.3 Pre-operative clinical photograph from an adolescent male with cavernous sinus thrombosis secondary to rhinosinusitis. Note the bilateral periorbital signs of oedema, cellulitis and subtle left Vth cranial nerve palsy.

The onset is noted by swelling around the eye. Oedema results from congestion of veins draining the eyelid and can be present when the infection is still confined to the sinus. Cellulitis from untreated sinusitis represents stage 1 of the disease with local spread of inflammatory elements to the lid. Postseptal cellulitis (stage 2) is confined to the orbit but has extended through the orbital septum, potentially with intraconal involvement. Patients will have eyelid swelling, chemosis and proptosis, potentially with impaired extraocular muscle function and diplopia (Figure 101.1). Postseptal cellulitis typically results from transmitted pressure from the sinus to orbital veins with leakage of inflammatory elements into the orbit. It is difficult to clinically differentiate postseptal cellulitis from subperiosteal abscess (stage 3), CT scanning is mandatory here and reflects the fact that the classification system pre-dates the ready availability of scanning.

Orbital cellulitis is far more common in children (50% under 6 years)¹⁷ and young adults (76–85% under 20 years).^{18,19} Visual problems are a late sign, but may be present if the problem is stage 2 (postseptal cellulitis) or beyond. Specific enquiries should be made regarding diplopia, visual acuity and colour vision; signs which indicate compromised optic nerve function. At stage 5 (cavernous sinus thrombosis) signs of chemosis, periorbital oedema, proptosis, progressive ophthalmoplegia, visual impairment and symptoms including headache and trigeminal parasthesia will be present (Figure 101.3).²⁰ In the case of orbital infection, cavernous sinus thrombosis will result from septic thrombophlebitis of the superior ophthalmic vein. Initially signs may be unilateral; bilateral disease propagates via the intercavernous sinuses.²¹ Published mortality from cavernous sinus thrombosis is high at between 14% and 79% and up to half of patients experience morbidity including residual cranial nerve palsies and blindness.^{14, 21} Animal experiments have demonstrated that visual loss may be

irreversible if retinal ischaemic time exceeds 100 minutes.²² Superiorly located orbital subperiosteal abscesses with severe frontoethmoiditis may indicate an increased potential for intracranial suppuration and should be aggressively evaluated.²³

EXAMINATION

Clinical endoscopic examination of the nose should be performed to help determine the site and extent of disease. In the case of orbital cellulitis, a formal assessment of the degree of chemosis, range of eye movements, degree of proptosis, relative afferent pupillary defect, visual acuity (using a Snellen chart), colour vision (using Ishihara plates) and inspection of the optic disc should be made. This should ideally be carried out by an ophthalmologist. This assessment should be repeated at least twice daily and where there is increasing concern, 4–6 hourly monitoring of the full range of eye movements, visual acuity and colour vision should be undertaken with regular temperature and pulse measurements. For intracranial complications a full neurological examination should be completed. The possibility of occult intracranial complications should always be considered, even in a patient with a normal neurological examination. If intracranial complications are found, neurosurgical opinion is required. Multidisciplinary involvement is important but leadership of care should be clear and preferably by an experienced ENT surgeon.

INVESTIGATIONS

Rhinosinusitis can cause complications in different sites simultaneously. In one series the frequency of developing both intracranial and orbital complications was 5.4%, which rose to 13–24% for those who required surgical intervention to drain orbital disease.²³ Investigations should therefore be used to confirm the diagnosis, extent and any occult complications.

Radiological

There is currently a wide range of techniques available for imaging the paranasal sinuses and surrounding structures. The aim of these investigations is to:

- confirm the diagnosis of the complication
- define the extent and site of the complication
- help plan treatment including surgical approach
- confirm that there is no other covert complication present
- Monitor the response to treatment.

Contrast enhanced computed tomography (CT) is advised as first-line imaging because of its superiority in demonstrating bony anatomy and pathology of the orbit and sinuses with its speed and ease of examination. MRI provides outstanding soft tissue detail without radiation

TABLE 101.2 Chandler stages

Stage 1	Stage 2	Stage 3	Stage 4	Stage 5
Preseptal cellulitis	Postseptal cellulitis or orbital cellulitis without abscess	Subperiosteal abscess	Orbital abscess	Cavernous sinus thrombosis/abscess
Inflammation does not extend beyond the orbital septum (where the medial orbital periosteal reflection attaches to the medial eyelid at the tarsal plate).	Inflammation extends into the tissues of the orbit.	There is abscess formation deep to the periosteum of the orbital bones, typically at the lamina papyracea from ethmoid sinusitis.	There is abscess formation within the orbit which has breached the periosteum.	The inflammatory process has extended into the cavernous sinus which thromboses and may progress to abscess formation.

exposure. It should be noted that CT scanning may miss up to 50% of early stage intracranial complications. A low threshold for MR imaging is advised if there is any clinical suspicion of intracranial involvement.

The diagnosis of the complication should be apparent from the clinical appearance. If there is full ocular movement and normal colour vision, no immediate radiological investigation is indicated unless there is concern about intracranial pathology. Imaging should be undertaken to confirm the presence and site of suspected abscess prior to surgical drainage. Plain X-rays have no role as they are unable to define anything but the grossest orbital abnormalities. The investigation of choice is high-resolution triplanar axial, coronal and sagittal CT scanning. This will give the greatest chance of picking up small abnormalities, which may be missed with uniplanar scans. Although magnetic resonance imaging (MRI) will define abnormalities in the orbit, there is no evidence that it is more accurate than CT²⁴ and the lack of bone definition for planning surgery makes it of limited value for first-line imaging. Ultrasound also will not demonstrate surgical anatomy and has high false positive and negative rates.^{24, 25}

Radiological findings

It is important to be familiar with the interpretation and analysis of triplanar imaging when managing patients with complications of rhinosinusitis as it aids the planning of surgical intervention. We would recommend, where possible, jointly reviewing the imaging with an experienced radiologist. Below are some of the common signs to look out for each stage of the Chandler classification.

- 1. Preseptal cellulitis** – eyelid swelling and thickening of the preseptal tissues with possible posterolateral extension to the temporal fossa. Importantly, CT will not distinguish between oedema, preseptal cellulitis and allergy.
- 2. Postseptal cellulitis** – the findings as above often with induration of the extraconal, intraconal and retrobulbar fat without abscess.
- 3. Subperiosteal abscess** – CT scans show a typical lenticular rim-enhancing collection adjacent to the lamina papyracea with a fat plane between it and the displaced medial rectus muscle (**Figure 101.4**). Lateral deviation and proptosis of the globe may be visible on

TABLE 101.3 Risk factors for simultaneous orbital and intra-cranial complications

axial images. Sight-threatening complications of optic neuritis or optic nerve ischemia may also be present without radiological signs. Subperiosteal abscess secondary to frontal sinusitis typically forms an abscess superiorly with anteroinferior globe displacement.¹⁶

- 4. Orbital abscess** – Scans may show multiple rim-enhancing orbital abscesses with surrounding cellulitis and a resultant proptosis.
- 5. Cavernous sinus thrombosis** – It is important to note that in the early stages CT scans appear normal. CT and MR venography are complementary in the diagnosis of cavernous sinus thrombosis.²⁷ There may also be thickening and increased signal intensity in the extraocular muscles in T2-weighted MRI.²⁸

Haematological investigations

The place of haematological investigations is three-fold:

1. to help identify any serious underlying disease process such as a haematological malignancy;
2. aid in assessment of fitness for surgery;
3. monitor the patient's response to treatment.

Other investigations

- Blood cultures
- Sinonasal/abscess pus culture ideally from initial nasal endoscopy

Figure 101.4 Coronal CT scan showing left maxillary and ethmoid sinusitis with associated medial orbital subperiosteal abscess (red arrow) and displacement of the globe.

- Urinalysis for diabetes mellitus, potentially causing immunocompromised
- Clinical observations. The simple regular monitoring of temperature should not be forgotten, any persisting infection may result in sustained or ‘spiking’ pyrexia requiring further clinical and radiological investigation.

TREATMENT

Medical

Almost all patients with complications of rhinosinusitis require admission for observation and treatment. Unless an abscess is demonstrated by radiological or other investigation, non-surgical management of rhinosinusitis complications is normally first choice. The exception is when vision is affected by pressure on the optic nerve from surrounding inflammation without abscess formation.

The aim of medical management is to control and eliminate both the disease process of the complication and of the primary rhinosinusitis. Antibiotics form the mainstay of medical treatment, but expert opinion suggests decongestant medications such as xylometazoline aids the resolution of acute rhinosinusitis by reducing mucosal oedema, although the evidence is inconclusive.²⁶ Selection of antibiotics is typically made on clinical grounds prior to identification of any organism or before culture-specific sensitivities are known. Broad-spectrum antibiotics are advised for severe complications of sinusitis to cover the likely organisms including *S. pneumoniae*, *S. anginosus* and other *Streptococcus* species, *H. influenzae*, *S. aureus*, *Moraxella catarrhalis* and anaerobic bacteria (*Prevotella*, *Porphyromonas*, *Fusobacterium* and *Peptostreptococcus* species).^{19, 29–31}

Polymicrobial and anaerobic isolates are more common in patients older than 15 years of age and in patients with intracranial complications.^{29, 32} *Streptococcus anginosus* species represent some of the most frequently cultured organisms from either orbital or intracranial

complications and have a tendency towards abscess formation.^{33, 34} Complications, especially intracranial, are often one-off events due to highly pathogenic organisms. There will be marked local variation in causative organisms and sensitivities, therefore liaison with microbiology colleagues is recommended. An initial regime of intravenous cephalosporin with metronidazole would be an appropriate first choice until case-specific cultures and sensitivities are known. In patients with antibiotic sensitivities, other appropriate antibiotics should be selected in accordance with local microbiology policies.

The evidence base for systemic corticosteroid use is lacking in complications of rhinosinusitis. The risk of direct pressure from inflammation may possibly be reduced though this needs to be balanced against the immunosuppressive action and side effects of the steroids. In general, the use of systemic steroids is not recommended unless there is evidence of pituitary insufficiency in cavernous sinus thrombosis.

In the absence of abscess formation or reduction in visual signs medical management should initially be implemented for the first 24 hours, with frequent monitoring as described previously (Figure 101.5). If there is no significant clinical improvement in the first 24 hours of medical treatment, surgical intervention should be considered. Also, if at any point there is any clinical deterioration, urgent repeat imaging with a view to emergency surgical intervention is likely to be required. For orbital complications, intravenous antibiotic administration should continue until clinical improvement is well established and only then should oral medications be substituted. Evidence for how long oral antibiotics should be continued is limited, though 14 days of culture directed antibiotics is often appropriate. In the early stages of cerebritis, appropriate antibiotic administration can prevent intracerebral abscess formation.³⁵ Once a brain abscess has formed, surgical drainage combined with a prolonged antibiotic course of 4–8 weeks is recommended.²⁹

CAVERNOUS SINUS THROMBOSIS

Prolonged broad-spectrum antibiotics must be given for at least 2 weeks beyond clinical resolution as bacteria sequestered within the thrombus may not be killed until the dural sinuses have started to recanalize.¹⁴ Relapse and recurrence of meningeal and ocular signs have been reported up to 6 weeks after recovery and cessation of antibiotics¹⁴ and follow-up for at least 6 months is advised.²⁶ Surgery is indicated only to drain any non-draining sinus infection or abscess collection.¹⁴ There remains no consensus for the use of anticoagulation; proponents suggest that anticoagulants prevent thrombus propagation and have anti-inflammatory properties.^{36, 37} Those against hypothesize that thrombus formation walls off infection and prevents its spread, with anticoagulants increasing the risk of intracranial bleeding in an already inflammatory environment. If anticoagulation is to be used rapidly reversible agents such as unfractionated heparin infusion should initially be used¹⁴ aiming for an activated partial thromboplastin time (APTT) between 1.5–2,³⁸ switching to low-molecular weight heparins once the condition has improved.

Surgical

The surgical treatment of patients with complications of rhinosinusitis can be divided into procedures necessary to manage the complication and surgery for the rhinosinusitis. Often these are performed at the same time and may involve joint working with neurosurgeons in the case of intracranial suppuration.

The surgery required for acute complications of rhinosinusitis is often similar to that used for managing chronic rhinosinusitis. The principles of draining any pus and establishing ventilation of the sinuses remain. Where complications have arisen from acute rhinosinusitis it is likely that the operative field will be inflamed and very haemorrhagic, potentially making endoscopic surgery much more difficult than in the presence of chronic rhinosinusitis alone.

Knowledge of the likely sinus origin of the orbital complication is important in planning any surgical treatment. In ethmoid sinusitis orbital abscesses are typically medial to the globe, and in frontal sinusitis abscesses often form more superiorly within the orbit. A relatively large study of 240 patients identified patients with proptosis but normal eye movements and visual acuity are likely to require surgery, whereas infections with cellulitis alone are likely to settle with medical management.¹⁸ Adolescent patients also appear more likely to develop complications requiring surgical intervention.³²

The debate about the best approach to drain orbital collections remains a current controversy. Advocates of endoscopic surgery suggest that endoscopic ethmoidectomy with removal of the lamina papyracea and pernasal

drainage of the orbital abscess is appropriate. The advantages of an endoscopic approach include avoiding facial scarring, ventilating the sinuses endonasally by operating on the osteomeatal complex, less post-operative orbital oedema, a shorter hospital stay and the absence of possible wound complications such as stitch abscesses.³⁹ More traditional external orbitotomy also has its proponents, and unless the surgeon is very familiar with endoscopic sinus surgery, it is more appropriate to use an external approach. If performing endonasal drainage the surgeon must be prepared to convert to external drainage if required and it is advised that patients and relatives are appropriately consented prospectively for both approaches. The external approach is also advised for abscesses that are not situated medially within the orbit adjacent to the lamina papyracea. The external approach uses a conventional Lynch–Howarth approach for an external ethmoidectomy, allowing an assistant to help keep the operative field clear whilst the subperiosteal abscess is drained. Occasionally, the orbital abscess will lie away from the lamina papyracea, especially if associated with frontal rhinosinusitis. As the abscess may lie in the roof of the orbit or further laterally, it is essential to obtain a CT scan preoperatively to define the position of any orbital collection and plan surgical treatment. Drainage of the abscess can be maintained with surgical drains either into the nasal cavity fixing to the septum or externally through the medial canthal incision. The evidence for performing concurrent surgical ethmoidectomy at the same time as draining the abscess is limited, as opposed to relying on medical treatment to deal with the rhinosinusitis and only draining the

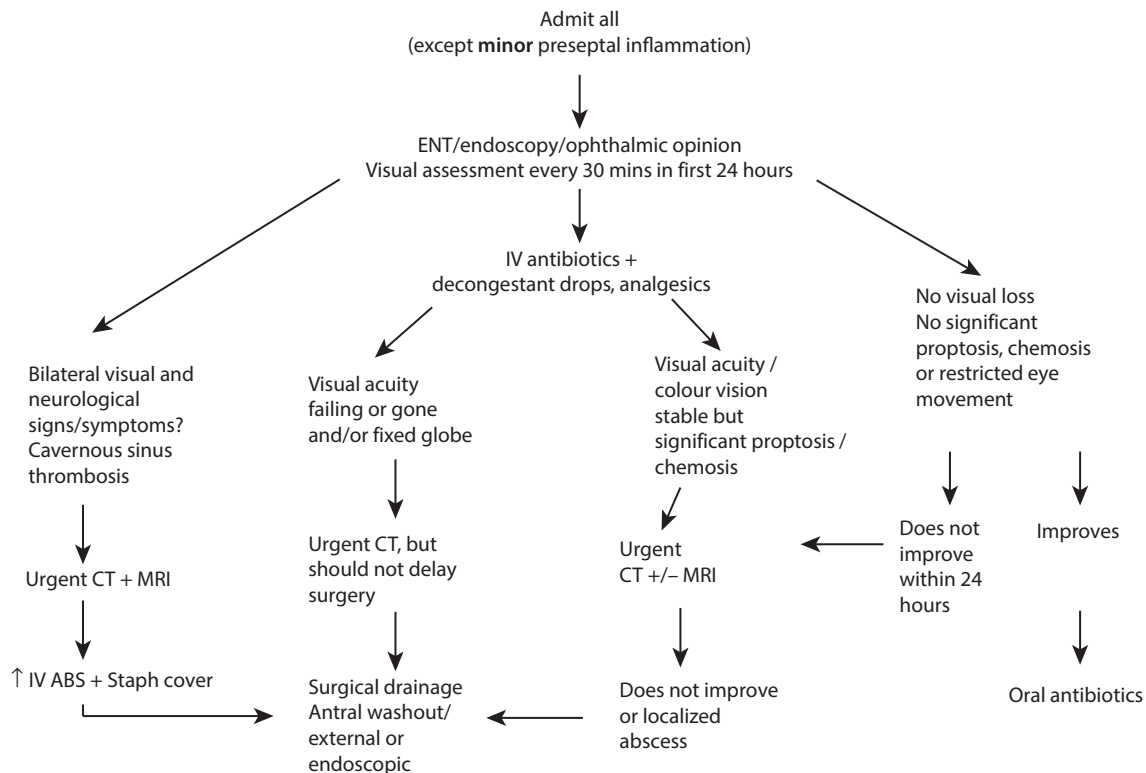

Figure 101.5 Management algorithm for orbital complications.

orbital collection surgically. However, the authors would advocate undertaking a maxillary washout or antrostomy and limited ethmoidectomy to allow all areas of pus to be drained. There are some early reports regarding possible medical management of carefully selected patients with small medial subperiosteal abscesses,⁴⁰ though at present we would advocate draining any orbital collection surgically with concurrent medical management.

Prognosis of orbital complications

If prompt treatment is carried out with adequate monitoring of patients, the prognosis for the return of normal vision is excellent. However, there is a small but significant risk of diplopia following surgery.⁴¹ Provided the patient's presentation is not delayed and there is effective teamworking with ophthalmologists, paediatricians where appropriate, and otorhinolaryngologists ensuring prompt surgical intervention if non-surgical management fails, full recovery of eye function should occur.

INTRACRANIAL COMPLICATIONS

Brain abscess

Brain abscess can occur as a complication of either local or distant spread. The frontal sinuses are the most common source followed by the ethmoid, sphenoid and maxillary sinuses.²³ Haematogenous spread is the most likely mechanism of distant spread. It is estimated that 40–60% of brain abscesses arise from paranasal sinus infections.⁴² The total reported incidence of intracranial complications from acute rhinosinusitis is between 3% and 17% of hospitalized sinusitis patients.^{42, 43}

Subdural empyema

Subdural empyema is one of the commonest intracranial complications of rhinosinusitis, typically from haematogenous spread.⁵ The brain is clearly more exposed as the infection is beyond the protective dura mater and allows the possibility of thrombosis of the dense network of veins in this space. Serious neurological injury can occur if not treated rapidly and aggressively with combined medical treatment and neurosurgical drainage to decompress the brain and evacuate the empyema. Subdural empyemas present with meningeal irritation and neurological signs such as seizures or focal deficits.

Extradural empyema

Extradural empyemas tend to be less symptomatic as the brain is protected by the dura mater. The signs are less marked and specific and are often only present when the collection reaches a size to cause mass effect.

Brain infarction

Cerebral ischaemia and infarction are rare vascular complications of sinusitis from either dural venous thrombosis

secondary to adjacent empyema, or cavernous carotid artery occlusion.²⁸

CLINICAL PRESENTATION

Early symptoms are often non-specific such as headache, fever, seizure, drowsiness, diplopia (with cranial nerve palsy) eye pain and nausea.⁵ There may not be a preceding history of acute rhinosinusitis and clinical examination will not always identify suppuration from the paranasal sinuses. Adolescent and young adult males are more commonly affected which may be due to the vascularity of the diploic system in this age group.²³ Frontal lobe abscesses are the most common intracranial abscess location. There may be specific neurological symptoms if there is a well-defined intracranial abscess including acute pain and possible loss of consciousness associated with meningitis. Some authors advocate scanning all patients with acute frontal rhinosinusitis or orbital cellulitis to exclude such serious complications, which may initially be clinically 'silent'.^{13, 42}

INVESTIGATIONS

MRI scanning has been shown to be superior to CT in the diagnosis of intracranial complications and is the investigation of choice for the diagnosis of suspected intracranial extension.²⁴ The example in [Figure 101.6](#) demonstrates the presence of a small subdural frontal abscess apparent on MR imaging but not visualized by a contrast enhanced CT scan.

As soon as an intracranial complication is detected, joint management of the case with neurological or neurosurgical colleagues is mandatory. If possible, surgery to drain affected paranasal sinuses should be undertaken synchronously with any neurosurgical operative intervention. If synchronous paranasal sinus surgery is to be undertaken, CT scanning is desirable to demonstrate the bony anatomy of the paranasal sinuses, provided any delay incurred in scanning is compatible with the patient's clinical condition. Intracranial complications may be relatively silent and a high index of suspicion should be maintained ([Figure 101.7](#)). Intracranial complications may also develop after the initial presentation and any change in neurological status should merit consideration for repeat imaging.

TREATMENT

For medical treatment see earlier in the chapter. The surgical treatment of intracranial complications will inevitably involve neurosurgical expertise. As far as the otorhinolaryngologist is concerned, discussion needs to take place as to whether the sinus surgery will be done at the same time as any neurosurgical procedure. There is unfortunately little evidence to help decide whether these should be done as separate procedures but, as with orbital cellulitis, it is the authors' practice to undertake the surgery for the complication at the same time as for the underlying rhinosinusitis. Intracranial complications are most likely to arise

Figure 101.6 Contrast enhanced sagittal CT scan of a child with acute sinusitis and headache. (a) No intracranial pathology was identified to account for the symptoms. An MRI scan of the same child (b) highlighted a small subdural frontal abscess (arrow illustrates pathology).

Figure 101.7 MRI images of a large frontal intracerebral abscess secondary to rhinosinusitis.

from frontal rhinosinusitis as opposed to the remaining paranasal sinuses, and endoscopic frontal surgery is likely to be challenging and potentially dangerous. In the acute setting, it is better to undertake a temporary frontal drainage procedure concomitantly with surgery for the intracranial condition. A frontal sinus trephine procedure with placement of an external drain is most commonly used, although endoscopic balloon sinuplasty has been used to drain acute frontal sinus collections pernasally⁴⁴ and may become more popular in future. Any definitive frontal

sinus surgical procedure can be deferred until the patient has fully recovered from treatment of the complication.⁴⁵

Prognosis from intracranial complications

The increased availability of scanning has no doubt led to earlier diagnosis and better outcomes.⁴⁶ Published mortality rates vary between 0 and 25%.^{5, 30} Unsurprisingly,

mortality varies according to the specific complication and increases with age and decreased level of consciousness on presentation.^{31,42} Persistent morbidity such as hemiparesis, epilepsy, altered cognitive function and cranial nerve palsies are reported in between 11% and 40% of cases.^{5,30,43} Early recognition of complications and multidisciplinary treatment is essential for the best possible outcome.

BONY COMPLICATIONS

Pott's puffy tumour

In the 18th century Percival Pott described the case of a patient with a pericranial abscess related to trauma. The area, he noted, was 'swollen and puffy'. The term Pott's puffy tumour is now used to describe a subperiosteal cellulitis or abscess of the frontal bone associated with frontal osteomyelitis and presenting with headache, swelling and, on occasion, a discharging frontal fistula (Figure 101.8). The infection can spread posteriorly giving rise to intracranial sepsis either by erosion of the posterior table or more likely by septic thrombophlebitis via the diploic veins.⁴⁷ The reported rate of coexistent intracranial complications is high between 29% and 60%, though not all are present on initial imaging^{47,48} which suggests prompt cross-sectional imaging and treatment are paramount. Both Gallagher and Jones^{48,49} noted a preponderance of *Streptococcus anginosus* infection in series of such patients, where positive cultures were obtained.

Management requires drainage of pus from the frontal sinuses, achieved either endoscopically or conventionally through a frontal sinus trephination via an incision in the superomedial aspect of the orbit. In the absence of a

subperiosteal or intracranial abscess, further surgery may not be necessary acutely. Prolonged antibiotic therapy, ideally culture-directed, for 6–8 weeks covering both aerobic and anaerobic organisms is recommended by the authors. Once the acute phase has subsided the patient should be re-evaluated to determine if a frontal sinus drainage procedure is required for long-term management. This can be undertaken endoscopically or externally through an osteoplastic frontal flap, or in combination (see Chapter 99 Frontal Sinus). However, as these infections rarely recur, in general, patients can be reassured this an unlikely occurrence.

A limited subperiosteal abscess may be drained through a Lynch Howarth brow incision. However, this does not allow adequate inspection of the frontal bone to assess for necrotic bone. An alternative is to perform a spectacle incision providing good exposure to the frontal sinus but resulting in a scar, which may not be acceptable cosmetically. A bicoronal scalp incision and flap provides excellent access to assess the whole frontal sinus enabling removal of diseased bone. This procedure is of such significant complexity that the inexperienced rhinologist should not undertake it.

Associated intracranial complications necessitate prompt neurosurgical intervention. This is typically performed through a bifrontal craniotomy enabling drainage of intracranial pus and removal of necrotic bone.⁵⁰ Complete removal of the posterior table will require frontal sinus cranialization. Extensive osteomyelitis of the anterior table may necessitate a Riedel's procedure⁵¹ with removal of the anterior wall and floor of the frontal sinus allowing the forehead skin to collapse onto the posterior table. Whilst this causes a significant cosmetic

Figure 101.8 Clinical photograph (a) & sagittal CT scan (b) through the frontal sinus showing Pott's puffy tumour; a discharging fronto-cutaneous fistula from the subperiosteal collection, frontal sinusitis with osteomyelitis and bone erosion of the anterior frontal sinus wall.

deformity, reconstruction with split calvarial bone or alloplastic materials can be undertaken at a later stage when all infection has resolved.⁵²

CHRONIC COMPLICATIONS

Chronic complications of rhinosinusitis usually result from chronic rhinosinusitis. As with acute complications, the nature of the complication depends on the particular sinus or group of sinuses involved. Mucocoeles are chronic, slowly expanding lesions in any of the sinuses that may result in bony erosion and can extend beyond the sinus (see [Chapter 100](#), Mucocoeles). It is unusual

for chronic rhinosinusitis to cause orbital cellulitis or intracranial complications unless there is an infective exacerbation.

ACKNOWLEDGEMENTS

We would like to acknowledge the previous work of Mr Robert Slack and Mr Richard Sim. This is an updated and revised chapter based initially on their work from the seventh edition. Additional acknowledgement must be made to Professor Nick Jones for his helpful advice and critical reading of the manuscript.

FUTURE RESEARCH

- ▶ There is continued controversy as to whether surgery for orbital abscess complications is best undertaken endoscopically or externally. The availability of local expertise often determines the preferred approach, though it may be possible for carefully designed clinical trials to provide more evidence.
- ▶ The numbers of patients presenting with complications of rhinosinusitis is relatively small, the symptoms can be varied and the time required to begin treatment is very short. This makes it very difficult to design studies that would result in level 1 or 2 evidence. Consequently the evidence presented here is mostly based on retrospective case series data.
- ▶ There is also little information to suggest why some individuals should develop complicated sinus disease when similar organisms are isolated from patients with uncomplicated disease. Bony sinus anomalies that narrow anatomically important areas such as the osteomeatal unit (OMU) which may predispose to sinusitis are seen with similar frequency in children, adults⁴⁹ and asymptomatic individuals making their significance unclear.⁵⁰ However, when specific measurements of OMU calibre are made, no significant difference between children and adults exists implicating additional mucosal immune mechanisms which require further investigation.⁵¹

BEST CLINICAL PRACTICE

- ✓ Careful, repeated clinical observations with a low threshold for repeat imaging if there is deterioration in clinical condition.
- ✓ Radiological investigations of choice are CT with MRI for suspected intracranial pathology.
- ✓ Broad-spectrum antibiotics with streptococcal and anaerobic cover form the mainstay of medical treatment.
- ✓ Surgical treatment is normally required for resolution in patients with abscess formation.
- ✓ Cultured *Staphylococcus aureus* should not be dismissed as a contaminant.
- ✓ A multidisciplinary approach is essential to ensure optimal outcome.

KEY POINTS

- The major complications of rhinosinusitis are orbital and intracranial infections, of which orbital complications are the more common.
- The incidence of complications is greatest in children and young adults.
- The speed of initiating treatment and confirming the diagnosis can greatly reduce the morbidity and extent of intervention required.
- Multidisciplinary care involving ENT surgeons with ophthalmology, paediatric and neurology/neurosurgical input as required is a standard of care

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: rhinitis, allergic rhinitis, sinusitis, nasal polyps, asthma, occupational, chronic obstructive pulmonary disease, hypersensitivity, allergens, bronchial hyperreactivity, nasal mucosa, bronchi, biopsy, nasal provocation tests, bronchial challenge tests, airway remodelling, quality of life, disease management, anti-allergic agents, anti-asthmatic agents, steroids, leukotriene antagonists, anti-IgE antibodies (omalizumab), immunotherapy and nasal surgery.

INTRODUCTION

The close relationship between the upper respiratory tract (nose and paranasal sinuses) and the lower respiratory tract (tracheobronchial tree) is something that is manifestly observed by all practising rhinologists. Whilst it can be observed in a number of rare conditions such as granulomatosis with polyangiitis, this close relationship is most striking in the conditions of asthma, rhinitis and nasal polyposis ([Table 102.1](#)). The relationship between the upper and lower respiratory tract is so evident in rhinitis and asthma that these conditions may be viewed as ends or parts of a respiratory inflammatory spectrum. Most patients with asthma also have rhinitis¹ and treatment of coexisting rhinitis may improve asthma. The concept of ‘one airway, one disease’ and the ‘unified airway’ in which the upper and lower airways act as a whole unit has been proposed, with rhinitis and asthma representing manifestations of the same inflammatory process.^{2, 3} However, there are also differences between rhinitis and asthma and not all patients with rhinitis have asthma.⁴

EPIDEMIOLOGICAL RELATIONSHIP BETWEEN RHINITIS AND ASTHMA

There is strong epidemiological evidence both from cross-sectional and longitudinal studies that rhinitis and asthma are related. The two conditions often coexist in the same patients, with rhinitis occurring in over 65% of allergic asthma patients and in over 80% of patients with non-allergic asthma.¹ In the Copenhagen Allergy Study,⁵ between 40–50% of allergic rhinitis patients had allergic asthma and the risk of allergic asthma was up to 300 times higher in allergic rhinitis patients than those without allergic rhinitis.

It is not only allergic rhinitis however that is associated with asthma; there is also an association between non-allergic rhinitis and asthma. Rhinitis has been shown to be an independent significant risk factor for asthma in both atopic and non-atopic individuals.⁶ There is also an association between asthma and chronic rhinosinusitis, irrespective of smoking behaviour.⁷ Sixty percent of chronic rhinosinusitis patients have associated lower airway disease (24% asthma, 36% small airway disease).⁸

RHINITIS AND NON-SPECIFIC BRONCHIAL HYPERRESPONSIVENESS

Many patients with allergic rhinitis who do not have asthma symptoms demonstrate bronchial hyperresponsiveness, a key feature of asthma.⁹ They showed increased bronchial sensitivity to stimuli such as methacholine (a parasympathomimetic agent) or histamine. In those with seasonal rhinitis and allergy to pollen, the degree and prevalence of bronchial hyperresponsiveness is significantly greater during the pollen season compared to outside this period.¹⁰ Those with perennial rhinitis have a higher risk of bronchial hyperresponsiveness compared to those with seasonal rhinitis.^{11, 12}

Patients with allergic rhinitis and bronchial hyperresponsiveness are at greater risk of developing asthma than those with normal bronchial challenges.¹³ However, not all patients with allergic rhinitis have increased bronchial hyperresponsiveness and there are large differences in the extent of airway responsiveness exhibited in asthma and rhinitis.

CAUSATIVE AGENTS IN RHINITIS AND ASTHMA

Asthma and rhinitis share many common risk factors. Some of the agents inducing asthma and rhinitis such as allergens and aspirin¹⁴ are well known to affect both the upper and the lower airways. This is compatible with the concept of a ‘unified airway’, although many studies have shown some differences in the genetic and environmental risk of these two conditions suggesting that there is an element of specificity for each condition.¹⁵

Bacterial enterotoxins, by acting as a superantigen, may play a role in the development and/or severity of asthma and allergic rhinitis.¹⁶ In a mouse model of allergic asthma, application of *Staphylococcus aureus* enterotoxin B to the nose or to the bronchus each resulted in a more severe bronchial eosinophilic inflammation.¹⁷ It has also been shown that there is increased *Staphylococcus aureus* colonization in the nose and specific IgE antibodies against *Staphylococcus aureus* enterotoxins in patients with nasal polyps.¹⁸

Upper respiratory tract viral infections, often caused by rhinovirus, are strongly associated with asthma

exacerbations in children and adults^{19, 20} Experimental induction of upper respiratory tract rhinovirus infection in allergic rhinitis patients has been shown to increase airway hyperreactivity and late asthmatic reactions after allergen challenge.²¹ However, rhinovirus also has the ability to infect the lower respiratory tract and induce a pro-inflammatory response, suggesting that rhinovirus-mediated asthma exacerbations may result from a direct lower respiratory tract reaction.²²

The most common precipitants of occupational asthma can all induce occupational rhinitis. Although rhinitis and asthma are closely related, the relationship in occupational disease is less well known. Occupational rhinitis, however, is often associated with occupational asthma, and this association is significantly greater with high molecular weight agents compared to low molecular weight agents.²² As patients with occupational rhinitis can often go on to develop occupational asthma, cessation of allergen exposure in occupational allergic rhinitis is important to try to prevent asthma.

RHINITIS AS A RISK FACTOR FOR ASTHMA

There are many studies which support rhinitis as a risk factor for asthma both in children and adults.^{6, 23–26} Physician-diagnosed allergic rhinitis in infancy has been shown to be independently associated with doubling the risk of asthma by 11 years old.²⁷ In another study, allergic rhinitis in childhood was found to be significantly associated with a two- to seven-fold increased risk of asthma in pre-adolescence, adolescence, or adult life.²⁸ Furthermore, the risk of childhood asthma persisting to middle age was three times higher in children with allergic rhinitis compared to those never having allergic rhinitis.²⁸

In adults, a study of college students found that the risk of developing asthma over a 23-year period was significantly higher in those diagnosed with allergic rhinitis compared to those without (10.5% vs. 3.6%).²⁹ A 15-year prospective study of Finnish twins found that patients with ‘allergic rhinitis including hay fever’ were more likely to develop asthma by four times if male and six times if female compared to patients without allergic rhinitis.³⁰ Some have found the prevalence of asthma to be associated to the severity and duration of rhinitis with the highest prevalence in patients with moderate/severe persistent allergic rhinitis³¹ whereas others report no correlation between the Allergic Rhinitis and its Impact on Asthma (ARIA) categories of rhinitis and the prevalence of asthma.³²

Allergic rhinitis usually precedes asthma and the term ‘The Allergic March’ has been used to describe the progression of allergic nasal disease in the upper airway to the lower airway. It is not clear, however, whether allergic rhinitis causes asthma or whether allergic rhinitis is just an earlier clinical manifestation of allergic disease in atopic patients who would in any case develop asthma. Children with atopic eczema have significantly greater risk of developing asthma and allergic rhinitis than those

with non-atopic eczema³³ and it has been suggested that the allergic march may begin even earlier with eczema³⁴ leading to rhinitis and then asthma.

The increased risk of asthma is not just limited to allergic rhinitis but is also found with non-allergic rhinitis.¹⁵ It has been reported that rhinitis increased the risk of asthma in both atopic and non-atopic patients by about three times.⁶ It appears that rhinitis and asthma are not just linked because they share atopy as a common risk factor.

INFLAMMATION OF THE UPPER AND LOWER RESPIRATORY TRACT IN RHINITIS, ASTHMA AND CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Similarities and differences between nasal and bronchial inflammation in asthma and rhinitis

There are many anatomical and physiological similarities between the upper and lower airways. They are both lined by pseudostratified ciliated columnar epithelium on a continuous basement membrane (Figures 102.1a and 102.1b). Throughout the submucosa there are mucous glands, blood vessels, structural cells (fibroblasts), some inflammatory cells (monocytic cells, lymphocytes and mast cells) and nerves. There are also significant differences however, between the upper and lower respiratory tracts. The nasal mucosa is highly vascular with an extensive subepithelial capillary and arterial system and venous cavernous sinusoids. Vascular dilatation can result in increased upper airway resistance and subsequent nasal obstruction. In contrast, bronchoconstriction is due to the contraction of airway smooth muscle which is present from the trachea to the bronchioles, rather than changes in the vasculature.

Inflammation is a key component in the pathogenesis of rhinitis and asthma and studies have shown a similar inflammatory infiltrate (eosinophils, mast cells, T-lymphocytes and cells of the monocytic lineage) involved in the inflammation of the nasal and bronchial mucosa. There also appears to be similar pro-inflammatory mediators (histamine, cysteinyl leukotriene), T-helper 2 (Th2) cytokines (interleukin IL-4, IL-5, IL-13 and granulocyte-macrophage colony-stimulating factor), chemokines (RANTES and eotaxin) and adhesion molecules in the inflammation of the upper and lower airways in rhinitis and asthma. Airway smooth muscle is important in the pathogenesis of asthma not only by causing bronchoconstriction but may also be involved by increased proliferation and the expression and secretion of a variety of proinflammatory mediators and cytokines.^{35,36} In patients with both rhinitis and asthma, the degree of inflammation in the upper and lower airways may be different. Greater eosinophilic inflammation has been found in the bronchi compared to the nose in untreated asthmatic patients with rhinitis.³⁷ Epithelial shedding and basement membrane thickening are key features of airway remodelling in asthma and have also been found in sinonasal specimens of patients with chronic rhinosinusitis.³⁸ The extent of epithelial shedding and reticular basement membrane thickening however are greater in the bronchi than in the nose in patients with both asthma and rhinitis.³⁷

Nasal and sinus inflammation in asthma and chronic obstructive pulmonary disease

Eosinophilic infiltration of the nasal mucosa has been demonstrated in patients with asthma irrespective of the presence of nasal symptoms,³⁹ further supporting the hypothesis that asthma and rhinitis are clinical manifestations of the same disease. There is also a strong association between chronic rhinosinusitis and asthma, with a higher

Figure 102.1 (a) Photomicrograph of nasal mucosa showing ciliated pseudostratified columnar epithelium on the surface with underlying basement membrane and lamina propria. The lamina propria contains prominent dilated, thin walled vascular channels some of which are filled by red cells or pink, flocculent protein rich material derived from plasma. A few mucosal glands are present towards the left. A light scattering of chronic inflammatory cells is seen in the mucosa. H&Ex200. (b) Photomicrograph of lower respiratory mucosa showing ciliated pseudostratified columnar epithelium on the surface with underlying basement membrane and lamina propria. The lamina propria contains a few mucosal glands towards the bottom of the image. No prominent vascular channels are present. A light scattering of chronic inflammatory cells is seen in the mucosa. H&Ex200.

rate of nasal polyps in asthmatic patients compared to non-asthmatics.⁴⁰ The triad of aspirin sensitivity, asthma and nasal polyps in aspirin-induced asthma is considered a separate clinical syndrome and found in about 10% to 15% of asthmatics.⁴¹

Patients with asthma often also have radiological evidence of sinusitis.^{42, 43} The frequency of abnormal CT scans has been reported to be similar in patients with mild to moderate asthma (88%) compared to those with severe steroid dependent asthma (100%).⁴⁴ However, the extent of sinonasal involvement is greater in the latter, as based on clinical symptoms and CT.

The relationship between the upper and lower airways in patients with COPD has been much less extensively studied than in asthma. Some have found no significant difference in the prevalence of rhinitis in patients with COPD compared to those without⁴⁵ and an association between COPD and the upper respiratory tract has not been widely appreciated. There is, however, increasing evidence that upper airway disease may be related to COPD.⁴⁶ Some studies have reported increased upper airway symptoms and nasal inflammation in patients with COPD.⁴⁷⁻⁵¹ There is a need for further research in this area including the impact of treatment of the upper airway in patients with COPD.⁵²

Bronchial inflammation and remodelling in rhinitis

In non-asthmatic patients with allergic rhinitis, there appears to be remodelling in the lower airways similar, although less marked, to that in asthma.⁵³ Studies of the bronchial mucosa in non-asthmatic allergic rhinitis patients and atopic non-asthmatics have shown an increase in the thickness of the basement membrane and in eosinophils, compared to normal individuals.^{54, 55} Natural exposure to pollen in non-asthmatic patients with seasonal allergic rhinitis, results in increased lymphocytes, eosinophils and IL-5 expression in the bronchial mucosa.⁵⁶ Nasal allergen challenge in patients with seasonal allergic rhinitis shows increased sputum eosinophils and bronchial responsiveness to methacholine with inflammation of the bronchial and nasal mucosa.^{57, 58}

Bronchial challenge of rhinitis patients leads to bronchial and nasal inflammation

In allergic non-asthmatic patients, endobronchial allergen challenge causes bronchial constriction and inflammation, with an increase in inflammatory cells recovered by bronchoalveolar lavage.⁵⁹ Endobronchial allergen challenge not only causes bronchial symptoms in non-asthmatic allergic rhinitis patients but also affects the nose, inducing nasal symptoms and inflammation resulting in reduced pulmonary and nasal function.⁶⁰ It has been shown that there is an increase in the number of eosinophils in the challenged bronchial mucosa and in the blood. In the nose, there is also an increase in eosinophils as well as eotaxin-positive cells in the nasal lamina propria with enhanced expression of IL-5, after bronchial challenge.⁶⁰

POSSIBLE MECHANISMS OF INTERACTION BETWEEN THE UPPER AND LOWER RESPIRATORY TRACT

The nose plays a crucial role in warming, humidifying and filtering air before it enters the lower airways. Impairment in nasal function can therefore impact on the lower airways. Nasal obstruction can lead to increased oral breathing, reduced filtered air and increased exposure of the lower airways to allergens. Bypassing the nose also results in colder air being delivered to the lower airways, which can also trigger bronchoconstriction in asthmatic patients.⁶¹ Although aspiration of nasal contents can occur in neurologically impaired patients, it is not thought to be responsible for the nasobronchial interaction under normal circumstances.⁶²

The upper and lower airways not only interact via their anatomical connection but there may also be neural reflexes and systemic mechanisms.⁶³ A nasobronchial reflex has been proposed although there has been controversy as to whether it exists with limited evidence to support its presence.⁶¹ A double-blind randomized study of nasal challenges in asthmatic patients with allergic rhinitis and in controls found that methacholine increased lower airway resistance but this could be blunted by pre-medication of phenylephrine to the nasal mucosa.⁶⁴ The implication is that the effect was through systemic absorption rather than a nasobronchial reflex. More recently it has been shown that nasal allergen provocation rapidly induces bronchial hyperresponsiveness by substance P binding to the neurokinin 1 receptor with an increased number of substance P-positive pulmonary nerves.⁶⁵ However, the precise interactions between the upper and lower airways are yet to be fully understood.

There is increasing evidence that the upper and lower airways are connected via a systemic route. Following local allergen challenge, there is high and rapid absorption of allergens in the nasal and bronchial vasculature.⁶⁶ There is also an increase in eosinophils in the blood and airway tissues as well as bone marrow eosinopoiesis.^{58, 60, 67, 68} Increased serum IL-5 levels occurs after allergen exposure⁶⁹ and appears to play a critical role in allergic airways eosinophilia and eosinopoiesis in the bone marrow.^{61, 70-73} In addition, it has been suggested that there is '*in situ* haemopoiesis' with basophils/mast cells and eosinophils accumulating in allergic tissue from *in situ* growth and differentiation of progenitors, stimulated by soluble haemopoietic factors derived from mucosal cell populations.⁷⁴

MANAGEMENT IMPLICATIONS

As rhinitis and asthma often coexist, a combined approach is recommended to manage the airways. The presence of disease in the lower airways can affect the results of investigations of the upper airways such as peak nasal inspiratory flow (PNIF) (Figure 102.2a). Although objective measures of nasal patency are not widely used in routine clinical practice, PNIF is reported to be the best validated technique for the evaluation of nasal flow through the nose⁷⁵

Figure 102.2 (a) Peak nasal inspiratory flow being measured. (b) Peak expiratory flow being measured.

and is quick, simple and cheap to use. It may be particularly helpful in evaluating children and adolescents with allergic rhinitis due to the subjective nature of the clinical information and the possibility that they may underestimate their symptoms.⁷⁶ However PNIF is affected by lower airway function⁷⁵ and has been reported to positively correlate with peak expiratory flow (PEF) in healthy children and adults (Figure 102.2b).^{77,78} PEF has been shown to be predictive of PNIF and low values of PNIF may be reflective of poor lower airway function rather than representing nasal obstruction.⁷⁸ Pulmonary function tests (particularly spirometry and PEF), in contrast objective tests of nasal patency are much more commonly used and can be helpful in confirming the diagnosis in asthma.⁷⁹

Treatment of rhinitis may reduce morbidity from asthma and patients with asthma should be assessed for rhinitis and vice versa.¹⁵ A retrospective cohort study of 4 944 patients with both allergic rhinitis and asthma (without any evidence of COPD) found that those treated for allergic rhinitis had a significantly lower rate of asthma-related emergency department visits or hospitalizations compared to those not treated.⁸⁰ Another retrospective study of 13 844 patients with asthma found that treatment with intra-nasal steroids of nasal conditions significantly reduces exacerbations of asthma leading to emergency department visits⁸¹ although it has also been reported that there may be bias in such an observational study.⁸²

Treatment options for rhinitis and asthma include pharmacological agents, immunotherapy and surgery for chronic rhinosinusitis. Although treatment regimes are well established for each individual condition, optimal management for coexisting rhinitis and asthma is still not agreed. Questions remain as to whether each condition should be treated separately or concurrently and which therapies should be used.⁸³

Medical management

Drugs for rhinitis and asthma can be given via local (intra-nasal or inhaled (intra-bronchial)), oral and parenteral routes. Topical glucocorticosteroids to the nose and bronchi are a highly effective treatment for rhinitis and asthma. Intra-nasal glucocorticosteroids administered for rhinitis have been reported to improve asthma symptoms and to reduce asthma exacerbations leading to emergency

department visits.^{81, 84–87} However, not all studies have shown an improvement in asthma with intra-nasal glucocorticosteroids in patients with rhinitis and asthma.^{88, 89}

The effect of inhaled intra-bronchial glucocorticosteroids on the nasal airway has been less well studied. However, one study reported that orally inhaled budesonide in patients with seasonal allergic rhinitis without asthma caused clinically significant anti-inflammatory effects in the whole airway.⁹⁰ This included the nasal mucosa which was not directly exposed to the drug with reduced seasonal eosinophilia both in the circulation and in the nose with a reduction in nasal symptoms. Oral glucocorticosteroids are also highly effective in asthma and rhinitis although its long-term use is limited by side effects.

H1-antihistamines are an important part of the treatment for allergic rhinitis. Some studies have also shown an improvement in asthma with oral antihistamines^{91–93} although others have not and they are not currently recommended for the treatment of asthma.⁹⁴ Anti-leukotrienes have also been found to be effective in improving allergic rhinitis and asthma.^{92, 95–101} The clinical response, however, is highly heterogeneous and they are generally considered as second line or add-on treatments.^{79, 102, 103}

The anti-immunoglobulin E monoclonal antibody omalizumab has been shown to be a safe and effective additional treatment in moderate to severe asthma in children and adults. By binding with free IgE, it inhibits the release of mediators and production of cytokines from mast cells and it has also been found to be effective in allergic rhinitis. In patients with concomitant allergic asthma and persistent allergic rhinitis, there is a clinically significant improvement in both asthma and rhinitis with omalizumab.¹⁰⁴ The ability to reduce IgE levels irrespective of allergen specificity means that the role of omalizumab in allergic disease is potentially huge; it has also been used in combination with immunotherapy.

Specific Immunotherapy

Immunotherapy is a technique that involves progressive incremental exposure to causative allergens in order to modulate the immune response and achieve clinical tolerance to the allergens. It may be administered via a subcutaneous (SCIT) or a sublingual (SLIT) route and both have been reported to be effective in allergic disease. Serious complications such as

anaphylactic reactions are uncommon, although are a major limitation of immunotherapy. SLIT is considered to be much safer than SCIT although less effective.¹⁰⁵

Immunotherapy is reported to be effective in asthma and allergic rhinitis with improvements in symptoms and medication use.^{105–109} However, it has also been highlighted that the quality of reporting of most immunotherapy trials is low¹¹⁰ and there are many questions about immunotherapy that remain unanswered. Nevertheless, immunotherapy has shown promising results. It appears that immunotherapy in children sensitive to a single allergen can alter the natural history of allergy and prevent development of new sensitizations.^{111–113} There is also some evidence, although limited at present, that immunotherapy has the potential to prevent the development of asthma in children with allergic rhinoconjunctivitis.^{114–117} There is a need for further research in immunotherapy, which may not only have a therapeutic role but may also prevent and alter the natural course of allergic disease.

Surgical management

In addition to improving nasal symptoms, endoscopic sinus surgery (ESS) may also improve asthma in patients with chronic rhinosinusitis and asthma. Studies have shown improved asthma symptoms and control with a reduction in the use of inhalers, systemic medications and hospital admissions for asthma following ESS in chronic rhinosinusitis patients.^{118–125} The positive effect on asthma has also been shown to continue long term following ESS,¹²⁶ with an improvement in severity of asthma, frequency of attacks and use of asthma medication, at an average follow-up of 6.5 years after surgery in one study.¹²⁷ Benefit in children with asthma and chronic sinusitis following ESS has also been reported, with a significant reduction in hospitalizations for asthma, school days missed and symptom scores in asthma and sinusitis.¹²⁸

Lung function tests following ESS in patients with asthma and chronic rhinosinusitis have shown improvement in some studies^{120, 122, 129, 130} whilst others have found no improvement.^{119, 128, 131} Some have also not found any significant improvement in asthma following ESS in patients with chronic rhinosinusitis with and without nasal polyps.^{132, 133} The reported difference in outcomes may be due to the heterogeneity and relatively small numbers of subjects and also to differences in outcome measures in these studies.⁵²

The first randomized prospective study comparing medical and surgical treatment of chronic rhinosinusitis with and without polyps in asthmatic patients found subjective and objective improvements in asthma in both treatment groups.¹³⁴ However, overall asthma control was better maintained in the medically treated group and medical treatment was also superior to surgery in the subgroup of patients with nasal polyps.

The presence of asthma has been reported to negatively affect the outcome of ESS on the upper airway.^{130, 135} Others, however, have found that asthma only has a negative impact on outcome in those with the most extensive sinonasal disease.¹³⁶ Furthermore, some report that asthma does not negatively affect outcome after ESS.^{137, 138}

QUALITY OF LIFE AND COSTS IN ASTHMA AND RHINITIS

Asthma and allergic rhinitis results in poorer quality of life, demonstrated by the European Community Respiratory Health Survey,¹³⁹ a population-based study of young adults, using the SF-36 questionnaire. They found that patients with both asthma and allergic rhinitis had more physical limitations than patients with only allergic rhinitis, but there was no difference between these two groups for aspects related to social/mental health. Patients with allergic rhinitis but not asthma were more likely to have problems with social activities, daily activities as a result of emotional problems, and poorer mental well-being compared to patients with neither asthma nor rhinitis. There were too few patients with asthma without rhinitis to study although it appears that impairment in social life in asthmatics may be related to nasal symptoms.

More recently, however, it has been reported that allergic rhinitis does not seem to further impair health-related quality of life or only has a minor impact in asthmatic patients. Health-related quality of life (based on the SF-36 questionnaire) is markedly reduced in patients with asthma with or without allergic rhinitis, compared to those with allergic rhinitis alone, without any significant difference between those with asthma alone and those with both diseases.^{140, 141} Other studies however, have shown that quality of life is worse in patients with asthma and allergic or non-allergic rhinitis compared to those with asthma alone.^{142–144}

Rhinitis and asthma are global health problems that cause significant morbidity with loss of productivity and have massive direct and indirect costs. Worldwide, it is estimated that there are 500 million people with allergic rhinitis, 300 million people with asthma and also hundreds of millions of people with non-allergic rhinitis/rhinosinusitis.^{79, 145} Although a global problem, there is geographical variation in the prevalence of rhinitis and asthma which tends to be lower in rural communities or low- to middle-income countries compared to Western developed countries.¹⁵ Rhinitis increases asthma costs particularly in children and young adults and those with coexisting asthma and allergic rhinitis have been found to have higher medical care costs by an average of 46% compared to those with asthma alone.¹⁴⁶

SUMMARY

The upper and lower respiratory tracts are intimately related as demonstrated by the similarities between rhinitis and asthma. Most patients with asthma have coexisting rhinitis whilst many rhinitis patients have asthma and an even greater number demonstrate non-specific bronchial hyperresponsiveness. Rhinitis and asthma are not only linked because they share atopy as a common risk factor; both allergic and non-allergic rhinitis are risk factors for asthma. Inflammation is a key component in the pathogenesis of both rhinitis and asthma and in many respects they appear to be manifestations of the same disease, representing a continuum of disease.

Airway smooth muscle present from the trachea to the bronchioles not only causes bronchoconstriction in asthma but may also be involved by increased proliferation and the expression and secretion of a variety of proinflammatory mediators and cytokines.^{35, 36} The difference between rhinitis and asthma may therefore be due to an epithelial-mesenchymal trophic unit¹⁴⁷ in rhinitis whereas in asthma there is an epithelial-mesenchymal-muscular trophic unit. Although the precise interactions between the upper and lower respiratory tracts are not yet fully understood, it is clear that optimal management of patients with rhinitis and asthma requires an integrated upper and lower airway approach.

As rhinitis and asthma often coexist, a combined approach is recommended to investigate and treat the upper and lower airways. Studies strongly support the 1999 World Health Organization workshop 'Allergic rhinitis and its impact on asthma' (ARIA)¹ and the 2008 update,¹⁴⁵ which recommended that:

- Patients with persistent allergic rhinitis should be evaluated for asthma by history, chest examination and, if possible and when necessary, assessment of airflow obstruction before and after bronchodilator;
- History and examination of the upper respiratory tract for allergic rhinitis is performed in patients with asthma;
- Proposal of a strategy combining the treatment of both the upper and lower airway disease in terms of efficacy and safety.

Although there are some recommendations in the treatment of coexisting allergic rhinitis and asthma in the ARIA 2008 update¹⁴⁵ and 2010 revision,¹⁴⁸ further research is required in this area.

BEST CLINICAL PRACTICE

- ✓ H1-antihistamines are effective in rhinitis.
- ✓ Intra-nasal corticosteroids are effective in rhinitis.
- ✓ Intra-nasal corticosteroids are inconstantly effective in asthma.
- ✓ Intra-nasal corticosteroids may reduce asthma exacerbations.
- ✓ Anti-leukotrienes are often effective in rhinitis and asthma.
- ✓ Anti-IgE monoclonal antibody is effective in both rhinitis and asthma.
- ✓ Allergen-specific immunotherapy is effective in both rhinitis and asthma.

FUTURE RESEARCH

- More prospective studies should assess the relationship between rhinitis and asthma.
- More studies are needed to assess nasal and bronchial inflammation in patients with asthma and COPD.
- Nasal remodelling is poorly understood.
- More studies are needed to understand the mechanisms of interaction between the upper and lower respiratory tract.
- Further large pivotal clinical trials are needed to assess whether the treatment of one target organ may improve outcome measures of the other target organ and to assess the specific impact of the different pharmacological agents, immunotherapy and surgery on the whole airway.

KEY POINTS

- The close relationship between the upper respiratory tract and the lower respiratory tract is something that is manifestly observed by all practising rhinologists, demonstrated by the similarities between rhinitis and asthma.
- Rhinitis and asthma may be viewed as ends or parts of a respiratory inflammatory spectrum.
- Most patients with asthma also have rhinitis and many patients with rhinitis have asthma.
- Allergy is associated with rhinitis and asthma.
- Allergic and non-allergic rhinitis are risk factors for asthma.
- Asthma and rhinitis share many common risk factors.
- There are many anatomical and physiological similarities between the upper and lower airways although there are also differences.
- There is a similar inflammatory infiltrate in the upper and lower airways in rhinitis and asthma.
- Bronchial challenge of rhinitis patients leads to nasal inflammation. Nasal challenge induces bronchial inflammation.
- The upper and lower airways not only interact via their anatomical connection but there may also be neural reflexes and systemic mechanisms.
- Treatment of rhinitis may reduce morbidity from asthma and patients with asthma should be assessed for rhinitis and vice versa.
- A combined approach is recommended to treat the upper and lower airways in patients with rhinitis and/or asthma.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: septoplasty, rhinoplasty, septorhinoplasty, functional rhinoplasty, nasal valve surgery, turbinate surgery and paediatric.

INTRODUCTION

Nasal breathing is the normal path of respiration in human beings. Nasal airway passage accounts for approximately half of the total airway resistance and this resistance is required for optimal respiratory physiology.¹ Nasal airway patency or its resistance can be measured by objective and subjective tools.

Rhinomanometry measures trans-nasal airflow and pressure during respiration to determine nasal airway resistance. Nasal cycle and mucosal pathology play a part in these measurements and would make the results based on one rhinomanometry reading less reliable or reproducible. Taking objective measurements before and after nasal decongestants can help distinguish between mucosal hypertrophy and structural deformity as the cause of nasal obstruction.² Acoustic rhinometry determines the nasal cross-sectional area and nasal volume through the analysis of reflected sound pulses within the nasal cavity but the nasal airflow is not included in this method and therefore the effects of dynamic collapse can be missed. Inaccurate placement of the probes during the measurements can also lead to erroneous results.

Due to the inherent problems with the objective measures, subjective tools are more commonly employed in the clinical and research settings. Visual analogue scale appears to be a simple and adequate tool to measure the nasal patency subjectively. The Nasal Obstruction Symptom Evaluation (NOSE) scale is a validated tool for nasal obstruction in adults. The five domains each score 0 (no symptoms) to 4 (severe symptoms) and the result is multiplied by 5 producing a maximum score of 100.³

From a practical point, the current technology cannot accurately determine the level or cause of nasal obstruction; clinical examination remains the mainstay of clinical diagnosis.

The nasal airway is composed of two nasal cavities, each with a medial and a lateral wall as well as a floor. The nasal cavity and its elements are referred to in a three-dimensional structure and we follow the terminology demonstrated in [Figure 103.1](#) in this chapter.

1. **Medial nasal wall:** This is mainly formed by the nasal septum which in itself is composed of bony, cartilaginous and membranous parts. The columella forms the most caudal part of the medial wall.

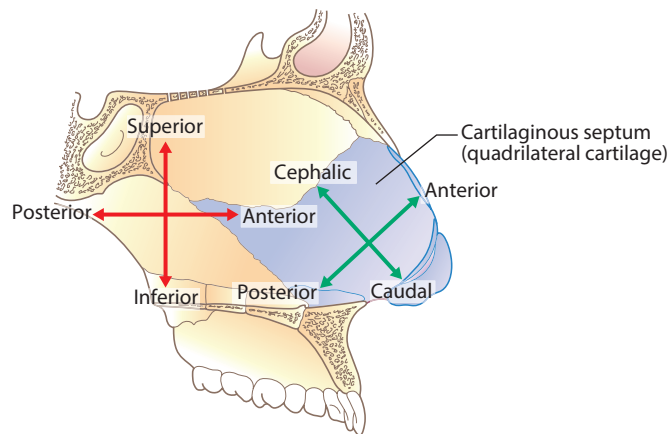

Figure 103.1 Terminology used in nasal and septal orientation. Red arrows refer to the nasal cavity; green arrows refer to the nasal septum.

2. **Lateral nasal wall:** This is formed by the turbinates, fibrofatty tissue and cartilages (sesamoid cartilages, accessory cartilages, upper lateral cartilage and the lateral crus of the lower lateral cartilage).
3. **Nasal floor:** This wall is formed by the floor of the nasal cavity and the nasal vestibule sill.

The elements involved in the nasal airway could have an adverse effect on the nasal airway patency. These elements are mainly incorporated in the nasal septum and the nasal valve areas and it is essential that they are carefully assessed during clinical examination.

NASAL SEPTUM

ANATOMY

The nasal septum is divided into bony, cartilaginous and membranous parts (from cephalad to caudal). The bony septum is mainly formed by the perpendicular plate of ethmoid and vomer. The palatine bones and maxillary crest form the most posterior parts of the bony septum (Figure 103.2). The cartilaginous septum (i.e. quadrilateral cartilage) is not an isolated cartilage and in fact is in unison with the upper lateral cartilages forming one cartilaginous unit.

AETIOLOGY

Nasal obstruction can be caused by septal deflection which can be developmental or secondary to trauma. In some cases, the trauma occurs in childhood and the patient does not necessarily remember the incident.

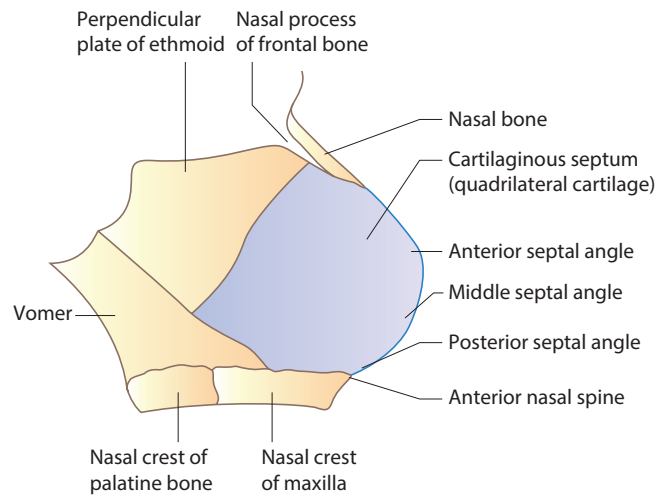

Figure 103.2 Nasal septal anatomy and its terminology.

DIAGNOSIS

An L-shaped strut of septum measuring approximately one centimetre in width is required to support the external nasal skeleton (Figure 103.3). Deviation at the nasal septum L-strut needs to be differentiated from the obstruction caused by the rest of the septum, as it will have implications on the management.

Septal examination should include inspection as well as palpation. During inspection, the position of deviation should be mapped in relation to the L-strut. Nasendoscopy will allow inspection of the anatomy in the neutral position and it also allows inspection of the elements that are not visible in anterior rhinoscopy; this at times can reveal adenoid tissue, mucosal abnormalities, nasal polyps or choanal pathology which can cause nasal obstruction.

Nasal airflow can be demonstrated by misting of the examination mirror or metal tongue spatula but this technique needs to be used with caution. Absence or reduction of the misting can be suggestive of a structural blockage but a satisfactory amount of misting does not necessarily indicate a patent nasal airway as perceived by the patient. This will be discussed further in the examination of the nasal valve.

Palpation is used to feel for attachment of the septum to the anterior nasal spine and to feel for fracture lines. In patients who have undergone septal surgery in the past, gentle palpation of the septum with an applicator (e.g. Jobson Horne probe) might indicate the areas deficient of cartilage.

During assessment, a decision is to be made as to whether the septal deflection is the sole cause of nasal obstruction. Nasal valve and mucosal elements need to be taken into consideration. The history of constant nasal obstruction points to an anatomical blockage whereas the intermittent obstruction points to the mucosal elements

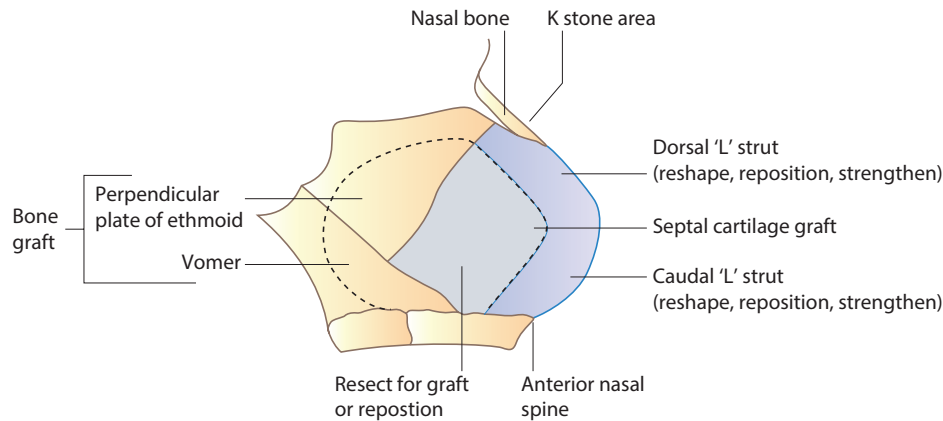

Figure 103.3 Septal cartilaginous L-strut with a minimum 10 mm width is preserved for structural support. The rest of the bony and cartilaginous septum can be used as grafts.

to be at least partially to blame. Significant improvement in nasal obstruction after application of topical nasal decongestants indicates the role of mucosal elements in nasal obstruction. Intermittent nasal obstruction, especially one that changes sides, can be due to nasal cycle. Patients who have had complete nasal obstruction might complain of this phenomenon after their successful nasal airway surgery. If the patient notices obstruction in the lateral decubitus, then the engorgement of turbinates on the dependent side or the collapse of the lateral nasal wall (i.e. nasal valve elements) on the opposite side can be blamed.

TREATMENT

Septal deviation can be present due to the inherent bend of the septal cartilage or as a result of septal tilt due to deviated bony septum. In cases where the septum is inherently straight, the septal tilt may be corrected by addressing the bony attachments; when the cartilage is inherently deformed, special techniques are employed.

Most septal deviations involve the caudal and dorsal L-strut to some degree but in cases where the obstruction does not involve the L-strut, the offending segment can be excised through submucosal resection (SMR).

SUBMUCOSAL RESECTION

In this technique, the L-strut is not addressed therefore a Killian incision for approach would suffice. A Killian incision is placed about 1 cm cephalad from the caudal end of the septum (Figure 103.4). At this point the perichondrium is less adherent to the underlying cartilage and the flap can be raised more easily. If the deviation is situated further cephalad, the incision for access can be made close to the offending segment.

The deviated part of the septum is freed from its peripheral cartilaginous and bony attachments. The *in-situ* bony deviation can be in-fractured to put the bony septum in midline or it can be excised conservatively. Bony septum

is an invaluable source of graft material for septal reconstruction; therefore the excision should be done conservatively. The harvested septum can then be used as a graft or it can be straightened and reinserted in its place. It can be secured to the remaining septum by sutures to avoid migration; some authors prefer to secure it by inserting bilateral intra-nasal splints.

SEPTOPLASTY

In most cases of septal deviation, the septal L-strut is involved. SMR is not effective in these cases as it cannot address the caudal and dorsal struts. Septoplasty techniques are needed to address these problems and the approach should provide access to the L-strut.

Hemitransfixion incision is designed to provide access to the whole septum including the caudal L-strut. The incision is placed at the caudal edge of the septum. The length of the incision depends on the access required (Figure 103.4). If access is required to the whole of caudal arm of the L-strut then a full hemitransfixion is used. However, if access is not required for the most posterior parts of the septum, then a partial hemitransfixion would suffice. If access is required to the floor of the nasal cavity then an extended hemitransfixion incision is used.

Generally, raising the mucosal flap on the concave side would be enough to allow access for excision of septal cartilage and bone, to detach the septal osseocartilaginous junction, to score the concave side and apply other relevant techniques. It also reduces the chance of septal perforation by keeping the opposite mucosa intact. In certain conditions, both mucosal flaps are raised, especially when the surgeon would like to keep the sutures in the mucosal envelope or in cases where access to both sides of the septum is required (e.g. S-shaped septal deformity).

Caudally, the perichondrium is adherent to the septal cartilage and care must be taken to identify the actual plane of dissection at the subperichondrial level. This can be achieved by scoring the area to find the desired plane.

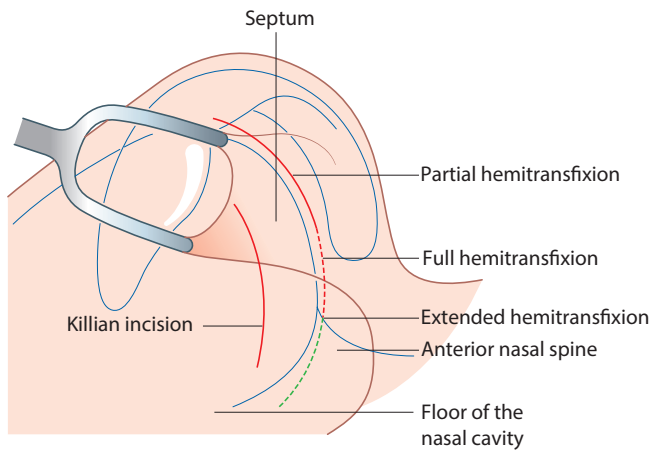

Figure 103.4 Placement of different incisions for approach to the septum.

If the flap is raised at the correct plane, minimal to no bleeding is encountered. The extent of the flap elevation depends on the plan of surgery. The flap can be raised as far cephalically as possible to have access to the perpendicular plate of ethmoid for harvesting bony grafts. Often it is easier to raise the flap anteriorly as far cephalically as possible and then to change direction more posteriorly and raise the flap from cephalic position caudally (i.e. back to front) by the help of a Pennington septum elevator (Figure 103.5).

When the bony osseocartilaginous junction between the quadrilateral cartilage and the bony septum is reached, this junction is disarticulated to gain access to the opposite side of the bony septum. Care must be taken not to perforate the mucosa on the other side when raising the mucosal flap from the opposite side of the bony septum. Often the disarticulation is not enough to allow the cartilaginous septum to return to midline and a sliver of bone or cartilage needs to be removed. The excision should be planned carefully to remove the bony or cartilaginous pieces as usable grafts rather than excising them piecemeal. Disarticulation of the quadrilateral cartilage from the maxillary crest is required to allow the septum to move to midline; often a sliver of bone or cartilage needs to be removed. The 1 cm of bony-cartilaginous junction at the L-strut is left undisturbed if possible but often this area requires special attention.

If access is required to the floor of the nasal cavity then an extended hemitransfixion is applied (Figure 103.4).

Pennington Septum Elevator, Double-Ended

Catalog#	Description	Length	Width 1	Width 2

Figure 103.5 Pennington septum elevator.

This would allow raising a tunnel underneath the septal spur which reduces the chance of mucosal tear over the spur (Figure 103.6). Raising the flap over a septal spur can be challenging as the perichondrial fibres of the cartilaginous septum and the periosteal fibres of the maxillary crest are interwoven. To reduce the chance of mucosal tear, two techniques can be employed.

BACK TO FRONT TECHNIQUE (CEPHALAD TO CAUDAL)

In this technique, the flap is raised more anteriorly at the caudal septum and raised towards the cephalic position; the direction of dissection is then moved posteriorly and the flap is raised from the cephalic position caudally. This way the plane of dissection is at the correct subperiosteal level initially and then continues at the subperichondrial level reducing the chance of mucosal tear.

FRONT TO BACK TECHNIQUE

In this technique, the mucoperichondrial flap is raised over the quadrilateral cartilage and the bony septum; this constitutes the anterior tunnel over the spur. Then another subperiosteal tunnel is raised posterior to the septal spur which constitutes the posterior tunnel (Figure 103.6). The mucosa left attached to the most prominent part of

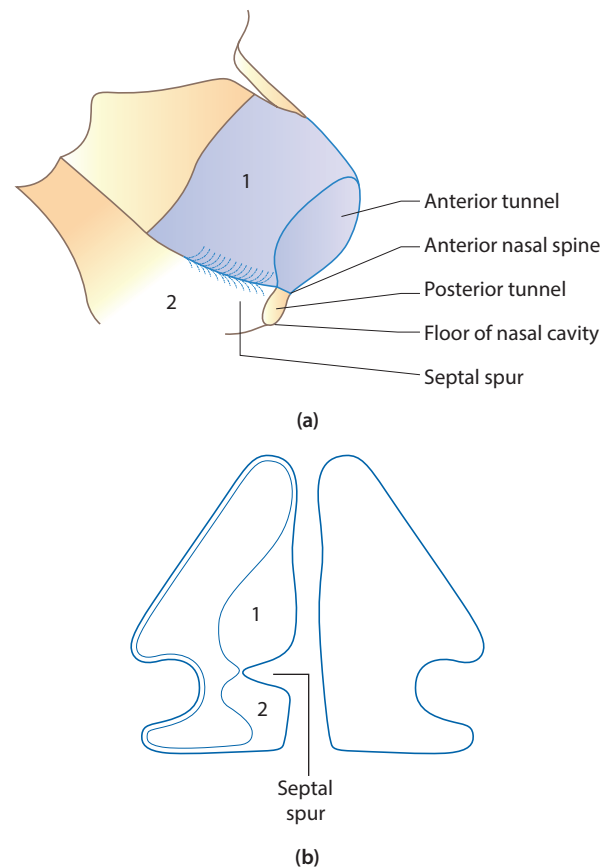

Figure 103.6 Anterior (1) and posterior (2) tunnels are raised to reduce the chance of mucosal tear over the septal spur.

spur is then addressed by sharp dissection without the tension of the mucosa on either side.

SEPTOPLASTY TECHNIQUES

In septoplasty, the attention is more on reconstruction rather than excision. The excision alone can be performed as SMR on the body of the septum but deviations of the L-strut require special reconstructive techniques.⁴

The deviated septum can be addressed by 1) Cutting techniques, 2) Grafting techniques, 3) Suturing techniques, and 4) Relocating techniques. The techniques can be used alone or in combination.

The surgical techniques described here are not exhaustive; the techniques and the choice of equipment and sutures are those of the senior author's (SA) who has found them reliable and reproducible.

CUTTING TECHNIQUES

Scoring of the septal cartilage on the concave side allows the septum to become straight, eliminating the deviation. The septum will be kept in position by the scar tissue in grooves created by scoring on the concave side; therefore, the septum should be kept in position, free of any tension until the scar tissue is set in place. This technique is not wholly reliable as under-scoring or over-scoring can result in unsatisfactory results. Also, if the flap is only raised on the concave side, the result of warping might be delayed due to the effects of attached perichondrium on the other side. For these reasons, it will be more predictable if the scored segment is splinted against a batten graft. In S-shaped septal deformities, the scoring needs to be done on the concave segments on both sides; hence the need for raising bilateral mucoperichondrial flaps. If the septum is fractured, the fractured line needs to be weakened by scoring or cutting through to allow the septum to return to midline; in this instance the concomitant grafting technique (splinting) is recommended.

Caudal septal deviation or dislocation is often addressed by excising the excess cartilage at the caudal arm of the L-strut. In the swinging door technique, an appropriate amount of caudal L-strut is excised to allow

the septum to return to the midline.⁵ The septum then needs to be secured to the midline again; this can be achieved by suturing the septum back to the anterior nasal spine or its periosteum. To apply sutures to the anterior nasal spine, a hole is made in the bone using a strong hypodermic needle or using a drill with a Fissure burr. The septum is then secured in place with 4x0 PDS sutures. Scoring technique is used to correct the convexity but the septum is splinted with a graft in order to avoid unsatisfactory results due to under-scoring or over-scoring (Figure 103.7).

Often the deviation at the dorsal L-strut of the quadrilateral cartilage is because of deviation of the bony attachment to the perpendicular plate of ethmoid. In these cases, the osseocartilaginous junction needs to be disarticulated all the way through (and sometimes encroaching into the last 1–1.5 cm). Traditional teaching warns us of septal collapse if this segment is disturbed; however this is simply not true. The quadrilateral cartilage of the septum is attached to the upper lateral cartilages and as long as this attachment and the attachment of the upper lateral cartilages to the nasal bones are intact and the bones are secure and stable, the septum will not collapse. If the bony cartilaginous junction at the dorsal L-strut needs to be disarticulated fully, it should be clearly documented in the operative notes for future operations.

GRAFTING TECHNIQUES

Often the deviated septum can be kept in a straight line if it is splinted against a graft. Both septal cartilage and septal bone (from perpendicular plate of ethmoid or from vomer) can be used for this purpose. The perpendicular plate of ethmoid is stronger and thinner compared to the septal cartilage.^{6,7} The technique involves harvesting a suitable piece of perpendicular plate of ethmoid which is then thinned down using a large diamond burr (e.g. 5 mm diamond burr). The graft is then perforated using a Fissure burr and it is splinted against the concave side of the septum (Figure 103.8). Care must be taken to position the bony strut a few millimetres from the septal edge so that it is not felt by the patient and it does not cause obstruction for dorsal reconstruction (e.g. spreader grafts). Often the septum is scored to

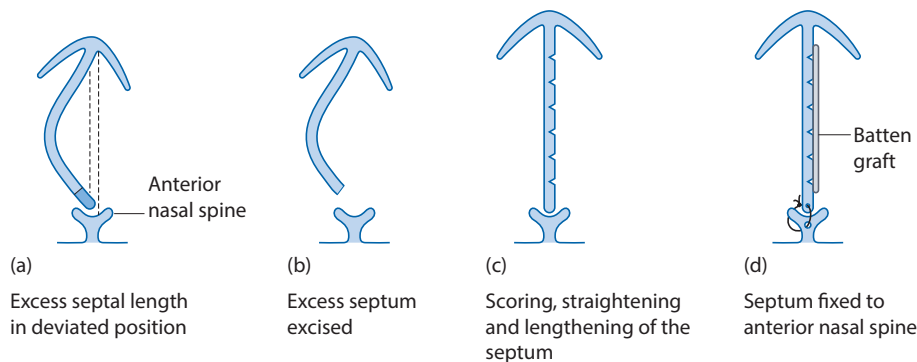

Figure 103.7 Swinging door technique is a reliable method in dealing with anterior septal deviations: (a) Septal convexity to the right has resulted in excess caudal septal length, (b) The excess length of the septum is excised, (c) The height of septum is restored after scoring of the concave side, (d) The weakened septum is splinted against a batten graft and secured to the midline.

Figure 103.8 Septal bony grafts form the perpendicular plate of ethmoid are used to splint the deviated or fractured parts of the cartilaginous septum: **(a)** Left septal deviation with a vertical fracture line is demonstrated, **(b)** The graft is harvested from the body of septum and the fracture line on the L-strut is cut through and divided, **(c)** The septum is splinted with an ethmoid bone graft.

make it more pliable to conform to the straight ethmoid bone. A fine absorbable or non-absorbable suture is used to secure the graft to the septum (e.g. 5×0 PDS®). This technique is more reliable than scoring alone as it eliminates the chance of residual deviation or over-correction due to underscoring or overscoring. A graft made from the septal bone can cause rigidity to the caudal septum; a side effect less noticeable if the batten graft is fashioned from the cartilaginous septum.

The deviation of the dorsal L-strut can be corrected by spreader grafts too. The concave part of the dorsal septum is scored to weaken the septum and to allow it to return to the midline; it is then splinted by spreader grafts and secured in place by sutures (e.g. 5×0 PDS®). For this particular technique, external approach provides better access of visualization however spreader grafts can be inserted through endonasal approach too.

SUTURING TECHNIQUES

A mattress suture can be used to control the septal curvature.⁸ In this technique, the septum is first scored (preferably underscoring) just enough to make it pliable so it can be shaped and kept in shape by fine sutures. The entrance and exit sutures are placed on the convex side and the knot is incrementally tightened until the desired position and shape is achieved. A fine non-absorbable suture (e.g. 5×0 Prolene®) is used for this purpose and bilateral mucoperichondrial flaps are raised so that the suture is covered by the septal mucosa.

RELOCATING TECHNIQUES

These techniques are used when the septum is dislocated off the midline and it only requires reinsertion onto the maxillary crest. The septum needs to be secured in its midline position and this is achieved by suturing the septum either onto the periosteum of the anterior nasal

spine or to the actual bone by drilling a hole onto it. Fine absorbable or non-absorbable sutures can be used for this purpose. At times other surgical techniques such as scoring and grafting are required to keep the septum in midline.

Often a deviated caudal septum can be improved by door-stop technique where the septal cartilage is dissected free along the maxillary crest and is relocated over the nasal spine which acts as a door stop and secures the caudal septum in a straighter position.⁹

SPECIAL SEPTOPLASTY CONSIDERATIONS

There are special cases related to septoplasty which deserve to be discussed separately.

Endoscopic septoplasty

This technique can be used to improve visualization particularly of more cephalic septal deformities. It also allows minimal access dissection to reach isolated deviated parts of the septum (more relevant in revision cases). Endoscopic septoplasty can be used concomitantly along with sinus surgery. It is also an effective teaching tool.¹⁰

External approach septoplasty

Most septoplasty techniques can be performed through the endonasal approach; in certain situations especially where the dorsal L-strut deformity is concerned, the external approach septoplasty can improve surgical access. External septorhinoplasty is also favourable in complex septal reconstructive cases such as extracorporeal septoplasty.

Extracorporeal septoplasty

In cases of a severely fractured and deformed septum, the correction and reconstruction can be achieved through an extracorporeal technique.¹¹ In this method, the septum (both cartilaginous and the bony segment) is excised in one piece as intact as possible. This requires detachment of the cartilaginous septum from upper lateral cartilages and its attachment to the maxillary crest posteriorly. The septum is then measured and a template is made to represent the new septum. Now two different techniques can be employed:

1. **Re-orientation:** The new L-strut is harvested from a straight section of the excised septum and it is reinserted in place.
2. **Reconstruction:** The septum is reconstructed by a variety of techniques (as described before) and then reinserted in its place. In cases of fractured septum, the fracture line is cut through or weakened to straighten the septum and then the septum is splinted against a graft as previously described. In cases where the septum is broken into many pieces, the segments of septum are splinted against a sheet of thinned down perpendicular plate of ethmoid or a PDS sheet (like a jigsaw puzzle). A fine absorbable or non-absorbable suture (e.g. 5x0 PDS®) is used to secure the pieces of septum to the ethmoid bone graft or the PDS sheet.

The neo-septum is then reinserted into its position. A Fissure burr is used to make a groove onto the maxillary crest for the septum to rest on. A hole is also made onto the anterior nasal spine so that the septum is secured caudally (e.g. 4x0 PDS®). The second point of fixation is to the upper lateral cartilages (e.g. 5x0 Prolene® or PDS). For further security, the neo-septum can be secured to the nasal bones at the K-stone area.

Paediatric septoplasty

There remains controversy about the optimal age and extent of septal surgery in the paediatric population. However, studies have demonstrated that septal surgery performed in children as young as 6 years old provides long-term satisfactory outcomes.^{12, 13} Delaying operation on children with deformed nasal skeleton and septal deformities can adversely affect nasal and facial growth and it prolongs patients' suffering from nasal blockage.¹²

Surgeons have addressed septal deformity in children with a range of techniques from closed reduction of septal deviation to the extracorporeal technique through an external approach septorhinoplasty.^{12, 14}

The most important aspect of surgery is to resect the cartilage conservatively and to avoid disrupting the endochondral ossification plates if possible. Excision should be kept to minimum and any excised segment should be reinserted after remodelling.¹²

Evidence from cleft rhinoplasty and septal surgery is used by those advocating surgical intervention in earlier years and justifying more extensive surgery, however, it is wise to avoid over-enthusiastic septal surgery in early years especially if the nasal blockage is unilateral delaying the definitive surgery to later teen years and early adulthood.

NASAL VALVE

The nasal valve is the narrowest portion of the nasal airway. Failure to properly address the nasal valve at primary surgery has been the cause of persistent nasal obstruction in a large proportion of failed septoplasties.¹⁵ The nasal valve is the area caudal to the nasal bones and it is unique in two aspects: 1) It contains the narrowest section of the nasal airway (i.e. internal nasal valve), and 2) It contains a mobile collapsible segment (i.e. lateral nasal wall and its contents).

The nasal valve has traditionally been divided into two 3D-areas: 1) Internal nasal valve, and 2) External nasal valve. This division is arbitrary as in reality there is no clear line between them and they are connected to each other through the lateral nasal wall soft tissues (e.g. at the scroll area).

ANATOMY

The described boundaries of nasal valves have not been consistent in the literature. For the purpose of this chapter, we describe each nasal valve with the following three walls ([Figure 103.9](#)).

Internal valve

- **Medial wall:** septum
- **Lateral wall:** caudal end of the upper lateral cartilage (ULC), anterior part of the inferior turbinate
- **Nasal floor:** floor of the bony aperture.

External valve

- **Medial wall:** septum, columella
- **Lateral wall:** lateral crus of the lower lateral cartilage (LLC), fibrofatty alar lobule
- **Nasal floor:** nasal sill.

The lateral nasal wall weak triangle contains the sesamoid cartilages and lies between the defined boundaries of the two valves forming part of their lateral walls. There is no universal term for this part of the nasal wall and different terms have been used interchangeably (e.g. weak lateral triangle, external lateral triangle).

Nasal valve angle refers to the angle between the caudal edge of the ULC and the septum, and it is measured at 10–15 degrees in Caucasian Leptorrhine noses (i.e. long narrow noses mostly seen in white individuals as opposed

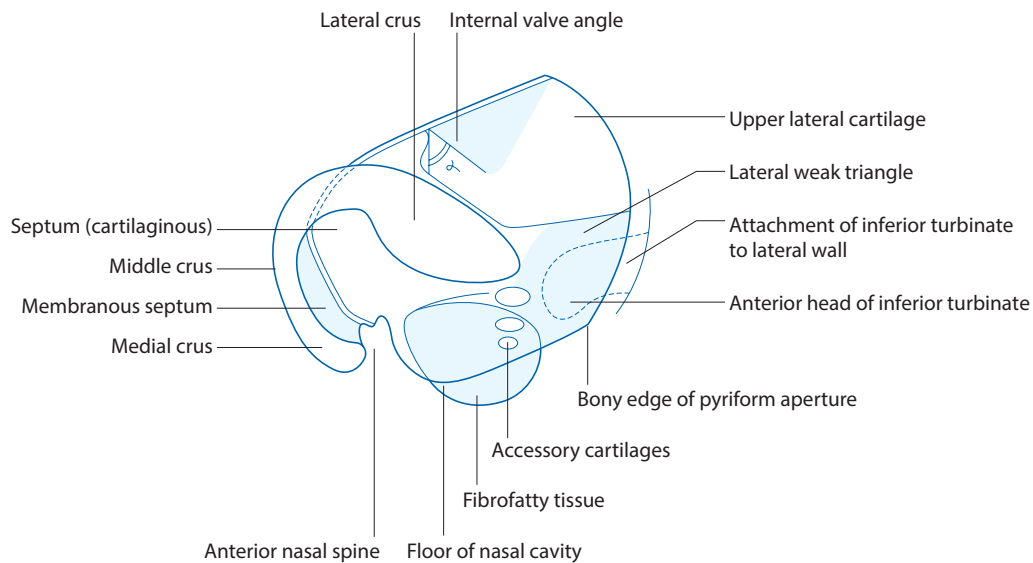

Figure 103.9 The elements incorporated in the nasal valve walls are demonstrated.

to the flat broad Platyrrhine noses seen in the black population). More acute internal nasal valve angles can be associated with nasal blockage and result in dynamic external valve collapse.

AETIOLOGY

The obstruction at the nasal valve can occur due to:

- **Static narrowing:** the nasal airway is narrowed or blocked secondary to deformed anatomy (e.g. congenital, developmental, traumatic or iatrogenic).
- **Dynamic collapse:** in this situation, the nasal airway is patent at rest and in expiration but the lateral wall collapses due to increased intra luminal negative pressure during inspiration. Dynamic collapse follows Poiseuille's principle and the Venturi effect (See Volume 2, [Chapter 28](#)) and the surgeon needs to understand the interplay between the nasal airflow, nasal wall resistance and the cross-sectional area of the nasal valve. To address the dynamic collapse, the surgeon needs to increase the cross-sectional area of the nasal airway on the collapsing side and/or strengthen the weakened lateral nasal wall. Also, increasing the airflow on the opposite side will help reduce the excessive flow on the collapsing side, improving the dynamic collapse.

Anatomical narrowing of the nasal valve is caused by the elements in the nasal valve walls.

Medial wall

1. **Septum:** anterior septal deviation or caudal dislocation can narrow the nasal valve area.
2. **Columella:** widened columella is caused by prominent footplates or prominent soft tissue (e.g. depressor septi nasi muscle). Asymmetry, dislocation and deviation of the footplate can narrow the external nasal valve.

Lateral wall

1. **ULC:** anatomical narrowing of the internal valve angle, sequela of lateral osteotomy (e.g. pinched bony nose and medialized ULC).
2. **Lateral crus of LLC:** Its configuration and alignment (e.g. cephalic position) can predispose to nasal obstruction.
3. **Fibrofatty tissue (alar lobule and lateral nasal wall weak triangle):** Its medialization usually follows weakened or medialized cartilaginous support (e.g. aggressive cephalic trimming, facial palsy).
4. **Inferior turbinate:** Mucosal swelling or bony prominence.

Nasal floor

1. **Soft tissue stenosis:** Developmental or iatrogenic (i.e. secondary to alar base surgery)
2. **Bony aperture stenosis** is a rare condition but it can be corrected surgically.

DIAGNOSIS

A thorough nasal examination is essential in diagnosing the cause of nasal blockage. Attention to nasal septal deformity as well as the nasal valve area is paramount. In many cases of dynamic external valve collapse, the internal valve is the culprit.

Misting of the examination mirror or a metal tongue spatula on nasal expiration does not equate with a patent nasal airway as it is perceived by the patient. In fact, lack of misting on the spatula test is a more reliable method to demonstrate nasal blockage; in these cases if the lack of misting persists despite adequate decongestion, it confirms static structural obstruction. Misting test relies on nasal expiratory flow and it can therefore miss the dynamic collapse which only occurs on inspiration.

A nasal speculum can be used to examine the anterior nasal cavity; however, the nasal airway and the valve area should be examined by an endoscope to assess the anatomy

Figure 103.10 The nasal airway and the nasal valve should be inspected in its neutral position. Nasal speculum can distort the anatomy and can hide the culprit. (Reprinted with permission from Anari S. Nasal Valve Surgery. *ENT News & Audiology* 2013; **22**(3): 44–6).

in its neutral position. Using a nasal speculum can distort the anatomy and can obscure the culprit (**Figure 103.10**). Nasal airway should be assessed at rest as well as inspiration and expiration; it should also be re-examined after nasal decongestion. Considerable improvement in nasal blockage after decongestion highlights the role of mucosal congestion in nasal obstruction. Treatment of the allergic elements and addressing the inferior turbinates should be part of the management plan in these cases.

Manipulation of the elements on the lateral nasal wall is required to identify the cause of the nasal valve blockage. Cottle's manoeuvre (i.e. gently pulling the cheek laterally) increases the cross-sectional area of the nasal valve however it is not a specific test as it lateralizes elements incorporated in the lateral walls of both the external and the internal nasal valves (**Figure 103.11**). Also, a person with normal nasal airway would generally perceive increased

Figure 103.11 Cottle's manoeuvre is not a specific test for the external valve. The internal valve is also affected via its attachments to the external valve elements; (a) Internal valve angle in resting position, (b) Opening of the internal nasal valve angle during Cottle's manoeuvre. (Reprinted with permission from Anari S. Nasal Valve Surgery. *ENT News & Audiology* 2013; **22**(3): 44–6).

nasal patency with Cottle's manoeuvre. Perhaps a negative Cottle's test is more informative suggesting that the cause of the nasal blockage does not rest in the lateral nasal wall.

A more precise way of examining the lateral nasal wall is by modified Cottle's manoeuvre where a soft-tipped instrument (i.e. Jobson Horne probe) is used to assess the structures internally. The probe can be used to lateralize each element very conservatively to assess patient's perception of nasal patency improvement during inspiration.

TREATMENT

Nasal valve dilators (e.g. Breathe Right® or Nozovent®) (**Figure 103.12**) and nasal steroid medications play a part in the non-surgical management of nasal valve obstruction.

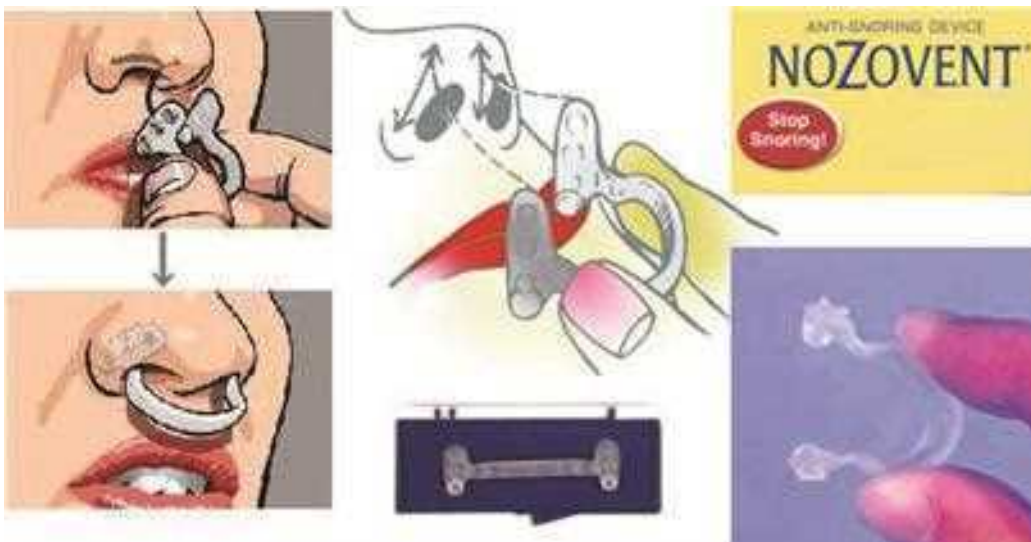

Figure 103.12 Nozovent.

The surgical techniques are divided into: 1) Cutting techniques (incision and excision); 2) Suturing techniques; 3) Grafting techniques; and 4) Relocating techniques.

The following list of surgical techniques is not exhaustive but the senior author has found them to be effective. The techniques are aimed at each of the offending segments.

Septum

The techniques to address the deviated septum have already been described in the previous section of this chapter.

Upper lateral cartilage

CUTTING TECHNIQUES

In cases where the internal nasal valve is narrow, excision of a few millimetres of the caudal ULC can increase the valve angle. This is based on the principle that the angle between the septum and upper lateral cartilage increases when moving cephalad. This can be achieved through external rhinoplasty as well as endonasal approach. If the length of the ULC is reduced, the excess mucosa needs to be trimmed to prevent obstructing the angle.¹⁶

SUTURING TECHNIQUES

The ULC can be flared using a suture connecting them to each other (Figure 103.13). This allows increase in the internal nasal valve angle. The knot needs to be tied incrementally to achieve the beneficial effect but to avoid undesirable aesthetic changes.¹⁷ This technique can be used along with spreader grafts to maximize the benefit.

Suspension sutures can be used to improve the internal valve area (Figure 103.14). A non-absorbable suture is used to anchor the ULC to the adjacent bony structures (e.g. orbital rim or frontal process of the maxilla).¹⁸ To improve the efficacy of this technique, the midfacial and nasal soft tissues need to be extensively undermined and the sutures should be placed without tension.

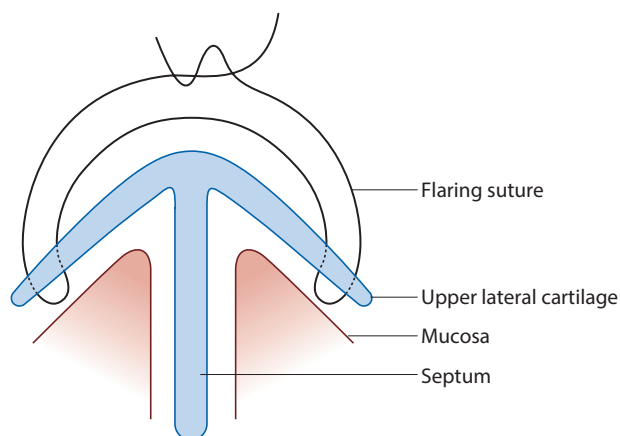

Figure 103.13 Flaring suture is used to splay the upper lateral cartilages and to open up the internal nasal valve angle and the cross sectional area of the internal valve.

GRAFTING TECHNIQUES

Spreader grafts are used to reconstruct the dorsal 'T' junction between the ULC and septum (Figure 103.15). Their use is both for functional and aesthetic purposes although some argue the magnitude of their functional advantage. These grafts can be inserted through the endonasal and external approach.¹⁹

Butterfly grafts can be taken from the septum or conchal cartilage and they saddle the dorsum to open up the midnasal vault and internal valve. They could have an undesirable aesthetic effect causing the supra-tip fullness. To reduce the supra-tip fullness, a hosting groove can be carved on the septal dorsum.²⁰

Figure 103.14 Suspension sutures can prevent the collapse of the lateral nasal wall.

Figure 103.15 Spreader grafts are placed between the upper lateral cartilages and the septum to reconstruct the dorsal septal 'T' segment.

Lateral crus of LLC

CUTTING TECHNIQUES

In cases of nasal tip ptosis (e.g. ageing nose), lateral crus trans-section and overlap (i.e. lateral crural overlay) results in improvement in nasolabial angle and air flow dynamics.^{21, 22}

SUTURING TECHNIQUES

Mattress sutures are used to control the lateral crus curvature.⁸ Cases of extreme convexity which result in invagination of the crus into the nasal vestibule can be corrected this way (Figure 103.10). The domal formation sutures can result in straightening of the lateral crus too.

Spanning sutures have been designed for nasal tip refinement but as they alter the tilt of the lateral crus, they increase support for the nasal side wall too. This is essentially a mattress suture securing the two lateral crura together. This suture is very powerful and it should be used to keep the crura in the desirable position; too much tension on the suture can have adverse effects and could lead to alar retraction.²³

Alar expansion sutures are essentially mattress sutures designed to splay the lateral crura and improve the valve area. The tension on these sutures should be controlled as they can cause alar retraction.²⁴

Lateral crus suspension sutures are used to support the lateral nasal wall (Figure 103.14). These are similar in principle and method of execution to suspension sutures used for ULC.¹⁸

GRAFTING TECHNIQUES

The lateral crus strut graft or alar strut graft is often a septal graft that is secured between the vestibular skin and the defective lateral crus and it may rest over the bony piriform aperture for further stability (Figure 103.16).²⁵ In some cases, a shorter version of the graft (the so-called mini-strut) is inserted underneath the lateral crus to strengthen it and to bring the severely convex or concave lateral crus to a more straightened configuration.

The alar batten graft is usually taken from the septal or conchal cartilage and placed in a subcutaneous pocket over the point of maximum collapse of the lateral nasal wall (Figure 103.16). This graft can be positioned cephalad, caudal or on the lateral crus and can extend over the bony piriform aperture for further stability.²⁶

Spanning grafts straddle the dorsal septum and they are attached to the lateral crura keeping them in the desired orientation and position. If required, a groove on the dorsal edge of the septum can host the graft preventing supratip fullness.²³

At times, an extremely convex or concave lateral crus can be completely excised from its bed and reinserted on the opposite side. Also the strip of cephalic trim can be used to splint the remaining lateral crus strip and reduce the excessive curvature; these techniques are described in a variety of names and fashions (e.g. turn-in flap, turn-over grafts, flip-flop grafts etc.).

RELOCATING TECHNIQUES

A cephalically-positioned lateral crus can lead to reduced support for the lateral nasal wall which can lead to external valve collapse. Reorientation of the lateral crus can be achieved by elevating the lateral crus from its original bed and reinserting it into a more caudal and posterior position (Figure 103.17). The lateral crus is repositioned on its own or with the added structural support of a strut graft usually taken from septum. This technique has been described both through the endonasal and external approach but the latter is technically less challenging.²⁷

Fibrofatty tissue

GRAFTING TECHNIQUES

Non-anatomic grafts (such as alar rim grafts or lateral wall grafts) are used to strengthen the collapsible lateral nasal wall (Figure 103.16). The grafts should be carved thin enough to cause little aesthetic disfigurement and yet they need to be strong enough to increase lateral nasal wall strength.

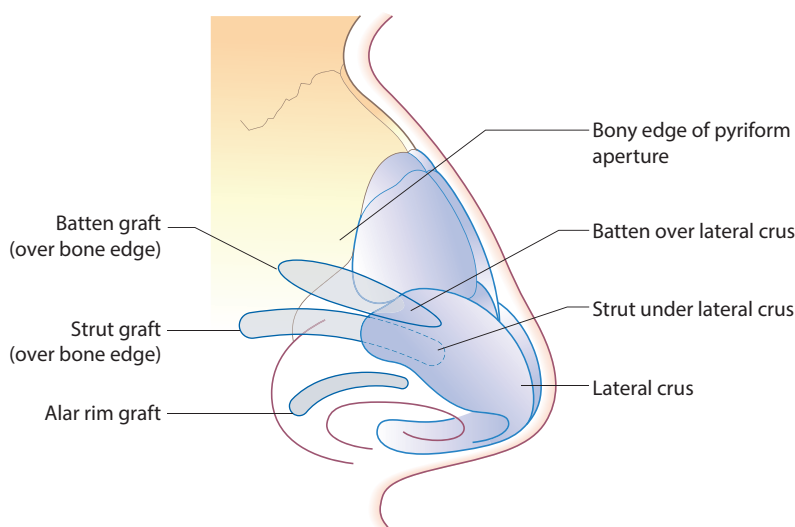

Figure 103.16 Position of alar strut, batten and rim grafts to support the lateral nasal wall from collapse.

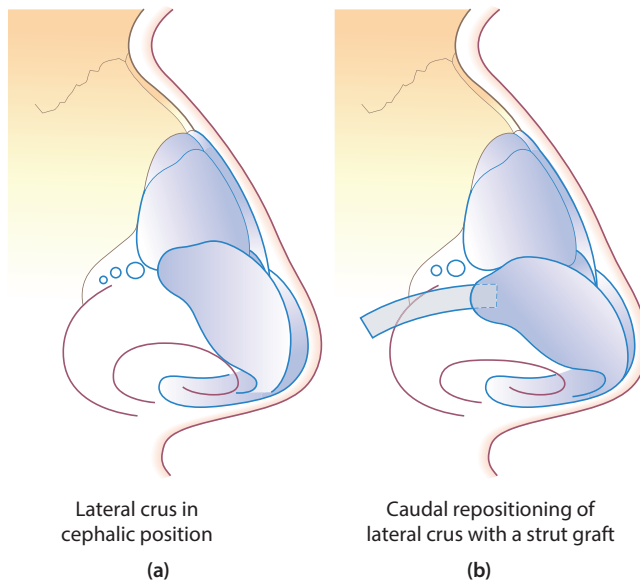

Figure 103.17 Repositioning of the lateral crus: (a) Lateral crus of the lower lateral cartilage is in its cephalic position (i.e. malposition). In this position, there is less support for the lateral nasal wall and the lateral nasal wall is prone to collapse on inspiration, (b) the lateral crus is repositioned into its orthotopic position with the help of a lateral crus strut graft. The lateral nasal wall has greater support in this position.

They are usually inserted in tight subcutaneous pockets over the maximum point of nasal wall collapse.

SUTURING TECHNIQUES

Lateral nasal wall suspension sutures are used to improve the narrowing in this segment.²⁸ Often the sutures are applied to the upper lateral cartilage or the lateral crus of the lower lateral cartilage and as a result the lateral nasal wall lateralizes (Figure 103.14). When the sutures are applied to the cartilage rather than the fibrofatty soft tissue, the result seems to last longer.

Inferior turbinates

Inferior turbinate enlargement can be compensatory on the opposite side of nasal obstruction or it can be part of the inflammatory nasal condition (e.g. allergic rhinitis).

The surgical techniques aim to reduce the size of inferior turbinates by reducing the conchal bone or the submucosal expansile venous plexus (See Chapter 105).²⁹ Cryosurgery, laser cautery, submucous electrocautery, linear mucosal diathermy, microdebridement of the submucosal venous plexus and radiofrequency have been used to address the dynamic mucosal element of the inferior turbinate engorgement. Radiofrequency-assisted turbinate reduction surgery has been suggested to cause minimal disruption to nasal function.³⁰

In cases of bony enlargement, the conchal bone is reduced while preserving the mucosa. Turbinate outfracture can improve the nasal airway with minimal trauma to the nasal lining, however the anterior head of the inferior turbinate – which plays an important part in the nasal valve area – is not easily amenable to lateralization.

Nasal sill/vestibule

CUTTING TECHNIQUES

Z-plasty is performed to improve the nasal valve narrowing.³¹ This technique is to address the stenosis at the internal valve angle mostly caused by inappropriate septo(rhino)plasty incisions and closure techniques.

GRAFTING TECHNIQUES

Composite skin and cartilage grafts harvested from the pinna concha can be used to improve the stenosis at the internal valve angle or the nasal sill (depending on the source of stenosis).

Columella

Widening of the columella can narrow the nostril size and result in external nasal valve narrowing. Widening of the columella or a protruding footplate can be addressed by excising, relocating or suturing techniques.³² Grafting techniques (e.g. columella strut graft) can improve the nasal droopy tip and improve nasal airflow dynamics; this is a commonly performed step in treatment of the ageing nose.

DRESSING AND SPLINTS IN NASAL AIRWAY SURGERY

The use of post-operative nasal packing remains a varied practice. Careful dissection and minimal trauma during surgery makes risk of bleeding minimal and obviates the need for nasal packing which would save the patient the discomfort of subsequent nasal pack removal. Septal quilting sutures have demonstrated a greater reduction in post-operative haematoma complications and have improved patient satisfaction in comparison with nasal packing.^{33, 34}

Some surgeons use septal splints to prevent adhesions especially when septal mucosal lacerations are present and concomitant turbinate surgery has been performed. Some use septal splints as an extra support for the septum especially when extensive reconstructive surgery has been performed.³⁵

Most surgeons protect the outer nasal skeleton after external septoplasty and nasal valve surgery by applying an external splint. Thermoplastic splints or Plaster of Paris can be applied without the need to pinch the nasal skeleton – an action that is best avoided if suturing or grafting techniques of nasal valve surgery have been employed.

COMPLICATIONS

Complications may arise from septal surgery but they are mostly due to poor surgical planning and operative techniques. These include bleeding, infection, saddle deformity, nasal tip depression, septal perforation, adhesion, septal haematoma, septal abscess, sensory changes including upper dental anaesthesia and upper incisors teeth discolouration.^{34, 36}

Certain aspects of nasal surgery may not necessarily be considered as complications but more as anticipated side effects; they should be discussed with patients (e.g. rigidity of the septum and nose after certain techniques especially bone grafting techniques; aesthetic changes associated with nasal valve surgery).

CONCLUSION

Septum and nasal valve both play important parts in the nasal airway. The result of nasal airway surgery is

dependent on the correct diagnosis and execution of the relevant techniques related to the offending segment of the nasal airway.

The patient must also be informed that almost all of the above nasal valve techniques will result in some aesthetic change to their nose. The option of surgical treatment should be discussed with this side effect in mind. When patients decline major nasal valve surgery which could result in noticeable aesthetic changes, a combination of septal surgery, turbinate surgery and minor nasal valve surgery can achieve comparable results with minimal aesthetic changes.³⁷

BEST CLINICAL PRACTICE

- ✓ In most cases of septal deviation, the septal L-strut is involved. SMR is not effective in these cases as it cannot address the caudal and dorsal struts; septoplasty techniques are needed.
- ✓ In certain situations, especially where the dorsal L-strut deformity is concerned, external approach septoplasty can improve surgical access.
- ✓ Certain aspects of nasal surgery may not necessarily be considered as complications but more as anticipated side effects.
- ✓ Nasal valve dilators (e.g. Breathe Right® or Nozovent® (Figure 103.12) and nasal steroid medications play a part in the non-surgical management of nasal valve obstruction.
- ✓ The most important aspect of paediatric septal surgery is to resect the cartilage conservatively and to avoid disrupting the endochondral ossification plates.
- ✓ In cases of severely fractured and deformed septum, the correction and reconstruction can be achieved through an open approach septorhinoplasty with the septum *in situ* or through extracorporeal techniques.¹¹

FUTURE RESEARCH

Studies on nasal airway surgery are often observational or retrospective. Variations in the causes of nasal obstruction, the surgical procedures performed and the outcome measures used to measure the change have added to the complexity of analyzing the evidence. It is often impossible to analyze the effects of one particular procedure in a study as often multiple procedures are used simultaneously in nasal airway surgery.

Nasal mucosal swelling, whether in its physiological form (i.e. nasal cycle) or in its pathological form (i.e. rhinitis), adds to the complexity of measuring the effects of surgical intervention. The same problem exists when employing objective measures such as rhinomanometry to measure the effect. There is a need for an objective tool to measure the nasal airway resistance and to identify the level of obstruction taking into account the nasal airflow. This tool should be able to measure nasal flow and resistance during nasal breathing to be able to detect the dynamic elements of nasal obstruction.

The subjective elements of nasal obstruction add to the complexity of analyzing the effects of surgical interventions as the lack of correlation between the subjective and the objective tools have been shown before in the literature.

Like other aspects of surgical practice, it would be very difficult and often unethical to conduct randomized controlled trials to produce the high level evidence for nasal airway surgery.

Future studies on surgical techniques need to have improved designs and their cohort needs to be comparable. Ideally only one surgical procedure needs to be performed so the effect can be measured solely on that particular procedure. Like any surgical study, the operator dependant factors play a part in the results and this needs to be taken into account when designing any study.

Tissue engineering is a rapidly developing field and further advances in this field would be very much welcomed by rhinoplasty surgeons who are always in need of cartilage for nasal support and nasal valve surgery.

KEY EVIDENCE

Several studies demonstrate a consistent benefit for nasal valve repair. Nasal airway surgery benefits are measured by patient-reported outcome measures (PROM) which are more clinically relevant than objective measures.

KEY POINTS

- Nasal airway surgery requires attention to the nasal septum as well as nasal valve areas.
- Correct diagnosis is essential in choosing the correct surgical technique.
- The patient's nasal airway should be examined in the neutral position using an endoscope.
- The nasal expiratory misting test can miss the dynamic elements of nasal obstruction.
- The nasal speculum can distort the anatomy and can hide the culprit.
- Cottle's manoeuvre is not a specific test for the external nasal valve.
- The nasal airway should be examined before and after topical decongestion to assess the effect of mucosal swelling on it.
- Most nasal valve procedures will have an aesthetic effect and the patient should be warned of these prior to the operation.
- Patient-reported outcome measures appear to be more clinically relevant than the objective measures.
- Nasal obstruction can be caused by septal deflection which can be developmental or secondary to trauma.
- In septoplasty, the attention is more on reconstruction rather than excision.
- Complications may arise from septal surgery but they are mostly due to poor surgical planning and operative techniques.
- There remains controversy about the optimal age and extent of septal surgery in the paediatric population.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search restricted to English papers using the keywords: septum, perforation, and reconstruction from a medline search as well as textbooks of otolaryngology published in English literature and local Audits.

INTRODUCTION

Definition: through and through defect or defects of the nasal septum. The exact prevalence of septal perforations is unknown as many perforations are asymptomatic, but in a general otolaryngology practice the clinician will encounter several patients with septal holes each year. Younger and Blokmanis¹ cite an incidence of just over 1%, which makes the condition relatively common. It must be remembered that racial traditions and fashion dictate that perforations in various parts of the body are a part of normal life and the anterior nasal septum is no exception. The majority of perforations involve the anterior quadrilateral cartilage of the septum. Kuriloff² has provided an extensive list of the local and systemic causes (Table 104.1). Currently, the most common cause of perforation in the UK is probably local trauma, although in a significant percentage, no clear history exists attracting the label of 'idiopathic'. The trauma is frequently self-induced or iatrogenic following surgery to the nasal septum or nasal instrumentation. Injuries to the cartilagenous skeleton of the nose may result in perforation through a compound fracture of the quadrilateral cartilage in the absence of any external deformity. Recreational drugs, for example crack or cocaine snorted nasally, are becoming increasingly common as a cause of septal necrosis.³ The prevalence of chronic specific infections producing perforations

is small, but there are a significant number of inflammatory conditions which should be excluded, particularly if the history does not give an easy clue to the aetiology.

SYMPTOMATOLOGY

The principle symptoms associated with perforations are crusting, epistaxis and whistling. Other symptoms include a feeling of dryness, emptiness in the nose or a general feeling of discomfort. In a series of 69 septal perforations, Brain⁴ showed that 62.4% were completely free from any symptoms. Size and position of the hole had a direct bearing on the presence of symptoms. Anterior perforations and large perforations where the anterior margin is in front of the nasal valve appear to be the most troublesome. This probably relates to the relatively slow mucociliary clearance from the anterior septum, low humidity in the anterior nares compared to controls⁵ and the loss of mucosa, all contributing to dryness and crusting. The accumulation of large crusts around the margin of the perforation produces a sensation of blockage. With large stable perforations, patients may feel the nose is empty or complain of 'blockage', even when nasal airflow is greater than average. These features may be due to turbulence of airflow in the nasal vestibule, although there is little evidence to support this. Huge perforations produce a common nasal cavity resulting in rhinolalia and an inability to

TABLE 104.1 Aetiologies of nasal septal perforations

Traumatic causes	Surface irritants	Infections	Neoplastic	Inflammatory
Nasal surgery	Cocaine insufflation	Syphilis	Melanoma	Sarcoidosis
Nose picking	Cocaine adulterants	Typhoid	Adenocarcinoma	Crohn's disease
Septal cauterization (bilateral)	Heroin inhalation	Diphtheria	Squamous cell carcinoma	Dermatomyositis
Nasal packing for epistaxis	Decongestant nasal sprays Intra-nasal corticosteroids	Tuberculosis	Metastatic carcinoma	Rheumatoid arthritis
Septal hematoma/abscess	Lime, cement, glass, salt, dust	Rhinoscleroma	Lymphoma	Relapsing polychondritis
Cryosurgery	Tar and pitch	Lepromatous leprosy		Granulomatosis with polyangiitis (GPA)
Intubation (nasogastric/tracheal)	Fumes (chromic/sulfuric acid)	Leishmaniasis		Systemic lupus erythematosus
Desiccation (ozena, deviated septum)	Arsenicals, mercurials	Mucor		
Radiation	Calcium nitrate, cyanide	Rhinosporidiosis		
Stab and gunshot wounds	Phosphorus, sodium carbonate	Alternaria		
Foreign bodies (button batteries)	Copper-smelting fumes	Actinomycosis		
		Aspergillosis		
		Histoplasmosis		
		Cryptococcosis		
		Coccidioidomycosis		
		Paracoccidioidomycosis		
		Candidiasis		

clear secretions.² Nasal mucosal cooling is associated with increased sensation of patency but this does not correlate with clinical observation in patients with nasal perforations whose intra-nasal temperature rises after successful closure.⁵

Inflammation in the perforation margin leads to recurrent epistaxes, often triggered when the crust separates or is removed. Epistaxis can be quite significant from the sphenopalatine vessels. Large areas of mucosal deficit, particularly where there is cartilage exposure, prevent normal mucus clearance, contributing to localized infection and more inflammation. The local inflammation in the nose is often perceived as a generalized sense of discomfort, felt internally and over the nasal bridge. Over time, necrosis of septal cartilage will lead to enlargement of the hole in 'active perforations', sometimes to such a size that surgical closure is impossible.

CLINICAL ASSESSMENT

A full history is necessary when investigating septal perforations to cover the wide range of aetiologies. Principally, it is important to identify episodes of nasal trauma, cautery or surgery and, in particular, a history

of substance abuse. Though patients may often deny it, aggressive nasal self-toilet with digital trauma or tissues will convert an inflamed mucous membrane to an ischaemic crusty area which ulcerates – the so-called 'pick ulcer'. Continued attempts to remove the crust invariably lead to cartilage exposure, cartilagenous necrosis and subsequent perforation.

An overall assessment of the external and internal nasal skeleton should be made together with nasal endoscopy. Endoscopy is the best method to assess the margins and state of the residual septum. Measurement of the dimensions of the hole is performed by introducing a small paper ruler into the contralateral airway and reading the scale through the hole. Saddle deformities, deviations of the nose or septum, columella retraction and intra-nasal adhesions are commonly seen and may require reconstructive rhinoplasty techniques to correct if surgery is contemplated. Nasal questionnaires using a linear visual analogue scoring system may be used as a measure of symptom severity. Although not essential in routine clinical practice, they do provide subjective assessment for comparing pre- and post-treatment symptoms and are a basic measure of outcome (Figure 104.1). Other outcome measures via validated questionnaire have been used to measure patient benefit from surgical repair.⁶

Nasal septal perforation questionnaire

NAME:

Please mark you own score by marking a line at the appropriate point.

0 = No symptoms, 10 = Worst symptoms.

		1		10
1	Crusts/scabs	<input style="width: 100%; height: 15px;" type="text"/>		
2	Nose bleeds	<input style="width: 100%; height: 15px;" type="text"/>		
3	Whistling	<input style="width: 100%; height: 15px;" type="text"/>		
4	Nasal discomfort	<input style="width: 100%; height: 15px;" type="text"/>		

Please mark the appropriate point for your symptoms in Questions 5 and 6

5	My nose feels empty	<input style="width: 100%; height: 15px;" type="text"/>	My nose feels blocked
6	Can clear secretions easily	<input style="width: 100%; height: 15px;" type="text"/>	Can't clear secretions at all

Figure 104.1 Nasal septal perforation questionnaire.

SPECIAL INVESTIGATIONS

Because of the wide range of aetiologies for septal perforation, history-taking is crucial. Any signs of inflammation around a perforation, however, should prompt investigation of other anatomical areas in the head and neck, as well as investigations for systemic inflammatory conditions. Nasal perforations may be the first sign of various granulomatous disorders, including Wegener’s granulomatosis, and occur with a variety of collagen disorders including relapsing polychondritis, systemic lupus erythematosus (SLE) and dermatomyositis. Of the infective causes, the clinician is guided by the health of the patient, but tuberculosis and syphilis should be excluded. A full blood count, erythrocyte sedimentation rate (ESR), urea and electrolytes, urine analysis, C-ANCA, treponemal investigations, ACE titres and a chest X-ray, together with a nasal swab, provide an adequate baseline. Other symptoms of inflammation in the respiratory tract, for example cough, middle ear effusions, an arthritis or skin rash, should prompt referral to a clinical immunologist.

There is little evidence that extensive investigations for patients with healed, stable and asymptomatic perforations contribute to a change in the management, particularly where the aetiology is clear. Routine biopsy of septal perforations to exclude vasculitis has been suggested,^{6,7} but biopsy rarely reveals anything other than chronic inflammation and is not usually sufficient for a specific diagnosis. Indeed, biopsy may convert an inactive perforation to an ‘active state’, resulting in significant enlargement of the hole. The role of routine biopsy in idiopathic perforations has recently been questioned. In two retrospective series, septal biopsy was shown to be non-specific for Wegener’s and was only of value in those perforations

with an irregular margin which were clinically malignant.^{8, 9} It is clear that the diagnosis of Wegener’s or its reactivation cannot be reliably inferred from biopsy of the nasal septum alone. Practically, therefore, perforations should be biopsied if there is an unexplained aetiology, with persistent inflammation, or if the perforation is irregular. Specimens should be examined for mycobacteria and fungi, and with immunocytochemistry to exclude a neoplasm.²

PREVALENCE OF SEPTAL PERFORATIONS

The prevalence of septal perforations following nasal septal surgery shows wide variation and has been reported as between 1.4% and 25%. The prevalence appears higher after submucous resection operations (17–25%) than the more conservative septoplasty procedures (1.4–5%).¹⁰ The use of nasal splints during septal surgery is known to produce a higher incidence of perforation.¹¹ Splinting is unnecessary in the majority of routine septal surgery unless established adhesions are being treated. Recent retrospective reports¹² have suggested an association between nasal steroid sprays and the development of nasal perforation. It is known that all steroid sprays can cause inflammation over the caudal septum, by direct irritation or their initial vasoconstrictor activity, particularly if there is a septal deviation which takes the brunt of the spray jet. Patients should be directed to use the spray with the opposite hand to the nostril being treated, minimizing the impact on the septum. Any ulceration after starting steroid spray use should be allowed to heal by withdrawing the medication.

MANAGEMENT

The majority of septal perforations are asymptomatic and require no specific treatment.⁴ The more anterior the lesion, the more likely it is to cause symptoms. This probably relates to accessibility by the patient to pick at the nose, but may also be related to fast airflow producing drying in the region of the internal nasal valve. The management can be divided into three groups.

PREVENTION

In a series of 50 perforation repairs at the Royal National Throat, Nose and Ear Hospital, 60% had a previous history of septal surgery. Meticulous attention to technique is required in elevating the mucoperichondrial flaps in the correct plane, particularly avoiding overlapping bilateral mucosal tears. Starting the dissection on the easier (usually the concave) side to raise one intact flap first, and using an autograft of cartilage or ethmoid plate to support any tears, is good practice. The mucoperichondrium over large spurs is often very thin, and tears may be inevitable. However, when the spur is removed, there will be a relative excess of mucosa which can be repaired with absorbable sutures. Quilting sutures in the septum after surgery should be tied loosely to allow for post-operative oedema. The authors have seen perforations caused by individual sutures tied tightly in the septum which resulted in ischaemic necrosis. Septal inflammation or ulceration should be treated by withdrawing the source of the irritation and promotion of healing, for example by eradication of pathogenic bacteria, avoidance of aggressive cleaning and use of mucosal protectants (petroleum jelly, sesame seed sprays). Antiseptic silicon barrier creams over 6–8 weeks will stabilize the mucosa in the majority of cases. In recalcitrant inflammation, thin reinforced silastic sheeting can be sutured to cover the caudal septum. If there is a large area of cartilage exposure, however, this still may not be sufficient to prevent progression to perforation. When a septal ulcer heals, the scar produced may leave a persistent area of squamous metaplasia which never reverts to a mucosal surface. Periodic and regular use of barrier creams may be necessary or the regular application of sesame seed oil which has a longer duration of effect than simple saline douching.

NON-SURGICAL

This, essentially, is aimed at reducing the drying effect in the nasal mucosa to alleviate crusts and epistaxis. Alkaline nasal douches, proprietary saline sprays and petroleum-based ointments are commonly used. There are no studies of the effectiveness of this type of regimen, but many patients adopt a twice daily ritual of douching and ointment application. It is usually obvious within 6–8 weeks whether this will be effective in maturing the margins of a perforation.

OBTURATION

The principle of obturation is to cover the inflamed mucosal margin. In 2002, Meyer¹³ cited the use of septal obturators in the management of perforations. Inert sheeting (usually silastic) was placed to prevent drying and encourage epithelialization over the cartilage/bony septum to create a mature mucosal edge. Evidence suggests that patients do derive benefit from the use of nasal obturators, but opinion on their usage and effectiveness is divided. Facer and Kern,¹⁴ in a retrospective study of 73 patients, reported 72.8% of obturators remained in place, but 27.4% of buttons were removed or were extruded. Brain⁴ described the long-term outcome of 102 patients with medium or large holes (1 cm perforations or larger). He described a good result in 44.4 and 32.4%, respectively. The main benefit from obturation appears to be the control of whistling and epistaxis. Often, crusting and nasal discomfort remain a problem.^{6, 15} The feeling of obstruction is improved when crusting is reduced, but the bulk effect of an obturator may increase blockage, particularly in anterior perforations with a narrow nasal valve. Poorly tailored silastic may irritate the mucosa, particularly with anterior holes close to the membranous septum. Patient interference and movement of the mobile membranous septum against the edge of the obturator can lead to granuloma formation. It is often for these reasons that patients request removal of the obturator.

SURGICAL

Enlargement of a nasal septal perforation to prevent whistling was described by Jackson and Coates in 1922,¹⁶ but there is little evidence to support its routine use in clinical practice. One retrospective article of widening of the perforation and posterior edge repair in larger holes (15–50 mm) evaluated the pre- and post-operative symptom scores obtained by a linear visual analogue questionnaire. Benefit was reported for the symptoms of crusting and epistaxis and overall nasal discomfort with a significant reduction in mean scores. This technique appears to offer some value for patients with persistent inflammation who could not retain a nasal obturator and who were deemed unsuitable for surgical repair.

SURGICAL REPAIR OF SEPTAL PERFORATIONS

The plethora of techniques for septal perforation repair described over the years attest to the fact that there is still a challenging technical problem for the nasal surgeon, although reliable surgical techniques with good outcomes have been published in the last 15 years. The variety of repairs may be classified as:

- Free grafts:
 - simple or composite autografts
 - allografts

- Pedicled flaps:
 - local nasal mucosal
 - buccal mucosal
 - composite septal cartilage and mucosa
 - composite skin/cartilage
- Rotation/advancement of mucoperichondrial or mucoperiosteal flaps.

Combinations of techniques have been employed in many small reports. In the larger series of observational outcomes of perforation repairs, two factors emerge that appear to have an important bearing on a successful outcome, to achieve closure in 80–90 % of cases. The first is that there is sufficient residual mucosa in the nasal fossa which can be mobilized and transposed allowing direct suturing of the mucosal defect (Figure 104.2).

The second is the routine use of a connective tissue interposition graft to support the repair. Bilateral mucosal flaps with the main blood supply derived from the sphenopalatine vessels form the basis of most techniques. Grafts have been reported using temporalis fascia,¹⁷ mastoid periosteum, cranial periosteum, cartilage (septal, auricular, rib) perichondrium and bone (either locally or from rib or the iliac crest).^{18, 19} Small defects can be closed with bipediced flaps, by making relieving incisions either superiorly or inferiorly.²⁰ Larger holes up to about 2 cm require larger flaps which are pedicled only posteriorly based on the sphenopalatine vessels, and are effectively transposition/rotation flaps.^{1, 20–23} Even if complete bilateral mucoperichondrial suturing of the hole is not possible, the use of a connective tissue graft between the leaves allows for epithelialization on the side of incomplete closure, as long as the flaps are protected from drying out and the reconstruction does not get infected. In the

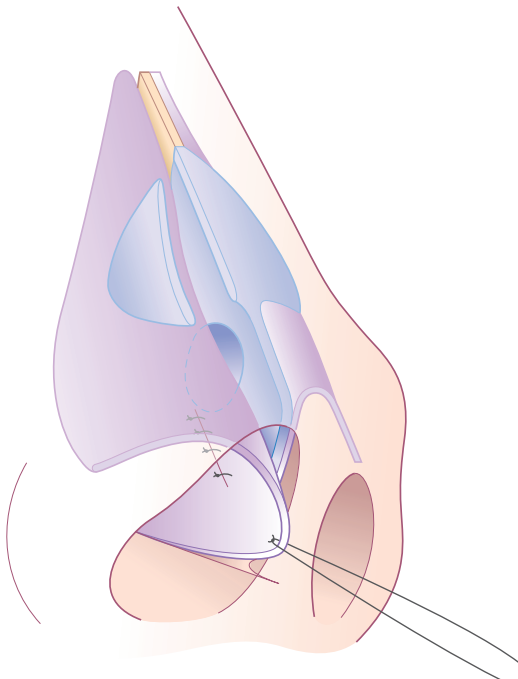

Figure 104.2 Extensive mobilization of the mucosal lining allows a round hole to be closed with sutures in a straight line.

presence of any dehiscence of the sutured mucosal defect, it appears that epithelialization occurs more reliably over fascia than cartilage or bone. Reports using acellular dermal allografts^{24, 25} instead of fascia appear to give similar success rates. The allografts are expensive, but it must be remembered that donor site morbidity from fascia is not a major issue and the repair is entirely the patient's own tissue. The use of other collagen xenografts may be an alternative. The primary author has used at least two layers of either temporalis or temporoparietal fascia, if necessary with a sandwich of cartilage as a composite graft where there is little supporting remaining quadrilateral cartilage (Figure 104.3), for the last 6 years with a current success rate of 87%.

Auricular cartilage, which is a useful graft, is often curved and care should be taken anterosuperiorly at the internal valve because any excess thickness at this level risks post-operative nasal block, requiring revision surgery. Where this may be a problem, a combined approach by raising an anteriorly based turbinate flap endoscopically either alone or with mobilization of mucosa from the floor and upper nose will often allow a tension free repair of the hole without the need for a cartilage graft between the layers. The patient should be counselled that a second usually minor procedure to divide the pedicle of the flap may be required at about 3 months if restriction of breathing is still present.

The nasal fossa is a contaminated area and therefore antibiotic prophylaxis is important. There are no studies as to the ideal length of the course, but the development of sepsis can have a potentially devastating effect on the residual cartilage producing a saddle deformity. Currently, the authors give a 10-day course and supplement this with topical antibacterial ointment.

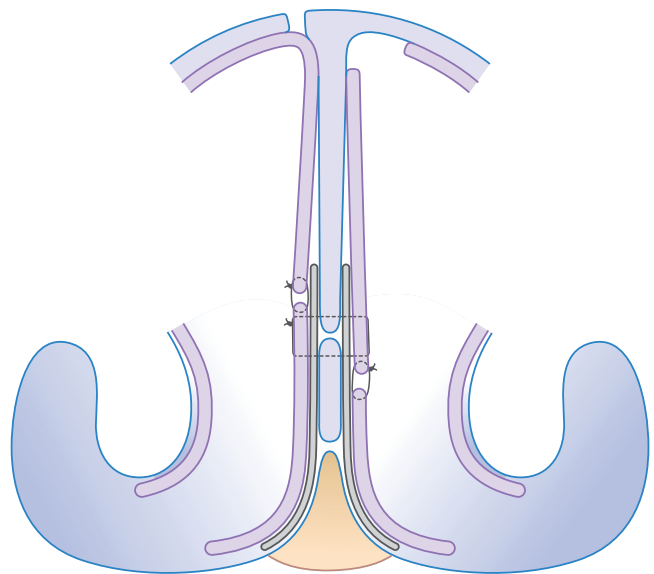

Figure 104.3 Bilateral mucosal flap repair with staggered mucosal rotation/transposition flap closure and connective tissue interposition graft. The fascia should extend to the nasal floor to cover any secondary defect inferiorly.

There is an anatomical limit to the amount of septal mucosa which can be transposed and this is directly inverse to the size of the septal hole. Large perforations (larger than 2.5 cm), particularly with a large vertical dimension as opposed to horizontal linear holes, still pose a problem. However, by extensive undermining along the nasal floor and inferior meatus inferiorly and under the upper lateral cartilage superiorly, substantial flaps may be created. The careful atraumatic elevation of flaps is technically demanding, particularly if the mucoperichondrium is inflamed, atrophic or there is a significant spur of the septum. The surgeon has four options for the approach.

Endonasal¹⁷

This approach is limited principally by nostril size and position of the hole. Design of the endonasal flaps is critical in this approach due to the limited access. Broad-based elevations via hemitransfixion incisions and bipediced flaps preserving anterior and posterior blood supplies with horizontal relieving incisions together with interposition grafts should give very good results for small holes (up to 0.5 cm).

Endoscopic

An anterior pedicled turbinate flap is raised to include the mucosa of the medial and inferior surfaces, reflected forwards and sutured to the margins of the septal perforation following submucosal mobilisation.¹⁸ Bilateral flaps provide a more secure repair although if the pedicle remains bulky, a second procedure to divide the attachment may be required. Unilateral septal flaps based on the anterior ethmoid vessels and including mucoperiosteum from the nasal floor can be transposed forward and sutured on one side to the margins of the hole.¹⁹ The opposite side epithelializes over several weeks and disturbance of the valve is minimal.

External rhinoplasty

Approach via a trans columella approach²¹ or a columella-philtrum incision: The external approach or its

modification by sectioning the columella below the medial crural footplates and connecting to a transfixion and intercartilagenous incisions provides excellent exposure of the septum and lower dorsum, particularly if concomitant rhinoplasty is required and especially when additional grafting is needed to the nasal valve or dorsum. Alar crease incisions only provide limited additional unilateral access and should not be combined with the trans-columella approach because of the risk of ischaemia to the columella flap. It is possible to design larger flaps through this approach and suturing of the mucosal hole is definitely easier than by the endonasal approach. The use of medially based pedicled buccal mucosal flaps have limited use for larger perforations, but are useful to repair secondary deficiencies of the membranous septum when the mucosa has been mobilized to close very anterior holes.

Mid-face degloving approach²⁶

This is an extensive dissection of the face which has been employed for very large holes (>2 cm). Used purely as an approach with standard rotation transposition mucosal flaps, it appears to offer little benefit over an external approach for successful closure but with a higher complication rate (vestibular stenosis, 20%). Variation of the technique by employing tissue expansion of the mucosa and skin grafting to the nasal sill appear to improve the success rate and reduce the incidence of nasal vestibular stenosis. Tissue expansion is achieved along the nasal floor using a small (1 × 3 cm) expander over 6–8 weeks with a total volume of 4–7 mL. This technique has the advantage of generating more lining for easier mucosal closure, but the extensive relatively traumatic dissection must be weighed against the degree of benefit to be gained by the patient. Reported success in this series was 18 out of 22 patients with holes from 2 cm to 4 cm diameter.

Although there is evidence of good technical success in surgical repair of the perforated septum for small–medium sized holes, objective evidence of patient benefit following surgical closure is limited. Lindemann et al.⁵ have shown improvements in nasal physiology particularly in end-inspiratory humidity and a reduction in symptom scores for epistaxis and nasal dryness.

BEST CLINICAL PRACTICE

- ✓ Meticulous attention to technique in the execution of septal surgery with adequately supported repair in the event of mucosal tears.
- ✓ Referral to specialist rhinologist/facial plastic surgeon for repair of small- to medium-sized holes.

FUTURE RESEARCH

- More supporting evidence of outcome measures including general health status is needed to confirm the benefits of surgical repair.
- Tissue engineering with the possibility to produce cartilage sheets and stable collagen as implants, which are guaranteed free from infection, will remove the need for a donor site.

KEY POINTS

- More than half of perforations are asymptomatic and do not require treatment.
- Trauma is the most common cause of septal perforation.
- Small to medium holes can be closed reliably by surgery.

SEARCH STRATEGY

Data in this chapter may be updated by a search using the keywords: turbinates, nasal surgical procedures, nasal obstruction and nasal procedures.

MANAGEMENT OF ENLARGED TURBINATES

Introduction

The inferior turbinates are dynamic structures that form a crucial part of the normal functional nose. However, they are structures that are relatively easy to access. They have been recognized as a cause of nasal obstruction and therefore subject to numerous operative techniques to either reduce their size or excise them completely.¹ Various surgical techniques of turbinate reduction or destruction have been described since the

middle of the 19th century. Despite a declining trend in England (United Kingdom), inferior turbinate reduction surgery remains a commonly performed procedure in ENT practice (Figure 105.1). Contemporary otorhinolaryngological literature states that the evidence base for the multitude of techniques for turbinate reduction is weak and that surgeons empirically offer surgery where the predominant symptom is nasal obstruction.² In fact, there is currently no ideal surgical procedure and most techniques offer only short-term benefit.³ Paradoxically, most specialist rhinologists who devote a major part of their practice to conditions of the nose perform surgery to the inferior turbinate infrequently.

Figure 105.1 Trends in adult turbinate surgery in England from financial year 2000 to 2016. E04.1 = Submucous diathermy to turbinate of nose. E04.2 = Excision of turbinate of nose NEC. (Source: Hospital Episodes Statistics, <http://content.digital.nhs.uk>)

History of turbinate surgery

Operative techniques to reduce the size of the inferior turbinates have been practiced since 1845. The first technique to be described was electrocautery: at the time this was being used for a wide variety of non-nasal medical complaints, justified by the misconception of nasal reflex neurosis. Hol and Huizing⁴ described 13 techniques of inferior turbinate reduction up to the present day.

Anatomy of the inferior turbinates

The inferior turbinate consists of a supporting cancellous conchal bone, named after the Greek for scroll, covered by specialized erectile mucosa.⁵ The turbinate is attached along the inferolateral aspect of the nasal cavity, extending from the inferior nasal valve to just anterior to the Eustachian tube. The conchal bone is firmly attached to the inferomedial surface of maxilla. The adjacent maxilla is very thick anteriorly and becomes thin in the midsection of the nose. The conchal bone is not a completely straight structure but curves superiorly reaching its highest point in the mid nasal cavity. The nasolacrimal duct opens into the superior aspect of the inferior meatus just between the thick anterior bone and the thin section in the mid part of the nose. The entrance of the nasolacrimal duct is protected by Hasner's valve.

From the applied point of view, these anatomical points are important to appreciate: during antral washout the trochar is passed into the inferior meatus below the turbinate to puncture the lateral wall of the nose into the maxillary sinus. The superior part of the attachment of the inferior turbinate is thin in the midsection of the nose and puncture is generally easy.

The blood supply is from the lateral branch of the sphenopalatine artery that enters the posterior aspect of the turbinate. Sensation is supplied by the trigeminal nerve; sympathetic nerves travel along the feeding arterial blood vessels; the parasympathetic supply also travels along the vascular supply but travels along the vidian nerve before entering the nose through the sphenopalatine foramen.

Physiology in health

The inferior turbinate is an important functional component of the normal nose. It warms inspired air and maintains linear rather than turbulent airflow within the nose.⁶ The turbinate is covered by a functional ciliated pseudostratified respiratory mucosa that is supported by a lamina propria, below which is a vascular layer rich in venous sinusoids (Figures 105.2a and 105.2b).

The normal inferior turbinate is a dynamic structure that varies in size according to the degree of congestion. The latter is determined by the control of blood flowing through the specialized erectile tissue. This change is governed by the autonomic neural supply: the sympathetic nerves induce reduction of blood flow and a decrease in volume whilst the parasympathetic supply congests the erectile tissue of the turbinate. The degree of congestion varies in a cyclical manner in a healthy nose every few hours and is coordinated so that when one side is congested the other is constricted. This phenomenon is known as the nasal cycle: it can be demonstrated in about 80% of humans but the purpose is unknown.⁷

Definition of an enlarged inferior turbinate

Operations to reduce the size of the inferior turbinate are generally based on the fact that it is enlarged. However, in clinical practice, this is usually a subjective assessment and diagnosis is normally made by exclusion criteria when dealing with the sensation of nasal obstruction. Various terms are used to describe this enlargement and there is a lack of standardization.⁸ The various terms include hypertrophic, congested, hyperplastic, and engorged turbinates.

In practice, gross congestion of both inferior turbinates in a patient with severe rhinitis may be obvious. However, it is important to appreciate that congestion may reflect stages of the nasal cycle. It is therefore important to consider the effect of spraying a topical decongestant onto the inferior turbinates before accepting the fact that the inferior turbinates are chronically congested.

Figure 105.2 Histology IT1 (a); Histology IT2 (b).

Histological studies of bilaterally enlarged inferior turbinates have shown dilated congested venous sinuses, subepithelial inflammatory cell infiltration, fibrosis of the lamina propria, and dilatation of mucous gland ducts.⁵ Other changes include an increase in pseudostratified surface epithelium, goblet cells and mucous gland acini. Histology of inferior turbinates from patients with non-allergic perennial and allergic rhinitis has shown degenerative change and fibrosis in the lamina propria in the non-allergic group whereas the allergic turbinates showed gross tissue oedema.⁹ In patients with septal deviation and contralateral inferior turbinate enlargement, an additional finding has been a two-fold increase in the bony concha compared to cadaver controls.

It is of note that the medial aspect of the mucosa is thickest in an enlarged turbinate.¹⁰ It has been suggested that surgery should therefore be targeted to the mucosa over the medial aspect of the turbinate and the inferior section that is rich in vascular sinusoids.¹¹

Pathogenesis of inferior turbinate enlargement

Whilst assessing a patient with enlarged inferior turbinates, it should be helpful to categorize the enlargement according to a classification proposed by Hol and Huizing.^{4, 12} The individual categories are judged according to clinical features as follows:

1. Compensatory hypertrophy
2. Protruded turbinate
3. Hyperplasia of the turbinate head
4. Hyperplasia of the whole turbinate
5. Hyperplasia of the turbinate tail.

Compensatory hypertrophy of the inferior turbinate is seen when the nasal septum is deviated to the opposite side, and the turbinate seems to fill the empty space. **Protrusion** is where the turbinate extends more medially into the nasal cavity than expected. It may be more apparent on the coronal CT images when the conchal bone may be seen to make a less acute angle with the lateral nasal wall. Hyperplasia of the turbinate head and whole length of the turbinate may both occur with chronic rhinitis. Should the head enlarge, the turbinate may enlarge anteriorly and obstruct the nasal valve. Hyperplasia of the posterior end is said to occur in patients with chronic sinusitis and post-nasal discharge.

In patients with rhinitis, the effect of the nasal cycle is accentuated; patients may become aware of the cycling effect on their sensation of nasal obstruction that may become significantly worse whilst in the supine position due to nasal reflexes. In patients with severe forms of rhinitis or significant rhinosinusitis, the inferior turbinates may become chronically enlarged. This effect becomes even more so should the patient self-medicate with xylo-metazoline to try and decongest the nose.

Sarcoidosis is an unusual disorder that may cause quite severe inferior turbinate enlargement and should be

considered if the turbinates do not respond to normal topical treatments for rhinitis.

Clinical features

Patients with enlarged inferior turbinates will invariably present with nasal obstruction. The complete nasal symptom complex together with nasal examination and endoscopy will normally lead to the correct clinical diagnosis of allergic or non-allergic rhinitis or chronic rhinosinusitis. The anterior head of the congested inferior turbinates may appear as a red swelling or be pale and purplish: the latter is typically associated with severe allergic rhinitis (**Figure 105.3**). The swollen anterior end is easily visible on examination of the nose and in primary care this is often mistaken for an inflamed nasal polyp.

Ideally, the nose should be examined before and 10 minutes after mucosal vasoconstriction: chronically congested inferior turbinates normally do not reduce in size but remain large. This is important to note if turbinate surgery is being considered.

Imaging is not normally required unless surgery is being considered for rhinosinusitis. However, when available, helpful information about the turbinates may be demonstrated. CT is the best imaging modality (**Figure 105.4**), although MRI may also yield useful information (**Figure 105.5**).

Physiological evaluation of the inferior turbinates

Nasal obstruction is a subjective symptom that has a complex pathophysiological mechanism that is not yet fully explained.¹³ It is not an uncommon phenomenon to find discordance between reported severity of nasal obstruction and clinical findings. It is thus important to measure the degree of obstruction in order to monitor the effects of surgery and audit the effectiveness of medical/surgical intervention. This can be done with a visual

Figure 105.3 Gross enlargement of the right inferior turbinate in allergic rhinitis.

Figure 105.5 Enlarged right inferior turbinate and septal deviation to the left: endoscopic view and MRI appearance.

analogue scale and the 22 question Sino-Nasal Outcome Test (SNOT-22).

A few departments will have access to physiological measuring techniques (Figure 105.6) such as acoustic rhinometry, anterior rhinomanometry and rhinospirrometry. These tools can demonstrate the degree of obstruction, the difference between each side of the nose and the change with nasal surgery. In the research setting measurements can be obtained before and after vasoconstriction, but in the clinical setting, this is not practical, and mucosal vasoconstriction should be induced in all cases. An overall assessment of the degree of nasal obstruction can also be obtained by measuring the peak nasal inspiratory flow using a specific nasal spirometer.

MEDICAL TREATMENT FOR THE ENLARGED INFERIOR TURBINATE

Firstly, rhinitis medicamentosa due to chronic abuse of vasoconstrictor agents should be sought and excluded. If present, the patient should be counselled on inducing factors and that their nose will become more obstructed until recovery starts to occur.

There is no contention amongst ENT specialists that the first line of treatment for enlarged inferior turbinates is medication. Topical nasal steroids are the mainstay of treatment for both allergic and non-allergic rhinosinusitis.

However, prolonged once/twice daily treatment for at least 3 months is necessary, with reassurance that topical nasal steroids are safe to use every day. Topical steroids are often combined with oral antihistamines, antibiotics and saline in the treatment of chronic rhinosinusitis.¹⁴

However, should medical intervention fail to provide good control, the option of surgery needs to be considered.

SURGICAL MANAGEMENT FOR THE ENLARGED INFERIOR TURBINATE

Surgery should ideally be restricted to patients with a significant symptomatology in whom operative intervention is likely to be effective. However, this is an area where there may be much diversity in opinion and practice with regard to the management of the inferior turbinate. As previously stated, it is paradoxical that specialist rhinologists operate on the inferior turbinate infrequently, but turbinate surgery is still a common procedure in the generality of the speciality. The explanation for this diversity is that with perceived enlargement of the turbinate it is very tempting to just reduce the size of the turbinate and this will generally result in an improved nasal airway. However, without addressing the driving forces for the condition, it is likely that any beneficial effect from inferior turbinate surgery will be short-lived. On the other hand, if underlying chronic rhinosinusitis is identified and corrected by

endoscopic sinus surgery, with or without septal deformity surgery, the turbinate will often respond in a positive way without the need for turbinate reduction surgery.

As well as the diversity of opinion as to when to operate on the inferior turbinate, there is also a wide range of different operations and techniques, each with their own proponents.

It is not realistic to expect that this situation will ever become standardized, but it may be possible to modify the way that surgeons perceive the inferior turbinate.

Perhaps the most important aspect to consider when operating on the inferior turbinate is to preserve the mucosa and maintain the mucociliary transport.

A simple system of classifying turbinate operations is proposed in [Box 105.1](#).

It may be necessary to excise the inferior turbinate for access during tumour surgery such as removal of an angiofibroma or inverted papilloma within the maxillary sinus. Resection may also be necessary in treating malignancy such as adenocarcinoma or melanoma. The inferior turbinate has been utilized as a pedicle graft in the closure of septal perforations or as a free graft source for repairing dural defects in the anterior skull base.

Individual techniques

The authors recommend that ideally inferior turbinate reduction should be restricted to submucosal mucosal preservation techniques where at all possible to minimize the risk of complications. However, acknowledgement is given to the fact that alternative techniques such as mucosal reduction by a microdebrider is safe and effective in experienced hands.

It is also acknowledged that some techniques require specific technology that may be expensive and it is unlikely that any one department will have a choice of all of the possibilities.

All techniques require mucosal vasoconstriction to minimize bleeding during the procedure. Performing the

surgery under endoscopic control facilitates precision surgery with minimal collateral damage.

MUCOSAL PRESERVATION SURGERY

The two simplest low-cost techniques are lateralization by outfracture and submucosal diathermy.

Lateralization

Lateralization by outfracture can be done by simply using an elevator to mobilize the concha by infracture, and then pushing the whole turbinate laterally. Although this probably results in the least improvement in the airway of the various techniques, it is very low risk, but can often be used as an adjunct to septal surgery or endoscopic sinus surgery to facilitate access to the nose. An alternative that may give a more effective result is to create a submucosal tunnel and outfracture the concha in segments via this tunnel.

Submucosal diathermy

Submucosal diathermy (SMD) is performed by passing an insulated Abbey™ needle along the length of the inferior turbinate in 2–3 different passes, and applying the diathermy at 70 W, as the needle is withdrawn. SMD is monopolar diathermy that generates intense heat at the electrode tip. This causes tissue destruction, inflammation and fibrosis. Initially, the nose is likely to feel more blocked until healing has occurred. There is a risk of extensive tissue destruction following excessive diathermy and the necrotic inferior turbinate will slough and crust over a prolonged period.

Classically, it is said that SMD will only be effective in patients that demonstrate good pre-operative turbinate reduction after applying a topical decongestant. Short-term results are good but this effect is often not maintained in the long term.

SUBMUCOSAL TECHNIQUES REQUIRING SPECIFIC TECHNOLOGY

Turbinate reduction can be achieved very effectively with a mini-microdebrider. A submucosal tunnel is created through a small incision of the anterior end of the turbinate ([Figure 105.7](#)). The erectile tissue can be reduced over the medial and inferior part of the turbinate by partial resection with a 2 mm diameter oscillating mini-microdebrider blade. Post-operative nasal packing is not necessary. This technique is effective, carries minimal risk, and the microdebrider can be controlled to preserve all of the overlying mucosa.

Submucosal microdebrider reduction has been combined with a procedure to divide the posterior nasal nerve at the sphenopalatine foramen. This procedure is known as functional inferior turbinosurgery (FITS) and aims to interfere with the autonomic control and reduce turbinate sensation.¹⁵

Mucosal preservation surgery

- Lateralization by outfracture
- Mini-microdebrider surgery
- Radiofrequency
- Coblation
- Turbinoplasty
- Submucosal diathermy

Mucosal destructive reduction surgery

- Superficial cautery
- Chemocautery with chromic acid or trichloric acid
- Cryosurgery
- Laser surgery
- Direct microdebrider mucosal reduction

Turbinate excision procedures

- Partial
- Subtotal
- Posterior end

Coblation® techniques utilizes a narrow electrode or wand that creates low temperature plasma of 85 degrees and effectively dissolves tissue and later induces fibrosis. Radiofrequency (RF) has also been used with good effect and utilizes high frequency alternating current to generate heat and ablate tissues.

All of the submucosal techniques allow for precise surgery that can be performed under endoscopic control. Reports suggest the techniques are effective and can be repeated if needed.

Turbinoplasty

This technique is designed to preserve functional mucosa over the surface of the turbinate whilst achieving substantial reduction in the volume of the turbinate. The turbinate is initially in-fractured and an incision made over the anterior head and along the inferior margin (Figure 105.7). The mucosa is elevated from both sides of the bony concha. The concha is then resected in varying degrees. The lateral mucosa is removed with a microdebrider and the medial mucosa placed so that it lies laterally and forms a 'neoturbinate'. The anterior end of the turbinate is typically reduced and moved away from the nasal valve by this technique. Support dressings are then placed in the nose.

Mucosal destructive reduction surgery

Some of these procedures will destroy the specialized mucosal surface of the turbinate and may cause long-term crust formation and underlying infection with prolonged

healing. It has been suggested that there is very little to justify some of these techniques in modern day surgery.¹

Turbinate excision techniques

These are much more radical techniques than the techniques described above.

Radical subtotal resection of the turbinate operation includes resection of the mucosa and bony concha along the length of the inferior turbinate (Figure 105.8). This operation can be painful and has a much greater chance of damaging the lateral branch of the sphenopalatine artery and cause heavy epistaxis. It also carries long-term risks of crusting and the empty nose syndrome (*vida infra*).

To reduce the risk of significant complications and improve the airway at the region of the nasal valve, the operation of partial resection was devised. The enlarged anterior head and anterior third of the inferior turbinate are excised (Figure 105.9). The line of resection is first crushed to limit bleeding. Angled scissors are then used to excise the required section of turbinate. This can be done utilizing a headlight but an endoscope gives greater precision.

Enlargement of the posterior end of the inferior turbinate is occasionally seen. Such cases often have irregular polypoid mucosa over the inferior turbinate and local resection may be appropriate. Historically this was done using a specific snare developed in the days where large posterior ends were seen with the aid of a post-nasal mirror. A more controlled way of doing this now is to use a microdebrider under endoscopic control.

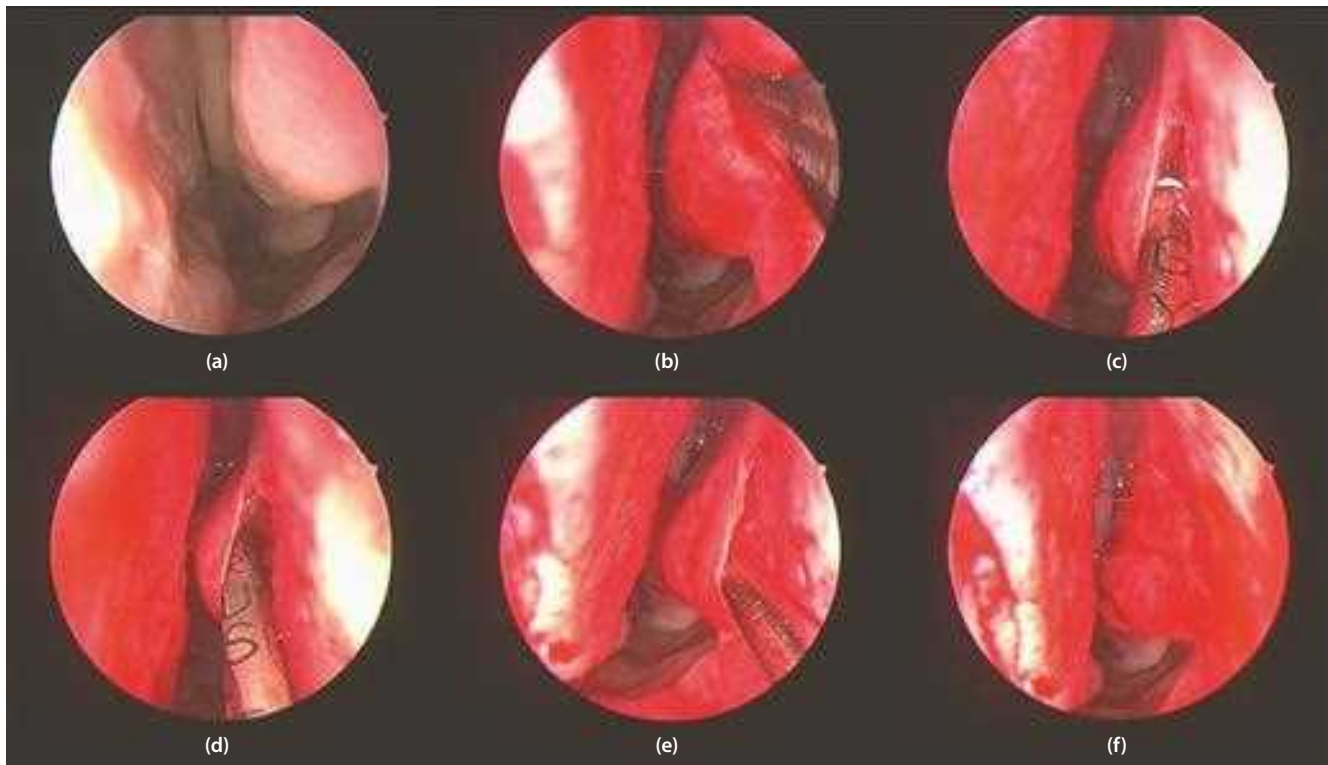

Figure 105.7 Submucosal turbinate reduction with mini-microdebrider blade. (a) Decongested left inferior turbinate (b) anterior turbinate incision (c-e) submucosal placement of microdebrider blade (f) replacement of mucosa against concha.

Figure 105.8 Appearance of radical excision of right inferior turbinate: endoscopic view and CT scan images.

Figure 105.9 Partially resected turbinate.

Laser surgery

Lasers can be used to reduce the size of the inferior turbinate by excision, vaporization or coagulation. They can be used under local anaesthesia as a day-case or office procedure. Several types have laser have been described and their action is dependent on the particular properties of the laser according to the wavelength. Several surgical laser techniques have been described: these vary widely from limited spot applications to the turbinate head through to spot applications, mucosal excision or vaporization of the anterior section or whole length of the turbinate.

The properties of the CO₂ laser favour tissue cutting and vaporization. Normally, a microscope, micromanipulator and angled mirrors to divert the beam onto the turbinate are required. The light energy is absorbed by water causing significant tissue heat to a depth of 4 mm but with limited collateral tissue damage. Long-term benefit and improved results compared to electrocautery have been described.¹⁶

The neodymium-yttrium aluminium garnet (Nd-YAG), potassium titanyl phosphate (KTP), and argon-ion lasers

can all be transmitted down a flexible fibre which makes them suitable to be used under endoscopic control. They are absorbed by haemoglobin and coagulate to a limited depth. The holmium yttrium aluminium garnet (Ho-YAG) is primarily absorbed by water but is able to remove bone as well as soft tissue.¹⁷

Although reports suggest that laser therapy is effective, the long-term results are in general less certain.¹⁰

Direct microdebrider mucosal reduction surgery

Direct debridement of the inferior turbinate is utilized as an effective means of relieving nasal obstruction in patients with gross inferior turbinate hypertrophy secondary to allergic or non-allergic chronic rhinitis. The mucosa is debrided down to periosteum along the medial aspect and inferior edge of the anterior two-thirds of the inferior turbinate. Bleeding is minimal as long as the periosteum is undisturbed. Healthy normal mucosa regenerates within 6–12 weeks following surgery and mucociliary clearance problems have not been observed.

TURBINATE SURGERY IN SPECIFIC CLINICAL SITUATIONS

Rhinosinusitis and endoscopic sinus surgery

In most patients undergoing endoscopic sinus surgery for chronic rhinosinusitis, there is no need to perform inferior turbinate surgery. Chronic rhinosinusitis will induce mucosal congestion of the nasal mucosa and inferior turbinates. Following endoscopic sinus surgery and post-operative medication, the degree of mucosal inflammation within the sinuses should significantly improve, with the benefit of reduction in the secondary congestion of the turbinates. Should inferior turbinate surgery still be deemed necessary, the authors would suggest that this is restricted to a mucosal preservation technique of surgery.

Septal deviation

Compensatory enlargement of the inferior turbinate is often observed on the opposite side to a septal deflection. It would therefore seem logical that turbinate reduction surgery would be indicated at the time of septal surgery. Formal study of this dilemma has, however, shown a positive effect from submucosal unilateral turbinate reduction as shown by acoustic rhinometry and patient self-assessment at 6 months following surgery.¹⁸

Histological studies have shown that enlargement of the inferior turbinate on the contralateral side to a septal deviation may be due to an increase in the size of the conchal bone as well as an increase in mucosal thickness.⁴ This would favour submucosal conchal resection and turbinoplasty in such cases.

Although these research findings are of interest, not all studies support the concept of simultaneous turbinate reduction and it is of note from clinical experience that most septal corrective surgery is performed without inferior turbinate reduction and patients generally have a satisfactory outcome.¹⁹ The potential risk of bleeding and adhesion formation also needs to be taken into account in deciding on whether to include turbinate reduction with septoplasty.

Septorhinoplasty

Some surgeons will routinely excise the inferior turbinates at the time of doing septorhinoplasty to maximize the chance of improving nasal obstruction. However, this will increase the potential for heavy bleeding post-operatively and is probably not going to result in any significant long-term advantage.

Sleep disordered breathing

There is a cogent argument to maximize the nasal airway in patients with sleep-disordered breathing, particularly when there may be a problem of compliance with CPAP due to nasal obstruction. This is an instance where there may be a tendency for surgeons to be radical in their approach to the inferior turbinate and to excise both turbinates whilst also correcting septal deformity. However, there is a lack of evidence to support a policy of radical excision in this group of patients and a more conservative approach is recommended. Most studies do support mucosal preservation turbinate reduction techniques as an adjunct to septal surgery for snoring, although none have demonstrated significant decrease in the apnoea-hypopnoea index of obstructive sleep apnoea patients.²⁰

Inferior turbinate surgery in children

Most children with nasal obstruction have rhinitis or adenoid enlargement. Rhinitis is mostly allergic and generally improves following treatment with anti-allergic medication and allergen avoidance. Should significant nasal obstruction persist and inferior turbinates remain large, there may be a case for turbinate reduction surgery.

Children with sleep disordered breathing and obstructive sleep apnoea may benefit from inferior turbinate surgery.²¹ A recent comparison of adenotonsillectomy with and without microdebrider-assisted inferior turbinoplasty has shown improved results in the children who underwent turbinate reduction.²²

A recent survey of turbinate reduction techniques in the USA showed that 80% of surgeons combined turbinate surgery with another procedure such as adenotonsillectomy, septal surgery and sinus surgery, and the most popular techniques are now the microdebrider and coblation®.²³

COMPLICATIONS

Inferior turbinate surgery is not without risk and consent for surgery should include a discussion about complications and their subsequent management.

The most immediate significant risk is severe haemorrhage, particularly after turbinate resection.

Procedures that are destructive to the mucosa may be followed by prolonged nasal crust formation that can take several weeks if not months to improve.

Long-term risks include nasal adhesions or synechiae between the turbinate and the septum. Visual change and blindness is rare but has been reported from the use of monopolar diathermy at the posterior end of the turbinate.

The danger of performing radical resection of tissue within the nasal cavities was recognized many years ago as a cause of ozaena and mucosal atrophy. Huizing suggests that too radical turbinectomy should be considered as a 'nasal crime'.¹² Patients undergoing radical resection risk developing chronic infected smelly crusting within the nose. Fortunately, this condition is rarely seen following inferior turbinate reduction surgery in modern otorhinolaryngology.

However, total resection of the inferior turbinate does carry a risk of inducing the 'empty nose syndrome (ENS)' in which the patient complains of nasal obstruction in the absence of an obstructive cause (Figure 105.9).²⁴ The pathophysiology is unclear but probably involves altered nasal receptor sensitivity, associated with humidity and conditioning of inhaled air; neuropsychological factors have also been suspected. Visible dryness or crusting are normally not seen. Should ENS occur after inferior turbinate resection, inserting a submucosal Medpor (Porex Surgical Inc) implant to effectively create a neo-turbinate has recently been described as a successful means of management.²⁵

OUTCOMES

Benefit from turbinate surgery would ideally be defined as improvement in both objective and subjective measurements of nasal airflow. Despite overwhelming data supporting the efficacy of turbinate surgery, of 93 studies reporting positive results, most were case series of retrospective reviews: only 14 reported acoustic rhinometry

results and 12 had rhinomanometric data²⁶ (evidence level 4 and 5). There have been few comparative studies and no systematic reviews of outcomes comparing the efficacy of different surgical techniques.² Furthermore, there is currently no specific quality of life assessment tool for turbinate reduction surgery.

In the largest randomized study to date, submucous resection and lateralization of the inferior turbinate resulted in sustained long-term improvement in nasal airflow and mucociliary clearance when compared to other surgical techniques (Figure 105.10).²⁷ Furthermore, over a fifth of patients in this series experienced atrophic rhinitis following radical turbinectomy.

A long-term study on a cohort of 341 patients who had submucous resection of the turbinate reported that 91.3% were symptom free at 10-year follow-up.²⁸ Rhinomanometric data demonstrated over 90% improvement of nasal airflow compared to the initial baseline and this was sustained at long-term follow-up.

Although newer surgical techniques such as Coblation® and radiofrequency ablation do not have long-term data yet, early results suggest that these techniques appear to offer promising short-term improvement in nasal airflow (Figure 105.11).^{29–31} RCT data are unusual but a recent study has shown a definite reduction in turbinate enlargement and subjective improvement in nasal obstruction after bipolar radiofrequency volumetric tissue reduction (RFVTR) compared to placebo at 6–8 weeks.³²

Figure 105.10 A comparison of long-term results between different surgical techniques based on average change in nasal airflow. Data for turbinectomy, carbon dioxide laser, cautery, cryotherapy, SMR and lateral displacement were derived from Passali et al.²⁷ The submucous debriding data was derived from Yañez and Mora.²⁸

RECENT RESEARCH ON THE INFERIOR TURBINATE

Computational fluid dynamics (CFD) is a numerical simulation application that enables the visualization of flow factors (velocity, pressure, vector, streamline and vortices) under variation flow conditions and has been used in the aerospace industry and civil engineering. Although computational fluid dynamic studies (CFD) remain an experimental tool in rhinology, CFD has enabled detailed study and understanding of nasal physiology. A three-dimensional nasal cavity is constructed from either MRI or CT scans before CFD simulations are performed by a super-computer. The physiological effects of modelling septal perforation, deviation and enlarged inferior turbinates have been studied extensively using CFD simulations.⁶

It has been demonstrated that despite a small increment of 1–2 mm in the overall dimensions of the inferior turbinate, a significant change in the air pressure around the nasal valve region occurs: nasal airflow is reduced and there is redistribution of airstreams to the upper parts of the nasal cavity.³³ The resultant negative pressure in the nasopharynx and reduced flow rate have been postulated to adversely affect the function of the surrounding muscles and mobility of the soft palate: the latter are common etiological factors for Eustachian tube dysfunction, snoring and obstructive sleep apnoea.³⁴

Although CFD simulations have yet to be performed on actual post-operative cases, it is possible to simulate outcomes following turbinate surgery. Partial turbinectomy, especially when the enlarged turbinate is reduced by a third, result in the return of near-normal airstreams and aerodynamics (Figure 105.12).³⁵ In contrast, radical turbinectomy causes an alteration of nasal aerodynamics akin to that observed in atrophic rhinitis.³⁶ Also, excision of the lower third of the inferior turbinate lowers the ability to heat inspired air by 11.7% due primarily to inducing turbulent airflow.

BEST CLINICAL PRACTICE

- ✓ Warn patients and document the risk of nasal crusting post-operatively. Include the possibility of long-term recurrence of nasal obstruction and possible revision surgery in the consent process.
- ✓ Always seek information about over-the-counter self-medication for the nose and consider the possibility of rhinitis medicamentosa.
- ✓ Re-examine the inferior turbinates again 10 minutes after applying a topical decongestant to assess the effect of vasoconstriction.
- ✓ Nasal endoscopy is strongly recommended before listing patients for inferior turbinate surgery.
- ✓ Consider a sinus CT scan if there is a suspicion of chronic rhinosinusitis in patients with chronically large inferior turbinates.
- ✓ Inferior turbinate surgery can result in heavy epistaxis. Check patients are not taking anticoagulants and utilize more conservative turbinate reduction techniques in preference to more aggressive techniques.

FUTURE RESEARCH

- There is a need for RCTs to compare different techniques of inferior turbinate reduction surgery after failed medical treatment. Comparisons should clearly separate allergic from non-allergic groups and restrict groups to adults or children. Trials should include short and long-term outcome data and review complications as well as clinical effectiveness.
- The clinical entity of the 'empty nose syndrome' needs clarification. Aetiology, diagnosis and management issues need to be investigated.

KEY POINTS

- Surgery of the inferior turbinate should be deferred until the patient has undergone an adequate trial of normally-effective medication.
- Large inferior turbinates may reflect an underlying allergic rhinitis. Consider effective conservative management regimes, including allergen identification and prevention, prior to committing to surgery.
- Always consider and exclude co-existent chronic rhinosinusitis prior to operating on enlarged inferior turbinates.
- Great caution should be exercised with regard to turbinate surgery in children. Inferior turbinate surgery is best avoided if at all possible.
- Beware of excessive resection of the inferior turbinates: this can induce chronic crusting and a sense of nasal obstruction.

Surgical anatomy of the nasal vascular system	1169	Secondary epistaxis.....	1179
Classification of epistaxis.....	1172	References	1181

SEARCH STRATEGY

Data in this chapter may be updated by multiple searches using the keywords: epistaxis, aetiology, management, treatment and therapies, arterial supply, venous drainage and key clinical areas. Main articles, RCTs and systematic reviews were searched. Results were augmented by a manual search through major references and texts. Many older references are cited because of their quality and value which has stood the test of time. Indeed newer publications frequently, simply repeat (often without acknowledgment) the findings of much earlier works and so in these cases I have used the original publication as the reference.

BACKGROUND

Epistaxis is defined as bleeding from the nose. This simple definition belies the difficulties associated with one of otolaryngology's commonest and most difficult to treat emergencies. The historical literature contains numerous references to epistaxis and its antiquity is reflected in the fact that the simplest treatment for a nose bleed (pinching the ala nasi) is called the Hippocratic technique.

While extensive review of the history of epistaxis is beyond the scope of this book, much of the historical literature remains relevant and students of this subject are advised to review the writings of Morgagni who even predicted nasal endoscopy in 1761!¹

SURGICAL ANATOMY OF THE NASAL VASCULAR SYSTEM

It is vital that the surgeon responsible for managing patients with epistaxis has a sound understanding of the nasal vasculature. The surgical anatomy of this system

has in recent years been revisited by those who raise nasal mucosal flaps in skull base surgery and the reader is advised to read some of the articles on that subject to help consolidate understanding of this crucial area.²

Arterial supply

The internal and external carotid arteries supply the nose via branches which anastomose extensively within the lateral wall, septum and across the midline. On the anterior septum an arterial plexus was identified as a frequent site of haemorrhage by James Little in 1879 and the same plexus was described one year later by Kiesselbach.³ As a result of these descriptions, the area most frequently implicated in epistaxis is known as Little's area or Kiesselbach's plexus. In the posterior nasal cavity, the vessels are larger than those in Little's area and can more easily be traced to their external or internal carotid origin.

EXTERNAL CAROTID ARTERY

The external carotid artery supplies the nasal cavity via facial and maxillary branches. The facial artery supplies the most anterior part of the septum (nasal septal rami of

superior labial artery), the vestibule (lateral nasal artery) and a small area of the nasal cavity (ascending palatine artery). The maxillary artery supply is via sphenopalatine and greater palatine branches. The greater palatine artery supplies the anteroinferior part of the nasal floor and septum.

The sphenopalatine artery is the most important supply to the nasal cavity. It enters through the sphenopalatine foramen and immediately divides into posterior septal and posterior lateral rami.⁴ The posterior lateral division gives the inferior and middle turbinate arteries. These vessels were studied in detail by Burnham in 1935 and his work remains the definitive reference on this subject.⁵ Burnham described how the inferior and middle turbinate arteries run in bony tunnels within the turbinates. Shaheen postulated that these bony conduits could reduce the likelihood of the arteries being involved in epistaxis.⁶ The posterior septal branch of the sphenopalatine artery runs medially across the face of the sphenoid to the posterior part of the septum then takes an undulating course anteroinferiorly in the muco-perichondrium. Its terminal branches anastomose in Little's area.

INTERNAL CAROTID ARTERY

The internal carotid contributes the anterior and posterior ethmoidal branches of the ophthalmic artery. The anterior ethmoidal artery, after arising in the orbit, runs under the superior oblique muscle to the anterior ethmoidal canal in which it traverses the ethmoid and nasal cavities. It terminates in the region of the ethmoid fovea in a meningeal branch and a larger branch to the nasal roof, olfactory cleft and superior turbinate. The posterior ethmoidal artery is smaller than the anterior ethmoidal artery and is present in only 80% of individuals.⁷ Like the anterior vessel, this artery runs medially but this time passes above the superior oblique muscle to enter the posterior ethmoidal foramen situated 5mm anterior to the optic canal and 10/15mm behind the anterior ethmoidal foramen. Within its canal, the posterior ethmoidal artery is accompanied by the sphenothmoidal nerve and a branch of the nasociliary nerve. This vessel also divides into a terminal meningeal branch and a branch to the posterosuperior nasal cavity, olfactory sulcus and sphenothmoidal recess.

INTERNAL AND EXTERNAL CAROTID TERRITORIES

The nasal cavity is the location of the principal internal-external carotid artery anastomoses in the head and neck. There has been debate over the relative importance of each supply to the nasal cavity. Shaheen showed that the area supplied by the ethmoidal arteries was much smaller than had previously been thought. His findings were supported by observing; sphenopalatine branches to the superior meatus and superior turbinate, the comparatively narrow calibre of the ethmoidal arteries and the fact that the larger of the two ethmoidal arteries, the anterior, is absent in as

many as 14% of cadaver dissections.⁶ The view that the middle turbinate marks a watershed between internal and external carotid circulations is erroneous as the arteriolar anastomotic network allows varying directions of flow to occur. Compensatory anastomotic flow for example via the facial arteries is thought to explain re-bleeding events which may occur following ligation or embolization.⁸

Venous drainage

The veins follow the arteries within the mucosa. The exception is the periarterial venous cuff surrounding the intra-osseous portions of the inferior and middle turbinate arteries. The veins of the lateral wall drain through the sphenopalatine foramen into the pterygoid venous plexus and to the internal jugular vein. Anteriorly, drainage is via superior labial and greater palatine veins to the facial vein and ultimately the external jugular system. Of particular note clinically is the retro-columellar vein running 2mm behind and parallel to the columella. This vein is in a particularly superficial area and is a common cause of venous epistaxis in children.

Key clinical areas

WOODRUFF'S PLEXUS

The role of Woodruff's plexus (WP) in epistaxis was at one time frequently discussed, especially in the North American literature.^{9, 10} Woodruff (1949) described a plexus of prominent blood vessels lying just inferior to the posterior end of the inferior turbinate (**Figure 106.1**).¹¹ He commented on how this plexus was a frequent site of adult epistaxis and described 14 cases of bleeding from this area. Many authors describe WP as a frequent source of so-called 'posterior' epistaxis despite the absence of any numerical evidence to support this. Shaheen in 1967 attempted to study and define WP but was unable to identify the plexus in nasal ethmoidal blocks.⁶ A more recent study with endoscopic photography and anatomical micro-dissection confirmed that the plexus does indeed exist but showed it to be a venous plexus and thus very unlikely to be important in epistaxis.¹²

LATERAL WALL OR SEPTAL BLEEDING?

There is general acceptance that overall the vast majority of epistaxis occurs from Little's area but there is debate on the relative importance of various other sites. Some suggest that WP is important and others nominate the septum or other regions of the lateral wall as prime sites. Numerous studies using various methods and examination techniques have produced diverse findings.^{10, 13-16} For example, Shaheen failed to find any lateral wall bleeding while Wurman did not report any septal bleeding.^{10, 16} Sixty percent of bleeding points identified by el-Simily were septal whereas 62% of those found by Rosnagle were on the lateral wall.^{17, 18} In a

Figure 106.1 Endoscopic photograph of Woodruff's plexus (right). IT: inferior turbinate, WP: Woodruff's plexus, NP: nasopharynx.

study of 50 patients with adult primary *posterior* epistaxis, McGarry identified the bleeding point in 94% (6% not located despite endoscopy), 70% bled from the septum and 24% from the lateral wall. There was no side predilection (50% left nostril and 48% right, 2% bilateral).¹⁹ These findings support the observation that posterior, like anterior, epistaxis is predominantly septal in origin (**Figure 106.2**).

ANTERIOR ETHMOIDAL ARTERY IN ENDOSCOPIC SINUS SURGERY AND IN TRAUMATIC EPISTAXIS

Detailed knowledge of this vessel is essential for surgeons carrying out endoscopic sinus surgery and for those planning its ligation for epistaxis. The artery is frequently encountered in a mesentery just below the skull base between the ethmoid fovea and the lamina papyracea. Inadvertent damage to the mesentery can lead to troublesome bleeding from the artery. Transection of the vessel during sinus surgery can result in retraction of the bleeding end into the orbit with subsequent pressure haematoma and risk of visual loss. In patients with orbito-ethmoidal fractures, severe and often intermittent epistaxis can occur due to damage to this vessel and in such cases open ligation may be the only option to control the bleeding. The vessel can be ligated as a treatment for epistaxis via an external (medial canthal) approach or endoscopically (trans-ethmoidal). The open approach via a medial orbital incision is the most reliable and preferred method and the artery may be clipped, bipolarized or ligated without entering the bulbar fascia (**Figures 106.3** and **106.4**).

Figure 106.2 Diagram of sites of bleeding in posterior epistaxis. (a) lateral nasal wall, (b) septum. Numbers are percentages (6% not located).

SURGICAL ANATOMY OF THE SPHENOPALATINE FORAMEN

The sphenopalatine foramen is the portal for the major arterial supply of the nasal cavity. Lateral to the foramen lies the pterygopalatine space. The foramen is formed by a U-shaped notch in the vertical portion of the palatine bone which is closed posterosuperiorly by the sphenoid bone. The foramen transmits the sphenopalatine artery, vein and the nasal palatine nerve (maxillary division of

Figure 106.3 Open approach to ligate left anterior ethmoidal artery. ALC: anterior lacrimal crest, PLC: posterior lacrimal crest, AEA: anterior ethmoidal artery.

the trigeminal nerve). Clinically this foramen is the key to the procedure of endonasal endoscopic sphenopalatine artery ligation (ESPAL). Surgical localization of the foramen can be difficult. Bolger et al. studied a small bony projection which lies anterior to the foramen in 96% of cases.²⁰ This landmark is called the crista ethmoidalis and its recognition during surgery may help in finding the foramen. The crista is variable in size but consistent in its position anterior to the artery and so it is a key landmark for the endoscopic surgeon (See [Figure 106.8](#)).

SURGICAL ANATOMY OF THE BLOOD SUPPLY OF THE INFERIOR TURBINATE

Severe secondary epistaxis is a serious complication of inferior turbinectomy. Understanding the vascular supply of the inferior turbinate may help in both the avoidance and the management of this complication. At its origin, the inferior turbinate artery runs anteroinferiorly in the submucosa where it is vulnerable to damage during radical turbinectomy. On reaching the inferior turbinate, it divides into three parallel branches each of which run in bony tunnels within the substance of the turbinate. These tunnels with their peri-arterial cuff of fibrous tissue and venous elements may prevent the artery constricting following turbinectomy and may predispose to post-operative haemorrhage.^{4, 14}

Attempts to control haemorrhage following turbinectomy should be directed towards the posterosuperior aspect of the inferior turbinate where pressure or bipolar to the submucosal segment of the artery should prove effective.

CLASSIFICATION OF EPISTAXIS

Clinical classification

Traditionally, epistaxis has been classified on the basis of presumed aetiology and publications include long lists of factors thought to cause the condition.²¹ As most cases are idiopathic and since case-control evidence does not exist for most of the putative aetiological factors, a causation-based classification is inappropriate.

A clinical classification based on the clearly observed patterns of presentation of epistaxis is more useful.

Adult or childhood epistaxis

There is a pronounced bimodal distribution in the age of onset of epistaxis. The condition is common in childhood, becomes less common in early adult life and then peaks in the sixth decade. Thus, while it can occur at any time in life, this variation with age is sufficiently pronounced to classify epistaxis as **childhood** (less than 16 years) or **adult** (greater than 16 years).

Primary or secondary

Between 70% and 80% of all cases of epistaxis are idiopathic, spontaneous bleeds without any proven precipitant or causal factor.²² This type of bleeding can be classified as **primary** epistaxis. As our understanding of the aetiology advances, the number of cases of true primary epistaxis will decrease but, at present, this definition encompasses the majority of cases.

A small proportion of cases are due to a clear and definite cause such as trauma, surgery or anti-coagulant overdose and can be classified as **secondary** epistaxis. The distinction between primary and secondary epistaxis is

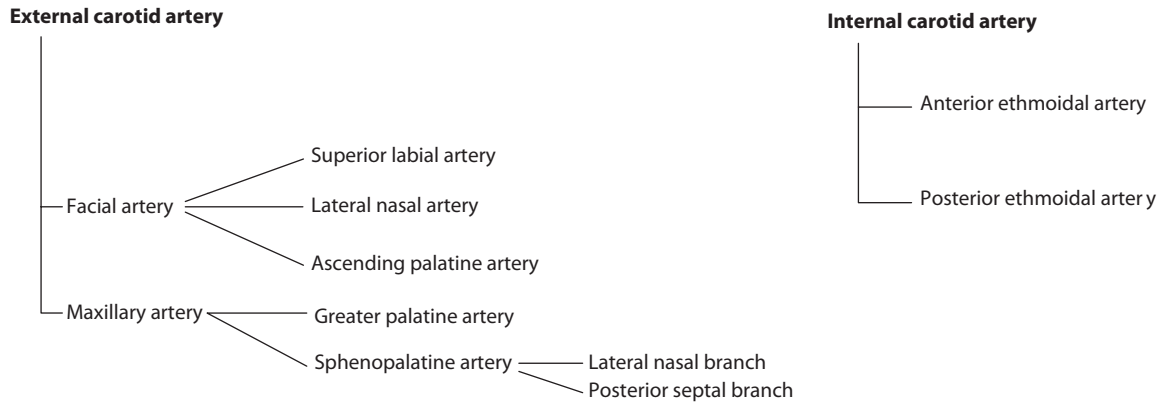

Figure 106.5 Schematic of blood supply to nasal cavity.

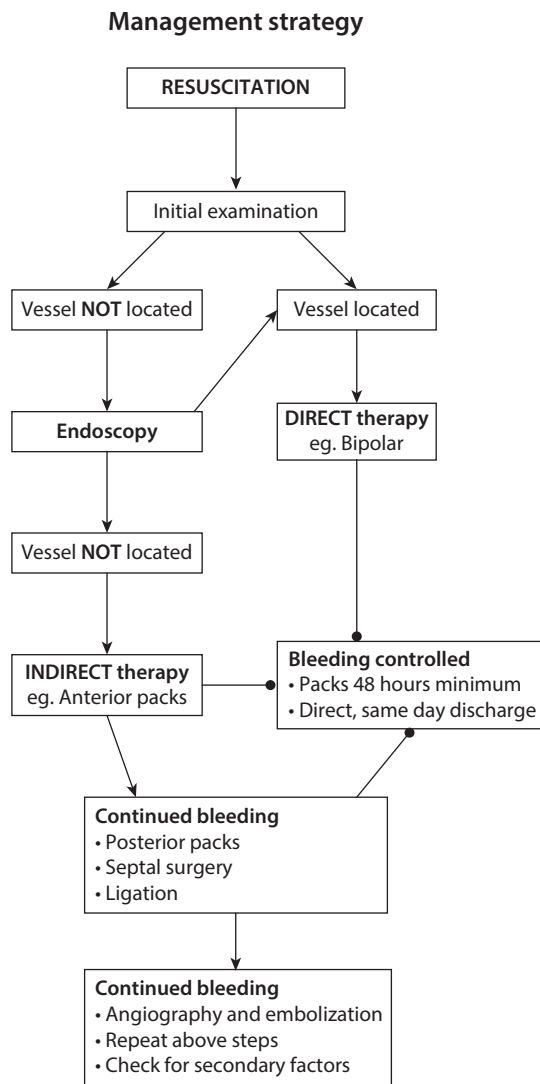

Figure 106.6 Management algorithm.

more than academic as the management of each type is quite different, e.g. techniques used to control primary epistaxis are unlikely to be successful for a secondary epistaxis due to coagulopathy.

Anterior and posterior epistaxis

The terms anterior and posterior epistaxis are frequently used but the definitions are imprecise and inconsistent and really not very useful. Pearson attempted to standardize the term posterior epistaxis as a bleeding point which cannot be located despite examination with a headlight, vasoconstrictors and suction.⁹ While this is a clinically useful definition, modern techniques of examination and endoscopy, are likely to see true posterior bleeds moving further and further back! Attempts to define anterior epistaxis as bleeding from Little's area are problematic, due to the lack of a precise definition of Little's area. To standardize the use of the term 'posterior epistaxis' and 'anterior epistaxis', the author proposes that their use be restricted to the following:

- **Anterior epistaxis** – bleeding from a source anterior to the plane of the piriform aperture. This includes bleeding from the anterior septum and rare bleeds from the vestibular skin and mucocutaneous junction. These should be the bleeds where the clinician will easily locate the bleeding point and management should be simple.
- **Posterior epistaxis** – bleeding from a vessel situated posterior to the piriform aperture, i.e. from within the nasal cavity. This allows further subdivision of these posterior or nasal cavity bleeding points into lateral wall, septal and nasal floor bleeding. These are the bleeds that will challenge the clinician the most.

Further descriptive classification based on the severity and frequency of the bleeding can also be used, e.g. whether recurrent (usually minor and non-life-threatening) or acute, severe. It is of interest that for adults at least, the severity of an epistaxis is inversely proportionate to its frequency. That is, recurrent primary epistaxis tends to be minor, non-life-threatening and often easily managed whereas acute, severe epistaxis is often a one-time event resulting in hospitalization and carrying a high morbidity.

For the remainder of this chapter, the clinical syndromes of adult epistaxis are discussed. Childhood epistaxis is discussed elsewhere in this textbook (Table 106.1).

TABLE 106.1 Classification of epistaxis

- **Primary:** no proven causal factor
- **Secondary:** proven causal factor
- **Childhood:** <16 years
- **Adult:** >16 years
- **Anterior:** bleeding anterior to piriform aperture
- **Posterior:** bleeding point posterior to piriform aperture

ADULT PRIMARY EPISTAXIS

Demography

Adult primary epistaxis is the variant that challenges otolaryngologists the most. The condition can occur at any age but is mainly a disease of the elderly. Between 7% and 14% of adults have epistaxis at some time or other but only 6% of cases are seen by otorhinolaryngologists.^{23, 24} The peak presentation is the sixth decade and most large case series reveal a slight male predominance (55 male, 45 female).^{15, 25} Most cases are minor, self-limiting or easily managed anterior bleeds but nevertheless a significant number require admission to hospital. The annual rate of admission to otolaryngology units in the northern UK with adult epistaxis is 30 per 100,000 per annum.²⁶ In Scotland, epistaxis is the commonest reason for adult admission to an ENT ward.²⁷ Fewer than 10% of hospitalized patients require a general anaesthetic procedure to secure haemostasis.²⁸ It is not surprising that such a common haemorrhagic condition of elderly patients is associated with significant morbidity and mortality. After head and neck cancer, epistaxis stands out as a prominent cause of mortality in ENT patients.

Aetiology

By definition the aetiology of primary epistaxis is unknown but there are clear suggestions that systemic factors may be important (Table 106.2).

CHRONOBIOLOGY

The frequency of admission is greatest in the autumn and winter months.^{28, 29} This seasonal variation correlates with fluctuations in environmental temperature and humidity.³⁰ A chronobiological rhythm is also observed at the circadian level where onset of bleeding and hospital admission show a biphasic pattern with peaks in the morning and late evening.^{31, 32} There are strong parallels between the circadian rhythms of primary epistaxis and those observed in subarachnoid haemorrhage.

NON-STEROIDAL ANTI-INFLAMMATORY DRUGS (NSAID)

Adult pattern epistaxis is associated with the use of NSAID. Patients are more likely than controls to consume NSAID. The NSAID used include prescribed and self-administered compounds especially aspirin. The action of non-steroidal anti-inflammatory drugs is mediated via an anti-platelet aggregation effect due to altered platelet membrane physiology.^{33–35}

ALCOHOL

Similar aetiological associations to those of NSAID have been found with alcohol. Epistaxis patients are more likely to consume alcohol than matched control patients and are more likely to have consumed alcohol within 24 hours of

hospital admission than other emergency admissions. The use of alcohol by epistaxis patients is associated with a prolongation of the bleeding time despite normal platelet counts and coagulation factor activity. Once again, the effects of NSAID and alcohol mirror those reported in subarachnoid haemorrhage.^{36, 37}

HYPERTENSION

This has long been considered a cause of epistaxis. However, a number of large studies have failed to show a causal relationship between hypertension and epistaxis.³⁸ Attempts to correlate epistaxis with secondary effects of hypertension or with the severity of hypertension have proved inconclusive.³⁹ Even if not causal, elevated blood pressure is observed in almost all epistaxis admissions. This apparent hypertension in acute admissions may be a result of anxiety associated with hospital admission and the invasive techniques used to control the bleeding.

SEPTAL ABNORMALITIES

Septal abnormalities are common and depending on the definition used between 1% and 80% of the population have a significant deviation.⁴⁰ Given such a high prevalence, the perceived association between epistaxis and septal abnormalities could be coincidence. One study found an association between septal deviation and *recurrent* epistaxis in young subjects.⁴¹ There is no clear case control evidence of an association between septal abnormalities and adult epistaxis.

Management

In order to be effective the management of adult epistaxis should follow an incremental sequence of interventions (Figure 106.6). The theoretical ideal treatment requires identification of the bleeding point and direct control of the bleeding, at source. First, the patient must be resuscitated, bleeding slowed, the nasal cavity examined and a treatment plan established.

RESUSCITATION

Given the high prevalence of coexistent cardiovascular disease, prompt and effective resuscitation is required. Sixty-five percent of cases are referred from an accident and emergency department and thus many will already have had some form of therapy.²⁸ First aid by pinching the ala nasi (the Hippocratic technique) is supported by the frequency with which the anterior part of the septum

is the source of bleeding. Otorhinolaryngologists should ensure medical students, nurses and other team members are fully aware of the precise technique for compression of the nostrils. In one study of Accident and Emergency staff, only 43% of trained medical and nursing staff could correctly demonstrate the Hippocratic technique.⁴² Recent surveys of junior doctors show that nothing much has changed and there is still poor understanding of initial management of epistaxis!⁴³ History and examination will help in assessing the amount of blood lost. In all but the most minor of bleeds intravenous access is established and baseline blood estimations are taken. A detailed history should be taken, looking for predisposing factors. Routine coagulation studies in the absence of a positive history are not indicated.^{15, 44}

ASSESSMENT

The patient should be assessed in a semi-recumbent position and nursing assistance is mandatory. Everyone involved should wear protective visors and clothing as blood aerosol contamination is common, especially when inserting nasal packing.⁴⁵ Basic equipment includes: couch or reclining chair, headlight, suction, vasoconstrictor solutions (lignocaine and pseudoephedrine solution has now widely superseded cocaine solutions) and a selection of packs, tampons and cautery apparatus. All specialist ENT units should also have access to rod lens nasal endoscopy equipment and bipolar electrodiathermy.

DIRECT OR INDIRECT THERAPIES

Treatment may be divided into direct (bleeding point specific therapies) or indirect treatments. Indirect treatments are those that do not require identification of the bleeding point. Direct treatments are logically and theoretically superior and, therefore, a committed search for the bleeding vessel should always be undertaken.⁹

DIRECT MANAGEMENT

There has been a slow but steady uptake of direct strategies throughout the UK. Despite this, however, a minority of cases admitted to otolaryngology units in the UK are managed by direct control of the bleeding point.²⁸ The reluctance to use direct approaches may be due to a perceived difficulty in locating bleeding points, but probably also reflects the fact that over 70% of cases are managed by the most junior members of the specialty.²⁷ Anterior epistaxis is usually very straightforward to identify and treat and over 90% of cases can be controlled with silver nitrate cautery or bipolar. The use of packing for primary anterior epistaxis is unwarranted and should be strongly discouraged.

Posterior epistaxis can occur from the lateral wall, floor or septum. As previously discussed there is evidence to support the septum as the principal locus. Systematic examination with a headlight will identify most bleeding points. Once identified, bleeding points can be directly

TABLE 106.2 Summary of aetiological evidence of adult primary epistaxis

- **NSAID:** proven association
- **Alcohol:** proven association
- **Hypertension:** no association
- **Septal deviation:** no association

controlled with bipolar diathermy, chemical cautery (difficult in posterior bleeds), electro-cautery or direct pressure from miniature targeted packs.⁴⁶

Endoscopic control

Failure to locate the bleeding point on initial examination is an indication for examination with a rod lens endoscope. Endoscopy identifies the source of posterior epistaxis in over 80% of cases.^{26, 10, 14, 46} Endoscopy enables targeted haemostasis of the bleeding vessel using insulated hot wire cautery or modern single fibre bipolar electrodes.²⁶ Success rates for immediate control by endoscopic guidance are consistently reported in the 90% range.²⁶ Monopolar diathermy should not be used in the nasal cavity as there have been reports of blindness due to current propagation.⁴⁷

Adoption of direct (including endoscopic) management strategies has been shown to facilitate out-patient management and to significantly reduce in-patient stay (Figure 106.7).²⁶

Indirect therapies

Failure to find the bleeding point is an indication for use of one of numerous traditionally favoured indirect strategies.

Nasal packing

Packing can be anteriorly or posteriorly placed. Anterior packing has been the mainstay of treatment for centuries. Skills required for accurate packing are difficult to acquire and with modern techniques of nasal surgery, less frequently encountered in a surgeon's training.

Ribbon gauze impregnated with petroleum jelly or Bismuth Iodoform Paraffin paste (BIPP) is inserted the entire length of the nasal cavity in attempt to tamponade the bleeding. Once inserted, the packs are left *in situ* for between 24 and 72 hours.⁴⁸ Continued or re-bleeding with packs *in situ* is observed in up to 40% of cases.⁴⁹ Complications of packing include; sinusitis, septal perforation, alar necrosis, hypoxia and myocardial infarction. Packing is usually considered an indication for antibiotic cover but the evidence base for this is lacking.

Figure 106.7 Single fibre bipolar unit for direct management of epistaxis.

Modern and now more frequently used variations on anterior packing include special tampons (Merocel® and Kaltostat®) and balloon catheters (Brighton or Epistat). Balloons and tampons are favoured by non-specialists as first-line therapy but are associated with similar complications and re-bleed rates to packing. If over inflated, balloons will prolapse anteriorly and posteriorly with the risk of hypoxia and alar necrosis.⁵⁰ There is no evidence of greater efficacy for packs compared to balloons or tampons.

Persistent bleeding or re-bleeding is an indication for further examination of the nasal cavity and renewed search for the bleeding point. There is no clear, universally agreed definition of failed packing but patients who continue to bleed should proceed to surgical management sooner rather than later. In the author's institution the agreed protocol is that all admitted epistaxis patients should be haemostased within 24 hours of admission. If this has not been achieved a rhinologist should be summoned to review the case. Patients should not be left on a ward with blood oozing from nasal packs or tampons while on-call teams change shift!

Hot water irrigation

Irrigation of the nasal cavity with water at 50°C has been proposed as an alternative to packing. Although this technique has seen little use in the UK, Stangerup reports similar levels of success comparing the hot water technique to anterior packing and balloon tamponade.^{49, 51} Up to one third of patients find the technique difficult to tolerate and so use of specialized irrigation catheters is recommended. The exact mechanism of action of this treatment is unclear but may, paradoxically, involve reflex vasodilatation and reduction in nasal lumen dimensions.⁵²

Systemic medical therapy

Tranexamic acid and epsilon aminocaproic acid are systemic inhibitors of fibrinolysis. Tranexamic acid has been shown to reduce the severity and risk of re-bleeding in epistaxis at a dose of 1.5g three times a day. Tranexamic acid does not increase fibrin deposition and so does not increase the risk of thrombosis. Pre-existing thromboembolic disease is a contraindication. At present anti-fibrinolytics are best reserved as adjuvant therapy in recurrent or refractory cases. There has been a recent increase of interest in this drug and it may become more important in managing secondary bleeds due to novel anticoagulants.⁵³

Topical haemostatic agents

Topical thrombin compounds have been marketed for operative field haemostasis in surgery. The use of these compounds in epistaxis is attractive to those looking for a simple fix. Compounds such as Floseal (Baxter Healthcare) have been used and results have been variable with some authors finding no real benefit.⁵⁴ In the author's experience these agents can only be considered an additional tool for the management of difficult (especially secondary) bleeds

and should never replace the main aim of identifying and directly treating the source of the bleeding.

Surgical management

If the techniques described above fail, surgical intervention is required. Endoscopic diathermy of the bleeding point under anaesthetic may control the bleeding but if the vessel still cannot be controlled (or even located) indirect surgical therapy is indicated. Surgical management for continued epistaxis consists of:

- Posterior packing
- Ligation techniques
- Septal surgery techniques
- Embolization techniques.

POSTERIOR NASAL PACKS

Posterior packing should be viewed as largely obsolete but in extreme cases or where no specialist rhinologist is available it may be indicated. It can, in extremis, be carried out under local anaesthetic but general anaesthesia is preferable. Nasopharyngeal tamponade is achieved using special gauze packs inserted transorally and positioned by means of tapes passed from the posterior choana to the anterior nares bilaterally. These posterior 'Bellocq' packs are secured against anterior gauze packing. The securing tapes are tied over padding positioned to protect the columella from pressure necrosis. An easier and perhaps kinder alternative is to insert a Foley urethral catheter (size 12 or 14) along the floor of the nasal cavity until the nasopharynx is reached. The Foley catheter is inflated with 15 ml of water, pulled forward to engage in the posterior choana and anterior packing is then inserted. The Foley catheter needs to be secured anteriorly taking care not to cause pressure over the columella. Posterior packing causes considerable pain and may cause hypoxia secondary to soft palate oedema. Sinusitis and middle ear effusions are common. More serious complications include necrosis of the septum and columella. Antibiotics and opiate analgesia are necessary. Once they have been placed, posterior packs should be left in position for a minimum of 48 hours or at least until a rhinological surgeon can attend to the patient.

LIGATION TECHNIQUES

Ligation is reserved for intractable bleeding where the source cannot be located or controlled by the techniques described above. Knowledge of the blood supply of the nasal cavity and the likely sources of epistaxis will inform the choice of ligation technique (Figure 106.5).

Ligation should be performed as close as possible to the likely bleeding point thus the hierarchy of ligation is:

- Sphenopalatine artery
- Internal maxillary artery
- External carotid artery
- Anterior /posterior ethmoidal artery.

Endonasal endoscopic sphenopalatine artery ligation (ESPAL)

ESPAL conforms to the ideal of controlling the bleed as close as possible to its nasal source. The sphenopalatine artery is the main supply of the nasal cavity and thus the most logical target for ligation. Modern endoscopic techniques have seen an increase in popularity of this procedure and it has now largely replaced all other ligations as the procedure of choice. The operation has been performed with an operating microscope but much more commonly using modern endoscopic techniques. Under general or local anaesthetic, an incision is made approximately 8 mm anterior to and under cover of the posterior end of the middle turbinate. The incision is carried down to the bone and a mucosal flap is elevated posteriorly until the fibro-neurovascular sleeve arising from the sphenopalatine foramen is identified. The foramen can be difficult to identify but its location is signalled by the crista-ethmoidalis.²⁰ Once the main vessel is identified, it can be ligated using haemostatic clips (Figure 106.9) and divided or coagulated using bipolar diathermy (Figure 106.8). In some series success rates for this procedure have reached almost 100%.⁵⁵ Complications including re-bleeding (anastomoses), infection and nasal adhesions are generally less common than with other procedures.

Internal maxillary artery ligation (IMAL)

This was more frequently used prior to the development of ESPAL procedures. The artery is exposed

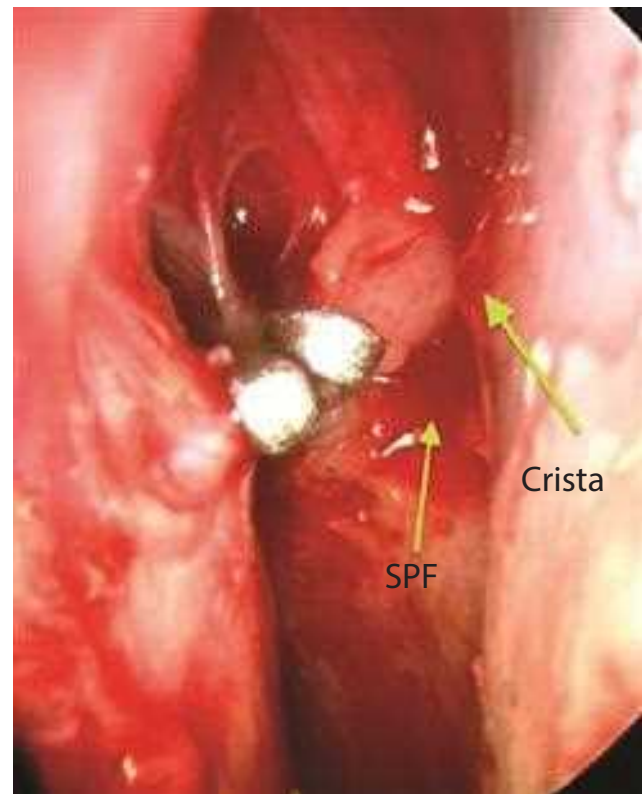

Figure 106.8 Haemostatic clips applied to main trunk of sphenopalatine artery (left) in procedure of ESPAL. Crista: crista ethmoidalis, SPF: sphenopalatine foramen.

Figure 106.9 Rotatable ligation clip applicators suitable for ESPAL.

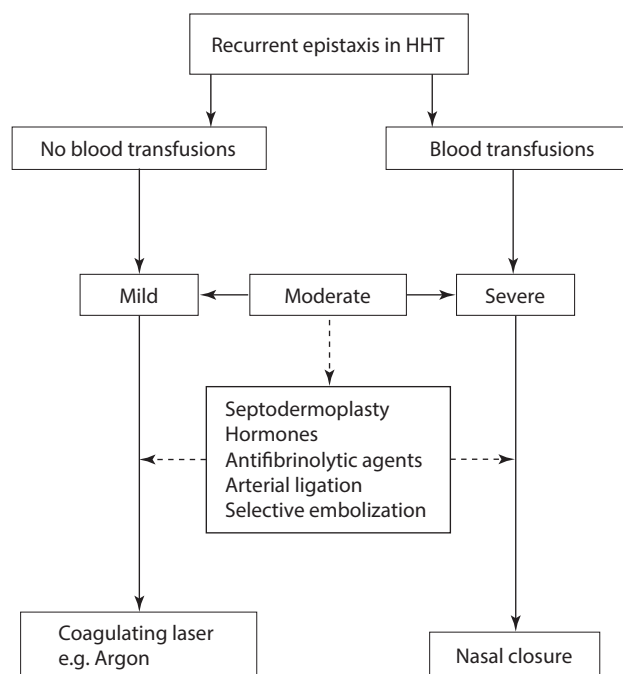

Figure 106.10 The management of HHT. From Lund and Howard, *Am J Rhinol* with permission.⁶⁸

trans-antrally via anterior (sublabial) or combined anterior and medial (endoscopic) techniques. In the traditional sublabial approach an antrostomy is formed taking care to preserve the infra-orbital nerve. The mucosa of the posterior wall of the antrum is then elevated and a window is made through into the pterygopalatine fossa. The branches of the internal maxillary artery are identified pulsating within the fat of the fossa and are carefully dissected out prior to clipping with haemostatic clips. The proximal internal maxillary artery, descending palatine and sphenopalatine branches are all clipped and ideally divided. An endoscopic variation of this technique uses a middle meatus antrostomy as an instrument port with a 4mm endoscope is inserted through a small canine fossa antrostomy.⁵⁶ Trans-antral ligation controls haemorrhage in 89% of cases and is comparable to embolization in both cost and efficacy.⁵⁷ Endoscopic trans-antral ligation of

the internal maxillary artery can also be carried out via a middle meatus antrostomy and is occasionally required when control of a damaged sphenopalatine artery is lost during ESPAL. Complications include: sinusitis, damage to the infra-orbital nerve, oro-antral fistula, dental damage and anaesthesia and rarely ophthalmoplegia and blindness.

External carotid artery ligation (ECAL)

ECAL represents a step further away from the nasal source of bleeding. Nevertheless, the relative technical ease of this procedure justifies its use in extreme cases and by non-rhinologists. This procedure can be carried out under local or general anaesthetic using either a skin crease incision or a longitudinal incision parallel with the anterior border of the sternomastoid. The carotid bifurcation is identified and the external carotid confirmed, double checked for arterial branches and then ligated in continuity. Some authors advocate anterior and posterior ethmoidal artery ligation as an adjuvant to this procedure. In one study, external carotid artery ligation secured haemostasis in 14 out of 15 patients.⁵⁸ Complications include wound infection, haematoma and neurovascular damage.

Anterior/posterior ethmoidal artery ligation (EAL)

Given the minimal contribution of these arteries to the nasal blood supply, their ligation is best reserved as an adjuvant to one of the procedures described above or in cases of confirmed ethmoidal bleeding (e.g. ethmoidal fracture, iatrogenic tear). The arteries are approached by a medial canthal incision which is carried down to the bone of the anterior lacrimal crest. Periosteal elevators are then used to elevate and laterally retract the bulbar fascia. The anterior ethmoidal artery is seen as a fibro-neurovascular mesentry running from the bulbar fascia into the anterior ethmoidal foramen. The vessel is clipped and divided and dissection is continued to identify the posterior artery which is located approximately 12 mm behind. Endoscopic trans-ethmoidal ligation of the anterior ethmoidal artery has been described. The popularity of ligation of these vessels in primary epistaxis possibly reflects the technical ease of the open procedure rather than any logical reason for ligating vessels with such a small contribution to the nasal blood supply (Figures 106.3 and 106.4).

SEPTAL SURGERY

When epistaxis originates behind a prominent septal deviation or vomero-palatine spur, septoplasty or submucosal resection (SMR) may be required to access the bleeding point. Some authors have advocated septal surgery as a primary treatment for failed packing. The rationale is that by elevating the mucoperichondrial flap for septoplasty or SMR, the blood supply to the septum is interrupted and haemostasis secured. In one study a strategy involving SMR and re-packing was found to be more effective and economic than ligation in patients who had failed with

packing, however, this was prior to widespread adoption of ESPAL techniques.⁵⁹

EMBOLIZATION

Embolization under angiographic guidance has been shown to control severe epistaxis in between 82% and 97% of cases.^{57, 60, 61} Under local anaesthetic, transfemoral Seldinger angiography is used to identify the bleeding points and display the nasal circulation. It is essential to exclude arteriovenous malformations, aneurysms and fistulae prior to embolization. Once the bleeding vessel is identified, a fine catheter is passed into the internal maxillary circulation and particles (polyvinyl alcohol, tungsten or steel microcoils) are used to embolize the vessels. The ipsilateral facial artery is also embolized in order to prevent re-circulation. Complications include skin necrosis, paraesthesia, cerebrovascular accident and groin haematomas.

Embolization is of similar efficacy to ligation techniques and, therefore, choice will depend on local expertise, availability and experience. The risks of embolization mean that it should be reserved for failed ligations or where no rhinological surgical expertise is available.

Adult recurrent epistaxis

Recurrent bleeding is more commonly seen in children. When recurrent bleeds occur in adults, secondary epistaxis is most likely. Bleeding is usually minor and troublesome rather than life-threatening and it is uncommon to see bleeding by the time the patient presents. A full and detailed history and examination should identify factors such as aspirin use, liver disease or bleeding from the margins of a septal perforation. Rarely nasal tumours present with recurrent blood-stained discharge which should be distinguished from epistaxis per se. Patients using topical nasal medications (particularly steroid sprays) frequently report minor recurrent bleeds.

If a bleeding point can be identified cautery is used but often no single vessel can be identified and an area of vestibulitis is found. Evidence for the efficacy of topical antiseptic creams is available from paediatric studies and it is likely (but unproven in adults) that chlorhexidine and neomycin creams may reduce the frequency of bleeding. An area of debate is what to do when aspirin being used for cardiovascular prophylaxis is responsible for recurrent bleeds. If there is a history of cardiovascular disease or vascular graft surgery then aspirin should not be discontinued, otherwise temporary cessation of aspirin may be required to allow the recurrent bleeding to settle.

SECONDARY EPISTAXIS

Epistaxis is commonly observed in patients with coagulopathy secondary to liver disease, leukaemia or myelosuppression. In such cases, treatment of the epistaxis demands close liaison with haematologists and physicians. The following causes of secondary epistaxis deserve special mention.

Trauma

Post-traumatic nasal haemorrhage does not conform to the normal pattern of epistaxis and its origin and severity is almost infinitely variable. Persistent bleeding can occur from the ethmoidal arteries following fronto-ethmoidal fracture. In this case the vessels may be lacerated, incompletely divided or even held open by fractures through their bony mesenteries. Severe haemorrhage refractory to packing should be managed by open approach ligation.

Catastrophic bleeding has been reported after head injuries due to delayed rupture of an internal carotid artery pseudo-aneurysm. Thus persistent or unexpectedly severe bleeding even some time after a head injury should be seen as an indication for CT scanning and angiography.⁶²

Post-surgical

Bleeding can occur after almost any nasal surgery and is seldom difficult to manage. An exception is the severe haemorrhage which occurs in between 3% and 9% of inferior turbinectomies.⁶³ As previously discussed bipolar to the main branch of the inferior turbinate artery will usually secure haemostasis. Anterior subtotal turbinectomy may carry a reduced risk of post-operative bleeding.⁶³

Iatrogenic damage to the anterior ethmoidal artery during endoscopic sinus surgery should be managed by bipolar of the vessel. Retraction of the vessel into the orbit can give rise to a tension haematoma of the orbit and is a surgical emergency (see elsewhere).

Massive and usually fatal epistaxis can result from damage to the internal carotid artery during posterior ethmoid or sphenoid sinus surgery. The bleeding is usually uncontrollable but packing, angiography and embolization may be tried.

Warfarin

Patients on warfarin constitute between 9% and 17% of epistaxis admissions.^{27, 64} Bleeding may be due to overdose or loss of control but can also occur in patients whose INR is within the therapeutic zone. With warfarin, direct therapies seldom work and packing may be required. Bleeding is often from multiple sites and attempts at instrumentation lead to further mucosal damage and bleeding. After resuscitation, anterior packs should be gently inserted and the haematology team consulted. With large areas of bleeding or oozing fibrin glue has been used as a haemostatic dressing.⁶⁵ When deciding to reduce, stop or even reverse warfarin, the medical history and the severity of the epistaxis must be considered. If the INR is within the therapeutic range and treatment seems to be controlling the bleeding it may be safe to continue the warfarin.⁶⁴

New oral anticoagulants: TSOACs

New target specific oral anticoagulants such as Rivaroxiban and Dabigatran are seeing increased use throughout the healthcare system. As a result numbers of secondary epistaxis cases in patients on these medications

are being seen in our ENT units. Unlike vitamin K antagonists the reversal of these new agents is often difficult to achieve and can be incomplete. Siegal has written a useful paper on the subject.⁶⁶

When dealing with epistaxis in patients on these compounds ENT surgeons are advised to liaise at the earliest opportunity with the local haematology team. In addition to discussing with haematologists about anticoagulant reversal it is important that no steps are taken to stop or reverse agents without first clarifying the indication for the medication. Liaison with cardiologists may be required to avoid catastrophic complications (e.g. stent occlusion) as a result of withholding antiplatelet or anticoagulant medication for what may even after all prove to be a very minor epistaxis.

Hereditary haemorrhagic telangiectasia

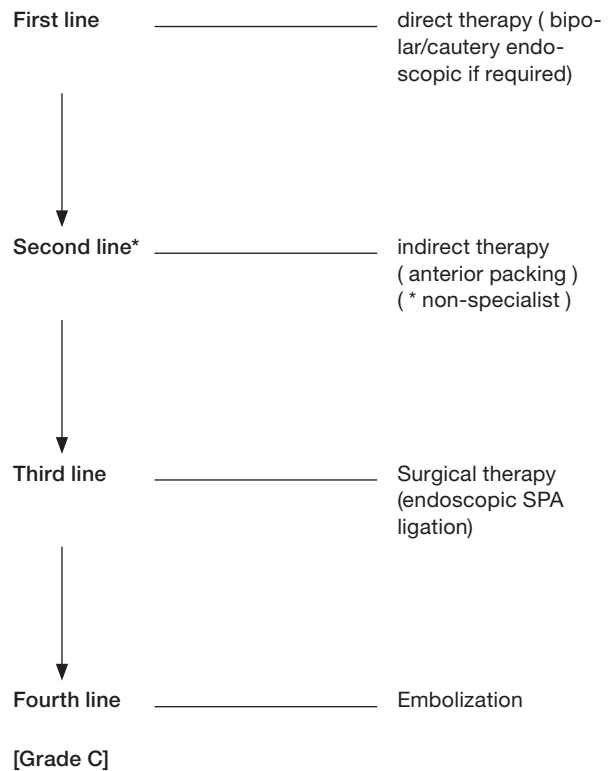

Hereditary haemorrhagic telangiectasia (HHT) or Osler-Weber-Rendu disease is an autosomal dominant condition affecting blood vessels in skin, mucous membranes and viscera. Penetrance is variable but reaches 97% by age 50 years and occasional atavistic cases are observed. The genetic abnormality has been located to chromosome 9q (HHT1) and chromosome 12q (HHT2). The classical features are telangiectasia, a-v malformations and aneurysms. Recurrent epistaxis occurs in 93% of cases.⁶⁷ Management involves packing, cautery, antifibrinolytics, systemic or topical oestrogens, coagulative lasers, septal dermoplasty, ligation and embolization and as a last resort permanent surgical closure of the nostrils (Young's operation). Laser photocoagulation has become a popular therapy and the NdYAG, Argon and KTP532 lasers have all been used with some success. Large multicentre comparisons of these treatments have not been conducted and due to the relative rarity of the condition this situation is likely to persist. **Figure 106.10** is an algorithm for management of this condition.⁶⁸ A recent study showed that the disability produced by Young's operation was more than offset by an improved quality of life due to reduced bleeding. Trials of systemic, topical or locally injectable Bevacizumab have produced conflicting results and at present the efficacy of this drug in HHT is unproven.⁶⁹

Tumours

Nasal tumours seldom present as epistaxis in isolation. More commonly tumours produce blood-stained discharge with other nasal symptoms (unilateral obstruction, pain, swelling). The risk, albeit small, of missing

a tumour is another good reason for using nasal endoscopy in epistaxis cases. Juvenile nasopharyngeal angiofibroma (JNA) and haemangiopericytoma (HPC) are rare vascular tumours which can present with recurrent or severe epistaxis in association with nasal obstruction. Treatment of JNA and HPC is mainly surgical but may include pre-operative embolization and are dealt with elsewhere in this textbook.

BEST CLINICAL PRACTICE

FUTURE RESEARCH

- Publications still consistently fail to classify epistaxis or define the study population. Thus studies involve heterogeneous groups of patients and different types of epistaxis making comparisons difficult. As result level 1 and 2 evidence is scarce.
- Multicentre comparisons of treatment and management strategies still do not exist.
- Basic research is required to identify initiating and aetiological factors.

KEY POINTS

- Direct bleeding point specific approaches are superior to indirect nasal packing strategies.
- Epistaxis secondary to drugs or coagulopathy requires management of the underlying cause.
- Endoscopic ligation of the sphenopalatine artery is the ligation of choice.
- The endoscope has revolutionized the treatment of epistaxis.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: nasal fracture, maxillofacial injuries, mandibular fractures, maxillary fractures, orbital floor fractures, nasoethmoid fractures and frontal sinus fractures, focusing on diagnosis, surgery, management and complications.

NASAL FRACTURES

INTRODUCTION

Treatment of nasal fractures was first recorded 5000 years ago during the early Pharonic period in Ancient Egypt. The Edwin Smith papyrus describes repositioning of deviated nasal bones with the fingers or elevators, the insertion of splints and the application of external dressings.¹ Just as then, nasal fractures are still very common. Isolated fractures of the nasal pyramid account for about 40% of all facial fractures. Furthermore, fractures of the nasal bones are often sustained along with other fractures of the facial skeleton. Delays in management can result in significant cosmetic and functional deformity that is often a cause for subsequent medicolegal action. The management of fractures of the nose is an important part of everyday ear, nose and throat (ENT) practice.

EPIDEMIOLOGY AND AETIOLOGY

Relatively little force is required to fracture the nasal bones, as little as 25–75 lb/in.² It is perhaps not surprising that young men are twice as likely to sustain a fractured nose as women. Subsequent refracture rates of 5% have been reported.³ The peak incidence is in the 15–30-year age group when assaults, contact sports and adventurous leisure activities are more common.⁴ In childhood, accident-prone toddlers not infrequently fracture their noses as well and these are often of a greenstick nature. Compound and comminuted fractures are more common in the elderly who are prone to falls.

CLASSIFICATION AND PATHOPHYSIOLOGY

Nasal fractures have been classified in a number of ways, for example, by the nature of injury, the extent of deformity and the pattern of the fracture.

Nature of injury

Most fractures result from laterally applied forces (> 66%). In a series reported by Illum et al. fractures following frontal injuries accounted for only 13%.⁵ Greater force is required to fracture the nose with a blow directed from the front as the nasal cartilages behave like shock absorbers.

Extent of deformity

A five-point grading system has been developed for the extent of lateral deviation of the nasal pyramid:

- **Grade 0:** bones perfectly straight
- **Grade 1:** bones deviated less than half of the width of the bridge of the nose
- **Grade 2:** bones deviated half to one full width of the bridge of the nose
- **Grade 3:** bones deviated greater than one full width of the bridge of the nose
- **Grade 4:** bones almost touching the cheek.

Pattern of fracture

Nasal fractures can also be subdivided into three broad categories that characterize the patterns of damage sustained with increasing force. This classification has some practical utility as each category of fracture requires a different method of treatment.

CLASS 1 FRACTURES

Class 1 fractures are the result of low–moderate degrees of force and hence the extent of deformity is usually not marked. The simplest form of a Class 1 fracture is the depressed nasal bone. The fractured segment usually remains in position due to its inferior attachment to the upper lateral cartilage which provides an element of recoil. The nasal septum is generally not involved.

In the more severe variant, both nasal bones and the septum are fractured. The fracture line runs parallel to the nasomaxillary suture ipsilateral to the side of the applied force to a point approximately two-thirds along the length of the nasal bone, where the bone becomes much thicker. The fracture line then connects across to the contralateral side and runs parallel and just below the dorsum. The cartilaginous septum is fractured approximately 0.5 cm below the dorsum and this aspect of the injury may extend posteriorly into the bony septum, through the perpendicular plate of the ethmoid and skull base. This fracture was first described by Chevallet and bears his name ([Figure 107.1](#)).

Class 1 fractures tend not to cause gross lateral displacement of the nasal bones and may not even be perceptible. Deformity generally results from a persistently depressed fragment, which is often due to impaction of the flail segment beneath the residual nasal bone. In children, these fractures may be of the ‘greenstick’ variety and significant nasal deformity may only develop at puberty when nasal growth becomes accentuated.⁶

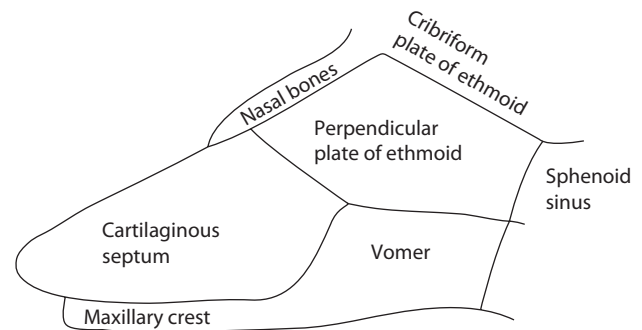

Figure 107.1 The distal part of a nasal bone is half the thickness of the proximal part. When it fractures, the nose is apparently deviated but the impression of deviation is optical (Chevallet fracture). It is important to recognize this injury. The edges of the stable segment can often be palpated. Figure courtesy of AGD Maran.

CLASS 2 FRACTURES

Class 2 fractures are the result of greater force and are often associated with significant cosmetic deformity. In addition to fracturing the nasal bones, the frontal process of the maxilla and septum are also involved. However, the ethmoid labyrinth and adjacent orbital structures remain intact (see Class 3). The pattern of deformity is determined by the direction of the force applied. A frontal impact tends to comminute the nasal bones and cause gross flattening and widening of the dorsum; while a lateral impact produces a high deviation of the nasal skeleton.

What may appear to be a simple dislocation of the quadrangular cartilage from the bony septum is in reality a complex ‘C-shaped’ fracture that extends from the quadrangular cartilage beneath the nasal tip, posteriorly through to the perpendicular plate of the ethmoid, to the anterior border of the vomer and then forward through the lower part of the perpendicular plate of the ethmoid into the inferior part of the quadrilateral cartilage. This pattern of fracture was first described by Jarjavay and bears his name ([Figure 107.2](#)).

As a rule of thumb, if the nasal dorsum is deviated laterally greater than half the width of the nose (Grade 2 or greater fracture), then a septal fracture must also be present. Septal fracture-dislocations tend to happen at points of weakness. They are where the quadrangular cartilage inserts into the cartilaginous dorsum, the bony septum and the maxillary crest. Both the nasal bone and septal fractures need to be reduced together in order to achieve a satisfactory cosmetic result.

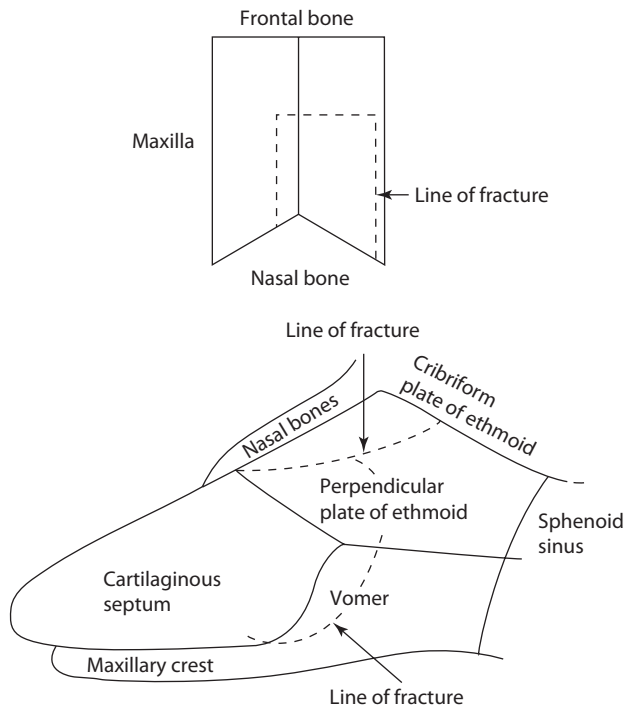

Figure 107.2 A Class 2 nasal fracture involves the thicker proximal portion of the nasal bone. It results in true deviation and also fracture of the perpendicular plate of the ethmoid and quadrilateral cartilage (Jarjavay fracture). Figure courtesy of AGD Maran.

CLASS 3 FRACTURES

Class 3 fractures are the most severe nasal injuries encountered and usually result from high velocity trauma. They are also termed naso-orbito-ethmoid fractures and often have associated fractures of the maxillae. The external buttresses of the nose give way and the ethmoid labyrinth collapses on itself. This causes the perpendicular plate of the ethmoid to rotate and the quadrilateral cartilage to fall backwards. These movements cause a classic, 'pig-like' appearance to the patient, with a foreshortened saddled nose and the nostrils facing more anteriorly, like the snout of a pig. There is also telecanthus, which may be exaggerated further by disruption of the medial canthal ligament from the crest of the lacrimal bone.

Two categories of naso-orbito-ethmoid fractures have been recognized by Raveh.⁷ In type I, the anterior skull base, posterior wall of the frontal sinus and optic canal remain intact. In type II, there is disruption of the posterior frontal sinus wall, multiple fractures of the roof of the ethmoid and orbit that may extend posteriorly to the sphenoid and parasellar regions. Multiple dural tears, cerebrospinal fluid leaks (CSF), pneumocranium and cerebral herniation may complicate this type of injury. (The management of this type of nasal fracture is covered later in this Chapter).

CLINICAL PRESENTATION

History

It is prudent to establish how and when the injury was sustained, not only for medicolegal purposes but also because

there is a limited period of time during which simple reduction is possible. There will almost certainly be some degree of nasal obstruction associated with the injury, but complete obstruction and persisting pain might indicate the presence of a septal haematoma. Enquiry should be made about any obvious change in the shape of the nose and of previous injuries or past nasal surgery. The patient may have a recent photograph that could be helpful to establish their claim.

Other injuries may also be present and may have been overlooked. Diplopia, visual disturbance and epiphora suggest orbital trauma. Loose teeth, an altered bite or trismus indicate the need for a dental opinion. The onset of watery rhinorrhoea and loss of the sense of smell, though uncommon, signal possible skull base damage and the need for a more detailed evaluation. Finally, it is worth enquiring about their leisure pursuits and any occupational hazards that might influence any decision to correct the deformity.

Key issues to consider when determining history include:

- details of how and when the injury was sustained
- nasal obstruction
- change in appearance
- anosmia; hyposmia; watery rhinorrhoea
- visual disturbance; diplopia; epiphora
- altered bite; loose teeth; trismus
- occupation; leisure pursuits.

Examination

The importance of clear and complete records of the clinical examination cannot be overemphasized. What is and what is not a new injury can be difficult to determine at a later date when litigation is contemplated. Inspect the nose for any external deformity. This may be extremely difficult in the acute situation when swelling may hide an underlying abnormality. A second inspection a few days later may be necessary. Gently palpate the nasal bones for a step deformity and make note of any surgical emphysema that could suggest a more serious injury. Make a detailed record of soft-tissue lacerations. Inspect the nasal cavities and check for the presence of a septal haematoma or deviation. A thorough general ENT/head and neck examination must also be completed.

Key issues to consider when examining a patient include:

- deviation, depression, step deformities
- mobility, crepitus, specific areas of point tenderness
- generalized swelling and specific bruising
- skin and mucosal lacerations
- septal fracture/haematoma/abscess/perforation.

INVESTIGATIONS

Unlike other fractures, nasal X-rays are not required to make the diagnosis or aid subsequent reduction. In a prospective study undertaken by Logan et al., it was concluded that X-rays were not cost effective.⁸ Their only possible utility is proof of injury in subsequent litigation. If there is

clinical evidence of a more serious facial injury computerized tomography (CT) scan should be acquired. Samples of any watery rhinorrhoea must be collected in those with suspected CSF leak and tested for b2 transferrin.

TREATMENT

The indications for surgical intervention in the acute phase are significant cosmetic deformity and nasal obstruction caused by a septal haematoma. However, a very significant number of patients (up to 80%) do not require any active treatment; many do not have a nasal fracture and, in those that do, the fracture may not be displaced.⁴ Soft-tissue swelling can produce the misleading appearance of a deformity which disappears as the swelling subsides. Reassurance is all that these patients may require. Topical vasoconstrictor drops are helpful to alleviate congestion and obstructive symptoms. A reexamination about 5 days later is prudent where there is uncertainty about the need for reduction.

Many patients will have a pre-existing nasal deformity caused by a previous incident. Manipulation of the nose will, at best, only return it to its most recent appearance. Patients that fall into this category may be better advised to consider a formal rhinoplasty when everything has settled down some months later. Others will be at continued risk of further injury because of an occupational hazard, sport or leisure activity. It is better to advise this group of patients to undergo a definitive septorhinoplasty when the risk of further injury no longer exists.

The timing of surgical assessment and subsequent reduction is crucial as there is a narrow window of opportunity to correct the deformity. Failure of referral or timely referral is a common cause of litigation in nasal injuries. Patients should be seen quickly, certainly within the first few days and no later than one week. Patients with a suspected septal haematoma should be seen urgently at the first possible opportunity. The optimal time for clinical assessment is around 4 days, by which time much of the oedema will have subsided and any underlying deformity become apparent. Review at 4 days allows sensible planning for reduction of the fracture on an elective operating list within the next 2 to 3 days, if it is to be reduced under a general anaesthetic. By 7 days, the bony abnormality will be easily palpable and still movable. Further delay makes effective reduction less likely and sometimes impossible without making osteotomies. In children, healing can take place even more quickly and earlier intervention is indicated.

Those patients for whom treatment is considered unnecessary should be given the contact details of the ENT clinic lest deformity become apparent over the ensuing weeks.⁴

Anaesthesia

Reduction of a fractured nose can be performed under local or general anaesthesia. Many studies have shown reduction of nasal fractures under local anaesthesia to be perfectly adequate and acceptable.^{9, 10}

Local anaesthesia has several advantages but the injections can be painful and the associated distortion of soft

tissues can hinder accurate assessment of the reduction and the literature is divided over the influence on outcomes. In a retrospective analysis of 324 patients, Courtney et al. found a higher number of patients seeking a septorhinoplasty when the initial reduction was performed under local anaesthetic (17.2%) than general anaesthetic (3.2%).³ On the other hand, Ridder et al. found that there was no significant difference in overall success rate.¹¹

Local anaesthetic can be used as a combination of external infiltration with internal application of topical preparations. Lignocaine is injected along the nasomaxillary groove, infraorbital nerve in its foramen and around the infratrochlear nerve. Jones and Nandapalan recently reported the use of topical EMLA (prilocaine and lignocaine) cream or AMETOP (amethocaine) gel to the external nose instead of infiltration.¹² They found less discomfort when the manipulation was carried out using the topical, local anaesthetic preparation compared with local infiltration. They achieved similar cosmetic and functional results.¹² Within the nose, sprays, injections, pastes or packs coated with local anaesthetic are all acceptable, using combinations of cocaine, lignocaine, adrenaline and phenylephrine. The vasoconstrictive element helps to reduce any bleeding associated with mucosal tears from instrumentation during the reduction, but must be used cautiously in hypertensive patients or those with cardiovascular disease.

There are easily identifiable groups of patients who are not suitable for reduction under local anaesthesia. Children and patients with low pain thresholds or significant anxiety states are better admitted for general anaesthesia. Likewise, attempts at reduction of fractures where there has been delay in presentation are better performed under general anaesthetic.

Methods of reduction

Closed techniques for nasal reduction have traditionally been used. The general principle of any fracture reduction is to mobilize the fragments first by increasing and then decreasing the degree of deformity. An initial slight increase in deformity away from the side of the blow to disimpact the fragments, followed by steady movement back towards and often slightly beyond the midline is usually required. Generally, this can be achieved by firm digital pressure. Sometimes instruments are necessary, particularly in those where there has been delay. Various elevators and forceps have been developed specifically for this purpose, such as Freer, Hills and Howarth elevators and Ashe and Walsham forceps ([Figure 107.3](#)). The instrument is held so that the index finger of the dominant hand is placed along the instrument in the line of the nose. In this way, the depth that the instrument must be inserted into the nasal cavity is easily gauged and inadvertent damage to the orbit avoided ([Figure 107.4](#)).

All Class 1 and most Class 2 fractures can be reduced with these techniques. In some Class 2 fractures, closed reduction alone may not achieve a satisfactory result as the final position of the nasal dorsum reflects the deformity of the underlying septum.^{1, 13-15} At least 50% of

Figure 107.3 Instruments used in nasal fracture manipulation. (a) Howarth's elevator; (b) Ashe's forceps (septum); (c) Walsham's forceps (nasal bones).

Figure 107.4 Determining depth of insertion of instrument into nasal cavity.

these fractures remain displaced because of overlapping segments of the fractured perpendicular plate of the ethmoid or septal cartilage, which can only be repositioned by open reduction. Occasionally, the bones are fixed, especially if the fracture is old, and osteotomies are necessary to release the fragments before manipulation. These should be performed cautiously to avoid the risk of extension into the orbit or, even worse, intra-cranially.¹⁶

Splints or packs may be necessary, depending on the stability of the reduction and the surgeon's preference. A splint or plaster applied to the nasal bridge maintains, to some extent, the position of the nasal bones and prevents accidental displacement. Splints are usually kept in place for about 7 days. It is advisable to refrain from contact sports for at least 6 weeks.

Very occasionally, open reduction techniques may be desirable or required to provide optimal results, despite the increased time and effort involved. Verwoerd identified the following indications for open reduction:¹⁵

- bilateral fractures with dislocation of the nasal dorsum and significant (pre-existent or recent) septal deformity
- infraction of the nasal dorsum
- fractures of the cartilaginous pyramid, with or without dislocation of the upper laterals.

For depressed tip or flail lateral fractures that are unstable despite closed reduction techniques, Kirschner (K) wires can be used. The wire is inserted under fluoroscopic guidance into the depressed fragment as well as neighbouring uninvolved bone (maxilla or frontal bone), and the wires are screwed together externally to maintain the position. The external wire can be covered by dressings or plaster to protect the wires from disruption and the patient from injury. The wires are removed after 2 weeks.

Some authors advocate a more aggressive approach to the treatment of acute nasal fractures which includes some 'rhinoplasty' techniques, such as release of upper lateral cartilages, hump removal and camouflaging cartilage grafts.¹⁷ Incorporation of these more advanced techniques into the management of the fractured nose requires expertise, more instrumentation and more operating time and this may not always be feasible or desirable.

Management of the nasal septum

Septal fracture is often missed and is a major reason for poor functional and cosmetic results. Kim et al. found that 46.9% of nasal fractures have a concomitant septal fracture.¹⁸ If a significant septal fracture-dislocation is present, it is wise to reduce this at the same time as the nasal bones. In fact, a satisfactory reduction of nasal bones is often not possible without improving the position of the septum. An often-quoted aphorism, 'where goes the septum, so does the nose' is not far from the truth.

Septal reduction can sometimes be performed with Ashe's forceps, but often requires a Killian or hemitransfixion incision, elevation of mucosal flaps to expose the

cartilage and bone fragments, and replacement and/or removal of cartilaginous and bony fragments, as in a standard septoplasty. Quilting sutures prevent a dead space from forming and a haematoma from collecting.

COMPLICATIONS

Poor cosmetic result

Attempts to reduce deformity are not always successful. Factors which contribute to an unsatisfactory cosmetic result include:

- extent of the injury
- time delay in surgical reduction
- poor surgical technique
- unrecognized and untreated septal fracture
- pre-existing nasal deformity
- post-operative trauma (in recovery room or subsequently)
- scarring and fibrosis.

Unfortunately, it is not uncommon for the shape of the nose to change over time due to subsequent scarring and fibrosis, loss of tip or dorsal support, or hump formation. Some patients inevitably require a septorhinoplasty despite apparent adequate reduction. It is wise to wait at least 6 months after the injury before embarking on septorhinoplasty to allow the fractures to heal, the oedema to settle completely so the underlying nasal skeleton is evident, and for any fibrosis to develop.

Nasal obstruction

Post-operative nasal obstruction is also common and there are many causes that include:

- valve obstruction
- collapse of upper lateral cartilages and depressed nasal bones
- septal deviation
- widened septum (haematoma)
- tip ptosis.

These causes need to be considered and addressed at a subsequent septorhinoplasty.

Epistaxis

Epistaxis at the time of injury may be impressive but is usually relatively brief. Occasionally, fractures involving the nasoethmoidal complex can cause laceration to the anterior ethmoidal artery. This may result in repeated, brisk and significant haemorrhage that only stops once the fracture has been reduced. Very occasionally, prolonged packing or ligation of the artery is required. Bleeding can also be troublesome at the time of reduction, particularly if instruments are used. Preparation of the nose with vasoconstrictive agents helps to minimize this blood loss.

Septal complications

A submucoperichondrial bleed not infrequently complicates nasal fractures. While most septal haematomas are relatively limited, some may strip the mucoperichondrium over an extended area and deprive the underlying cartilage of its source of nutrition. This can lead to cartilage necrosis and ultimately nasal deformity. Septal haematomas present with an acute unilateral or bilateral nasal obstruction and, on inspection, there is a reddish-purple, fluctuant swelling of the caudal septum. A deviated septum can be confused with a septal haematoma. Gentle pressure on the bulging area will ascertain that it is fluctuant if a collection is present. Untreated, an abscess may develop and the patient becomes very unwell with a fluctuating fever and severe facial and cranial pain. Rarely, cavernous sinus thrombosis or other forms of intra-cranial sepsis can ensue.

The haematoma or abscess must be drained as soon as possible. This can be performed under local or general anaesthetic, either by using needle aspiration or preferably an incision. Often the collection will have become organized and so impossible to aspirate. In this situation, a small window of mucoperiosteum should be excised ensuring there is no corresponding defect on the contralateral side which could predispose to a perforation. Once drained, quilting sutures from one side through cartilage to the other are inserted to eliminate the dead space. Packs or splints can be used to provide gentle pressure on the septum. The patient must be reexamined within 48 hours to establish that the collection has not recurred. The management of a septal abscess is similar, but with the addition of appropriate antibiotic therapy.

Septal perforations may also develop after nasal fractures, usually as a result of septal haematomas and their surgical treatment. Loss of cartilaginous septal support can also lead to a saddle nose deformity, as well as columellar retraction and a broadened septum.

KEY POINTS

- Nasal fractures are common and awareness of the basic principles of management ensures good outcomes.
- All significant nasal injuries should be assessed within a few days if there is cosmetic deformity and within 24 hours if nasal obstruction is evident to exclude a septal haematoma.
- It is important to assess each patient carefully and be vigilant over potential complications.
- Document all details carefully in case of subsequent litigation.
- Not all referred patients actually have fractures and even some with fractures do not need surgery.
- Most cases can be reduced adequately with closed techniques, unless the fractures are complex or a significant septal fracture-dislocation is present.
- There are no significant differences between the outcomes of local versus general anaesthesia: more important predictors of outcome include pre-existing deformity, severity of injury, delay in assessment and poor surgical technique.
- Residual cosmetic deformity and nasal obstruction are relatively common complications and it is wise to counsel patients about these from the outset.
- A formal septorhinoplasty can be performed in cases of poor outcome, best performed at least 6 months after the injury.

BEST CLINICAL PRACTICE

- ✓ Prompt medical review within 24–48 hours of all significant nasal injuries, with urgent ENT referral if a septal haematoma or if a Class 3 fracture is present.
- ✓ Exclusion of related injuries to face, orbit, jaws and central nervous system (CNS) at initial assessment and appropriate specialist referral if present.
- ✓ ENT assessment at 4 to 5 days if cosmetic deformity or nasal obstruction are present.
- ✓ Closed reduction at 7 days, or open reduction if more complex.
- ✓ Review 7 days post-operatively with removal of external nasal splint.
- ✓ No contact sports for at least 6 weeks post-operatively.

FUTURE RESEARCH

- ▶ More prospective studies are required comparing closed and open reduction techniques.
- ▶ More prospective studies are needed to compare nasal bone reduction with nasal bone reduction and septoplasty.
- ▶ Studies need to be undertaken to determine whether a more aggressive approach to the initial management of nasal fractures (such as open reduction, septoplasty, 'rhinoplasty techniques') will prevent subsequent septorhinoplasty.

FACIAL FRACTURES**INTRODUCTION**

Injuries to the face are common and account for 10% of all accident and emergency department attendances. Aesthetically, first impressions of a person in terms of their intellect, ability, trustworthiness and even sexual orientation are influenced by facial appearance. Functionally the facial skeleton provides support to the muscles of facial expression and these in turn act as the sphincter that protects the eyes and make the mouth competent. The facial skeleton holds and supports the eyes in the optimum position for binocular vision and the orbital margins provide additional protection for the globes. Historically the success of facial fracture management was judged entirely on the final dental occlusion. While it is important to ensure that a normal bite is achieved, it is just one of the criteria that define today's standard of care. Equally important is the restoration of both the vertical and transverse facial dimensions. This can be achieved by extended craniofacial bone exposure and the use of rigid and semi-rigid internal fixation. In addition, meticulous attention to the repair of soft tissues injuries ensures the best possible cosmetic result.

KEY POINTS

- Maxillofacial trauma is extremely common. Ten percent of all accident and emergency attendances are related to facial injuries.
- Immediate assessment of the airway is essential.
- Most facial fractures are managed by semi-rigid internal fixation through extended subperiosteal exposure of the fracture.
- Wiring of the jaws is no longer the standard of care.
- Cerebrospinal fluid (CSF) rhinorrhoea and retrobulbar haematoma should be excluded in all middle-third facial injuries.

AETIOLOGY

Fractures of the nose, mandible and middle third of the face are usually caused by road traffic accidents, physical violence, falls, attempted suicide, and sporting injuries (Figure 107.5). Most injuries are low energy and heal predictably. Higher-energy injuries cause gross comminution of the bones and do not heal as well. It is important to ascertain the exact mechanism of injury not only for medicolegal reasons, but also to ensure that an adequate screening examination is undertaken to detect other injuries and so that a prognosis on the likely stability of any repair can be given.

KEY POINTS

- Successful outcome involves restoration of pre-morbid facial proportions, dental occlusion and accurate soft tissue repair.
- Road traffic accidents, interpersonal violence, attempted suicide and sports injuries are the most common cause of facial fractures.
- The mechanism of injury will provide insight on the possible degree and extent of the injury and the methods that will be necessary for repair.

PRIMARY CARE

The initial survey

Maxillofacial injuries endanger the airway and can cause profuse haemorrhage. Associated neck injuries are common and should always be suspected and excluded. Advanced trauma and life-support protocols dictate that a rapid and accurate primary survey should be undertaken in the following sequence:

1. **Airway.** Evaluate and secure the airway, while maintaining alignment of the neck in case there is an unstable cervical spine injury.
2. **Breathing.** Make sure that there is adequate ventilation.
3. **Circulation.** Control sources of blood loss.
4. **Disability.** Assess the level of consciousness and neurological dysfunction.
5. **Exposure.** Ensure that all other injuries are identified.

The establishment of a safe airway and effective ventilation is essential so that hypoxia and carbon dioxide retention is prevented and the resultant post-traumatic cerebral oedema minimized. Oral or nasal bleeding, posterior displacement of the tongue secondary to mandibular fractures or the result of postero-inferior displacement of the maxilla in middle-third injuries may further compromise the airway. It may be necessary to reduce these fractures immediately and place temporary bridal wires around dentoalveolar segments to increase bony stability. Although the correct surgical procedure for the rapid relief of acute upper airway obstruction is often a cricothyroidotomy, there is occasionally merit in performing an immediate tracheostomy if it can be conducted swiftly and safely. Haemorrhage from facial fractures can be torrential and demands immediate attention. The use of anterior and posterior nasal packs has been abandoned in favour of the epistat (Figure 107.6). It is important to remember that any injury to the upper middle third of the face is likely to have shattered the anterior skull base.

Figure 107.6 Epistat in anatomical model. Palpation of the posterior balloon in the nasopharynx ensures no intra-cranial intubation.

Inadvertent intubation of the anterior cranial fossa through the cribriform plate or medial wall of the orbit is a distinct possibility and should be borne in mind when attempting to pass any tube through the nose. Intense shock should not be attributed to a facial injury until abdominal, pelvic, orthopaedic or thoracic causes have been excluded. Use of the Glasgow Coma Scale will alert the clinician to impending intra-cranial complications. Immediate neurosurgical advice should be obtained if the patient's conscious level deteriorates. CSF rhinorrhoea must be suspected in any high-level nasoethmoid or maxillary fractures. This demands prophylactic antibiotic therapy to prevent meningitis. Tetanus prophylaxis should be administered in any non-immune patient.

Principles of primary management

Once the primary survey of the injury has been completed, a secondary survey is carried out to exclude other injuries and to categorize the extent of the facial injury. The soft tissues of the face are carefully scrutinized and any lacerations or cuts noted together with the proximity to relevant anatomical structures including the eyebrows, conjunctival margins, nasal aperture and the vermillion border of the lips. Facial nerve function should be documented and the integrity of the parotid duct assessed. Visual acuity and ocular movements are recorded. Any orbital injury may be complicated by a retrobulbar haemorrhage and retinal detachment, both of which are preventable and treatable causes of permanent blindness.

A full hard-tissue examination is conducted by palpating the orbital margins, zygomatic projection, nasal skeleton and mandibular outline. If conscious, the patient is asked whether their bite is comfortable and if it feels normal, and if there is any numbness. A full dental examination is necessary so that any fractured or missing teeth that may have been inhaled are identified and accounted for. Finally, the dental occlusion and maxillary or mandibular instability is formally assessed and documented.

Radiographic evaluation

All major trauma patients should have chest, cervical spine and pelvic X-rays as soon as possible. The selection of X-rays of the facial skeleton is discussed later, but it is certainly worth including the facial skeleton on any computerized tomography (CT) scan that might be required for a patient with multiple injuries. Early detection of these injuries greatly simplifies their management. The timing of any maxillofacial intervention is controversial. Historically, it was usual to await resolution of any facial swelling before the assessment process began. Patients might wait for 5 to 7 days before surgery was considered. With modern-day techniques, there is a trend to fix facial fractures earlier. This policy avoids the so-called double insult of accidental and surgical trauma. Swelling can be reduced by nursing the patient in the head-up position with ice packs, together with a single

dose of dexamethasone. Facial wounds should be cleaned and lacerations closed as soon as possible, if necessary under local anaesthesia.

Any facial fracture that communicates with the oral cavity through the periodontal ligament of teeth should be regarded as compound and parenteral prophylactic antibiotics given.

BEST CLINICAL PRACTICE

- ✓ Maxillofacial fractures can endanger the airway.
- ✓ Be aware of associated cervical spine injuries.
- ✓ Consider tracheostomy at the outset in patients with extensive trauma.
- ✓ Close soft tissues injuries as soon as possible.
- ✓ CT scans of the head and facial bones help to define the extent of both facial and cerebral injuries.
- ✓ Do not forget to give tetanus prophylaxis.
- ✓ Exclude cervical spine injuries.
- ✓ Check visual acuity in all patients with middle-third facial injuries lest they have a retrobulbar haemorrhage.

MANDIBULAR FRACTURES

Introduction

The mandible is a parabolic-shaped bone with a complex articulation that consists of paired synovial joints – the temporomandibular joints – and movements that are, in part, guided by the dental occlusion. Satisfactory rehabilitation of the fractured mandible requires accurate reduction, adequate fixation and mobilization. The traditional method of treatment was immobilization of the fracture with intermaxillary fixation (IMF) (Figure 107.7). More recently, it has been realized that the advantages of such treatment in terms of cost and simplicity were far outweighed by a number of disadvantages. At the outset, there were always concerns about the airway lest it became compromised by soft-tissue swelling or vomiting. The period of immobilization was uncomfortable and inconvenient for the patient as it imposed dietary restrictions.^{19, 20} Furthermore, the use of wires placed the

Figure 107.7 Eyelet wires fastened to the dentition and interconnected is the simplest form of intermaxillary fixation.

surgeon and nursing staff at risk of needlestick injuries.²¹ To make matters worse, the fixation achieved by this method was often inadequate, particularly if the dentition was incomplete or in bad repair (Figure 107.8).

The widespread use nowadays of miniplates and extended subperiosteal exposure of the craniofacial skeleton to achieve fixation means that there are now few indications for closed reduction of any facial fracture. In this way, correct anatomy and occlusion is restored.^{22, 23} One further and very significant advantage of not using IMF is that in severely injured patients a tracheostomy might be avoided.

Surgical anatomy

The mandible will fracture when subjected to direct and indirect force. Stereotypical fracture configurations are recognized that are determined by the direction and magnitude of the applied force and whether the teeth are in or out of occlusion at the time. Fractures happen at points of potential weakness where the bone is relatively thin (Figure 107.9). The angles of the mandible may be weakened by unerupted wisdom teeth, the parasymphysis by the long root of the lower canine and the condylar neck by its slender anatomy. It is also common for the mandible to fracture in more than one place,

Figure 107.8 This fracture of the angle of the mandible has been managed inappropriately by intermaxillary fixation – the posterior segment of the left mandible is not controlled. The molar tooth in the line of the fracture should be extracted and an alternative form of fixation applied.

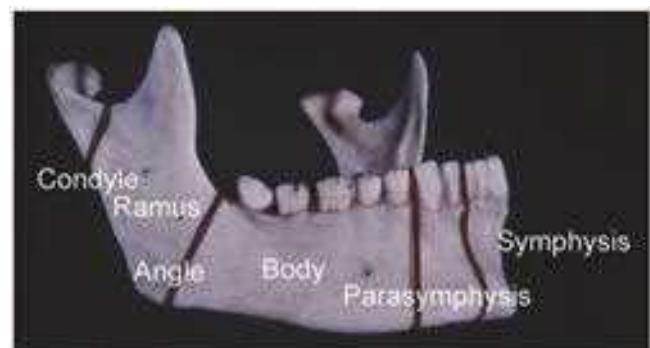

Figure 107.9 Lines of weakness in the mandible that determine the pattern of fractures in the mandible.

for example, the parasymphysis (site of direct violence) and condylar neck (site of indirect violence). It is obviously sensible to look carefully for more than one fracture. Displacement of the fracture depends on a variety of factors, the most important of which are the pull of attached muscles.

Signs and symptoms

The signs and symptoms produced by mandibular fractures are determined by the site of the fracture.

Fractures of the body, angle and symphysis are associated with:

- a step deformity palpable either externally or intraorally
- asymmetry of the lower dental arch and derangement of the occlusion
- pain and paradoxical movement and crepitus on distraction of the fractured segments
- haematomas in the buccal sulcus or floor of the mouth
- blood-stained saliva
- anaesthesia of the lower lip.

Fractures of the condylar neck are associated with:

- tenderness over the temporomandibular joint
- trismus
- deviation of the jaw towards the injured side on opening the mouth
- inability to move the mandible to the side opposite the fracture
- deviation of the jaw to the fractured side at rest with an anterior open bite secondary to gagging of the molar teeth in fracture dislocation
- symmetrical anterior open bite in bilateral fractures of the necks of the condyles.

Closed reduction techniques

As stated previously, the use of IMF plays a much smaller role in modern maxillofacial surgery. Simple mandibular fractures can be held in normal occlusion and plated without much difficulty.²⁴ Nevertheless, IMF still has a part to play in two groups of patients. First, those with undisplaced fractures and no neural deficits who want to avoid more complex surgery and, second, those with unilateral condylar fractures. In the emergency room, a simple tie wire placed around the teeth either side of a displaced fracture can reduce pain, bleeding from bone ends and make nursing easier in the hours and days before a planned open reduction and internal fixation.

THE INTACT DENTAL ARCH

There are several methods of applying wire to an intact dental arch to provide IMF. Perhaps best known are eyelet wires. This is very simple but is only possible in those situations where there are two adjacent

teeth in contact. The main disadvantage is that it is difficult to combine eyelet wires with elastic traction and it can be awkward to thread wire through tight interdental contact points, particularly in an awake patient. A simple and ingenious modification is the Leonard button (Figure 107.10), an eyelet wire with a small metal disc instead of a loop.

THE INCOMPLETE DENTAL ARCH

Arch bars

An arch bar is a strip of metal that is wired to each jaw using several individual teeth. The bar may be prefabricated using a model made from a pre-operative dental impression (Figure 107.11), or may be made at the time of surgery by adapting a pre-formed pattern. Arch bars can span short gaps within each jaw, but will not cope with large gaps or when there is no posterior tooth. Their main advantage is that they provide a relatively simple means of stabilizing more complex fractures and at the same time provide indirect fixation.

Intermaxillary bone pins

A rapid method of intermaxillary fixation has been described.²⁵ A mono-cortical screw is placed through the mucosa between the canine and first premolar on each side and jaw. The screws are then wired together or connected with elastic bands. It is important to ensure that

Figure 107.10 The Leonard button – a simple device that facilitates intermaxillary fixation by either wire or elastic bands.

Figure 107.11 Intermaxillary fixation has been achieved by the use of prefabricated arch bars connected by elastic bands.

the path of the screw enters bone and avoids the roots of teeth. These specially designed screws are brittle and care must be exercised when inserting them lest they break.

External fixation

The use of rigid and semi-rigid fixation has diminished the need for external fixation. External fixation is now only indicated for those patients with gross tissue loss as might be seen in the theatre of war and for those with pathological fractures, particularly when the patient is too unwell to undergo extensive surgery. A number of methods have been described and are in current clinical use. By far the simplest is the placement of cortical screws and then connecting them with an external bar made of acrylic. We have found that a mini-Pennig orthopaedic fixator provides an elegant means of stabilizing fractures (Figure 107.12), as well as avoiding pin tract problems, and the need for constant tightening and adjustment.

Internal fixation

ACCESS

Intra-oral incisions

Wherever possible, bone plates should be placed through an intra-oral approach. Mucogingival incisions are made so that the resultant flap includes the periosteum. It is essential that a sufficient cuff of mucosa is raised so that the plate is completely covered after closure. Care must be taken to avoid inadvertent damage to the mental nerve in the anterior region.

Extra-oral incisions

External incisions are used for the lower border of the mandible and condylar neck. Lower border plates are ideal when there is gross comminution or tissue loss. They are also preferable in fractures of grossly resorbed edentulous mandibles.²⁶ In these situations, it is better to use bicortical screws and thicker plates that can provide

superior fixation. The incision is made two finger-breadths below the lower border of the mandible in order to avoid damage to the mandibular branch of the facial nerve. The incision is deepened through the platysma muscle and then blunt dissection exposes the lower border of the mandible. Condylar neck fractures are approached through a retro-mandibular incision while higher condylar neck fractures are better exposed through a pre-auricular incision.²⁷

PRINCIPLES OF MANDIBULAR FIXATION

The zones of tension and compression mentioned earlier dictate the ideal position and plate configuration around a fracture site. In simple mandibular fractures, monocortical 2 mm plates provide adequate fixation because of the phenomenon of load sharing between the fracture and the osteosynthesis. In the anterior mandible, two plates are used while posteriorly one plate is usually sufficient²⁸ and in both situations 6 mm long screws are used. The placement of plates in the region of the mental nerve can be technically demanding (Figure 107.13). In complicated fractures where there is gross comminution, tissue loss or infection, a load-bearing osteosynthesis with rigid internal fixation and bicortical screws are required.

CONDYLAR NECK FRACTURES

There is no topic more controversial in maxillofacial trauma than the management of condylar fractures. The 'gold standard' management of most displaced mandibular fractures is reduction and internal fixation. There is just one exception – fractures of the condyle. In the case of condylar fractures, functional adaptation, neuromuscular rehabilitation and altered condylar mechanics may compensate for the deficiencies of IMF in terms of accuracy of reduction. Bilateral displaced condylar neck and high-intra-capsular fractures generally have poor outcomes and are better managed by an open reduction.²⁹ Several factors determine the best approach to the condyle. These include the position of the fracture, available skin creases, tissue laxity and last but not least, the experience of the operator.

Figure 107.12 A mini-Pennig wrist fixator used to provide external fixation.

Figure 107.13 Fixation of a fracture in the parasymphyseal region of the mandible using plates. The lower plate has been manipulated beneath the mental nerve.

A retromandibular incision provides the most direct and simple approach to the ramus and subcondylar region, albeit that the surgeon must be careful not to damage the facial nerve. An additional pre-auricular incision can be usefully employed with higher condylar neck fractures. In recent years, there has been enthusiasm for endoscope-assisted repair techniques that are technically difficult to perform but avoid large facial scars.^{30, 31} Once exposed, the fracture is reduced and fixed with miniplates.

KEY POINTS

Mandibular injuries

- Mandibular injuries are often multiple.
- IMF following closed reduction is no longer acceptable practice for the majority of mandibular injuries.
- Most fractures are treated with non-compression miniplates.
- The management of condylar neck fractures is controversial.
- Endoscopic techniques may have a role in the management of certain mandibular fractures.

Signs and symptoms of mandibular fractures include:

- bony step deformity;
- deranged occlusion;
- pain;
- sublingual haematoma;
- blood-stained saliva;
- mobile teeth in the fracture line;
- anaesthesia of the lip;
- trismus.

Signs and symptoms of condylar neck fractures include:

- tenderness over the temporomandibular joint (TMJ);
- trismus;
- lateral open bite;
- anterior open bite.

FRACTURES OF THE MAXILLA

Introduction

Fractures of the midfacial skeleton can be subdivided into lateral (zygomatic) or central (maxillary, nasal, nasorbithmoid) fractures. The symptoms and signs of maxillary injuries depend on the level of the fracture (Figures 107.14 and 107.15). The classical features of a midfacial fracture are circum-orbital ecchymosis (panda facies), facial oedema and emphysema, lengthening of the face and an anterior open bite. Not all of these signs need be present. An infra-orbital nerve sensory deficit is not uncommon in higher fractures and bruising at the junction of the hard and soft palate is frequently present.

Surgical anatomy

The bone of the midfacial region is generally very thin and offers little resistance to anterior and lateral forces.

Figure 107.14 Severe multilevel Le Fort fracture with typical 'panda eyes'. An epistat has been inserted to arrest haemorrhage.

Figure 107.15 (a) 3D CT reconstruction demonstrating vertical, horizontal and transverse disruption to the entire craniofacial skeleton. (b) Post-operative view, note bilateral titanium orbital floor reconstruction.

Le Fort³² described three levels of midfacial fracture (Figure 107.16):

1. **Le Fort 1** This fracture runs above the floor of the nasal cavity, through the nasal septum, maxillary sinuses and inferior parts of the medial and lateral pterygoid plates.
2. **Le Fort 2** This is a fracture which runs from the floor of the maxillary sinuses superiorly to the infraorbital margin and through the zygomaticomaxillary suture. Within the orbit, it passes across the lacrimal bone to

the nasion. The infraorbital nerve is often damaged by involvement in this fracture.

3. **Le Fort 3** This represents a disconnection of the facial skeleton from the cranial base. The fracture traverses the medial wall of the orbit to the superior orbital fissure and exits across the greater wing of the sphenoid and zygomatic bone to the zygomaticofrontal suture. Posteriorly, the fracture line runs inferior to the optic foramen, across the lesser wing of the sphenoid to the pterygomaxillary fissure and sphenopalatine foramen. The arch of the zygoma is also broken.

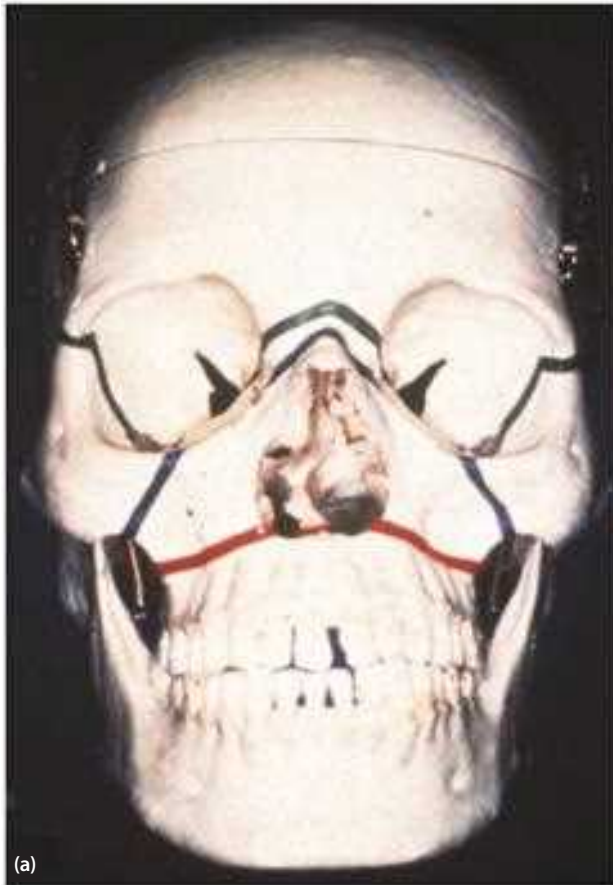

Figure 107.16 (a) and (b) The Le Fort injuries: red, Le Fort 1; blue, Le Fort 2; green, Le Fort 3.

While the Le Fort classification is attractive and accurate for low-energy injuries, in high-energy injuries there are very few instances of pure Le Fort fractures and most configurations involve multiple Le Fort levels,³³ together with zygomatic and nasal/nasoethmoid components. Authors have described thickened areas of bone between the maxilla and skull base which act as buttresses.³⁴ In essence, these thickened areas of bone provide a strategy for reconstruction^{34, 35} and are key areas for osteosynthesis.

Signs and symptoms

Middle third facial fractures produce the following symptoms and signs:

- epistaxis
- circumorbital ecchymosis
- facial oedema
- surgical emphysema
- lengthening of the face
- infraorbital anaesthesia.

Principles of management

EMERGENCY TREATMENT

Midfacial fractures can easily compromise the airway with torrential epistaxes and posterior impaction of the maxilla. The bleeding can be arrested by using epistats or anterior and posterior nasal packs. If retroposition of the maxilla is a problem, it can be pulled forwards using the index and middle finger placed behind the patient's soft palate.

REDUCTION

The maxilla is mobilized by a combination of digital pressure and traction on arch bars or interdental wires. The position of the maxilla is 'eye-balled' with reference to the bony buttresses and dental occlusion. This can be difficult when the bone fragments are comminuted or the dentition is mutilated. Rowe maxillary disimpaction forceps can prove invaluable if the maxilla is impacted.

FIXATION

Modern management of the fractured maxilla parallels that of the mandible.³¹ Internal fixation with

1.3 or 1.5 mm, low-profile miniplates placed along the buttresses provides very satisfactory stabilization of the fractured segments. Access to fractures of the anterior and lateral maxilla can be achieved through a gingivo-buccal incision ensuring that there is an adequate cuff of unattached mucosa to isolate the plates from the mouth at closure. The posterior limit of the incision should be no further than the first permanent molar to preserve a good blood supply. The buccal fat pad may be avoided by angling the scalpel blade or cutting diathermy at 45° to the gingival cuff. Subperiosteal elevation with preservation of the infraorbital nerve allows reconstruction of the paranasal and zygomatic buttresses. The infraorbital rim needs to be reduced and fixed in Le Fort 2 maxillary fractures, nasomaxillary fractures, zygomatic injuries and orbital floor repairs. A number of skin incisions can be used (Table 107.1) all of which have advantages and disadvantages.

KEY POINTS

Maxillary fractures

- Maxillary fractures may involve the orbits.
- They may disrupt the occlusion.
- Internal fixation has replaced external fixation for the majority of maxillary fractures.
- Most high-energy maxillary fractures are not pure Le Fort injuries and are also comminuted.
- Haemorrhage may be arrested with anterior and posterior nasal packs or epistats.

ZYGOMATIC COMPLEX FRACTURES

Surgical anatomy

The body and processes of the zygomatic bone make up the lateral middle third of the facial skeleton. Blows to this part of the face are common and may cause either a depressed fracture of the entire zygomatic bone or a fracture of the zygomatic arch (Figure 107.17). These injuries were originally termed 'tripod fracture' because of the disruption of the three commonly recognized articulations:

1. fronto-zygomatic
2. infraorbital rim
3. zygomaticomaxillary buttress.

In fact, there are two further articulations worthy of consideration:

1. zygomatic arch;
2. zygomaticosphenoid.

The lateral middle third of the face provides support and protection for the globe of the eye. Accurate anatomical reduction of such fractures is important for facial appearance, optimum function of the eye, and because of its close proximity to the coronoid process, for opening and closing the mandible.

Signs and symptoms

The lateral aspect of the face is best examined from the front, above and behind the patient. It will be swollen and bruised. A subconjunctival haemorrhage is almost invariably present in fractures of the zygomatic body (Figure 107.17). Even if the eyelid is closed by oedema, it is essential that the eye is examined and its acuity recorded. Eye movements may be restricted, particularly in upward gaze if there is an orbital floor dehiscence and blow-out of the orbital contents (Figure 107.18). The zygomatic prominence may be difficult to assess initially because of soft tissue swelling but, once this has decreased, reduced projection will become more obvious. A step deformity of the infraorbital margin may be palpable and the frontozygomatic suture may be tender to touch. In arch fractures, there is often a palpable depression and limited mouth opening. Finally, the sensation of the cheek may be altered

Figure 107.17 Typical appearance of a patient with a fractured zygoma. A slight depression of the cheek is clearly visible and he has a subconjunctival haemorrhage.

TABLE 107.1 Orbital access

Incision	Advantage	Disadvantage
Transconjunctival	Good exposure, aesthetic	Slight risk of entropion
Transconjunctival with cantholysis	Excellent exposure	Risk of lid malposition
Transconjunctival with transcaruncular extension	Excellent exposure of medial orbit wall	Technically difficult
Lower eyelid	Straightforward to execute	Risk of increased sclera show, ectropion Visible scar
Infraorbital	Rapid, minimal increased scleral show	Poor cosmesis

Figure 107.18 Reduced ocular movement and enophthalmos associated with an orbital floor injury.

if there has been damage to either the zygomaticotemporal or zygomaticobuccal nerves.

Imaging

Whilst most fractures are visible on 15 and 30° occipitomental X-rays, CT scanning is increasingly becoming standard of care particularly if there are signs of diminished ocular motility. Hess charting should be obtained in all cases with subjective diplopia.³⁶

Management

Minimally displaced fractures may be managed conservatively with a full explanation to the patient and instructions not to blow their nose for a period of 2–3 weeks. It is prudent to review the patient after 10 days when much of the swelling will have resolved to make sure that no active intervention is required. Displaced fractures require reduction with or without fixation. Reduction may be achieved in a number of ways. The precise method will depend on the surgeon's preference and the configuration of the fracture. Each method has its advocates and offers certain advantages over others (Table 107.2).

GILLIES TEMPORAL APPROACH

The hair is shaved just anterior to the ear and both infra-orbital margins are exposed for comparison. Following infiltration with local anaesthetic and adrenaline solution, a small incision is made down to the superficial temporal fascia. The fascia is then incised and an elevator is passed down on the temporalis muscle so that its tip lies just under the fracture. The bone is then elevated.

POSWILLO HOOK

The point of application of the hook is the intersection of a line drawn vertically from the lateral orbital margin and a horizontal line drawn from the inferior margin of the nose. The hook is inserted through a stab incision and the zygoma lifted back into position.

INTRA-ORAL OR KEEN APPROACH

A mucogingival incision is made in the buccal sulcus in the molar/premolar region. An elevator may be passed behind the zygomatic body to elevate the fracture.

Diastasis at the frontozygomatic suture and high-energy injuries are typically unstable. Closed reduction does not allow examination of the articulations of the zygoma. Minor discrepancies may be missed and only come to light some days later.

In reality, surgical exposure of the relevant articulations together with experience ensures good outcomes for the overwhelming majority of patients. The zygoma may be plated at the frontozygomatic suture, infraorbital margin, zygomatic buttress and zygomatic arch. Wound closure is extremely important. Optimal draping of the soft tissues requires meticulous closure of the periosteum over the plates. Some surgeons 'hitch' the deep tissues to superior tissues to provide further support.³⁷

TABLE 107.2 Zygomatic complex fractures – advantages and disadvantages of surgical approaches

Approach	Indication	Advantage	Disadvantage
Gillies	Medially displaced body fractures, zygomatic arch fractures	Elevating site distant from fixation site	Requires skin incision, may be conspicuous in the bald patient
Dingman	Medially displaced body fractures	Uses common skin incision to that of frontozygomatic access	May be difficult to plate frontozygomatic suture and elevate simultaneously Incision may become stretched
Poswillo hook	Posteriorly displaced fractures Not arch fractures	Good mechanical advantage, quick, only one suture required	Access point of hook is prominent on the lateral cheek prominence and may be noticeable
Keen	Medially displaced fractures, arch fractures	Avoids cutaneous scars	Does not address displacement at the frontozygomatic suture Elevation and plating at this site are difficult simultaneously Theoretical contamination of the fracture site with oral microorganisms
Coronal	Laterally displaced arch fractures	The only approach for this rare fracture	Extensive surgical exposure

Post-operative care

The patient is instructed not to blow their nose and, for the first 12 hours, they should be closely observed for signs or symptoms of a retrobulbar haemorrhage. Increasing pain, proptosis, ophthalmoplegia, diminishing visual acuity and a palpable increase in ocular pressure should alert the attendant to this and indicate the need for urgent exploration and evacuation of any haematoma. Most long-term complications relate to malunited fractures. It is important to realize that early accurate anatomical reduction provides the best results. Secondary reconstruction is difficult because of bony remodelling and fibrosis in the overlying soft tissues.^{38, 39}

KEY POINTS

Retrobulbar haemorrhage can involve:

- decreased visual acuity;
- diplopia;
- ophthalmoplegia;
- proptosis;
- tense globe;
- dilated pupil;
- loss of direct light reflex.

BEST CLINICAL PRACTICE

Management involves:

- ✓ dexamethasone 4 mg/kg bolus, 2 mg/kg, 6-hourly;
- ✓ acetazolamide 500 mg i.v.;
- ✓ mannitol 20%, 200 mL;
- ✓ finally, remove the sutures and consider surgical decompression by a lateral cathotomy.

ORBITAL FLOOR FRACTURES

Introduction

The form and function of the globe depends on the integrity of the bone and soft tissue of the orbit. Blunt trauma to the globe⁴⁰ or adjacent bone can lead to a fracture of the thin bone of the orbital floor.⁴¹

Signs and symptoms

The cardinal signs of an orbital floor fracture are enophthalmos and hypoglobus (depressed pupillary level). Enophthalmos is most apparent when the contralateral eye is normal. Other signs include supratarsal hollowing, hooding of the eye, narrowing of the palpebral fissure width and an infraorbital nerve deficit. A small fracture of the orbital floor can lead to a trap door phenomenon. If the orbital fat or inferior oblique muscle becomes trapped in the fracture configuration, then interference with muscular function results in diplopia on upward gaze (Figure 107.18).

Imaging

CT imaging with axial, coronal and sagittal reformatting provides best standard of care

BEST CLINICAL PRACTICE

Ophthalmology review

- ✓ Assessment of visual acuity is mandatory. Retrobulbar haemorrhage causing loss of sight is a rare occurrence but is treatable and should be sought in every orbital injury.
- ✓ Hess charting allows comparison of the visual fields of each eye. Post-operative charting can be used to assess the quality of repair.
- ✓ Hertel exophthalmometry gives an objective analysis of the position of the globe. It has limited value in acute trauma.

Management

Significant orbital floor injury requires exploration and repair. The approach will be determined by the size and position of the blow-out fracture. All soft-tissue components should be mobilized and supported by a graft. Various grafts and materials have been used for this purpose. polydimethylsiloxane (PDS) are readily available and most suited for smaller defects. Titanium alloplasts, either prefabricated or custom-made using CAD-CAM technology are extremely useful especially when there are concomitant zygomatic complex fractures.⁴²

NASO-ORBITO-ETHMOID COMPLEX FRACTURES

Definition and classification

Naso-orbito-ethmoid (NOE) fractures involve the anatomical confluence of the nose, orbits and ethmoids. This is a complex area and these injuries are often overlooked. Reconstruction at a later date is extremely difficult. The most useful classification of these injuries was devised by Markowitz et al.⁴³ who defined them in terms of their attachment to the medial canthal ligaments (Table 107.3).

TABLE 107.3 Classification of naso-orbito-ethmoid complex fractures

Classification	
Type I	Single large central fragment bearing the canthal ligaments
Type II	Fragmentation of the central fragment, medial canthal ligaments attached to bone
Type III	Comminution of the central fragment with no bone attached to canthal ligaments

Signs and symptoms

Loss of nasal projection and tipping up of the end of the nose are common features of these injuries (Figure 107.19). Splaying of the nasal root and telecanthus indicates gross comminution. There is usually blunting of the canthal angle and movement of the medial canthus can be elicited by displacement of the lateral palpebral ligament.

Management

Type I fractures can be stabilized using miniplates. Surgical access is through a coronal flap, intra-orally and lower eyelid incisions may be required. Type II and III fractures are also repaired with miniplates, but require a transnasal canthopexy to reduce the telecanthus and hold the position of the medial canthal ligaments. This is accomplished by means of plates and/or a wire. The lacrimal integrity should be assessed pre- or peri-operatively and stented primarily if damaged.

UPPER FACIAL THIRD FRACTURES INVOLVING THE FRONTAL SINUS

Fractures involving the frontal sinus may lead to deformity and be complicated by infection. These injuries are classified according to the involvement of the anterior and/or posterior table and whether or not there is damage to the nasofrontal duct.⁴⁴ The principal aims of treatment are to leave the patient with a safe and functional sinus and with no cosmetic deformity. Fractures of the anterior table may be treated conservatively if there is no cosmetic deformity, while displaced fractures require reduction and fixation. Fractures of the posterior table demand a neurosurgical opinion and may need an obliterative procedure or cranialization with obliteration of the frontonasal recess and its lining.^{45, 46} Persistence of

Figure 107.19 Patient with a naso-orbito-ethmoid fracture with typical loss of nasal projection and tilting of the nasal tip.

the epithelial lining with inadequate drainage predisposes to mucocoele formation.⁴⁷

Soft tissue injuries

Accurate repair of soft tissue injuries including skin and fascia layers is mandatory for optimum results. Facial wounds should be closed as soon as possible provided they are clean. Meticulous debridement with antiseptic solution is essential. Grit from the roads can tattoo wounds badly and be a real problem and are best removed using a sterile nylon scrubbing brush.

Experience with cutaneous malignancy demonstrates that sizeable areas of tissue loss can be dealt with primarily, so some selective removal of poorly viable wound margins would appear to be sensible. It is crucial to ensure that any underlying bony injury is repaired to enable correct support and soft tissue draping.

The facial nerve and parotid duct are frequently damaged in significant soft-tissue injuries. The facial nerve is easiest to find and repair in the first 48 hours, while the peripheral branches can still be stimulated. Epineural repair provides the patient with the best chance of a good recovery.

Identification and alignment of key landmarks such as the vermilion border of the lip, eyebrow, alar margin of nose, ear and eyelids is essential for a good cosmetic result. Similarly, the use of deep sutures (4/0 vicryl or equivalent) to take tension out of the wound and to avoid dead space together with appropriate skin sutures (5/0 or 6/0 monofilament) produces the best results. Shelved lacerations should be managed by placing sutures with a bigger 'bite' on the more depressed side, and triangular edges by the 'corner stitch' technique. Sutures are best supported by steristrips and removed after 4–7 days. Chloramphenicol eye ointment can be applied to the wound 4 times daily for one week.

The patient should be instructed in wound care and told to avoid direct sunlight on the wound for one year.

PAEDIATRIC FACIAL INJURIES

Fortunately, serious maxillofacial injuries in this age group are uncommon. Minor injuries, particularly soft tissue and dentoalveolar are, however, frequent. The treatment concepts and protocols are similar to adult patients.⁴⁸

Soft tissue injuries

Minor soft-tissue injuries are managed in the same way as adult patients. Consideration should be given to the use of resorbable sutures to avoid unnecessary general anaesthesia for suture removal. Cyanoacrylate glue can be used with care but not in the presence of substantial connective tissue damage.

Injured anterior teeth

Dental injuries to the upper anterior teeth are extremely common, but their management and prognosis is

extremely complex. The optimal treatment protocol is determined by a number of factors that relate to the type of tooth fractured, the presence and level of any root fracture, the vitality of the pulp and the state of development of the root. It is essential that an expert opinion is sought from a maxillofacial surgeon or paedodontist. Fractured teeth can be temporarily repaired, exposed pulps capped with calcium hydroxide based pastes and mobile teeth splinted to adjacent teeth. Anterior permanent teeth that have been avulsed should be reimplanted at the first available opportunity and splinted. If the reimplantation is delayed, the tooth should be kept moist in the mouth of the patient or parent. Alternatively, the tooth could be stored in a glass of milk.

Fractures of the facial bones

As stated previously, the principles of reduction and fixation of facial bone fractures in children are the same as for adults. Plates should be placed using short screws to avoid damaging developing tooth germs and all mandibular metal work removed after 3–6 months so that it does not interfere with growth. Fractures of the condyle are usually treated conservatively as there is an immense capacity for remodelling and any intervention might damage the growth centre.⁴⁹ Fronto-naso-ethmoid injuries differ in

their fracture pattern because the development of the frontal sinus may not be complete. Any extensive dissection of the medial canthal area may lead to excessive subperiosteal bone formation and therefore repairs in this area should be supported by acrylic buttons in the immediate post-operative phase.⁵⁰

BEST CLINICAL PRACTICE

Paediatric dental injuries

- ✓ Consider whether the injury might be non-accidental.
- ✓ Reimplant avulsed teeth as soon as possible.
- ✓ Use short screws and take care not to damage unerupted teeth.
- ✓ Remove plates 3–6 months after surgery.
- ✓ Manage condylar fractures conservatively.

FUTURE RESEARCH

- The controversy on the virtues of open and closed management of condylar neck injuries will persist. The management and outcomes of intra-capsular fractures may well become revolutionized by alloplastic materials.

KEY POINTS

Soft tissue injuries

- Accurate repair of soft tissue injuries including skin and fascia layers is mandatory for optimum results.
- It is crucial to ensure that any underlying bony injury is repaired to enable correct support and soft tissue draping.
- Identification and alignment of key landmarks such as the vermilion border of the lip, eyebrow, alar margin of nose, ear and eyelids is essential for a good cosmetic result.

Paediatric Facial Injuries

- Fortunately, serious maxillofacial injuries in this age group are uncommon. Minor injuries, particularly soft tissue and dentoalveolar are, however, frequent.
- The treatment concepts and protocols are similar to adult patients. The principles of reduction and fixation of facial bone fractures in children are the same as for adults.
- Fractures of the condyle are usually treated conservatively as there is an immense capacity for remodelling and any intervention might damage the growth centre.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using keywords: CSF leak, CSF rhinorrhoea, spontaneous CSF leak, skull base repair and intrathecal fluorescein.

INTRODUCTION

Few procedures reflect the tremendous benefits of endoscopic techniques in quite the same way as the endoscopic closure of CSF leaks. Although the ultimate chance of success may in some measure depend on the aetiology of the leak,¹ remarkable results of 90% success rates at the initial attempt with success rates up to 97% with revision have been published.^{1, 2} Despite these impressive figures there continues to be isolated enthusiasm for open approaches in some neurosurgical centres. Some published neurosurgical series have success rates as low as 60% with predictable sequelae from brain retraction and sacrifice of the olfactory nerves, to say nothing of the coronal flap and frontal craniotomy. Recent neurosurgical publications have recommended open approaches in the face of adverse prognostic factors such as prior radiation or elevated intra-cranial pressure.

Although rhinorrhoea can be a socially troubling symptom, the principal motivation for repair of CSF leaks is to reduce the risk of meningitis or other intra-cranial complications. The incidence of meningitis in patients with an active CSF leak has been quoted as 10% year on year^{3, 4} although a more recent study suggested that the incidence may be as low as 0.3% per year per active leak per person.⁵

Daudia et al. found that in 11 patients with 190 years of active leaks 21 developed meningitis resulting in an overall risk of 19% although most occurred in the first year of the leak.⁵

The repair of a newly diagnosed CSF leak is not an absolute surgical emergency and time can be taken to properly work-up and investigate the patient. During this time the simple advice of telling the patient not to blow their nose or to sneeze 'with their mouth open' and not to use CPAP needs to be reinforced. Nonetheless, because of the risk of meningitis, surgical repair should be performed at the earliest reasonable opportunity. Even today meningitis is associated with a definite mortality rate. Few studies have followed patients with repaired leaks over the long term. A publication from the Mayo Clinic⁶ identified recurrence of leaks in a group of 21 patients at an average of 50.8 months after corrective surgery. The longest interval to recurrence in this group of patients was 28 years.

In patients with a history of a CSF leak it is worth checking their pneumococcal antibody titres and recommending vaccination with a 23-valent polysaccharide PNC vaccine or a 7-valent conjugate PNC vaccine if it is low.

In recent years, the spectrum of leaks seen in major centres has changed significantly. Most of the leaks seen

today are either 'spontaneous' or what might be termed 'anticipated'. The 'anticipated' category of leaks comprises those seen after anterior skull base or sellar or parasellar tumour resection. In these patients, the bony defect is often substantial and this has required a reappraisal of reconstructive techniques.

While a variety of classification systems of CSF leaks exist, perhaps the most useful is the time-honoured system of classification by aetiology. CSF leaks can be considered as congenital, spontaneous or post-traumatic. Post-traumatic leaks can be further divided into those associated with head trauma, those seen as a complication of sinus surgery and those seen as a part of skull base surgery. A small number of patients with tumours also present with CSF leaks.

HEAD TRAUMA

CSF leaks are quoted as occurring in perhaps 2% of head injuries and 12% to 30% of skull base fractures.⁸ Most CSF leaks occur as a result of blunt trauma. They may present as CSF otorrhea, CSF otorhinorrhea or CSF rhinorrhea. The conventional viewpoint is that most traumatic CSF leaks will heal with conservative treatment including bedrest. Insertion of a lumbar drain may sometimes be required. It is likely that only the sinus mucosal aspect of the defect closes as the dura does not regenerate. This produces a relatively fragile closure and work by Bernal-Sprekelsen et al.⁹ has suggested a substantial continuing risk of meningitis in these patients. The authors suggest that this 'mono-layer of protection' may be eroded by either the pulsatile effect of the brain or by inflammation within the nose.⁹ With the widespread availability of endoscopic closure, performed with statistically small risks, this conservative management paradigm might be challenged, changing towards a more active interventionist policy.

Massive head trauma with complex comminuted and displaced fractures of the skull base can be incredibly difficult to treat. Open approaches may be of value for these patients. The decision to proceed with an open approach is sometimes made easier by the presence of intra-cranial injuries requiring attention or significant fractures of the posterior wall of the frontal sinus. Free tissue transfer has been reported as being helpful in carefully selected groups.¹⁰ In massive 'egg-shell' fractures of the sphenoid sinuses, fat obliteration can be considered, leaving the treatment of possible subsequent mucocoeles that may develop to a secondary procedure.

CONGENITAL CSF LEAKS

Congenital CSF leaks in association with encephalocele or meningoencephaloceles are uncommon. These are well diagnosed on MRI and this scan is recommended when sinus opacity is demonstrated adjacent to a skull base defect. Brain tissue contained within the encephalocele is invariably non-functioning and can be removed as part of the surgical procedure. Congenital abnormalities of

Figure 108.1 Coronal CT scan of meningo-encephalocele medial to and eroding the left middle turbinate.

the inner ear such as the Mondini Dysplasia may present with substantial CSF leaks where the CSF has only briefly transversed the perilymphatic space. Such leaks, in addition to presenting as hearing loss or recurrent meningitis, may also present with CSF otorrhea or CSF otorhinorrhea (Figure 108.1).

CSF LEAKS ASSOCIATED WITH TUMOURS

Tumours causing substantial erosion of the skull base may present with CSF rhinorrhea. Occasionally where tumour shrinkage occurs, for example during induction chemotherapy, CSF leaks may also occur. The closure of the CSF leak is part of the surgical treatment of the tumour and for the closure to be successful it is important for the margins of the CSF leak to be clear of tumour, particularly in malignant disease. Persisting CSF leaks in the face of residual untreated tumour may present a considerable challenge. A study by Boudreaux and Zins¹¹ described open treatment of CSF leaks in 14 high-risk patients. Nine of the 14 patients had malignant brain tumours. A success rate of 85% was reported.

SPONTANEOUS LEAKS

A good deal of recent interest has centered on 'spontaneous CSF leaks' sometimes described as 'idiopathic'. The association of spontaneous leaks with middle-aged

women with a raised body mass index is now well known. These leaks are thought to represent a variant of benign intra-cranial hypertension.¹² These patients have a generally elevated intra-cranial pressure, this diagnosis being made on lumbar puncture after surgical repair. It is not possible to measure this pre-operatively as the persistent leak reduces the pressure although there may be radiological features of increased intra-cranial pressure such as an empty sella, enlarged ventricles or diffuse erosion of the skull base.¹ When the CSF is actively draining – for example, perhaps at the time of lumbar puncture for fluorescein installation prior to repair, the intra-cranial pressure is often reduced. It is thought that the elevated intra-cranial pressure is due to poor CSF resorption by the arachnoid villi.¹² This increased intra-cranial pressure with associated pulsatile forces produces thinning of bone that is most evident in the weakest areas of the skull base. Herniation of the meninges and brain, often with CSF leakage, most often occurs in the lateral recess of a well pneumatized sphenoid, in the area of the lateral lamella of the cribriform and in the ethmoid roof. These may be multiple sites of weakness of the skull base.

Imaging and diagnosis are similar to other varieties of CSF leaks. In cases of multiple cranial base defects, intrathecal fluorescein can be helpful in localizing the exact location of active leakage. Identification of ‘spontaneous’ as the likely aetiology of the leak pre-operatively is helpful in counselling the patient.¹ Spontaneous leaks are most likely to recur and the success rates for endoscopic closure are worse than for other aetiologies.¹ In one study, 21% of spontaneous leaks recurred, going up to 46% if there were radiological signs of a raised intra-cranial pressure compared to 2% if the leak was not spontaneous.¹ With spontaneous leaks there can be re-leakage at the site of repair but there can be multiple areas of weakness of the skull base and with untreated underlying elevated intra-cranial pressure other areas may break down and leak.

Areas of substantial skull base dehiscence may benefit from additional reinforcement with a bone or cartilage graft. This is sometimes easier said than done with a thin bony skull base and difficulty in finding a reliable ‘edge’. CSF leaks in the lateral recess of well pneumatized sphenoid sinuses may be best approached by the transantral transpterygoid approach described by Bolger.¹³ Post-operatively, the elevated intra-cranial pressure may be helped by oral acetazolamide. Selected patients may benefit from shunting. Success with employing a gastric bypass for morbid obesity has also been described.¹²

CSF LEAKS COMPLICATING SINUS SURGERY

A rate of serious complications in the order of 0.5% or less is generally quoted for endoscopic sinus surgery (Figure 108.2). CSF leaks diagnosed intra-operatively or post-operatively would be included in this category of serious complications.

A publication by Bachmann et al.¹⁴ looked at the incidence of occult cerebrospinal fluid fistulae during

Figure 108.2 Coronal CT scan image revealing left skull base injury, clinically presenting with a CSF leak, complicating endoscopic sinus surgery.

sinus surgery. They found a 3% incidence of occult leaks utilizing the beta-trace protein assay. They had reviewed 69 consecutive patients, ‘all-comers’, undergoing surgery at the hands of an experienced surgeon in a tertiary referral centre. None of the patients with occult leaks displayed any symptoms or sequelae out to the follow-up period of 6 months. The authors speculated that occult leaks may be more common than previously thought and that small leaks may self-heal. The important caveat to be included with this study is that these patients need to be followed long term to examine the likelihood of delayed meningitis.

Some of the details of CSF leaks complicating sinus surgery are covered in the complications chapter of this book. Image-guided surgery, while indisputably helpful in individual cases, has not reduced the likelihood of complications in large case series. Powered instrumentation, the other great technological advance in sinus surgery in recent times, has changed the scale of complications, making brain parenchymal injury more likely than eminently treatable CSF leaks. With brain parenchymal injuries has come the need to exclude significant intra-cranial adverse vascular events.

As a general rule, CSF leaks complicating sinus surgery, diagnosed intra-operatively should be repaired under the same anaesthetic. Local intra-nasal tissue can be used for the repair with generally good results. The most likely anatomical sites for CSF leaks complicating sinus surgery are the very thin bone of the lateral lamella of the cribriform plate, the area of the anterior skull base where it is weakened by the anterior ethmoid neurovascular bundle and posteriorly where there may be confusion as to the exact anatomical relationship between the last posterior ethmoidal cell and the sphenoid sinus.

In unusual circumstances, a decision can be made not to repair the CSF leak under the same anaesthetic. Where the degree of surgical disorientation is such that attempts at repair might result in further damage such as an orbital or brain parenchymal injury, an argument can be made for referring these patients to specialist centres for closure. The wound can be carefully packed with particular care being exercised during the ‘wake-up’ from anaesthesia.

Figure 108.3 Plain skull film demonstrating pneumocephalus complicating the use of positive airway pressure. Permission pending from Kopelovich J, et al. *J Clinical Anesthesia* 2012 Aug; 24(5): 415–18.

It is crucial that the patient does not receive positive pressure mask ventilation after extubation for fear of substantial pneumocephalus developing (Figure 108.3).

CSF leaks complicating sinus surgery may also become evident in the post-operative period. Any complaint of clear rhinorrhea post-operatively needs to be taken seriously and investigated vigorously. The appropriate investigation of such leaks will be dealt with later in the chapter.

REPAIR OF SURGICALLY-INDUCED SKULL BASE DEFECTS

Endoscopic approaches to the anterior skull base and sellar and parasellar regions are increasingly employed for the treatment of a variety of pathological processes. Small defects can be repaired in the same way as defects of other aetiologies. For larger defects, free-fat grafts can be successfully employed. More recently, interest has focused on the use of vascularized tissue flaps. The idea of CSF leak repair utilizing vascularized septal or turbinate flaps is not new. Yessenow and McCabe reported excellent success rates utilizing this tissue in transnasal, extracranial, non-endoscopic repair of CSF leaks nearly 30 years ago.¹⁵

Most reports have focused on posterior septal flaps. The so-called ‘Hadad-Bassagasteguy’ flap utilizes septal mucoperiosteum and mucoperichondrium based on the nasoseptal artery. Kassam et al.¹⁶ reported its general utility in 75 patients undergoing endonasal endoscopic cranial base surgery. Harvey et al.¹⁷ reported on the experience of two skull-base centres over a 12-month period comprising 30 patients. They related using a variety of

flaps including the posterior septal flap as well as inferior turbinate and nasal floor flaps. They emphasized technical aspects relating to the flap including avoiding injudicious initial posterior septectomy, decisions regarding a concomitant hemi-transfixion or Killian septal incision and careful preservation of the flap during surgery. They also emphasized the use of multi-layer skull base reconstruction initially supported by an inflated Foley catheter balloon.¹⁷

INVESTIGATION OF CSF LEAKS

A story of clear rhinorrhea, sometimes tasting salty and often posturally provoked, with an appropriate antecedent history is clinically suspicious for a CSF leak. Such patients must be investigated vigorously. As compelling as such a history appears, these patients do not always end up having CSF leaks as shown by Bateman and Jones in 9 patients presenting with highly suggestive histories.¹⁸ Further investigation is therefore required. Endoscopic examination of the nose may be unrevealing but is part of the initial work-up.

The next goal is to obtain fluid for testing. Ideally this can be obtained at the office visit, sometimes with postural provocation (Figure 108.4). When this is unsuccessful we will sometimes have patients run up stairs in an effort to increase intra-cranial pressure and produce drainage or strain on a closed glottis. If this fails, patients are given vials to take home to catch fluid for testing. In the United States the beta-2-transferrin test is widely available and the most commonly used. A downside of the test is that it may only be performed in certain major centres and thus it may take a few days to get a result. The beta-2-transferrin test provides excellent sensitivity, specificity and positive and negative predictability in the diagnosis of CSF leaks.¹⁹ A concomitant serum value enhances its utility. Occasional false positives have been reported in certain liver diseases or hereditary disorders of protein metabolism. It has been suggested in some European

Figure 108.4 Collection of posturally provoked CSF rhinorrhea.

studies that beta-trace protein is an even better test than beta-2-transferin in detecting CSF leaks.¹⁹

IMAGING FOR DIAGNOSIS OF CSF LEAKS

The clear majority of CSF leaks can be diagnosed using beta-2-transferin testing and reformatting of ultra-fine cut CT scan images of the sinuses. The coronal scan is most helpful in examining the ethmoid roof but other views are useful in diagnosing leaks at other anatomical sites. These images are most often obtained as part of planning for image-guided surgery. Details of a bony defect may be seen or an area of opacification or an air fluid level in an adjacent sinus. In the situation where there is an opaque sinus adjacent to a skull base defect an MRI scan should be performed to help diagnose a possible encephalocoele or meningocoele. Where a defect is not visualized in the sinuses, a CT examination of the temporal bones should be considered to exclude CSF oto-rhinorrhea in difficult to diagnosis cases.

In some centres MRI cisternography is performed if fine cut CT scans and beta-2-transferin testing do not provide a diagnosis. A variety of technical modifications of the MRI enhance its ability to detect the area of the leak.²⁰ More commonly in cases where the diagnosis is unclear, CSF contrast studies are considered (Figure 108.5). This may utilize radiographical contrast such as iohexol or alternatively a radio-active tracer. These investigations

Figure 108.5 Intrathecal contrast CT study revealing left skull base defect.

require the patient to be actively leaking at the time of the study. As they need an intrathecal contrast agent of one sort or another, these tests are associated with a slightly greater risk than non-invasive studies. Radionuclide cisternography involves intrathecal administration of a tracer via a lumbar puncture followed by imaging once the tracer has had an opportunity to make its way to the skull base. Strategically placed nasal pledgets are also used. It is our practice to cut these pledgets into different shapes as this helps to identify their position in the nose after they come out. Radioactive tracers of different half lives can be considered. Localization of CSF leaks by Gadolinium-enhanced MRI cisternography has also been described. Gadolinium is injected into the subarachnoid space. This is an 'off-label' use of gadolinium in the United States and requires a separate consent. Aydin et al.²¹ found this technique useful in 43 of 51 patients. No neurological sequelae were seen from the injection.

CONTROVERSIES IN REPAIR

INTRATHECAL FLUORESCEIN

It is my practice to use intrathecal fluorescein as part of the repair of all CSF leaks planned as a discrete procedure. Separate consent is obtained for the intrathecal use of fluorescein as its use via this route is not approved by the FDA. There is at least a theoretical advantage to giving this while the patient is awake and a German publication describes employing intrathecal fluorescein the afternoon before surgery.²² In this publication, fluorescein is administered without CSF withdrawal to minimize CSF displacement.²²

As a practical matter in the United States fluorescein is mostly administered in the operating room after induction of general anaesthesia. Our neurosurgical colleagues perform a lumbar puncture and insert a lumbar drain. Ten cc's of the patient's CSF is withdrawn and this is mixed with 0.1 cc of 10% fluorescein suitable for injection. The mixture is then re-injected slowly over 10 minutes timed by the clock. The patient is placed slightly head down and sufficient time is allowed for the fluorescein to equilibrate throughout the subarachnoid space. The nose is closely examined with zero degree and angled telescopes and sites of leakage are disclosed by the bright green colour of the fluorescein. Usually the light of the telescope is sufficiently broad spectrum to achieve this – occasionally a blue light filter is helpful. The intrathecal fluorescein is of use, firstly in diagnosing a CSF leak, secondly in disclosing its exact location and thirdly, by its absence, providing evidence of success of the repair (Figure 108.6).

Complications of fluorescein's intrathecal use have been reported.²² The most common complication cited has been seizures but in general this has been associated with use of the wrong formulation of fluorescein, occipital application, a higher than recommended dose or rapid bolus injection. Other complications have been attributed to the simultaneous use of intrathecal radiographical contrast material. Citing these concerns,

Figure 108.6 Intra-operative slow re-injection of patient's CSF mixed with fluorescein.

Zuckerman and Del Gaudio²³ described excellent success rates in 42 CSF leaks repaired without using intrathecal fluorescein or indeed lumbar drains. They relied on high-resolution CT and intra-operative image guidance for leak identification. The use of topical 5% fluorescein applied intra-operatively to the surgical site has also been described.²⁴ This can also be used as an office-based diagnostic test. The authors recommend skin testing the patient with fluorescein eye drops to rule out allergy the day prior to the procedure.²⁴

LUMBAR DRAINS

The routine use of lumbar drains in elective CSF leak repair is controversial. Our practice is to use one when intrathecal fluorescein has been employed. The drain is placed at the time of initial lumbar puncture and then 'closed' and re-opened immediately prior to repair. Lumbar drains can be associated with important complications and their use requires specialist nursing management. In our hospital, patients with lumbar drains are managed on the neurosurgical floor.

We feel that the reduction in intra-cranial pressure afforded by the lumbar drain offers an extra measure of insurance for the repair. Certainly, however, series of successful repair without lumbar drains of selected patients with CSF leaks have been described.²³

TECHNICAL ASPECTS OF THE REPAIR

Whatever preferences and prejudices a surgeon might have regarding specific aspects of the surgical repair, evidence can be found in the literature to support that view. Successful repair of CSF leaks requires identification of the exact site of leakage. This may require considerable dissection in difficult to find leaks. In contrast to routine endoscopic sinus surgery where mucosal

Figure 108.7 Bioabsorbable transparent plate. 'Handle' provides for ease of manipulation. Permission pending from Potter, NJ, et al. *Laryngoscope* 2015; **125**(6): 1313–15.

preservation and avoidance of scarring is of paramount importance, in cases of CSF leak repair, scarring incited by mucosal stripping helps form a dense repair. No literature exists favouring one graft material over another and therefore the choice is largely based on surgeon preference, ease of manipulation, cost etc. Likewise no literature exists regarding the use of onlay versus underlay grafts. In general, free grafts have been preferred to vascularized flaps for smaller defects because of technical ease of manipulation and obviation of the potential for contraction with healing. Recent interest in closing large defects associated with skull base surgery has favoured pedicled flaps.^{16, 17} While bone or cartilage grafts are helpful in medium-sized defects they have not been used for large repairs or generally in small defects. There is some evidence to support the use of fibrin glue to reinforce the closure. In a pig model, Almeida et al.²⁵ showed that fibrin glue enhanced closures had superior graft adherence and higher 'burst pressures'. Neurosurgical authors²⁶ have recommended dural sealants as an adjuvant to surgical repair in high-risk patients. A concern is that these 'sealant' materials may add to the cost of the surgery without significantly improving success rates. Potter et al.²⁷ have described the use of bio-absorbable plates as part of the surgical repair of CSF leaks in patients with an elevated BMI. Dlouhy et al.²⁷ described young age and elevated BMI as independent variables predictive of post-operative CSF leakage after endoscopic pituitary surgery. Potter et al.²⁸ recommended use of semirigid bio-absorbable plates as part of the surgical repair of CSF leaks in patients with an elevated BMI, describing a significant reduction in leak rates after pituitary surgery following their use (**Figure 108.7**).

We place a 'break-layer' of Gelfoam[®] under the area of repair and then place a Meroceol[®] pack. The Gelfoam[®] isolates the repair from shearing forces when the pack is removed. As mentioned earlier in the chapter, inflated catheter balloons¹⁷ may provide temporary structural support after major skull base repairs.

CONCLUSION

Remarkable progress has been made in the endoscopic treatment of CSF leaks. Advances have occurred both in pre-operative imaging and diagnosis as well as in technical

refinements of the surgical closure. Areas of interest in the future might include a better understanding of patients with spontaneous leaks and advances in the reconstruction of significant skull base defects from endo-nasal craniotomies.

KEY POINTS

- Endoscopic repair is treatment of choice.
- Beta-2 transferrin or Beta-trace protein are highly accurate diagnostic tests.
- High-resolution CT scans are needed in all cases.
- Intrathecal fluorescein helps in difficult cases.
- Precise layered closures give best results.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: granulomatous disease, Wegener's granulomatosis, granulomatosis with polyangiitis, sarcoidosis, Churg Strauss syndrome, cocaine-induced midline destructive lesion, nose and paranasal sinuses. The evidence is mainly levels 2/3 with some level 4 randomized trials. The clinical recommendations are predominantly grades C with some B and D.

INTRODUCTION

A granuloma is an organized collection of macrophages, known as epithelioid cells, which fuse to form multinucleated giant cells. This histological configuration is encountered in a number of infective, inflammatory and neoplastic conditions of the nose and sinuses (Table 109.1) and is also seen in various conditions in which vasculitis plays a role. Vasculitis may be primary or secondary and is further classified according to the size of vessel affected (Table 109.2).

Whilst many of these conditions are systemic, they may be limited to the upper respiratory tract or present with otorhinolaryngological symptoms; the ear, nose and throat (ENT) surgeon must therefore maintain a continuous low threshold of suspicion to establish the diagnosis at the earliest opportunity.

SARCOIDOSIS

Sarcoidosis is a systemic granulomatous condition of unknown aetiology which may affect any part of the body, but most frequently involves the lungs and intra-thoracic lymph nodes, in over 90% of cases.³ It has a global incidence of 6–16 per 100,000 population per annum but there is significant geographical variation, with 64 cases

per 100,000 in Scandinavia.⁴ It is 10–20 times more common in African-Americans (36.5–81.8 per 100,000) than Caucasians (1.2–19 per 100,000). Besnier first used the term 'lupus pernio' to describe cutaneous lesions in 1889, but it was Boeck who recognized the more generalized nature of the condition 10 years later.^{5,6}

Age and sex

Sarcoidosis is a condition of young adults with a peak onset between the third and fourth decades. It is slightly more common in women than men.⁷

Aetiology

The aetiology of sarcoidosis remains unknown, but theories suggest an immunological response to an unidentified antigen in genetically predisposed individuals.⁸ The antigens may be infectious or environmental, and possibilities include mycobacteria, fungi, chemicals such as beryllium and zirconium, pine pollen and peanut dust.⁹ There are abnormalities of both the cell-mediated and humoral immune systems.⁴ Macrophages and T-cell activation lead to release of cytokines including tumour necrosis factor (TNF), with resultant granuloma formation.¹⁰

Clinical features

Sarcoidosis is a multisystem disease; the reported distribution of clinical manifestations tends to reflect the bias of the treating physician. It primarily affects the lower respiratory tract but may involve almost any organ or system in the body (Table 109.3). It involves the upper respiratory tract in up to 18% of cases.¹¹ Sinonasal sarcoid is reported in 1–4%, more frequently than previously realized, and it is generally agreed that nasal manifestations are almost always part of chronic multisystem sarcoid.¹² Nasal symptoms commonly include obstruction, crusting, bleeding or facial pain (Table 109.4). A staging system for sinonasal involvement has been described to help tailor treatment: stage I is reversible involvement of the nose alone; stage II is moderate but potentially reversible disease of the nose and/or limited sinus involvement; and stage III is severe, irreversible and extensive sinonasal disease.⁴

The nasal mucosa often has a rather characteristic granular appearance, sometimes referred to as a ‘strawberry skin’

because of the tiny pale granulomas against hypertrophic erythematous mucosa. This is generally very friable and there may be ulceration, crusting and adhesions. The anterior nasal septum is most often affected and may perforate, particularly if traumatized by surgery. The nasal bones may be involved by a process similar to the dactylitis seen in the fingers; patients may present with a soft-tissue mass or expansion of the nasal bridge. This may be associated with thickening and purplish discoloration of the overlying skin known as lupus pernio (Figure 109.1), which is a cutaneous manifestation of chronic systemic sarcoid.³ Facial pain is experienced by one in five patients with nasal sarcoid.¹² There may be hyposmia due to mechanical obstruction of the olfactory cleft by crusting or fibrosis or as a result of direct neuropathy.

Salivary gland enlargement is seen in 5–10% of cases, more rarely associated with facial palsy and uveitis when it is termed uveoparotid fever or Heerfordt’s syndrome.⁸ The larynx is involved in 1–5% of cases, most commonly the supraglottis (85%), with symptoms of cough, hoarseness, dysphagia and more rarely stridor.¹³ Tracheal involvement is rare but bronchial sarcoid is common. Chronic progressive pulmonary fibrosis occurs in 25% of cases of chronic pulmonary sarcoid.³

Diagnosis

No test is pathognomonic for sarcoidosis. Diagnosis therefore relies on a combination of clinical features, imaging, histology, biochemical and serological testing and the exclusion of other granulomatous diseases. Previously the most reliable investigation, the Kveim test has been withdrawn in the UK for unproven health and safety reasons.¹⁴ It involved intra-dermal injection of splenic tissue from a patient with sarcoidosis, with biopsy of the resulting skin nodule. The classic histological appearance is that of a non-caseating granuloma with central epithelioid cells

Figure 109.1 Typical appearances of nasal lupus pernio.

Figure 109.2 Axial CT scan showing typical pulmonary infiltrates in systemic sarcoidosis. (Courtesy of Dr Timothy Beale.)

surrounded by lymphocytes and fibroblasts. Biopsy should target potentially affected tissue such as the lung, skin and lymph nodes; lip biopsy of minor salivary glands can be useful.⁸ Biopsy of nasal mucosa is only of use if it appears abnormal, when over 90% of samples are positive; random biopsy of macroscopically normal mucosa is negative in 92%.¹²

Serum angiotensin converting enzyme (ACE) is elevated in up to 85% during active disease, but this is non-specific as it is also elevated in other conditions such as tuberculosis, leprosy and primary biliary cirrhosis.¹⁵ Serum and urinary calcium levels are elevated in approximately 15% of cases.⁴

Imaging of the lower respiratory tract shows varying degrees of pulmonary involvement, which allow staging of the disease (Figure 109.2). Stage I is bilateral hilar lymphadenopathy, stage II is hilar lymphadenopathy and pulmonary infiltrates, stage III is pulmonary infiltrates alone and stage IV is pulmonary fibrosis.¹⁶ Bronchoscopy will allow biopsy. Plain X-rays of the nasal bones may show rarefaction or punctate osteolysis in up to one quarter of cases and this, together with soft tissue changes, may also be seen on computerized tomography (CT) scanning (Figure 109.3).¹⁷ CT will also demonstrate secondary involvement of the sinuses though will not distinguish between active disease and secondary infection. Bilateral lacrimal gland enlargement may also be seen.

Magnetic resonance imaging (MRI) of the brain may show granulomatous involvement of the basal meninges.

Treatment

Sarcoidosis has a variable clinical course that often correlates with the mode of presentation; an acute onset with arthritis and erythema nodosum is usually self-limiting, whilst a more insidious onset with lupus pernio and sinonasal involvement tends to be more chronic.¹⁸ Up to

Figure 109.3 Coronal CT scan showing sclerosis and osteolysis of the nasal bones associated with a soft tissue mass in nasal sarcoid.

two-thirds of patients will spontaneously remit, generally those with stage I and II pulmonary disease, while 10–30% follow a chronic course with relapses despite systemic therapy.¹⁹ Some patients require no treatment at all, but international guidelines suggest systemic or intra-lesional steroid treatment for life-threatening disease or if critical organs are involved.²⁰ Despite a lack of controlled studies, steroids remain the mainstay of treatment for severe disease, with the addition of agents such as methotrexate to reduce the steroid dose if required. Hydroxychloroquine has been used for cutaneous and sinonasal sarcoidosis, although the response rate is less than 50% and there is a risk of ocular toxicity.²¹ Lupus pernio may respond dramatically to medical treatment.²² There has been recent interest in TNF-alpha inhibitors such as infliximab and etanercept.²³

Nasal symptoms may be helped with topical treatment including intra-nasal steroids, glucose and glycerine drops, and nasal douching. Surgery has a limited role, particularly in the presence of active disease, although endoscopic sinus surgery can be undertaken to remove obstructing lesions or for secondary bacterial infection, with success in selected cases.²⁴ Septal surgery should be avoided if possible as an increased rate of septal perforation has been reported.³ Symptomatic laryngeal disease that fails to respond to systemic treatment may be treated with transoral laser and intra-lesional steroid injections.²⁵

GRANULOMATOSIS WITH POLYANGIITIS (WEGENER'S)

Granulomatosis with polyangiitis (GPA) is a systemic condition characterized by granulomatous inflammation of the respiratory tract and necrotizing vasculitis affecting small- to medium-sized vessels with focal or proliferative glomerulonephritis.²⁷ GPA was formerly known

as Wegener's granulomatosis, after Wegener's article on rhinogenic granulomatosis in 1939, but has been renamed as part of a move towards a vasculitis terminology based on pathology.^{28, 29} GPA classically involves a triad of upper airway, lung and renal disease, but limited or localized forms of the condition have been reported in up to 30% of cases.³⁰ Thus, the true incidence of the condition is difficult to determine. Whilst up to 1967 only 138 unequivocal cases had been recorded in the literature, the incidence is now estimated to be 10–15 per million per year with a prevalence of up to 5 per 100,000 population in Europe.^{30–32}

Age and sex

The mean age at diagnosis is 40–50 years.³³ The age of presentation in our own cohort ranges from 15 to 78 years ($n = 180$ patients), although it has been reported in younger children. Cabral's paediatric series reported a median age at diagnosis of 14.2 years (range 4–17 years).³⁴ Men and women are equally affected, although in children there appears to be a female preponderance.^{34, 35} GPA is predominantly a Caucasian disease (over 90%).²⁶

Aetiology

GPA appears to be an autoimmune disease, given its strong association with antineutrophil cytoplasmic antibodies (ANCA). *In vitro* studies have shown that ANCA binds to and activates neutrophils, which then release oxygen radicals, inflammatory cytokines and lytic enzymes and adhere to and kill vascular endothelial cells.³⁶ ANCA may also induce immune complex formation.²⁶ In GPA, cytoplasmic ANCA (c-ANCA) are specific for proteinase-3 (PR3), an endogenous peptide. There is evidence that a mimic peptide may be introduced via an exogenous infective agent such as *Staphylococcus aureus*.³⁶ This theory is supported by the higher rate of chronic nasal *S. aureus* carriage in patients with GPA, in whom it is associated with more frequent relapses.³⁷

Clinical features

Any part of the body may be affected and in generalized disease there is often associated general malaise, disproportionate to the clinical findings. Limited forms of the disease are now well recognized; the European Vasculitis Study Group classified GPA as 'localized' (respiratory tract involvement only with no features of systemic vasculitis), 'early systemic' or 'generalized' disease.³⁸ In the USA, 'limited' GPA refers to systemic non-life threatening disease rather than truly localized forms.³⁹ Whilst many of these cases may progress to generalized disease, there is some evidence that a subset (approximately 5%) will remain localized.⁴⁰ The frequency with which different sites are involved, both at presentation and subsequently, varies with the interest and specialty of the reporting physicians.⁴¹ Duration of symptoms before a diagnosis is made remains highly variable and can be more than one year.⁴²

The head and neck is the most common site of involvement at presentation, in 73–93% of cases.^{33, 43} The nose and sinuses are involved in more than 80%, with symptoms including nasal obstruction, crusting, discharge and bleeding. In addition, patients may complain of facial pain.⁴² Destruction of the intra-nasal structures may follow, including the septum, turbinates and sinuses with formation of a single large cavity. While there is intra-nasal destruction of bone and cartilage in some patients with GPA, leading to septal perforation and a characteristic nasal collapse, there are none of the gross destructive changes of the midfacial skin seen in NK/T-cell lymphomas and basal cell carcinomas.

Approximately one-third of patients develop otitis media with effusion with associated conductive hearing loss due to eustachian tube dysfunction, and more rarely pain and suppuration. Sensorineural hearing loss also occurs in 35%.⁴³ Facial nerve paralysis has been recorded in 8–10%.⁴⁴

Subglottic or upper tracheal stenosis occurs in 16% of cases, although it is 5 times more common if GPA presents in childhood.⁴⁵ It may present as progressive dyspnoea on exertion or as acute airway obstruction. Localized GPA requires exclusion in an adult presenting with an apparently idiopathic subglottic stenosis.⁴⁶

Oral symptoms are rare but ulceration may be seen and 'strawberry' gingival hyperplasia is said to be pathognomonic.⁴⁷

Ocular manifestations, including conjunctivitis, dacryocystitis and episcleritis, occur in approximately 50% of patients at some point.⁴³ Approximately, 2% develop proptosis from a granulomatous mass within the orbit (**Figure 109.4**). Visual loss occurs in up to 8%, usually from optic nerve ischaemia due to inadequately treated retro-orbital disease.

Necrotizing vasculitis in the lungs causes cough, haemoptysis and pleuritic pain. The pulmonary lesions often cavitate and can usually be seen radiologically. Over 75% of patients develop renal involvement; early treatment is vital since damage is irreversible.⁴³ Cutaneous manifestations include ulceration and nodules, and both polymyalgia and polyarthritis have been described. Neurological sequelae include meningitis, mononeuritis multiplex and neuropathy of cranial nerves.²⁶

Diagnosis

The ANCA test, first described by van der Woude in 1985, has significantly improved the diagnosis of GPA and other vasculitides.⁴⁸ There are two main staining patterns: c-ANCA, 90% of which are PR3-ANCA; and perinuclear (p-ANCA), 90% of which are specific for myeloperoxidase (MPO-ANCA).⁴⁹ In general, patients with GPA have c-ANCA, whereas p-ANCA tends to occur in other conditions, such as microscopic polyangiitis (MPA) and eosinophilic granulomatosis with polyangiitis (EGPA). Using combined immunofluorescence and enzyme-linked immunosorbent assay techniques, the sensitivity and specificity of c-ANCA are 91% and 99% respectively; the sensitivity falls to 60% with localized disease.⁵⁰ C-ANCA is positive

Figure 109.4 (a) and (b) Axial CT scans showing sclerosis and opacification of the nasal cavity associated with widespread infiltration of the orbit in GPA.

in over 90% of patients with generalized active disease and titres have been shown to correlate well with disease activity.⁵¹ However, 10% of patients with GPA have a positive p-ANCA result and up to 20% may be ANCA-negative; in localized disease this figure may rise to 30%.²⁶ In addition, there may be false-positive c-ANCA results with cocaine abuse.⁵² Other blood tests should therefore also

be requested, including a full blood count, erythrocyte sedimentation rate, c-reactive protein, serum urea and creatinine and serum ACE. Urinalysis and chest X-ray should be performed. Tissue biopsy may be helpful in ANCA-negative patients where suspicion remains high, but is non-diagnostic in up to 50% of head and neck specimens.²⁶ Paranasal sinus biopsies tend to yield more positive results than nasal specimens.⁵³ The main histological features are granulomatous inflammation, vasculitis and necrosis.

The American College of Rheumatology proposed a clinical classification in 1990 to distinguish GPA (Wegener's) from other vasculitides (**Table 109.5**).⁵⁴ The Chapel Hill Consensus added PR3-ANCA to the definition in 1994.⁵⁵

CT and MRI may show characteristic features (**Figure 109.5**). In a series of 74 patients, over 90% showed

TABLE 109.5 1990 American College of Rheumatology criteria for the classification of Wegener's granulomatosis

Criteria	Definition
Nasal or oral inflammation	Painful or painless oral ulcers or purulent or bloody nasal discharge
Abnormal chest X-ray	Nodules, fixed infiltrates or cavities
Abnormal urinary sediment	Microscopic haematuria with or without red cell casts
Granulomatous inflammation on biopsy	Histologic changes showing granulomatous inflammation within the wall of an artery or in the peri- or extravascular area (artery or arteriole)

* For classification purposes, a patient shall be said to have Wegener's granulomatosis if he/she has satisfied any two or more of these four criteria. This rule is associated with a sensitivity of 88.2% and a specificity of 92.0%.

Figure 109.5 Coronal CT showing typical appearances of Wegener's in the nose with septal destruction, hyperostosis and opacification of the sinuses together with orbital infiltration.

non-specific mucosal thickening in the nasal cavity or paranasal sinuses, 62% showed evidence of bone destruction and 78% had new bone formation in the walls of the sinus cavities.⁵⁶ In addition, the orbit was affected in 37%. Whilst the diagnosis of systemic GPA is made clinically, in a patient without a history of previous sino-nasal surgery the combination of bone destruction and new bone formation on CT is virtually diagnostic, especially when accompanied on MRI by a fat signal from the sclerotic sinus wall, so-called 'tramlining'.⁵⁷ These findings can be helpful in localized sinonasal GPA, where the clinical diagnosis is uncertain and the c-ANCA test may be negative. Imaging of the chest may show nodules, progressive cavitation or fibrosis. Imaging of the larynx should be considered in any patient with symptoms suggestive of subglottic stenosis.

Treatment

Untreated, GPA is a lethal disease with a mean survival of 5 months.⁵⁸ Rapid diagnosis remains of great importance since a fulminating course with a fatal outcome can occur in as little as 48 hours. The introduction of systemic corticosteroid treatment improved mortality rates to 50%.³² However, it was the combination of oral cyclophosphamide with corticosteroids that improved remission rates to 93%.⁵⁹ Despite this, over half of patients will have at least one relapse, and the potential side effects of cytotoxic treatment are not insignificant.³³ Treatment regimes today aim to induce remission and then maintain it, whilst minimizing side effects, and the European Vasculitis Study Group (EUVAS) has undertaken several controlled trials to inform treatment algorithms.⁶⁰

Remission-induction therapy is typically with a combination of high-dose steroids and cyclophosphamide or methotrexate.²⁶ The usual daily dose of cyclophosphamide is 2mg/kg, to a maximum of 200mg per day. There is significant morbidity associated with long-term cyclophosphamide treatment, with side effects including alopecia, haemorrhagic cystitis, opportunistic infections and malignancies; leukaemia and lymphoma are 11 times more likely, and there is a 33-fold increase in the risk of bladder cancer.⁶¹ Strategies to reduce these adverse effects include shorter treatment durations and the use of intermittent 'pulsed' cyclophosphamide. Several randomized trials have shown that pulsed therapy is as effective as oral treatment in achieving remission, but it is associated with a higher relapse rate.⁶² Methotrexate, an antimetabolite, has been shown in randomized trials to be an effective alternative to cyclophosphamide in inducing remission in patients with limited and less severe GPA.⁶³ More recently rituximab, an anti-CD20 monoclonal antibody, has been shown to be as effective as cyclophosphamide in inducing remission.⁶⁴ The multicentre randomized double-blind RAVE (Rituximab for ANCA-Associated Vasculitis) trial also suggested that rituximab may be superior in relapsing disease.

High-dose glucocorticoids are an essential part of remission-induction treatment, and prednisolone is initially given at a dose of 0.5–1 mg/kg daily, to a maximum

of 80 mg per day; this can then be tapered over the course of several months before stopping completely where possible.⁶⁵ Patients may require further courses of glucocorticoids to manage disease exacerbations and relapses. The side effects of long-term systemic therapy are well known, including osteoporosis, diabetes, hypertension, proximal myopathy, weight gain and cataracts.

Remission-maintenance therapy aims to keep GPA quiescent with minimal treatment morbidity. Methotrexate can be used, with similar relapse rates compared to long-term cyclophosphamide treatment.⁶⁶ These patients should receive folic acid supplementation to prevent folate deficiency. Azathioprine is an alternative immunosuppressive agent with less morbidity than cyclophosphamide, and a randomized controlled trial showed equivalent remission control.⁶⁷ Both methotrexate and azathioprine may be used as monotherapy to maintain remission, but are also given as steroid-sparing agents to reduce the dose of prednisolone required by some patients.

Multiple controlled trials have been undertaken in an effort to try and find less toxic but equally effective immunosuppressive agents. Mycophenolate mofetil, a purine synthesis inhibitor, has shown promise in this area but a large multicentre randomized controlled trial showed a higher relapse rate when compared with azathioprine.⁶⁸ Leflunomide, a T-cell inhibitor that targets purine synthesis, appears to be well tolerated and effective in remission maintenance.⁶⁹ Deoxyspergualin, an immunomodulatory agent which inhibits lymphocyte differentiation, appears to be effective in maintaining remission and reducing steroid requirements.⁷⁰ Tumour necrosis factor antagonists, such as infliximab and etanercept, have shown less promising results. A multicentre placebo-controlled trial of etanercept plus standard therapy showed no benefit compared to placebo.⁷²

The possible association between GPA relapses and *S. aureus* infection in the nose prompted trials of long-term antibiotic treatment, namely trimethoprim-sulphamethoxazole (co-trimoxazole), with mixed results. A double-blind placebo-controlled trial showed that relapse rates were reduced compared to controls.⁷² However, another randomized trial reported that co-trimoxazole did not maintain remission as effectively as methotrexate.⁷³

Whatever treatment is used, patients require regular monitoring for both treatment side effects and disease activity. Serial monitoring of c-ANCA can be useful; it frequently becomes negative when the disease is under control but this is not always the case, particularly in localized forms.

Topical nasal treatment such as douching, intra-nasal steroids and nasal lubricants may be helpful for symptomatic relief of crusting and bleeding. Surgery is generally reserved for cases that are refractory to medical treatment, or for complications of GPA.²⁶ Endoscopic sinus surgery is rarely helpful in improving symptoms, but may be undertaken in selected cases. Endoscopic dacryocystorhinostomy has been reported to improve epiphora, but should be avoided in active disease.⁷⁴ Septal perforation repair is not recommended but the use of a silastic septal button

can be beneficial. Augmentation rhinoplasty to correct a saddle-nose deformity should be deferred until the disease has been in remission for at least one year. A series of 13 patients in remission from Wegener's reported a 92% overall success rate from dorsal augmentation without reactivation of disease.⁷⁵ Grommets are best avoided if possible, because of the risk of chronic otorrhoea; hearing aids are a better option to treat both conductive and sensorineural hearing loss.⁴⁴ It has been said that 50% of patients with subglottic stenosis will require a tracheostomy at some point, but recent studies suggest that conservative treatment may avoid this in most cases. Conservative laser surgery combined with endoluminal balloon dilatation and intra-lesional steroid injection appears to give satisfactory results.⁷⁶

EOSINOPHILIC GRANULOMATOSIS WITH POLYANGIITIS (CHURG STRAUSS)

In 1951, Churg and Strauss described a syndrome of allergic angiitis and granulomatosis, a rare systemic vasculitis which has more recently been named 'eosinophilic granulomatosis with polyangiitis' (EGPA).^{77,78} The Chapel Hill consensus defined it as 'eosinophil-rich and granulomatous inflammation involving the respiratory tract, and necrotizing vasculitis affecting small to medium-sized vessels, associated with asthma and eosinophilia'.⁵⁵ It is the rarest of the ANCA-associated vasculitides, with an estimated annual incidence of 0.5–4 per million in Europe, although may be underestimated.³¹ However, in asthmatics this incidence rises to 67 per million.⁷⁹

Age and sex

The mean age at diagnosis is 50 years (range 4–75 years).⁸⁰ Both male and female preponderances have been reported, but overall there appears to be no significant difference.^{79,81,82}

Aetiology

The aetiology remains unknown but it may be an autoimmune disease mediated by Th2-cells which activate both eosinophils and neutrophils.⁸³ Direct eosinophilic infiltration and the release of cationic proteins and cytokines then cause tissue injury.⁸⁰ High levels of eosinophils and immunoglobulin E (IgE) in vessels and tissues also suggests a direct role in the development of the vasculitis, possibly an allergic response to an unknown allergen. EGPA has been reported to occur after treatment with the leukotriene receptor antagonist zafirlukast.⁸⁴ However, this appears to relate to the unmasking of vasculitis by the reduction in systemic steroid treatment that zafirlukast allowed, rather than be a true causative effect.⁸⁵ Other suggested precipitants include vaccination, desensitization therapy and inhalation of various aeroallergens, which all support an allergic aetiology.⁸⁶

Clinical features

Asthma occurs in approximately 99% of patients, and is characteristically late-onset; in 83% of cases it precedes the vasculitis by an average of 8 years.⁸⁷ Sinusitis symptoms are present in up to 93%, and have been reported to worsen prior to diagnosis in 28% of patients.^{81,88} Allergic rhinitis and chronic rhinosinusitis with nasal polyps occur in up to 75% of cases.⁸² Patients frequently complain of nasal obstruction, rhinorrhoea, anosmia and sneezing, as well as crusting and epistaxis to a lesser degree; nearly half may have undergone previous nasal surgery before the diagnosis is made.⁸¹

Neurological symptoms are common, with mononeuritis multiplex in up to 76% and peripheral polyneuropathy in approximately one-quarter of cases.⁸⁹ Central nervous system involvement is less common, but is the second commonest cause of death.⁹⁰

Cutaneous symptoms including papules and nodules occur in up to 50% of cases. Cardiac involvement is less common but is the major cause of mortality, usually from granulomatous myocarditis.⁷⁹

Three clinical phases of EGPA have been described, although they do not necessarily follow each other consecutively.⁹⁰ The first, prodromal, phase may persist for several years, and is characterized by adult-onset asthma and upper respiratory tract inflammation. Phase two is characterized by peripheral eosinophilia, usually with pulmonary infiltrates and eosinophilic gastroenteritis. The third phase is that of the systemic vasculitis, including constitutional symptoms, neurological and cutaneous involvement.⁸⁰

Diagnosis

Diagnosis is based on the typical clinical features with a peripheral eosinophilia of greater than 10% of the white cell differential, plus tissue biopsy. Histology shows necrotizing vasculitis, extravascular necrotizing granulomas and tissue eosinophilia, but it is rare to see all three features on one biopsy.⁸² ANCA is positive in 40–75% of cases, typically p-ANCA specific for MPO but occasionally c-ANCA is seen.^{80,86} There is evidence that ANCA modulates the phenotype, with a more vasculitic disease in ANCA-positive patients.⁸⁷ The French Vasculitis Study Group series reported significantly more peripheral neuropathy, ENT and renal involvement in patients with a positive p-ANCA, as well as less frequent cardiac pathology.⁷⁸ There was a higher relapse rate in ANCA-positive cases but significantly reduced mortality.

Chest X-ray usually shows transient peripheral infiltrates, but pleural effusions are seen in up to 10% of cases.⁷⁹ Sinusitis imaging shows non-specific widespread opacification consistent with chronic rhinosinusitis with polyps, and patients are perhaps more likely to develop frontoethmoidal mucocoeles.⁶¹ The American College of Rheumatology clinical criteria for the classification of EGPA includes pulmonary and sinus radiological abnormalities (Table 109.6).⁹¹

TABLE 109.6 1990 American College of Rheumatology criteria for the classification of Churg Strauss syndrome

Criteria	Definition
Asthma	History of wheezing or diffuse rales on expiration
Eosinophilia	Eosinophilia >10% on white blood cell differential count
Mononeuropathy or polyneuropathy	Development of mononeuropathy, multiple mononeuropathies, or polyneuropathy
Pulmonary infiltrates, non-fixed	Migratory or transitory pulmonary infiltrates on radiographs
Paranasal sinus abnormality	History of acute or chronic paranasal sinus pain or radiographic opacification of the paranasal sinuses
Extravascular eosinophils	Biopsy including artery, arteriole or venule, showing accumulations of eosinophils in extravascular areas

*For classification purposes, a patient shall be said to have Churg Strauss syndrome if he/she has satisfied any four or more of these six criteria. This rule is associated with a sensitivity of 85% and a specificity of 99.7%.

The differential diagnosis includes parasitic and fungal infections, eosinophilic pneumonia, idiopathic hypereosinophilic syndrome and other vasculitides.

Treatment

Treatment is primarily with high-dose systemic steroids, which are tapered when possible. Those with organ or life-threatening disease, or those requiring persistently high doses of steroids may require treatment with cyclophosphamide to induce remission.⁸⁸ Methotrexate has also been used for both induction and maintenance of remission, and azathioprine and mycophenolate mofetil may be helpful as steroid-sparing agents.⁷⁹ Interferon-alpha has been successful in treating refractory cases.⁹² Overall remission rates are high (91%) but over 25% relapse either within the first 3 months or much later, after 5 years.⁸⁶ Survival has improved with the advent of corticosteroid and immunosuppressive treatment, with mortality similar to that of the normal population.⁸⁸ Sinonasal symptoms should be treated with topical nasal steroids, douching and endoscopic sinus surgery as required, which may be multiple times.⁸¹

COCAINE-INDUCED MIDLINE DESTRUCTIVE LESION

Cocaine use via intra-nasal inhalation is known to cause mucosal inflammation. Septal perforation has been reported in approximately 5% of chronic users, but more aggressive midfacial destruction has also been noted.⁵² Such cocaine-induced midline destructive lesions (CIMDL) can mimic localized or systemic GPA as well as neoplasia.

Aetiology

Cocaine is the trigger but patients who develop CIMDL appear to be predisposed to produce ANCA. Nearly 90% have a positive p-ANCA against human neutrophil elastase (HNE), which may increase apoptosis and the local inflammatory response to injury.⁵²

Clinical features

Patients complain of chronic nasal obstruction and bleeding, with change in shape of the nose and nasal regurgitation as the lesion progresses to destroy the nasal framework and in particular the palate; this is more common than in GPA patients where it occurs only rarely. There are rarely systemic symptoms. Not all patients will admit to cocaine use. Examination confirms a variable degree of destruction of the septum, turbinates, lateral nasal wall and floor (Figure 109.6).

Diagnosis

The differential diagnosis includes infections, GPA and neoplasia, and these must be excluded. Whilst the majority of patients with CIMDL will have a positive HNE-ANCA, over 50% of patients will also have a positive PR3-ANCA. This makes differentiation from limited GPA more difficult, but studies have shown no evidence of HNE-ANCA positivity in either normal controls or patients with GPA.⁹³ Histology is often very similar to that of GPA, with vasculitis and fibrinoid necrosis, so may not be helpful unless it confirms GPA.⁵² Urine, blood and hair can be tested for cocaine if necessary.

Treatment

There is no role for immunosuppression, and patients must stop using cocaine to prevent further progression. Conservative treatment includes nasal douching, debridement of necrotic areas and topical or systemic antibiotic therapy. Surgical correction of septal perforation or nasal deformity should not be attempted until the patient has been clear of cocaine for at least 6–12 months.

EOSINOPHILIC GRANULOMA

This is a clonal proliferation of Langerhans cells associated with a heterogeneous inflammatory infiltrate of eosinophils, histiocytes, lymphocytes, plasma cells and neutrophils. It is now regarded as a neoplastic condition with a variable clinical course.^{94, 95} It is also considered a manifestation of histiocytosis-X and is sometimes referred to as Langerhans cell histiocytosis or Langerhans granulomatosis.

Age and sex

A wide age range from infancy to over 80 years has been recorded, but about 85% of cases are detected in the first

Figure 109.6 Cocaine-induced midline destructive lesions. (a) Oral endoscopy showing a 1cm hard palate perforation with regular margins; (b) Nasal endoscopy showing extensive destruction of the nasal septum and inferior turbinate as well as the hard palate perforation; (c) Coronal and (d) axial CT showing extensive destruction of the septum and turbinates (Courtesy of Dr Matteo Trimachi).

three decades of life; 60% are young children. Males are affected twice as frequently as females.

Clinical features

Whilst all organs may be affected, eosinophilic granuloma predominantly occurs in bones. The skull is a common site of involvement, in particular the temporal, frontal and parietal bones. The usual presentation is a painful swelling of the involved bone, often for many months, associated with cervical lymphadenopathy. Mandibular lesions produce toothache, gum ulceration and loose teeth, whereas involvement of the temporal bone may simulate acute mastoiditis.

Diagnosis

Radiological evaluation shows punched-out bony lesions and radiolucent areas around the teeth. Lesions in the skull often show bevelled margins due to angulated destruction of the cortical bone. Macroscopically, the lesions are soft and yellow or red-brown in colour; biopsy material is best

obtained by curettage. Microscopically, the Langerhans cells are mixed with other inflammatory cells. The cytoplasm of the Langerhans cells may be eosinophilic and Charcot–Leyden crystals may be found in ordinary histiocytes. There is intense osteoclastic activity at the periphery of the granuloma due to prostaglandin and cytokine production by the Langerhans cells.⁹⁶ During the healing phase of the granuloma, the stroma becomes increasingly fibrotic.

Treatment

Treatment depends on whether or not the eosinophilic granuloma is localized and/or solitary. Solitary, or ‘type II disease’, is at least five times more common than polyostotic disease. Some solitary lesions will spontaneously regress. With unifocal disease a combination of curettage/excision and radiotherapy is usually curative, provided that no new lesions develop within the first year. A proportion of patients will develop a generalized disease with hepatosplenomegaly, lymphadenopathy, skin lesions and further osseous lesions, so called ‘type I disease’.

The course of this can be rapid with a poor prognosis; additional chemotherapy has been advocated in these circumstances. At present, the most effective chemotherapy regime appears to be etoposide and steroids given for periods of 12 months or more dependent on the response.⁹⁷ Alpha interferon and bone marrow transplantation have also been used successfully.

GIANT CELL GRANULOMA

Granuloma-like aggregates of giant cells in a fibrovascular stroma characterize this benign condition otherwise referred to as 'giant cell reparative granuloma' or 'giant cell reaction of bone'. It was first described by Jaffe in 1953 in the jaws, although other craniofacial sites have been reported.⁹⁸

Age and sex

These lesions commonly occur in children and young adults, with a female to male preponderance of 2:1.

Clinical features

Pain and swelling over the affected bone are the most common symptoms, but diplopia, hearing loss, vertigo and tinnitus have also been reported. The maxilla and mandible are most commonly affected followed by the sphenoid and temporal bones.^{98,99} Bilateral symmetrical involvement of the jaws by giant cell granulomas is seen in cherubism, a rare inherited childhood condition (Figure 109.7).¹⁰⁰

Diagnosis

CT shows expansile lytic lesions with a 'soap bubble' centre and well-demarcated edges. Histologically, the granuloma

has a cellular fibroblastic stroma containing aggregates of giant cells. These cells are smaller and have fewer nuclei than in a true giant cell tumour. The lesions are benign despite the presence of mitoses, which may cause the inexperienced pathologist difficulties. To add to the confusion, the microscopic appearance of giant cell granuloma is indistinguishable from that of the solid variant of aneurysmal bone cysts. Biochemical investigations (serum calcium, phosphate and alkaline phosphatase) should be undertaken to distinguish it from the brown tumour of hyperparathyroidism.

Treatment

Curettage alone is associated with recurrence in 15% of cases and excision should be undertaken where possible.⁹⁹

CHOLESTEROL GRANULOMA

This is a rare granulomatous foreign body reaction to cholesterol crystals precipitated in the tissues, and has also been referred to as a chocolate cyst or orbital cholesteatoma.

Age and sex

In 6 cases managed by the senior author, the age ranged from 31 to 89 years (mean 59 years) with a male preponderance of 5:1.

Aetiology

It is presumed to result from haemorrhage due to trauma, but there must also be abnormal ventilation and drainage of the involved sinus.¹⁰¹

Figure 109.7 (a) and (b) Coronal CT scans of upper and lower jaw showing typical appearances of cherubism.

Clinical features

Although more common in the ear, these lesions may affect the maxillary or frontal sinuses, producing bony expansion, cosmetic deformity and displacement of adjacent structures, such as the globe. The differential diagnosis includes a mucocele and a dermoid or epidermoid cyst.

Diagnosis

Typical CT appearances are of a cyst-like expansion of the sinus that does not enhance with contrast. A very high signal is produced on all MRI sequences.

Histologically, it has a characteristic appearance of granulation tissue containing foreign body-type giant cells surrounding clefts created by the cholesterol crystals.¹⁰²

Treatment

Surgical drainage and marsupialization is required, by whichever approach facilitates complete removal of the granulation tissue to prevent recurrence.^{103, 104}

GRANULOMATOUS NEOPLASIA – EXTRANODAL NK/T-CELL LYMPHOMA

Many terms, most notably ‘midline lethal granuloma’, have been used to describe the condition now known to be an extranodal NK/T-cell lymphoma, nasal type (ENKTCL).^{105, 106} It is included in this chapter for completeness due to this historical nomenclature. This rare non-Hodgkin’s lymphoma (NHL) causes destruction of the midface and was the subject of great pathological debate. Now recognized as a distinct entity by the

WHO, it is most common in south-east Asia and South America.¹⁰⁶

Age and sex

NK/T cell lymphoma may occur at almost any age from the first to the ninth decade, but is most common in the fifth or sixth decades. A male preponderance has been reported.¹⁰⁷

Aetiology

ENKTCL appears to be caused by the Epstein-Barr virus.¹⁰⁸

Clinical features

ENKTCL usually arises in the nasal cavity and spreads to involve adjacent structures including the orbits, oral cavity, skin and paranasal sinuses. The intra-nasal granulomatous mass initially causes symptoms of obstruction, discharge and bleeding. Progressive destruction of the nasal skeleton and overlying skin occurs (**Figure 109.8**).

Diagnosis

Early diagnosis is important, as the prognosis for widespread disease is much worse. Good quality representative biopsy material from tissue beneath the slough and crust is essential. Histologically, the infiltrates are polymorphic and atypical cells may be arranged in a necrotizing angiocentric growth pattern. The tumour consists of neoplastic T-lymphocytes with a significant inflammatory infiltrate.¹⁰⁹ Immunohistochemistry is usually positive for CD56, CD2 and cytoplasmic CD3.¹⁰⁶ Granulomas and giant cells are not present in T-cell lymphomas; thrombosis and necrosis are, however, common findings. Imaging and bone marrow biopsy are also required for staging purposes.

Figure 109.8 ENKTCL affecting the midface with (a) early ulceration and (b) significant central destruction.

Treatment

This is an aggressive tumour but tends to have a dramatic response to radiotherapy, which is therefore the recommended treatment for localized disease.¹¹⁰ The role of

chemotherapy has not yet been established, but may be given in addition for recurrent or disseminated disease.¹¹¹ Local recurrence rates range from 31–67%, with an overall 5-year survival rate of 38–45%.¹⁰⁶

BEST CLINICAL PRACTICE

- ✓ The sensitivity and specificity of c-ANCA in GPA are 91% and 99% respectively.
- ✓ Pulsed cyclophosphamide therapy is as effective as oral treatment in achieving remission in GPA, but it is associated with a higher relapse rate.
- ✓ Rituximab is as effective as cyclophosphamide in inducing remission in GPA and may be superior in relapsing disease.
- ✓ Methotrexate and azathioprine have shown similar relapse rates compared to long-term cyclophosphamide treatment for GPA.
- ✓ Subglottic stenosis due to granulomatous disease can be satisfactorily treated with conservative laser surgery combined with endoluminal balloon dilatation and intra-lesional steroid injection.

FUTURE RESEARCH

- ▶ The aetiology of these conditions remains obscure and requires further investigation.
- ▶ It is uncertain whether all cases with limited GPA progress to systemic disease or what triggers this progression.
- ▶ The sensitivity of c-ANCA requires refinement, particularly in limited forms of GPA.
- ▶ Further multicentre controlled trials are required to inform treatment with newer, less toxic medications for these rare conditions.

KEY POINTS

- Many patients with systemic granulomatous conditions present first to ENT surgeons. It is important to maintain a low threshold of suspicion in order to make an early diagnosis and avert more severe systemic disease.
- Any patient with blood-stained discharge and crusting in the nose has a granulomatous condition until proven otherwise.
- No one test is completely reliable and a combination of clinical findings combined with diagnostic investigations is required.
- Secondary or tertiary referral may be required to diagnose and manage the condition.
- Management should be multidisciplinary.
- A range of medications is available, of which steroids combined with cytotoxic drugs are the most frequently used.
- Patients on long-term systemic steroids should be monitored for complications.
- Surgery is generally reserved for refractory cases or complications of disease.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: olfaction, smell, anosmia, dysosmia, phantosmia, age, odour identification, psychophysics, odour threshold, odour discrimination, presbyosmia, head trauma, olfactory epithelium, olfactory bulb and UPSIT.

INTRODUCTION

The ability to detect environmental chemicals is a primary function of the nose. A proper functioning sense of smell allows a person to discriminate between thousands of largely organic, low-molecular mass, volatile compounds and provides information regarding: (1) the safety of a substance or environment (e.g., spoiled food, leaking natural gas); (2) the aesthetic properties of everyday objects (e.g., rose, dirty laundry); and (3) elements of basic communication (e.g., mother/infant interactions). When combined with gustatory and somatosensory stimuli, the sense of smell determines the flavours of foods and beverages, and aids the process of digestion by triggering normal gastrointestinal secretions. Moreover, the olfactory system contributes significantly to a person's quality of life. Among 750 patients presenting to our centre with largely olfactory problems, more than 68% experienced altered quality of life, 46% described changes in appetite or body weight, and 56% reported influences in daily living or psychological well-being.¹ Loss of smell can result in significant psychological disruption and even generate feelings of physical and social vulnerability and victimization.² The importance of smell is also emphasized by the consequences of its loss in those who depend on it for their livelihood (e.g., cooks, homemakers, firefighters, plumbers, wine merchants, chemical plant workers, etc.). Loss of smell can also adversely affect nutrition, especially in the elderly and, importantly, has been associated

with longevity. In a recent longitudinal study of over a thousand non-demented older persons, mortality risk was nearly two and a half times higher in those with low than with high odour identification test scores after adjusting for sex, age, education and other variables.³

Although otorhinolaryngologists are often the first physicians that patients with smell complaints visit, some patients find themselves making repeated appointments to multiple physicians until their olfactory problem is adequately addressed. Unfortunately, olfactory health is generally disregarded by physicians. This is beside the fact the abnormalities of smell are ubiquitous. There are at least 2.7 million (1.4%) adults in the United States with olfactory dysfunction; presumably similar numbers exist world-wide.⁴ Also, most patients who complain of decreased 'taste' function actually have an unrecognized impairment of smell.¹ Diminished 'taste' is typically due to loss of flavour sensations derived from retronasal stimulation of the olfactory receptors, rather than impairment of taste-mediated sensations, *per se*.³ Importantly, a patient's lack of olfactory function can be an early sign of a number of serious disease states, including nasopharyngeal carcinoma, Alzheimer's disease, Parkinson's disease, frontal meningiomas, multiple sclerosis, and sinus infections.^{5, 6} While some patients initially present to their physicians with a frank complaint of smell impairment, others can be completely unaware of their dysfunction, making routine clinical assessments of olfaction imperative.

The necessity of the physician to properly evaluate for abnormalities of smell function is also supported in the medicolegal arena, with claims of accidental and iatrogenic smell disturbance often resulting in substantial financial awards. Routine clinical quantitative measurement of smell function can now be easily performed in the office setting, allowing a physician to:

- validate and characterize a patient's olfactory complaint
- identify patients who might be malingering
- quantify and document known presurgical smell impairment
- longitudinally, follow the course of smell function in the midst of a therapeutic intervention or during recovery from previous loss.

This chapter summarizes important aspects of olfactory anatomy and physiology, describes the common olfactory disorders encountered in clinical practice, and provides current practical techniques for the evaluation and management of smell disturbance.

ANATOMY AND PHYSIOLOGY

The nose: Structure in relation to smell

The human nose contains two independent nasal passages that are dynamic conduits that subservise both respiration and olfaction. The nasal cavities not only warm and humidify inspired air, but they help to eliminate most airborne pathogens and environmental pollutants – a number of which can be toxic to the olfactory system.⁷ The olfactory neuroepithelium exists within a small region of nasal mucosa (said to be ~2cm²) in the upper recesses of the nasal chambers lining the cribriform plate and sectors of the superior turbinate, middle turbinate, and septum (Figure 110.1).⁸ The olfactory cleft, an opening of approximately 1 mm wide that sits 7 cm deep to the nostril, harbours the majority of the olfactory neuroepithelium which is difficult to observe even by modern endoscopic techniques.⁹ While most of the air stream coming into the nose is shunted through the passages around the inferior and medial turbinates and along the septal wall, only 10–15% of the air reaches the olfactory neuroepithelium.¹⁰ Thus, minor changes in nasal architecture and airflow can result in substantial air-flow blockage to olfactory regions without much impairment in nasal respiratory ability.^{7,11} For example, relatively small polyps located in the superior meatus can deflect incoming air currents away from the olfactory cleft, resulting in smell impairment.¹¹ On the other hand, too patent an airway, as seen with excessive turbinate removal, can improperly shunt air away from the olfactory cleft, resulting in at least some deterioration in olfactory acuity.¹² It is important to remember that while chronic rhinosinusitis can lead to swelling of the mucosa and a mechanical conductive block, there is evidence for local inflammatory toxicity to the olfactory neuroepithelium that may not be alleviated with surgical intervention.¹³ A significant amount of retronasal airflow from the nasopharynx occurs during swallowing and

Figure 110.1 CT scan of paranasal sinuses and associated nasal structures. The * is within the right maxillary sinus, below the right eye. The inferior portion of the middle turbinate is indicated by the white arrowhead and the inferior turbinate by the circle. Note the attachment of the middle turbinate to the cribriform above. A short fat white arrow is in the left anterior ethmoid sinus and points to the anterior ethmoidal neurovascular bundle as it emerges from the left orbit and courses along the roof of the ethmoid. The central small open arrow is located in the anterior cranial fossa directly above the bony crista galli. The long thin arrow situated with the olfactory cleft points to the cribriform plate. The five-pointed star in the right olfactory fossa is adjacent to the vertical lamella of the cribriform plate. From: Lanza DC, Clerico DM. Anatomy of the human nasal passages. In: Doty RL (ed) Handbook of olfaction and gestation. New York: Marcel Dekker, 1995, p. 60. Copyright © 1995 by Marcel Dekker, Inc.

deglutition. This retronasal route is vital to the production of flavour from swallowed foods – adding *smell* to both *taste* and *touch*.

The human nasal passage is intermittently affected, at least in some individuals, by the ‘nasal cycle’. This cycle, an autonomic ultradian rhythm of periodic alternating side-to-side nasal turbinate engorgement and disengorgement, is said to occur in 80% of the normal population with a cycle frequency ranging from 40 minutes to 4 hours.⁷ The nasal cycle itself, which is less frequent in the very young and the very old, does not appear to affect overall olfactory sensitivity in the normal nose; however, intermittent engorgement in the context of a pre-existing structural distortion can result in a noticeable, albeit transient, blockage of a nasal passage (e.g., when turbinate adhesions are present).

Four neural systems within the human nose

Most land mammals have four major specialized neural systems within the left and right sides of the nose:

- The main olfactory system (Cranial Nerve I or CN I).
- The accessory olfactory system (i.e., the vomeronasal system).

- The trigeminal somatosensory system (CN V)
- The nervus terminalis or terminal nerve (CN 0).^{14, 15}

While CN I mediates common odour sensations (e.g., vanilla, rose, chocolate), CN V mediates both chemical and non-chemical stimuli in the form of somatosensory sensations (e.g., irritation, burning, cooling, tickling, touch). CN V is also responsible for inducing reflexive responses, such as secretions of mucus and halting of inhalation, that help to prevent or minimize chemically-induced or thermally-induced damage to the linings of the nose and lungs. The vomeronasal system is non-functional in humans; while a rudimentary vomeronasal tube is present on each side of the septum with an opening into the human nose, it has no centrally-projecting nerve and humans do not possess an accessory olfactory bulb, the target of such a nerve. CN 0 was discovered after the other cranial nerves had been named, and consists of a loose plexus of ganglionated nerves that, in most mammals, is in close proximity to the vomeronasal organ and nerve. Its neurons are immunoreactive to the peptide hormone gonadotropin-releasing hormone (GnRH), implying a yet-to-be characterized association with endocrine processes. It has been suggested by some that CN 0 may be a vestige of an ancient nerve whose function was lost or superseded by other parts of the nervous system, although this argument is weak, given that it is so well conserved among a wide range of vertebrates, including humans.

Olfactory neuroepithelium and neural transduction

Before neural transduction can begin, odourants must (a) enter the nose during either active (e.g. sniffing) or passive (e.g., diffusion) processes, (b) pass through the olfactory cleft, and (c) move from the air phase into the largely aqueous phase of the olfactory mucus. During mastication, odourants from the oral cavity actively move into the nasal cavity via the nasal pharynx (retro-nasal direction). Mucus is important in that it ensures a moist and protective environment for the olfactory neuroepithelium, and aids in dispersing odourants to the olfactory receptors. From the mucus, odourous chemicals either diffuse or are transported by specialized proteins (termed odourant binding proteins) to the receptors.

The olfactory neuroepithelium has an ultrastructure of variable uniformity and, contrary to many textbooks, cannot be discerned reliably from the surrounding respiratory epithelium by the naked eye. It is a pseudostratified columnar epithelium, supported by a highly vascularized lamina propria. Throughout life, islands of respiratory-like epithelial metaplasia appear within the epithelium, presumably as a result of cumulative viral, bacterial, and other insults.¹⁴ In the adult, at least six distinct classes of cells – defined morphologically, biochemically, and functionally – can be identified within the neuroepithelium (Figure 110.2).

- The *bipolar sensory receptor neuron* is derived embryologically from the olfactory placode, is of CNS origin, and extends odourant receptor-containing cilia into the mucus.
- The *supporting or sustentacular cell* insulates the bipolar receptor cells from one another, regulates mucus production, transports molecules across the epithelium, and detoxifies and degrades odourants.
- The *duct cell of Bowman's glands* secretes most of the mucus within the olfactory receptor region.
- The poorly understood *microvillar cell* is located at the surface of the epithelium and, like the supporting cell, sends tufts of microvilli into the nasal mucus.
- The *horizontal (dark) basal cells*, one of two main classes of stem cells within the basement membrane of the epithelium.
- The *globose (light) basal cells*, a multipotent basal cell that can give rise to neurons and non-neuronal cells, including the horizontal basal cells.¹⁴

Figure 110.2 Low-power electron micrograph (× 670) of a longitudinal section through a biopsy specimen of human olfactory mucosa taken from the nasal septum. Four cell types are indicated: ciliated olfactory receptors (c), microvillar cells (m), supporting cells (s) and basal cells (b). The arrows point to ciliated olfactory knobs of the bipolar receptor cells. d = degenerating cells; bs = base of the supporting cells; lp = lamina propria; n = nerve bundle; bg = Bowman's gland. Photo courtesy of David T. Moran.

The number of olfactory receptor cells exceeds that of any other sensory system except vision; collectively, the surface area of the cilia is quite large – exceeding 20 cm² in the human.¹⁵ Seven domain transmembrane olfactory receptors, which reflect the expression of the largest known vertebrate gene family (on the order of 1000 genes or pseudogenes, accounting for ~1% of all expressed genes), are found on the 10–30 cilia that project into the nasal mucus from each of these cells.¹⁶ Approximately 6 million receptor cell axons ultimately coalesce into 30–50 fascicles, termed the olfactory fila, which traverse the cribriform plate and pia mater to synapse with second-order neurons within the glomeruli of the olfactory bulb. The olfactory receptor neurons primarily use the neurotransmitter glutamate to excite OB neurons, while dopamine appears to be a necessary modulator of olfactory nerve input.¹⁷ The process of actually transforming the chemical energy of receptor binding into a neural signal – signal transduction – requires a complex cascade of events, some of which involves activation of G proteins (e.g., that of an olfactory-specific subtype, G_{olf}) and various second-messenger enzymes.^{18, 19}

It is important to recognize that the olfactory nerve cells, as well as the proximal extraneural spaces, can serve as conduits for the movement of viruses and exogenous agents from the nasal cavity into the brain. This was recognized many years ago as a major route of polio viruses into the brain, leading to programmes to cauterize the olfactory epithelium of school children with zinc sulphate in Toronto and other major cities to avert contracting polio during epidemics. This ‘olfactory vector’ route has been proposed as a potential explanation for both the olfactory loss and the aetiology of some forms of common neurodegenerative diseases, such as Alzheimer’s disease and idiopathic Parkinson’s disease,²⁰ although evidence for this hypothesis in these cases remains largely circumstantial.

The olfactory bulb and central projections

The olfactory bulbs are complex structures located on the ventral surface of the frontal lobes directly over the cribriform plate. The first synapse of the incoming bipolar olfactory receptor cell neurons occurs within spherical structures making up a distinct layer of the bulb – the glomeruli. A given receptor projects to only one glomerulus, and any given glomerulus appears to receive most of its input from a restricted region of the epithelium. The main afferent second-order neurons are termed mitral and tufted cells. A considerable amount of convergence of information occurs at the level of the glomeruli. The mitral and tufted cells, in turn, send collaterals that synapse within the periglomerular and external plexiform layers, resulting in ‘reverberating’ circuits in which negative and positive feedback occur. The apical dendrites of the mitral and tufted cells are influenced by interneurons

and centrifugal fibres, most of which are GABAergic or dopaminergic.²¹

It is generally believed that the olfactory system is unique among sensory systems in that information from the sensory receptors is sent directly, and primarily ipsilaterally, into cortical regions without synapsing in the thalamus. However, some cortical projections from primary to secondary (i.e. orbitofrontal) cortex do ultimately relay through the thalamus, and there are some contralateral projections via the anterior commissure. The latter arise largely from pyramidal cells of the anterior olfactory nucleus (AON; a structure whose cells are primarily in the rostral olfactory peduncle). Higher order brain regions in addition to the AON that are targeted by the mitral and tufted cells of the bulb include (from rostral to caudal):

- The piriform cortex.
- The olfactory tubercle.
- The entorhinal area.
- The amygdaloid cortex (a region contiguous with the underlying amygdala).
- The corticomедial nuclear group of the amygdala.

There is a rich supply of centrifugal fibre projections from sectors of the olfactory cortex and other central structures to the olfactory bulb which modify and control olfactory input.^{21, 22} Structures involved in centrifugal activity include the AON, piriform cortex, lateral entorhinal cortex, regions of the amygdala, raphe nuclei, locus ceruleus, and regions of the hypothalamus.²² Third-order projections occur, in a reciprocal fashion, to numerous regions, including the mediodorsal nucleus of the thalamus, the posterior and medial hypothalamus, the hippocampus, and the orbitofrontal cortex, the latter of which also receives second-order projections. Areas of the cortex that result in smell perception when stimulated include the pre-piriform and intermediate piriform cortices. Lesions of the olfactory system anterior to the olfactory trigone (including the neuroepithelium, fila, bulb, and tract) can result in total lack of smell on the affected side. However, lesions within olfactory structures more posterior to the olfactory trigone do not typically cause complete loss.^{22, 23}

OLFACTORY DISORDER CLASSIFICATION

Olfactory disorders are classified according to standard schemata. It is important to differentiate between a patient’s chemosensory complaint and the findings of objective testing, which are not always in congruence. *Anosmia* refers to an inability to detect qualitative olfactory sensations (i.e., absence of smell function); *Partial anosmia* defines an ability to perceive some, but not all, odours; *Hyposmia* or *microsmia* refers to decreased sensitivity to odours; *Hyperosmia* reflects increased sensitivity to common odours; *Dysosmia* (sometimes termed *cacosmia* or *parosmia*) is distorted or perverted smell perception

to odour stimulation; *Phantosmia* is a dysosmic sensation perceived in the absence of an odour stimulus (a.k.a. olfactory hallucination); and *Olfactory agnosia* refers to an inability to recognize an odour sensation, even though olfactory processing, language, and general intellectual functions are essentially intact, as in some stroke patients. Other less commonly used terms include *Heterosmia* – a condition where all odours smell the same, *Presbyosmia* – a decline in smell sense with age, and *Osmophobia* – a dislike or fear of certain smells. Presbyosmia is less specific than the other terms noted above (e.g., it does not distinguish between anosmia and hyposmia) and is laden, by definition, with the notion that it is age *per se* that is causing the age-related deficit. Olfactory dysfunction can be either bilateral or unilateral (sometimes termed binasal or uninasal), and bilateral testing usually reflects the better functioning of the two sides of the nose.

CLINICAL EVALUATION OF SMELL FUNCTION

History

Proper assessment of a patient's smell function requires:

- A detailed clinical history
- Objective quantitative olfactory testing
- A thorough physical examination emphasizing the head and neck with appropriate brain and rhinosinus imaging.

It is important to recognize that patients frequently confuse 'taste problems' with true smell loss, and that many deny any olfactory disturbance until formal testing proves otherwise. Several focused questions can help establish the nature of the olfactory disturbance. Was olfactory functioning previously normal? Does the patient have a problem with smell, taste, or both? What is the timing of onset, duration of impairment, and pattern of occurrence? *Sudden olfactory loss* can be consistent with possible head trauma, ischaemia, infection, or a psychiatric condition. *Gradual loss* may indicate a progressive and obstructive lesion in or around the nasosinus region, particularly if the loss is unilateral. *Intermittent loss* may suggest an inflammatory process in association with nasal and sinus disease. Is the problem seasonal, suggesting an allergic seasonal rhinitis? Is there a history of precipitating antecedent events, such as head trauma, viral upper respiratory infections, chemical or toxin exposures, and nasosinus surgeries? Does the patient have any nasal discharge that is mucous-appearing (e.g., allergy), purulent (e.g., infection), or clear (CSF rhinorrhea after trauma)? Does the patient use drugs of abuse, such as intra-nasal cocaine, ethanol, or tobacco? Each of these substances has been associated with some form of olfactory impairment; for example, chronic alcoholism can result in significant impairment in smell discrimination²⁴ and cigarette

smoking results in a loss of olfactory ability that is proportional to the cumulative smoking dose.²⁵ Cessation of smoking can result in improvement in olfactory function over time.

It is essential to determine all medications used by the patient since many reportedly cause smell and taste disturbance. For example, smell or taste loss or disturbances are reported in the Physicians' Desk Reference (PDR) as a potential side effect of hundreds of medications.²⁶ Does the patient have comorbidities that can contribute to smell impairment, such as renal failure, liver disease, hypothyroidism, diabetes, or dementia? Delayed puberty in association with anosmia (with or without midline craniofacial abnormalities, deafness, and renal anomalies) suggests the possibility of Kallmann's syndrome or some variant thereof. Is there a recent history of epistaxis, discharge (clear, purulent or bloody), facial numbness or weakness, nasal obstruction, allergies, headache or irritation (i.e., signs that may have localizing value)? A positive family history suggests a genetic aetiology. A history of headache which can suggest sinusitis, migraine, or intra-cranial tumour should be sought. Are smells present without an obvious stimulus? A simple partial seizure, or aura, may not be obvious and other signs of ictal activity should be explored (e.g. limb shaking, difficulties with speech, unresponsiveness, automatisms, loss of consciousness, and déjà vu). Given the strong relationship of Alzheimer's disease and idiopathic Parkinson's disease to smell impairment, one should also look for memory- and parkinsonism-related complaints in older patients. A physician should also be aware of pending litigation and the possibility of malingering since olfactory loss is a compensatable injury. Malingering is readily detected in most patients by forced-choice olfactory testing. Malingerers frequently perform more poorly than expected on the basis of chance on such tests.²⁷

Physical examination and evaluation

Patients complaining of smell disturbance typically require a general assessment of the head and neck and more detailed otolaryngological and neurological examinations. Are there any signs of trauma such as healing wounds, scarring or distorted nasal or skull architecture? Inspection of the nasal passages can begin with a simple nasal forceps examination to view the peripheral nasal cavity for signs of polyps, congestion, deviation of septum, or inflammation. However, this method is limited, and often nasal endoscopy, employing both flexible and rigid scopes, is needed to ensure thorough assessment of the olfactory meatal area. A deviated septum, *per se*, does not imply a smell disturbance since the olfactory cleft can remain patent; however, the additional presence of polyps, masses, adhesions of the turbinates to the septum may adequately obstruct airflow. Rarely, foreign bodies can be present, particularly in the context of a psychiatric disturbance. Nasal mucus membranes must be examined for colour, surface texture, swelling, inflammation, exudate, erosion, ulceration, epithelial metaplasia, and atrophy.

The presence of mucopus above the eustachian tube orifice suggests posterior ethmoid and/or sphenoid sinus disease. However, mucopus below the eustachian tube implies involvement of the osteomeatal complex. A pale mucous membrane suggests allergy, usually as a result of oedema within the lamina propria. Atrophy of the lamina propria is suggested by unusual spaciousness, dryness and crusting, as is seen in atrophic rhinitis. Exposures to environmental or industrial pollutants can result in metaplasia within the epithelium, in addition to swelling, inflammation, exudates, erosion, and ulceration.

The neurological evaluation should focus on cranial nerve function, with particular attention to the optic nerve (CN II), trigeminal nerve (CN V), and the facial nerve (CN VII). Visual acuity, visual field, and optic disc examinations aid in the detection of possible intra-cranial mass lesions resulting in increased intra-cranial pressure (papilloedema) and optic atrophy, especially when considering Foster Kennedy syndrome (described below). General sensation over the face should be done (e.g., cotton, pin-prick, temperature). The nasal tickle, performed by using cotton to tickle the inside of one nostril, is also useful since an asymmetric withdrawal response suggests impairment of trigeminal fibres within the nose. The face should be symmetrical and full strength, with intact taste on the anterior two-thirds of the tongue bilaterally. Signs of frontal lobe injury and memory impairment may also aid in the diagnosis.

Biopsy of the olfactory epithelium is occasionally helpful. However, the interpretation of such biopsies is complicated by sampling issues and the fact that metaplasia of respiratory-like epithelium occurs throughout the olfactory epithelia in persons with no olfactory problems. Some laboratory tests, such as blood serum tests, may also be helpful in evaluating for underlying medical conditions suggested by history and physical examinations, such as infection, nutritional deficiencies (e.g. B6, B12), allergy, diabetes mellitus, and thyroid, liver, and kidney disease.³ Contrary to many textbooks, there is no proven efficacy of zinc or vitamin A treatments in cases where frank deficiencies are lacking.

Quantitative olfactory testing

Several standardized and practical psychophysical tests have been developed over the last several years, including a number of brief self-administered tests ranging from the 3-item Pocket Smell Test™ to the 40-item University of Pennsylvania Smell Identification Test or UPSIT.²⁸ The UPSIT is commercially known as the Smell Identification Test™ and is the most widely used olfactory test, having been administered to more than one million patients worldwide (Figure 110.3).²⁹ The UPSIT can be self-administered in 10 to 15 minutes by most patients in the waiting room, and scored in less than one minute by non-medical personnel. Available in more than 30 different languages, this test consists of four booklets containing 10 microencapsulated ('scratch and sniff') odourants apiece. Test results are in terms of a percentile score of a patient's performance relative to age- and sex-matched controls, and olfactory function can be classified on an absolute basis into one of six categories: normosmia, mild microsmia, moderate microsmia, severe microsmia, anosmia, and probable malingering. Since chance performance is 10 out of 40, very low UPSIT scores reflect avoidance, and hence recognition, of the correct answer, allowing for determination of malingering. The reliability of this test is very high (test-retest $r = 0.94$).

Although most olfactory problems are bilateral, and bilateral testing reflects the better functioning side of the nose, in some instances, unilateral testing is warranted.²³ To accurately assess olfaction unilaterally, the naris contralateral to the tested side should be occluded without distorting the patent nasal valve region. Such occlusion not only prevents air from entering the olfactory region from the naris (orthonasal stimulation), but prevents active movement of odour-laden air into the occluded side from the rear of the nasopharynx (retronasal stimulation). An easy way of doing this is to seal the contralateral naris using a piece of Microfoam™ tape (3M Corporation, Minneapolis, MN) cut to fit the naris borders. The patient is instructed to sniff the stimulus normally and to exhale through the mouth.

Figure 110.3 The four booklets of the 40-odorant University of Pennsylvania Smell Identification Test (UPSIT; commercially known as the Smell Identification Test™). Each page contains a microencapsulated odorant that is released by means of a pencil tip. This test, which has been administered to ~ 400,000 patients since its development, is the most widely used olfactory test in the world, with English, French, German, and Spanish versions available. The UPSIT is considered to be the “eye chart for the nose.” Photo courtesy of Sensonics, Inc., Haddon Hts., NJ 08035 USA. Copyright © 2000 by Sensonics International.

While, in most cases, olfactory dysfunction can be adequately characterized by the UPSIT, some physicians employ, alone or in combination with the UPSIT, a smell threshold test. A commonly employed test employs phenyl ethyl alcohol as the odourant and establishes the threshold employing a staircase procedure.³⁰ Thresholds determined using this procedure are similar in principle to audiometric thresholds using the von Bekesy procedure. Like the UPSIT, threshold testing can be done either bilaterally or unilaterally.

The recording of olfactory event-related potentials (OERPs) is available in some specialized medical centres as an additional means of assessing the integrity of the olfactory system. Using brain electroencephalography (EEG), the test consists of discerning synchronized brain activity recorded from overall EEG activity following brief presentations of odourants. Unfortunately, OERP testing requires complex, specialized and expensive equipment capable of delivering well-delineated ‘square wave’ odourant pulses into the nose within the background of continuously flowing warmed and humidified air. Although OERPs can be useful in some cases in detecting malingering, and are generally sensitive to alterations in olfactory function due to a wide range of causes, unlike their visual and auditory counterparts, they are *unable* to discern where in the pathway the anomaly exists that is causing the problem.

Imaging studies

There are multiple ways of medically imaging patients with smell disturbance. Plain radiographs are rarely useful due to an inability to capture details of the osteomeatal complex. Computed tomography (CT), on the other hand, has proven to be the most useful and cost-effective technique to assess sinonasal tract inflammatory disorders, and is superior to magnetic resonance imaging (MRI) in the evaluation of the bony structures (e.g. ethmoid, cribriform plate, olfactory cleft). In particular, coronal CT scans are useful in evaluating paranasal anatomy. MRI is better to evaluate soft tissue, and is the technique of choice to image the olfactory bulbs, tracts, and cortical parenchyma. Positron emission tomography (PET), single-proton emission computed tomography (SPECT), and functional MRI (fMRI) presently have limited usefulness outside of research institutions.

CAUSES OF SMELL DISTURBANCE

There are a number of known aetiologies, many non-mutually exclusive, for olfactory disturbance (Table 110.1). The majority of cases of presumably permanent chronic anosmia or hyposmia are due to prior upper respiratory infections, head trauma, and nasal and paranasal sinus disease – most causes reflecting permanent damage to the olfactory neuroepithelium.¹ [Level 1 evidence] Despite extensive evaluations, a substantial proportion remains idiopathic.

TABLE 110.1 Reported agents, diseases, drugs, interventions and other aetiologic categories associated in the medical or toxicologic literature with olfactory dysfunction. Note that categories are not mutually exclusive

Air Pollutants & Industrial Dusts	
Acetone	Formaldehyde
Acids (e.g. sulfuric)	Grain
Ashes	Hydrazine
Benzene	Hydrogen selenide
Benzol	Hydrogen sulphide
Butyl acetate	Iron carboxyl
Cadmium	Lead
Carbon disulphide	Nickel
Cement	Nitrous gases
Chalk	Paint solvents
Chlorine	Paper
Chromium	Pepper
Coke/coal	Peppermint oil
Cotton	Phosphorus oxychloride
Cresol	Potash
Ethyl acetate	Silicone dioxide
Ethyl & methyl acrylate	Spices
Flour	Trichloroethylene
Drugs	
Adrenal steroids (chronic use)	Propylthiouracil
Amino acids (excess)	Thiouracil
Cysteine	Antivirals
Histidine	Cardiovascular/hypertensives
Analgesics	Gastric medications
Antipyrine	Cimetidine
Anaesthetics, local	Hyperlipoproteinaemia medications
Cocaine HCl	Artovastatin Calcium (Lipitor)
Procaine HCl	Cholestyramine
Tetracaine HCl	Clofibrate
Anticancer agents (e.g., methotrexate)	Intra-nasal saline solutions with:
Antihistamines (e.g., Chlorpheniramine malate)	Acetylcholine
Antimicrobials	Acetyl, b-methylcholine
Griseofulvin	Menthol
Lincomycin	Strychnine
Macrolides	Zinc sulfate
Neomycin	Local Vasoconstrictors
Pencillins	Opiates
Streptomycin	Codeine
Tetracyclines	Hydromophone HCl
Tyrothricin	Morphine
Antirheumatics	Psychopharmaceuticals (e.g., LSD, psilocybin)
Mercury/gold salts	Sympathomimetics
D-Penicillamine	Amphetamine sulphate
Antithyroids	Fenbutrazate HCl
Methimazole	Phenmetrazine theoclate
Endocrine/Metabolic	
Addison's disease	Hypothyroidism
Congenital adreanal hyperplasia	Kallmann's syndrome
Cushing's syndrome	Pregnancy
Diabetes mellitus	Panhypopituitarism
Froelich's syndrome	Pseudohypoparathyroidism
Gigantism	Sjögren's syndrome
Hypergonadotropic hypogonadism	Turner's syndrome

(Continued)

TABLE 110.1 (Continued) Reported agents, diseases, drugs, interventions and other aetiological categories associated in the medical or toxicologic literature with olfactory dysfunction. Note that categories are not mutually exclusive

Infections – Viral/Bacterial	
Acquired immunodeficiency syndrome (AIDS)	Fungal
Acute viral rhinitis	Influenza
Bacterial rhinosinusitis	Rickettsial
Bronchiectasis	Microfilarial
Lesions of the nose/Airway blockage	
Adenoid hypertrophy	Nasal Polyposis
Allergic rhinitis	Rhinitis medicamentosa
Perennial	Structural abnormality
Seasonal	Deviated septum
Atrophic rhinitis	Weakness of alae nasi
Chronic inflammatory rhinitis	Vasomotor rhinitis
Hypertrophic rhinitis	
Medical Interventions	
Adrenalectomy	Influenza vaccination
Anaesthesia	Laryngectomy
Anterior craniotomy	Oophorectomy
Arteriography	Paranasal sinus exenteration
Chemotherapy	Radiation therapy
Frontal lobe resection	Rhinoplasty
Gastrectomy	Temporal lobe resection
Haemodialysis	Thyroidectomy
Hypophysectomy	
Neoplasms – Intra-cranial	
Frontal lobe gliomas and other tumours	Parasagittal meningiomas
Midline cranial tumours	Tumours of the corpus callosum
Parasagittal meningiomas	Suprasellar cholesteatoma
Tumours of the corpus callosum	Suprasellar meningioma
Olfactory groove/cribriform plate meningiomas	Temporal lobe tumours
Osteomas	
Neoplasms – Intra-nasal	
Neuro-olfactory tumours	Leukemic infiltration
Esthesioepithelioma	Nasopharyngeal tumours with extension
Esthesioneuroblastoma	Neurofibroma
Esthesioneurocytoma	Paranasal tumours with extension
Esthesioneuroepithelioma	Schwannoma
Other benign or malignant nasal tumours	
Adenocarcinoma	
Neoplasms – Extranasal and Extracranial	
Breast	Lung
Gastrointestinal tract	Ovary
Laryngeal	Testicular
Neurologic	
Amyotrophic Lateral Sclerosis	Familial dysautonomia
Alzheimer's disease	Guam ALS/PD/Dementia
Cerebral abscess (esp. frontal or ethmoidal regions)	Head trauma
Down syndrome	Huntington's disease
	Hydrocephalus

(Continued)

TABLE 110.1 (Continued) Reported agents, diseases, drugs, interventions and other aetiological categories associated in the medical or toxicologic literature with olfactory dysfunction. Note that categories are not mutually exclusive

Neurologic	
Korsakoff's psychosis	Syringomyelia
Migraine	Temporal lobe epilepsy
Meningitis	Hamartomas
Multiple sclerosis	Mesial temporal sclerosis
Myasthenia gravis	Scars/previous infarcts
Paget's disease	Vascular insufficiency/anoxia
Parkinson's disease	Small multiple
Refsum's syndrome	cerebrovascular accidents
Restless Leg Syndrome	Subclavian steal syndrome
Syphilis	Transient ischemic attacks
Nutritional/metabolic	
Abetalipoproteinemia	Trace metal deficiencies
Chronic alcoholism	Copper
Chronic renal failure	Zinc
Cirrhosis of liver	Whipple's disease
Gout	Vitamin deficiency
Protein calorie malnutrition	Vitamin A
Total parenteral nutrition w/o adequate replacement	Vitamin B6
	Vitamin B12
Pulmonary	
Chronic obstructive pulmonary disease	
Psychiatric	
Anorexia nervosa (severe stage)	Malingering
Attention deficit disorder	Olfactory reference syndrome
Depressive disorders	Schizophrenia
Hysteria	Schizotypy
	Seasonal affective disorder

In general, loss of olfactory function can be subdivided into two classes: (a) *conductive or transport impairments* from obstruction of the nasal passages (e.g., chronic nasal inflammation, polyposis, etc.); and (b) *sensorineural impairment* from damage to the olfactory neuroepithelium, central tracts, and connections (e.g., viruses, airborne toxins, tumours, seizures, etc.). In some circumstances, it is difficult to classify an olfactory disorder into one of these classes, since blockage of airflow to the receptors and damage to the receptors or other elements of the olfactory neuroepithelium can be simultaneously involved. Chronic rhinosinusitis, for example, can produce damage to the olfactory membrane in addition to blocking airflow, and altered membrane function can, over time, lead to degeneration within the olfactory bulb, a central structure. Although we are currently able to treat many causes of olfactory disturbance due to conductive factors or inflammation of the olfactory epithelium, most olfactory disorders due to sensorineural factors remain untreatable.

In most cases, hyperosmia reflects a patient's heightened response to an odour, rather than an increased ability to smell, *per se*. This problem has been reported in some conditions associated with a change in hormone

balance, such as in pregnancy and Addison's disease (adrenal-cortical insufficiency), as well as head trauma, migraine, drug withdrawal, epilepsy (interictal period), multiple-chemical sensitivity, and psychosis. While hyperosmia is relatively rare, dysosmia is more common. Usually dysosmia reflects dynamic alterations of degeneration or regeneration within the olfactory neuroepithelium over time, and it is not uncommon for patients who eventually develop anosmia to report having experienced weeks of dysosmia preceding the experience of anosmia. Dysosmia implies an olfactory system that is intact at least to some degree, as total smell loss does not typically accompany most cases of dysosmia.¹ Severely debilitating, long-lasting, and intractable chronic dysosmias have been treated by surgical ablation of regions of the olfactory neuroepithelium, or by surgical removal of a diseased olfactory bulb or bulbs.³¹ Olfactory hallucinations or phantosmias can occur from a problem anywhere along the olfactory neural pathways, from the nose to the cortex. Sometimes they are associated with ictal epileptiform activity (e.g., simple partial seizures), nasal sinus disease (e.g., infection), and head trauma. If someone believes a smell is present (hallucination) and persistently gives this smell personal reference to outside events, despite contradicting evidence, this patient may suffer from *olfactory reference syndrome* – a depression-related disorder. In some cases, there may be a pathological correlate in the form of right hemispheric lesions.³² Olfactory agnosia is an extremely rare phenomenon, although it appears to be less commonly investigated than visual and auditory agnosia. It is associated with lesions of the right inferior temporal lobe and often linked to prosopagnosia (agnosia for familiar faces).

The more common disorders or entities associated with olfactory impairment are discussed in more detail below, beginning with the more frequent ones.

Upper respiratory infection

Upper respiratory viruses, such as those associated with the common cold and influenza, are considered the most common aetiology of permanent olfactory loss in man. Other infectious causes that have been reported include hepatitis, herpes simplex encephalitis, and variant Creutzfeldt-Jacob disease. It is not clear what predisposes someone to viral-induced smell dysfunction or the precise mechanisms behind it. Often the smell-affecting respiratory illness is described as being more severe than usual. In a study of olfactory biopsies of 4 patients with anosmia and 11 patients with hyposmia due to a viral illness, Jafek and colleagues³³ noted that patients with anosmia had markedly reduced numbers of receptors and those receptors were abnormal compared to those patients with hyposmia. Given the ability of the olfactory neuron to regenerate, spontaneous recovery of some smell function is theoretically possible over a prolonged period; however, complete recovery is less likely the longer the patient has the loss and is likely inversely related to the degree of dysfunction. In general, it is necessary to exclude other aetiologies prior to making a diagnosis

of post-viral anosmia. HIV-infected patients are said to show an early impairment in odour thresholds and a later decline in odour identification and discrimination function which appears to parallel a general reduction in cognitive abilities.³⁴

Head trauma

Head trauma often results in smell loss, particularly where rapid acceleration/deceleration of the brain occurs (i.e. coup/contrecoup injury) (Figure 110.4). Blunt trauma to the occiput has been found to produce greater olfactory loss than trauma to the front of the head.³⁵ Following head trauma, the loss of smell is usually, but not always immediate, although it may take a while for the patient to recognize the presence of the dysfunction. In some cases, months can pass before the smell loss is apparent to the patient. Common mechanisms include disruption from shearing forces of the olfactory fila through the sinonasal tract, and direct contusion and ischaemia to the olfactory bulb and frontal and temporal poles. Fracturing of the cribriform plate is not a prerequisite for smell loss. The prevalence of olfactory loss following head trauma is around 15% and, on average, is proportional to the severity of the injury.^{35,36} As would be expected, such prevalence is much higher in patients referred to specialized smell and taste centres for evaluation and treatment. For example, among 268 patients evaluated at our centre who had experienced head trauma, 66.8% had anosmia, 20.5% hyposmia, and 13% had normal smell function. MRI images may reveal damage to the olfactory bulbs, tracts and areas of the temporal and frontal lobes.³⁶ Animal research shows that intra-cranial haemorrhage and ischaemia can lead to degeneration of the olfactory epithelium without transection of the olfactory nerves.³⁷ [Level 1 evidence] Iatrogenic trauma, such as surgery, can cause smell impairment and has been seen with such procedures as sinus surgery and laryngectomy.³⁸

Nasal and sinus disease

While the olfactory impairment that follows a viral syndrome or head trauma can be classified as *sensorineural*, the dysfunction that results from nasal and sinus disease is usually considered *conductive* – in other words, there is impaired air flow to the olfactory receptors. Theoretically, any inflammatory or obstructive process in the nose can result in a disturbance of smell function, with common examples being allergic rhinitis, rhinosinusitis, nasal polypsis, intra-nasal tumours and previous nasal surgery. In the evaluation of 240 patients with allergic rhinitis, Ryzewski and colleagues found that 21.4% of patients had smell impairment and there was a significant correlation between olfactory thresholds and levels of eosinophils in the blood and nasal discharge.³⁹ Treatments in the form of surgery (e.g., excision of polyps) or medication (e.g., administration of topical or systemic steroids) may improve olfactory function in some cases; however, complete return is not typical. Thus, while chronic rhinosinusitis

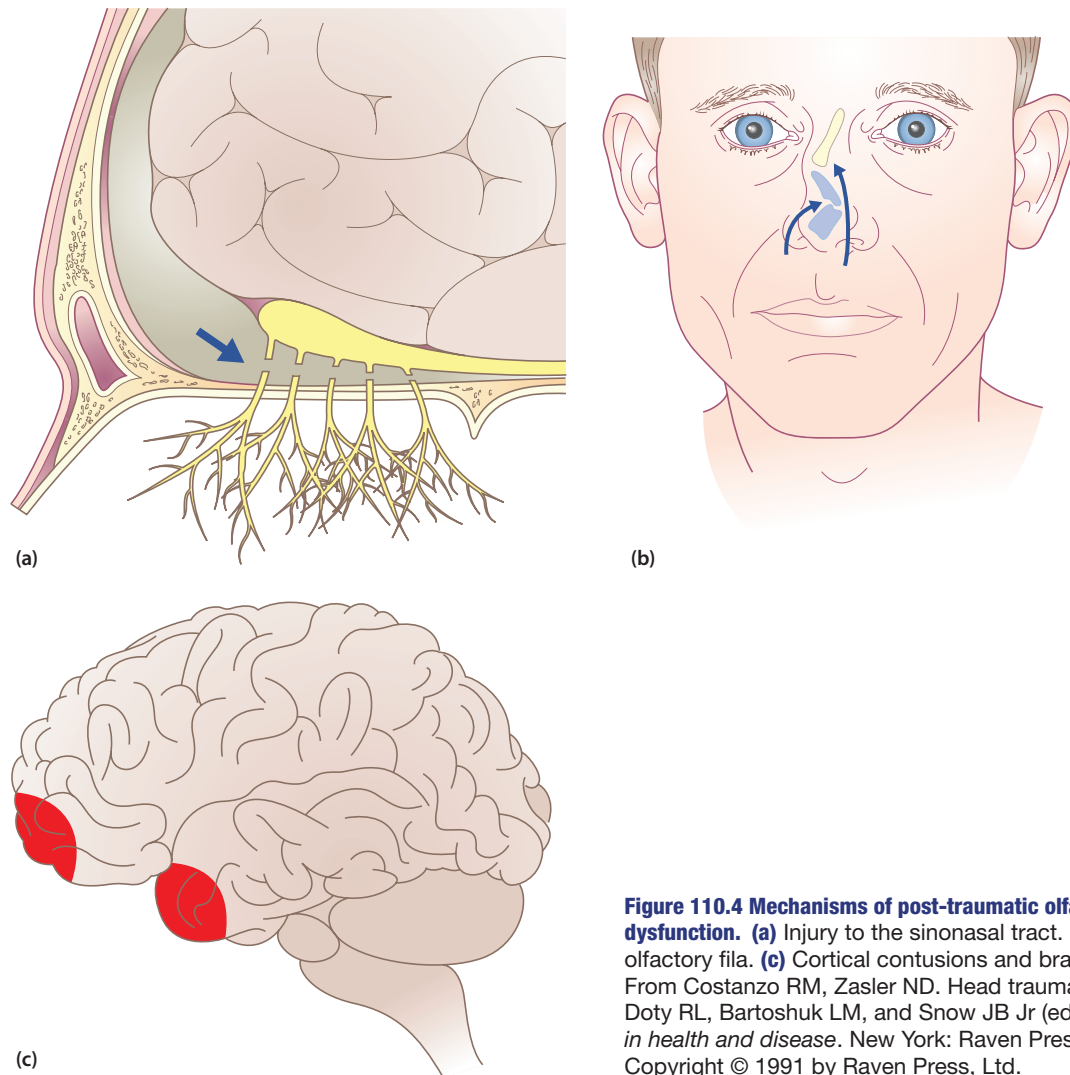

Figure 110.4 Mechanisms of post-traumatic olfactory dysfunction. (a) Injury to the sinonasal tract. (b) Tearing of the olfactory fila. (c) Cortical contusions and brain hemorrhage. From Costanzo RM, Zasler ND. Head trauma. In: Getchell TV, Doty RL, Bartoshuk LM, and Snow JB Jr (eds) *Smell and taste in health and disease*. New York: Raven Press, 1991, p. 713. Copyright © 1991 by Raven Press, Ltd.

can result in nasal airflow blockage, there is also a component of direct toxicity to olfactory neurons and impaired ciliary motility resulting in abnormal clearance of mucus. These combined factors make any one treatment modality limited. In one study, it was found that systemic steroids can temporarily reverse conductive olfactory impairment in 83% of patients while topical steroids helped in only 25% of patients – making systemic steroids a useful diagnostic tool.⁴⁰ The severity of histopathological changes within the olfactory mucosa of patients with chronic rhinosinusitis is positively related to the magnitude of olfactory loss, as measured by the UPSIT.⁴¹ Biopsies from the neuroepithelial region of patients with nasal disease are less likely to yield olfactory-related tissue than biopsies from controls.⁴² Anosmic rhinosinusitis patients generally exhibit a more pathological epithelium (e.g., disordered arrangement of cells and increased islands of respiratory epithelium) when compared to non-anosmic patients with rhinosinusitis.⁴³ Excessive dryness of the nasal mucosa – as seen in atrophic rhinitis, Sjögren’s syndrome, and repeated nasal surgery – can cause olfactory dysfunction, since a moist receptor environment aids chemoreception and transduction.

Tumours and mass lesions

A number of tumours in and around the olfactory bulbs or tracts can cause olfactory disturbance. Examples include olfactory groove meningiomas, frontal lobe gliomas, and suprasellar ridge meningiomas arising from the dura of the cribriform plate. Due to the olfactory nerve’s close location to the roof and medial wall of the orbit, as well as the optic nerves and tracts, structural lesions affecting smell may also affect vision. Also, olfactory tumours may extend into the frontal lobes resulting in symptoms of dementia and possibly the release of primitive reflexes (e.g., grasping, snout, and glabellar). Mass lesions need not be in the olfactory tracts to cause smell impairment. Ishimaru and colleagues⁴⁴ identified two patients with hyposmia from tumours to the right frontal lobe; the hyposmia reversed with craniotomy and tumour resection. Mass lesions around the olfactory region can result in a *Foster-Kennedy syndrome*, which consists of: (a) ipsilateral anosmia, (b) ipsilateral optic atrophy, and (c) contralateral papilledema secondary to raised intra-cranial pressure.⁴⁵ *Pseudo Foster-Kennedy syndrome* has been reported in patients with increased intra-cranial pressure who had previous

unilateral optic atrophy.⁴⁶ Similarly, tumours in central regions of olfactory processing (e.g., mesial temporal lobe) can also potentially affect smell. Headache often accompanies a complaint of smell loss when the aetiology is a mass lesion. Lymphoma has been known to infiltrate into olfactory areas and cause dysfunction. Similarly, granulomatous diseases – such as syphilis, sarcoidosis, SLE, and Wegener's granulomatosis – often result in anosmia. In patients suspected of having a neoplasm, neuroimaging is essential.

Neurodegenerative diseases

Olfactory deficits have been described in a number of neurological disorders (**Table 110.1**). Importantly, olfactory dysfunction may be the first clinical sign of Alzheimer's disease (AD) and idiopathic Parkinson's disease (PD). Smell testing is useful in identifying persons who have PD, as well as those who either have, or are at risk for having, AD. In PD, bilateral olfactory deficits occur before the onset of most of the classical neurological signs and symptoms and are unrelated to disease stage, use of anti-parkinson medications, duration of the illness, and severity of the symptoms, such as tremor, rigidity, bradykinesia or gait disturbance.^{5,6} Measurement of smell function can be useful to distinguish PD among the other disorders that share many non-olfactory symptoms and signs, such as progressive supranuclear palsy, multiple-system atrophy, parkinsonism induced by the proneurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), and essential tremor.^{6,20} In a male patient suspected of PD, based on history and physical who is less than 60 years of age, an UPSIT score of 31 carries a 91% sensitivity and 88% specificity of correctly diagnosing patient suspected of having PD.⁶ In a woman suspected of PD, who is less than 60 years old, an UPSIT score of 33 carries a 79% sensitivity and 85% specificity.⁶

With regard to AD, Graves and colleagues⁴⁷ found that olfactory dysfunction in the presence of one or more APOE-e4 alleles was associated with a very high risk of subsequent cognitive decline, and smell testing identified persons who came to exhibit later cognitive decline better than did a global cognitive test. Devanand and colleagues⁴⁸ found that patients with mild cognitive impairment scored lower on the UPSIT than did the controls, and that patients with low UPSIT scores (<34) were more likely to develop AD than the other patients. When low UPSIT scores were accompanied by a lack of awareness of olfactory deficits on the part of the patients, they found that this predicted the time to development of AD. UPSIT scores from 30 to 35 showed moderate to strong sensitivity and specificity for diagnosis of AD at follow-up. In later life, individuals with Down syndrome show similar clinical and pathological changes to AD patients and have lower performance on a modified UPSIT compared to controls matched on mental age. However, it is not clear whether this is due to AD-related pathology, *per se*, as Down syndrome children as young as 12 years old exhibit smell dysfunction.⁴⁹ [Level 1 evidence]

The olfactory loss associated with multiple sclerosis is directly proportional to the number of MS-related demyelinating lesions in central brain regions associated with olfactory processing (e.g., inferior middle temporal lobe and periorbital frontal cortex).⁵⁰ [Level 1 evidence] Olfactory function actually increases and decreases as the plaque numbers increase and decrease.⁵¹ Therefore, knowledge of a patient's UPSIT score largely predicts the plaque load in the olfaction-related regions. [Level 1 evidence]

Schizophrenia is associated with significant deficits in olfactory threshold sensitivity and odour identification.⁵² [Level 1 evidence] The fact that there is an inverse correlation with UPSIT scores and disease progression suggests that there may be progressive neurodegenerative changes within olfactory-related pathways and smell testing can be used as a marker of disease progression.⁵²

Epilepsy and migraine

Olfactory auras, also described as hallucinations, are rare but frequently associated with seizures and headaches. Olfactory auras consist of sudden unexplained sensations of smell that are usually unpleasant (although not always) and are rarely isolated events.⁵³ In epilepsy, mesial temporal lobe structures involved in the usual processing of odour information – such as the amygdala and hippocampus – have been implicated as the generators of ictal olfactory sensations (simple or complex partial seizures) that often evolve into secondarily generalized seizures.⁵⁴ Common aetiologies include mesial temporal sclerosis and tumours.⁵⁴ Some cases of epilepsy have been associated with hyperosmia during the inter-ictal period, although most patients with long-standing epilepsy and intractable seizure activity, such as candidates for temporal lobe resection, are hyposmic.⁵³ The effect of migraine on smell function is less understood. The concept of certain smells provoking or exacerbating a migranous headache – osmophobia – may exist similar to that of photophobia or phonophobia.

Other causes and considerations

Less than 5% of patients who present to a specialized centre for smell and taste disorders have a chemosensory disturbance that can be directly attributed to an exposure of a toxic compound.¹ There are numerous chemical agents that have been reported to affect smell function, including acrylates, cadmium, benzene, formaldehyde, solvents and nickel dust, among others (**Table 110.1**).⁵⁵ Tobacco smoking results in diminished olfactory ability as a function of cumulative smoking dose, and importantly, smoking cessation can result in improvement in olfactory function over time.²⁵ Medications are also a common cause of smell disturbance and should be considered early, especially in the context of a new drug therapy (**Table 110.1**).⁵⁶

Several endocrine disorders evidence disorders of smell. For example, Kallmann's syndrome, or hypogonadotropic hypogonadism, is an X-linked or autosomal recessive neuronal migrational disorder associated with anosmia

Figure 110.5 Scores on the University of Pennsylvania Smell Identification Test (UPSIT) as a function of age and gender in a large heterogeneous group of subjects. Numbers by data points indicate sample sizes. From Doty RL, Shaman P, Applebaum SL, et al. Smell identification ability: changes with age. *Science* 1984; **226**: 1441-3. Copyright © 1984 by the American Association for the Advancement of Science.

(aplasia of the olfactory bulb) and hypogonadism (pituitary involvement). [Level 1 evidence] Similarly, patients with septo-optic dysplasia (de Morsier's syndrome) can have hyposmia, visual symptoms, and precocious puberty.

Age-related deficits in smell function are well documented and decreased smell function is present in most elderly patients, including ones who are healthy and taking no medications (Figure 110.5).⁵⁷ Under the age of 65 years, approximately 1% of the population has major difficulty smelling. Between 65 and 80 years, this increases remarkably, with about half of the population exhibiting at least some decrement in the ability to smell. Over the age of 80, this figure rises to nearly 75%.⁵⁴ Despite the association with age, the complaint of smell loss should never be attributed simply to age, as often an accumulation of damage over the years is the culprit and a single event, such as a bad cold, can be the precipitating factor. In general, the age-related changes in smell function are reflected not only in damage to the olfactory receptors but related decreases in number of glomeruli within the olfactory bulb.⁵⁸ Whether age-related factors increase the susceptibility of the epithelium to damage from exogenous agents is not clear. What is clear, however, is that smell loss in older persons adversely affects the quality of life. Chemosensory loss has been implicated as a cause – particularly in the elderly – of malnutrition, weight loss, and worsening of a medical illness.

TREATMENT OF SMELL DISORDERS

The most effective treatments available are those for *conductive* anosmia, where there is an obstruction of airflow through the nose to the olfactory neuroepithelium. As noted above, the typical causes of mechanical obstruction include nasal sinus disease, including inflammation, and intra-nasal neoplasms. After diagnosis is confirmed using tools such as nasal endoscopy and CT scanning of the sinuses, the next appropriate course of action may

include topical or systemic steroids. Conductive and sensorineural olfactory loss are often distinguishable using a brief course of systemic steroid therapy since patients with conductive impairment often respond positively to the treatment, although long-term systemic steroid therapy is not advised. Topical nasal steroids are often ineffectual in returning smell function because the steroid fails to reach the affected regions in the upper nasal passages. Increased efficacy presumably occurs when the nasal drops or spray are administered in the head-down Moffett's position.⁴⁰ Proper allergy management is essential and may require the use of an antihistamine. When a bacterial infection is suspected (e.g., infectious sinusitis), a course of antibiotics should be used. Surgery should be considered for: (1) very large and medically-refractory polyps; or (2) situations where a malignant neoplasm is suspected. Importantly, pre- and post-intervention olfactory testing should be performed to establish intervention efficacy, as well as to screen for subsequent slow relapse that is characteristic of most conductive disorders. In cases where rheumatological granulomatous disease is suspected, such as Wegener's granulomatosis or sarcoidosis, further immunomodulation using agents such as cyclophosphamide or methotrexate may be necessary.

Sensorineural impairment of olfaction is typically more difficult to manage, and the prognosis for patients suffering from long-standing total loss due to upper respiratory illness or head trauma is poor. The majority of patients who recover smell function subsequent to trauma do so within 12 weeks of injury.³⁵ Patients who quit smoking typically have dose-related improvement in olfactory function and flavour sensation over time.²⁵ Central lesions, such as CNS tumours that impinge on olfactory bulbs and tracts can often be resected with significant improvement in olfactory function. When epilepsy or migraine is suspected, a course of anti-epileptic or anti-migraine medications might prove beneficial. Medically-refractory epilepsy resulting in olfactory disturbance can be successfully treated with surgery. For

example, Chitanondh⁵⁹ reported successful treatment of 7 patients with seizure disorder, olfactory hallucinations, and psychiatric problems by stereotactic amygdalotomy, concluding ‘stereotactic amygdalotomy has a dramatic effect on olfactory seizures, auras, and hallucinations. It is a safe surgical procedure and can be done without neurological deficit’. In patients with multiple sclerosis, immunomodulatory therapies, including interferon beta and occasional steroids, is the mainstay of treatment. When depression or psychosis is suspected, a course of an anti-depressant and appropriate psychiatric referral may be necessary.

Medications that induce distortions of olfaction can often be discontinued and replaced with other types of medications or modes of therapy. In addition to direct effects on the olfactory system, the side-effects of many medications is to detrimentally dry the nasal mucosa (e.g., anti-cholinergics). Dopaminergic and cholinergic therapies do not improve the olfactory dysfunction seen in Parkinson’s disease, and there is no evidence that neuroleptics alter the olfactory loss of patients with schizophrenia. Despite the fact there are advocates for zinc and vitamin therapies, there continues to be no strongly compelling evidence that these therapies work except in cases where frank zinc or vitamin deficiencies exist.

In patients with complete anosmia, supportive measures are necessary to protect them from further harm; thus

- Smoke and carbon monoxide detectors need to be installed and properly working
- When possible, electric appliances should be used instead of gas appliances
- Expiration dates for food products should be scrutinized and old food items checked by someone with normal smell function or discarded
- A balanced diet – particularly in the elderly – must be kept to prevent weight loss and malnutrition. Adding flavour enhancers (e.g., monosodium glutamate, food colouring, chicken or beef stock) to foods can also help with their appeal.

A physician needs to be cognizant of medicolegal ramifications in his or her evaluation and management. In cases of personal injury malingering is not uncommon,

and may be distinguished from true anosmia by the pseudo-disappearance of trigeminal function or unusually low UPSIT test scores (i.e., those below chance responding), suggesting active avoidance of the correct answer. When queried on a standardized questionnaire, malingerers were found to minimize factors that might be otherwise associated with their chemosensory complaint. For example, relative to non-malingerers, malingerers reported significantly fewer allergies, dental problems, cigarettes smoked, surgical operations, nasal sinus problems, and use of medications. They also reported significantly more putative symptom-related psychological duress, interference with daily activities, weight loss, decreased appetite, and taste loss. Litigation involvement was found to be higher in malingerers than non-malingerers. Age, sex, education, and length of written symptom descriptions did not differentiate malingerers from non-malingerers.²⁷

PROGNOSIS

Spontaneous recovery of function appears to vary depending on the severity of the disturbance. Thus, for patients whose odour identification ability is less severe (e.g., UPSIT scores above 25), prognosis for complete recovery is much better than for those with complete anosmia. In one study, for example, odour identification tests were administered to 542 patients complaining of smell dysfunction on two occasions separated from one another by 3 months to 24 years.⁶⁰ The percentage of anosmic and microsmic patients exhibiting statistically significant change in function, as defined by 4 UPSIT points, was 56.72% and 42.86%, respectively. However, only 11.31% of anosmic and 23.31% of microsmic patients regained normal age-related function over time. Age, severity of initial olfactory loss, and the duration of dysfunction at the first test occasion were significant predictors of the amount of change. Interestingly, aetiology, sex, time between the two test administrations, and initial smoking behaviour were not strong predictors.

Given such factors, an important part of management for many patients is to use quantitative olfactory testing and establish the true degree of olfactory loss so that some

FUTURE RESEARCH

In general, the medical community needs to become better educated regarding the importance of the chemical senses for the well-being and everyday function of human beings, and to realize that accurate assessment of these senses is critical for (a) establishing the validity of a patient’s complaint, (b) distinguishing between complaints of taste and olfactory dysfunction, and (c) monitoring the efficacy of treatment regimens. The basis of the olfactory loss in the earliest stages of a number of neurodegenerative disorders, including Alzheimer’s disease and idiopathic Parkinson’s disease, needs elucidation, as gene therapy and other therapeutic modes may be of future value in

reversing not only the olfactory dysfunction, but other elements of these diseases. There is dire need to establish the mechanisms involved in olfactory cell degeneration and regeneration, as well as in the production of appositional bone growth in the region of the foramina of the cribriform plate, which may be an age-related process. A greater understanding of these and related phenomena, such as the nature of inflammation associated with rhinosinusitis, may ultimately lead to topical or systemic treatments that can mitigate smell dysfunction secondary to damage to the olfactory receptor cells or closure of the foramina of the cribriform plate.

estimate or prognosis can be given. Importantly, age- and sex-related normative data allows one to put into perspective a patient's overall problem. For example, many older

patients find it rather therapeutic to know that, while his or her smell function is not what it used to be, it still falls above the average of his or her peer group.

KEY POINTS

- The olfactory system contributes significantly to a person's quality of life.
- A patient's lack of olfactory function can be an early sign of a number of serious disease states, including nasopharyngeal carcinoma, Alzheimer's disease, Parkinson's disease, frontal meningiomas, multiple sclerosis, and sinus infections.
- Too patent an airway, as seen with excessive turbinate removal, can improperly shunt air away from the olfactory cleft, resulting in at least some decrement in olfactory acuity.
- A significant amount of retronasal airflow from the nasopharynx occurs during swallowing and deglutition. This retronasal route is vital to the production of flavour from swallowed foods – adding *smell* to both *taste* and *touch*.
- Throughout life, islands of respiratory-like epithelial metaplasia appear within the epithelium, presumably as a result of cumulative viral, bacterial, and other insults.
- The number of olfactory receptor cells exceeds that of any other sensory system except vision; collectively, the surface area of the cilia is quite large – exceeding 20 cm² in the human.
- The olfactory nerve cells, as well as the proximal extraneural spaces, can serve as conduits for the movement of viruses and exogenous agents from the nasal cavity into the brain.
- It is essential to determine all medications used by the patient since many reportedly cause smell and taste disturbance.
- Several standardized and practical psychophysical tests have been developed over the last several years, including a number of brief self-administered tests ranging from the 3-item Pocket Smell Test™ to the 40-item University of Pennsylvania Smell Identification Test or UPSIT.
- The majority of cases of presumably permanent chronic anosmia or hyposmia are due to prior upper respiratory infections, head trauma, and nasal and paranasal sinus disease – most causes reflecting permanent damage to the olfactory neuroepithelium.
- A number of tumours in and around the olfactory bulbs or tracts can cause olfactory disturbance.
- Olfactory deficits have been described in a number of neurological disorders. Importantly, olfactory dysfunction may be the first clinical sign of Alzheimer's disease (AD) and idiopathic Parkinson's disease (PD).
- The olfactory loss associated with multiple sclerosis is directly proportional to the number of MS-related demyelinating lesions in central brain regions associated with olfactory processing (e.g., inferior middle temporal lobe and periorbital frontal cortex).
- Schizophrenia is associated with significant deficits in olfactory threshold sensitivity and odour identification.
- Under the age of 65 years, approximately 1% of the population has major difficulty smelling. Between 65 and 80 years, this increases remarkably, with about half of the population exhibiting at least some decrement in the ability to smell. Over the age of 80, this figure rises to nearly 75%.
- *Sensorineural* impairment of olfaction is typically more difficult to manage, and the prognosis for patients suffering from long-standing total loss due to upper respiratory illness or head trauma is poor.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: orbital anatomy; nasolacrimal system; epiphora; endoscopic dacryocystorhinostomy; thyroid eye disease; Graves' ophthalmopathy; orbital decompression; optic nerve decompression; silent sinus syndrome; orbital pseudotumor; orbital neoplasm; and orbital tumour. The evidence in this chapter is mainly levels 3 and 4. The clinical recommendations are predominantly B and C.

INTRODUCTION

Given its intimate relationship to the paranasal sinuses, a thorough understanding of the orbit is essential for the otorhinolaryngologist. We are faced with a wide variety of orbital conditions due to the general proximity of the sinonasal cavity as well as the surgical corridor the sinuses provide (**Box 111.1**). The most common conditions include epiphora, thyroid eye disease, optic nerve compression, imploding maxillary sinus, pseudotumor, and orbital neoplasms.

RELEVANT SURGICAL ANATOMY

Orbital anatomy

The orbit is a quadrilateral pyramid, with its base facing forwards, laterally and slightly inferiorly (**Figure 111.1**). The orbit contains the globe, extraocular muscles, nerves, vessels and other associated structures including the lacrimal apparatus. The average volume in the adult Caucasian orbit is 30ml.¹ The orbit receives contribution from 7 distinct bones: maxillary, zygomatic, ethmoid, lacrimal, sphenoid, frontal, and palatine bones all of which make unique contributions to each orbital wall.

Medial wall

The medial wall is most relevant to otorhinolaryngologists due to the proximity of the paranasal sinuses. From an anterior to posterior direction, the bony contribution of anterior lacrimal crest originates at the frontal process of the maxilla. The lacrimal bone makes up the second one half of the lacrimal sac fossa and the posterior lacrimal crest. The lamina papyracea (arising from ethmoid bone) makes up the majority of the medial orbital wall. The paper-thin bone overlies the ethmoid sinuses.² The anterior and posterior ethmoid foramina are found in the superior aspect of the orbit along the fronto-ethmoidal suture line. The anterior ethmoid foramen is a useful

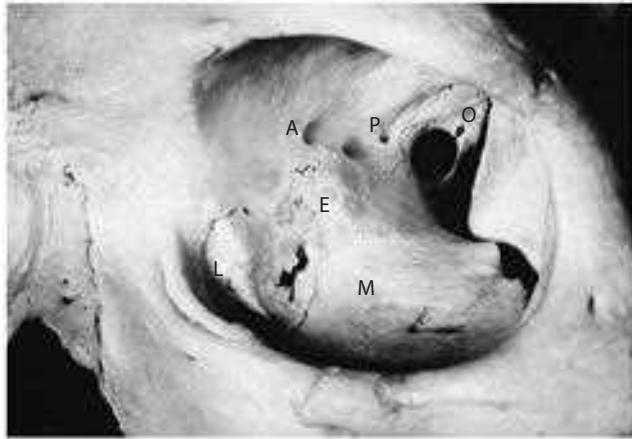

Figure 111.1 The orbit. A, anterior ethmoidal foramen, P, posterior ethmoidal foramen, O, optic canal, E lamina papyracea, M, maxilla, L, lacrimal bone.

landmark and is identified 20–25 mm posterior to the anterior lacrimal crest and the posterior ethmoid foramen is 30–35 mm posterior to the anterior lacrimal crest.³ The thick bone of the sphenoid body forms the most posterior portion of the medial orbital wall adjoining the optic canal.

Superior wall

The roof of the orbit is formed primarily by the frontal bone.² The superior margin has a supraorbital notch or foramen with its respective nerves and vessels.⁴ The trochlea is a connective tissue sling anchoring the tendinous portion of the superior oblique muscle to the orbital wall and the trochlear fovea, a small depression lying close to the superomedial orbital margin.⁴

Inferior wall

The floor is formed by the orbital surface of the maxilla, the zygomatic and the palatine bone. At approximately the midpoint of the orbit floor runs the infraorbital groove containing the maxillary division of the trigeminal nerve (V2) leading to the infraorbital foramen. Medial to the infraorbital nerve, the orbital floor is relatively thin and fractures more easily than the lateral aspect.⁴

Lateral wall

The zygomatic process of the frontal bone, the orbital surface of the zygoma and the greater wing of the sphenoid form the lateral wall. These bones join at the zygomatico-sphenoid suture line, creating the thickest boney wall. The lateral tendons all attach to the lateral tubercle, which is found 3–4 mm posterior to the lateral orbital rim.⁴

Orbital contents

The orbit is lined by the fibrous periorbita. It is attached to bone at the orbital margin, suture lines, the trochlear

fossa, fissures, the lateral tubercle, the anterior lacrimal crest, and perforating vascular foramina. Other than these locations, the periorbita is loosely attached and easily dissected. The globe and other orbital tissue structures are surrounded by orbital fat, which cushions the globe and facilitates in orbital movement. This is further aided by orbital connective tissue septae that slide over each other for smooth movement.⁵

Nasolacrimal system

The nasolacrimal drainage system consists of the superior and inferior canaliculi which feed into the common canaliculus, lacrimal sac and subsequently the nasolacrimal duct.⁶ The system begins at the punctum of each eyelid where the canaliculi initially run at 90° to the lid margin for 1–2 mm before running parallel with the lid margin. After 10 mm they join to form the common canaliculus. The common canaliculus angles inferiorly and forward for 3–5 mm before entering the lacrimal sac. The nasolacrimal duct exits from the inferior portion of the lacrimal sac and continues in an inferior direction for approximately 12 mm before entering the nose 10–15 mm behind the anterior end of the inferior turbinate and 16 mm above the floor of the nasal cavity at Hasner's valve. The lacrimal bone that attaches inferiorly with the base of the inferior turbinate forms the posterior wall of the bony canal and the frontal process of the maxilla forms its anterior boundary.

The lacrimal sac is protected in the concavity of the lacrimal fossa of the medial orbital wall. The fossa is formed anteriorly by the harder frontal process of the maxillary bone and posteriorly by the softer lacrimal bone. The frontal process forms the anterior lacrimal crest and the remainder of the anterior portion of the fossa.

Epiphora

Epiphora from nasolacrimal system obstruction is either anatomic (70%) or functional (30%).⁷ This includes complete blockages anywhere from the lacrimal punctum to the nasal cavity. Functional obstructions, on the other hand, are a result of either significant narrowing within the lacrimal system that delays normal lacrimal flow or a failure of the lacrimal pumping mechanism. Dacryocystorhinostomy (DCR) is performed to relieve epiphora resulting from an obstruction of the nasolacrimal system.

The majority of nasolacrimal system obstruction is unknown. Idiopathic obstruction is seen more frequently with increasing age and demonstrates a female preponderance. Less common causes include surgical trauma, facial trauma, granulomatous conditions such as Wegener's granulomatosis and sarcoidosis, malignancy, infections, and radiation exposure. It should be noted that while a significant number of patients suffer nasolacrimal injury after FESS (up to 15%), actual obstruction resulting in epiphora is very rare.⁸

ENDOSCOPIC DACROCYSTORHINOSTOMY

Indications

A DCR is indicated when there is a symptomatic distal obstruction of the nasolacrimal duct that is not relieved by probing and syringing. It is not indicated when the obstruction is in the canaliculi or puncti as the endoscopic DCR will not bypass these areas.

Pre-operative evaluation and studies

A thorough history and physical examination is essential to aid in identification of the site of obstruction. The patient should be questioned on history of radiation, neoplasm, midface trauma, systemic diseases, sinonasal disease and ocular conditions.

Syringing and probing the nasolacrimal system can aid in identification of the site of obstruction. Inability to flush through the inferior canaliculus indicates obstruction at the site of the punctum or inferior canaliculus whilst reflux of saline through the other canaliculus indicates a distal obstruction. Probing with a Bowman lacrimal probe also helps identify the level of obstruction. Nasal endoscopy is also useful to exclude anatomic abnormalities that may interfere with an endoscopic approach.

An ophthalmologist will often perform a fluorescein dye disappearance test in the office. Fluorescein is applied to the eye and after 10–15 minutes a bluelight filter is used to attempt to identify fluorescein runoff into the nose. Radiographic tests include a dacrocystogram, which can identify diverticula, stenosis, strictures, dacryoliths or a tumour. Dacryoscintigraphy uses radio-nucleotide. ^{99m}Tc also may be helpful when identifying for a functional obstruction when there is free flow on a syringe test along with an abnormal fluorescein dye disappearance test. Computed tomography (CT) is generally not indicated unless there is suspicion for neoplastic etiology or history of midface trauma requiring further evaluation.

Surgical procedure

Create a posteriorly based mucosal flap

The initial goal is to expose the lacrimal bone and frontal process of the maxilla. Initially a superior incision should be made horizontally 10 mm above the axilla of the middle turbinate. This incision should extend from 2–3 mm posterior to the axilla and run forwards for approximately 10 mm onto the frontal process of the maxilla. The blade should then be turned vertically and a cut made on the frontal process of the maxilla from the superior incision to just above the insertion of the inferior turbinate. Finally, a cut is made horizontally and the inferior mucosal incision made form the insertion of the uncinata to join the vertical incision.

Elevation of the mucosal flap

Elevation is best accomplished with a suction freer. It is critical to stay on the bone to avoid losing the surgical plane in the transition from the hard bone of the frontal process of the maxilla to the softer lacrimal bone (Figure 111.2).

Remove lacrimal bone

A round otologic knife can be used to flake off the lacrimal bone overlying the posterior portion of the lacrimal sac.

Removal of frontal process of the maxilla

This bone is much harder and overlies the anterior aspect of the lacrimal sac. This can be accomplished with a Kerrison punch or a DCR drill bur. The sac should be exposed fully by removing all bone up to the mucosal incisions. The sac will form a prominent bulge into the nasal cavity (Figure 111.3).

Figure 111.2 Elevation of posteriorly based mucosal flap over left nasolacrimal crest.

Figure 111.3 Resection of left anterior lacrimal crest with Kerrison punch.

Expose the agger nasi cell

By exposing the agger nasi cell, the mucosa of the lacrimal sac will be able to lie against the mucosa of the agger cell, allowing for a wider marsupialization of the lacrimal sac.

Marsupialize the lacrimal sac

Insert a lacrimal probe through the inferior canaliculus (Figure 111.4) and tent the lacrimal sac up with the probe. Make a vertical incision with two subsequent horizontal incisions on the superior and inferior portion of the sac to create the widest possible anterior and posterior flaps. Once the sac is marsupialized, it should be lying flat on the lateral nasal wall (Figure 111.5).

Reposition the mucosal flap

Cut the mucosal flap so only a superior and inferior limb are present and reapproximate this over the bone at the bone–lacrimal sac junction at both the superior and inferior aspects of the lacrimal sac flaps.

Figure 111.4 Probing of the inferior canaliculus.

Figure 111.5 Incision of the left lacrimal sac. Then create an anterior and posterior flap, incisions should be made along the dotted lines.

Pass the Crawford silastic tubes

The lacrimal tubes are inserted into the superior and inferior punctae and passed into the nasal cavity. They can be secured by tying the tubes together. Place a small piece of gelfoam along the mucosal flaps to hold them in place.

Post-operative management

Patients are discharged on saline sprays, 7 day course of oral antibiotics, and topical antibiotic eye drops for 2 weeks. Patients are endoscopically evaluated with removal of crusting at 2 weeks. Crawford tubes are removed at 4–6 weeks and the lacrimal system is checked for patency using the fluorescein dye disappearance test.

Complications

Complications demonstrated in endoscopic DCR are similar to those reported in endoscopic sinus surgery including epistaxis, occurring in 2% of patients.^{9, 10} Other possible complications of the procedure include obstruction and subsequent rhinosinusitis of the frontal or maxillary sinus, orbital penetration with damage to the extraocular muscles, cerebrospinal fluid leak and orbital haematoma.

THYROID EYE DISEASE**Introduction**

Thyroid eye disease (Graves' ophthalmopathy) is an incompletely understood autoimmune disease with infiltration of T lymphocytes and macrophages into the orbital tissue as well as an increased glycosaminoglycan deposition with subsequent enlargement of orbital fat and extraocular muscles.^{1, 11, 12} The increased volume in the fixed bony orbit impairs venous drainage resulting in chemosis and periorbital edema. This ultimately leads to increased retrobulbar pressure and enlargement of extraocular muscles potentially leading to loss of vision. The increased volume may result in significant proptosis and possible globe subluxation, exposure keratitis, or corneal ulceration. Approximately 50% of patients who have thyroid eye disease will develop orbital manifestations.¹³

Thyroid eye disease has two phases; an inflammatory phase and a burnt-out phase. The inflammatory phase typically lasts from 6 months to 3 years. During this phase, inflammation, fibrosis, and adipogenesis occur resulting in the changing ocular findings.¹⁴ The burnt-out phase is defined as a period of disease where the ocular findings do not progress during a minimum of 6 months.

Conservative treatment options include eye lubrications, eyelid taping, and patching for the patients with dryness and diplopia, as well as controlling thyroid function. In the inflammatory stage, corticosteroids, immunosuppressants, orbital irradiation, and surgical decompression may also be necessary to improve symptoms and reduce optic nerve compression. Subsequently, in the burnt-out stage, lid surgery, strabismus surgery, and orbital decompression may be required.¹⁴

ENDOSCOPIC ORBITAL DECOMPRESSION

Indications

Indications for orbital decompression include compressive optic neuropathy, exposure keratitis, diplopia, and cosmesis. Both external and intra-nasal decompression has previously been described. Otorhinolaryngologists typically perform an endoscopic approach only or in conjunction with other approaches.

Pre-operative evaluation and studies

Given the wide variety of procedures possible with varying degrees of decompression, careful discussion with the ophthalmology team is critical for understanding the degree of decompression necessary. In general an endoscopic decompression is indicated for patients with moderate to severe thyroid eye disease. It may be performed in conjunction with an open approach for the orbital floor and lateral wall if further decompression is necessary. The procedure is generally utilized for thyroid orbitopathy but can also be used as a corridor to gain access to orbital tumours, biopsy of indeterminate orbital lesions, or palliative therapy for malignant tumours causing visual symptoms.¹⁵

A complete ophthalmology examination is necessary prior to the procedure. This includes evaluation of the degree of proptosis, assessment of eye movements and diplopia, measurement of visual acuity, and colour vision. Pre-operative consent must include discussion of risks including permanent double vision and need for strabismus surgery.

A CT scan evaluating the orbits and sinuses is required to review relevant anatomy. Typical findings include a greater than two-fold enlargement of extraocular muscle bodies, sparing the tendinous portions. The medial and inferior rectus muscles are most commonly involved although all muscles may be enlarged (**Figure 111.6**).¹⁶ The surgeon should identify the middle turbinate attachment, location and course of the anterior ethmoid artery, and the presence of an onodi cell as the optic nerve may course through the lateral aspect of the cell.

Surgical procedure

Perform a maxillary antrostomy, complete ethmoidectomy and sphenoidotomy

During sinus surgery, it is important to completely resect the uncinata process. In addition, we advocate resection of the middle turbinate for improved exposure and decreased risk of adhesions. During dissection, special attention should be made to identify all ethmoid cells have been removed along the lamina papyracea. The maxillary antrostomy should be as large as possible to allow for ideal exposure during decompression.

Resection of medial orbital wall bone

The orbital wall should be penetrated in a controlled fashion. Typically a j-curette or Freer elevator can be used. Care should be taken to perform this gently to avoid

Figure 111.6 (a) Axial and (b) coronal CT scans in thyroid eye disease showing the classical 'Coca Cola' bottle sign of auto-decompression (axial) and compression of orbital apex due to enlarged extraocular muscles.

trauma to the periorbita. The fragments can be freed from the periorbita with the j-curette or Freer elevator and subsequently removed with Blakesley forceps. Take care not to penetrate the periorbita at this time as prolapsing fat will make surgery more difficult. All bone should be resected superiorly up to the ethmoid roof, inferiorly to the orbital floor, anteriorly to the maxillary line and posteriorly to

the face of the sphenoid sinus. Care should be taken when removing bone superiorly to avoid skull base injury that may produce either a cerebrospinal fluid leak or ethmoidal vessel injury.

Down fracture of the orbital floor

Start by elevating the periorbital fat off the medial orbital floor. Use a spoon curette to down fracture the medial aspect of the orbital floor. The bone of the orbital floor is significantly thicker than the medial orbital wall and requires increased force. The bone often fractures in one large piece at the infraorbital canal junction. Note that if

Figure 111.7 (a) Axial and (b) coronal CT scans of patient with thyroid eye disease before and after endoscopic decompression.

the down fracturing is not performed bilaterally, there is an increased risk for post-operative diplopia, especially in the horizontal plane.

Incision of periorbital

The incision should begin at the posterior limit of the decompression and follow a posterior to anterior direction to prevent prolapsing orbital fat from obstructing visualization. A series of parallel incisions should be made in this fashion. In patients without optic neuropathy, a fascial sling can be left in place overlying the medial rectus to prevent diplopia.¹⁷ A curved seeker can be used to gently dissect the remaining fibrous bands between fat lobules.

Prolapse of orbital fat into maxillary and ethmoid sinuses

If done completely, a significant amount of fat will prolapse in the sinuses. The eye may be balloted to confirm fat herniation and allow further prolapse.

Post-operative considerations

It is critical prior to extubation and in the immediate post-operative period to have a clear discussion with the anaesthesia team. This potentially will avoid aggressive post-extubation mask ventilation, which can result in orbital subcutaneous emphysema. Expect large amounts of post-operative swelling, oedema, and erythema. Our patients are typically observed overnight and discharged on broad-spectrum antibiotics and instructed to start nasal irrigations. Patients should avoid nose blowing for 2 weeks to prevent subcutaneous emphysema or even prolapse of the globe.

Results

Post-operative diplopia is frequently encountered with 15–63% of post-operative patients reporting new-onset or worsening diplopia.^{15, 18–22} In most cases, this is temporary and resolves spontaneously over weeks to months. Strabismus surgery will be considered in 8–10 months following decompression if diplopia persists.

The average ocular recession from endoscopic decompression ranges from 3.2–5.1 mm reduction of proptosis with an inferior and medial wall decompression.^{17, 19, 23} Concurrent lateral decompression provides an additional 2 mm of recession.¹⁹ Post-operative deterioration of visual acuity is demonstrated in less than 5% of patients.^{24–26}

OPTIC NERVE COMPRESSION

Optic nerve compression is a rare entity requiring decompression. The optic nerve may be decompressed for a number of indications.

Endoscopic optic nerve decompression

Traumatic optic neuropathy is the most common indication for endoscopic or open optic nerve decompression.

Unfortunately, success rates are limited for this procedure.²⁷⁻³⁰ Traumatic optic neuropathy was initially felt to be secondary to vascular compromise from external compression resulting in injury to the optic nerve. More recent investigation has favoured the theory that manual compression results in a conduction block and focal demyelination leading to compressive optic neuropathy.³¹

Benign or malignant tumours of the skull base can occasionally compress the orbital apex. Meningiomas of the skull base, in particular, produce a hyperostotic reaction with mass effect from the soft tissue component that may directly impact the orbital apex. Benign fibro-osseous lesions or sinonasal tumours can in a similar fashion result in compression of the apex or the optic nerve itself.

Many different approaches have been described for optic nerve decompression including transorbital, transantral, extra-nasal transthemoid, intra-nasal microscopic, and craniotomy approaches. We believe the endonasal approach is superior as it offers a number of advantages over other approaches such as preservation of olfaction, quick recovery period, lack of external scars, and excellent intra-operative visualization. However, the ideal approach should be dictated by the pathology and its location.

PRE-OPERATIVE CONSIDERATIONS AND STUDIES

A thorough ophthalmologic history and physical examination should be performed. A fine cut CT scan of the sinuses and orbit should be evaluated for optic canal compression, fracture, or bone displacement and sinus anatomy for endoscopic considerations. An MRI of the orbits should also be considered for evaluation of the optic nerve and orbital contents.

PROCEDURE

Perform a complete ethmoidectomy and sphenoidotomy

Pay special attention to removing all bony partitions off the lamina papyracea. Additionally, open up the sphenoidotomy maximally, especially laterally. Identify the optic nerve, carotid artery and the opticocarotid recess (**Figure 111.8**). Image guided surgery is ideally employed here.

Fracture the lamina papyracea in posterior ethmoid region

As in orbital decompression, eggshell fracture and remove bone of the lamina in the posterior ethmoids. Again, pay special care not to penetrate the periorbita.

Drill down the bone of the optic strut

Use a diamond drill with copious irrigation to avoid thermal injury to the optic nerve. Drill along the nerve, not across it. As the bone thins, gently flake it away. The amount of decompression depends on the pathology. For cases of traumatic optic neuropathy and thyroid eye disease, the optic nerve should be decompressed for a distance of 1 cm posterior to the face of the sphenoid sinus (**Figure 111.9**).³² Further decompression of the nerve can

Figure 111.8 Silent sinus syndrome with inferior collapse of orbital floor associated with maxillary sinus outflow obstruction.

Figure 111.9 Axial T1-weighted post-contrast MRI demonstrating a large infiltrative orbital mass. It was initially reported to be an aggressive malignant neoplasm. Subsequent biopsy demonstrated orbital pseudotumor.

be created with incision of the sheath itself. If this is to be performed, the incision should be in the superomedial quadrant as the ophthalmic artery may lie in the inferomedial quadrant of the optic nerve sheath in approximately 15% of cases.³³ The incision should be made from

a posterior to anterior direction and which includes the release of the tendinous ring of Zinn. Be prepared for a possible CSF leak which can be closed with a mucosal flap.

POST-OPERATIVE CONSIDERATIONS

Close communication with the ophthalmologic team is critical. They will aid in serial eye examination and help guide the generally required high dose oral steroids. Additionally, antibiotics and gentle saline rinses are recommended. To minimize intra-conal pressures, nasal packing is not utilized following the procedure, and the patient should be instructed on avoiding nose blowing and straining post-operatively.

Imploding maxillary sinus

Imploding maxillary sinus or silent sinus syndrome is believed to originate from obstruction of the osteomeatal complex of the paranasal sinuses leading to hypoventilation of the maxillary sinus. This enclosed cavity in certain settings is thought to undergo air resorption, thus creating a suction effect of subatmospheric pressure within the maxillary antrum.^{34–36} The development of a pressure vacuum within the sinus, in turn, results in the accumulation of mucous into the antrum, subclinical inflammation and eventual collapse of the maxillary sinus through attenuation of the maxillary bony side walls. The hallmark of the disease is lack of traditional chronic sinusitis symptoms. Instead patients present with enophthalmos, occasionally with double vision as well.

Diagnosis is typically confirmed though CT imaging, demonstrating maxillary atelectasis and decreased height of the orbital floor ([Figure 111.8](#)). Treatment for imploding maxillary sinusitis is correcting the underlying pressure system of the maxillary sinus. Although historically this was done with a Caldwell-Luc, it is now treated with an endoscopic maxillary antrostomy. Depending on the severity of bone resorption, the patient may also require surgical intervention to restore height to the orbital floor. This can be done as a single procedure or in a staged fashion.

Orbital pseudotumor

Orbital pseudotumor, or idiopathic orbital inflammation, is a diagnosis of exclusion. The exact etiology of this condition is unclear, but it should be in the differential diagnosis of orbital pathology as it comprises 10% of orbital lesions.³⁷ The clinical signs include proptosis, diplopia, pain, eyelid swelling, ptosis and chemosis. Similar lesions can arise elsewhere in the head and neck including the pterygopalatine and infratemporal fossae.

Pseudotumor presents as a nonspecific orbital mass on CT and/or MRI ([Figure 111.9](#)).³⁷ Diagnosis is one of exclusion, most commonly ruling out lymphoma. Most clinicians should have a low threshold for biopsy if the clinical course is not typical of pseudotumor. Histology generally demonstrates polymorphous inflammatory infiltration of T and B cells, plasma cells, eosinophils, neutrophils and a variable degree of fibrous tissue proliferation.³⁸

Treatment of orbital pseudotumor is typically medical, most commonly with oral steroids, but is also treated with radiotherapy, chemotherapy or immunosuppression for refractory cases. Surgical intervention is only considered to establish a diagnosis, or for emergent treatment of compressive symptoms as a temporizing measure.

Orbital neoplasms

Orbital neoplasms can broadly be divided into benign and malignant lesions. Otorhinolaryngologists participate as part of a multidisciplinary team in treatment. Benign neoplasms most commonly consist of fibro-osseous lesions, neural lesions, and vascular lesions, while malignant neoplasms are generally divided into epithelial, non-epithelial, lymphoma, and metastatic.

Benign neoplasm

FIBRO-OSSEOUS LESIONS

Benign fibro-osseous lesions affecting the optic nerve and orbit are similar to lesions dealt with in the paranasal sinuses. These lesions are primarily fibrous dysplasia, ossifying fibromas, and osteomas. Fibrous dysplasia is either monostotic or polyostotic fibrous dysplasia ([Figure 111.10](#)). Asymptomatic lesions are observed with surveillance imaging. Those resulting in orbital or optic nerve compression require surgical intervention. Conversely, ossifying fibromas are aggressive and can be locally destructive, in these cases, early resection

Figure 111.10 Axial CT scan with right-sided fibrous dysplasia with encroachment of the optic nerve.

is recommended. Finally, osteomas are benign, osseous lesions presenting with slow growth. They have an increased incidence along the frontoethmoidal suture line and accordingly may encroach on the orbit. Similar to fibrous dysplasia, if asymptomatic, these can be observed with surveillance imaging.

NEURAL

Neural-derived neoplasms of the orbit and orbital apex most commonly consist of gliomas, neurofibromas, schwannomas, and meningiomas. As with most orbital lesions, presentation is dependent on tumour pathology and position within the orbit. Neurofibromas and schwannomas tend to present more anteriorly within the orbit, and meningiomas and gliomas are often retrobulbar. Optic nerve meningiomas are of special significance as removal or even biopsy of these lesions can cause damage to the blood supply of the optic nerve resulting in visual loss. Typically optic nerve meningiomas are treated conservatively unless the patient develops visual loss.

VASCULAR

Vascular lesions include lymphangioma, orbital varices and arteriovenous malformations. Complete surgical resection for vascular lesions is often not feasible, but orbital apical decompression often may play a role in management. Non-encapsulated lesions, or lesions that infiltrate critical orbital structures should only be decompressed if they are causing optic neuropathy.

Malignant neoplasms

EPITHELIAL

Primary epithelial tumours of the orbit are very rare. When present, they generally involve the lacrimal gland.

Lacrimal gland tumours range from pleomorphic adenoma to aggressive neoplasms such as adenoid cystic and squamous cell carcinoma.³⁹ Open surgical resection is often the treatment of choice as endoscopic access with clear margins is often challenging.

NON-EPITHELIAL

The most common non-epithelial neoplasm is rhabdomyosarcoma. It typically presents in childhood and should be considered on the differential in any child presenting with progressive proptosis. Other sarcomas such as liposarcoma and leiomyosarcoma, although rare, can present in the orbit.

LYMPHOMA

Lymphoma typically presents as a painless enlarging mass. Surgical intervention, as with lymphoma of other areas, consists of biopsy only. Ultimate treatment depending on tumour type and stage consists of radiation therapy and/or chemotherapy.³⁹

METASTATIC

Metastatic neoplasm must be considered in the differential for any orbital lesion. The most common are neuroblastoma, leukaemia, breast carcinoma, lung carcinoma, and prostate carcinoma.

CONCLUSION

Otorhinolaryngologists must have a thorough understanding of the wide variety of pathology that occurs in the orbit due to the close proximity of the paranasal sinuses. This is relevant both in terms of paranasal sinus involvement of orbital lesions as well as treatment corridors through the nose. Most of these lesions are best treated by a multidisciplinary team for optimal outcomes.

KEY POINTS

- A thorough understanding of the orbital anatomy is essential for otorhinolaryngologists given the close proximity to the paranasal sinuses.
- Optimal results in endoscopic DCR require both knowledge of the site of obstruction as well as optimal surgical steps to ensure patency.
- Traumatic optic neuropathy is the most common indication for endoscopic optic nerve decompression. Unfortunately, success rates are limited for this procedure.
- There is a wide variety of orbital neoplasms and accurate diagnosis and workup are necessary to identify the correct treatment plan.
- Treatment of orbital pathology requires a close working relationship between ophthalmologists and otorhinolaryngologists.

DIAGNOSIS AND MANAGEMENT OF FACIAL PAIN

Rajiv K. Bhalla and Timothy J. Woolford

Introduction	1253	Dental pain	1259
Background	1253	Other causes of facial pain encountered by the otolaryngologist	1259
Sinogenic facial pain	1254	Persistent idiopathic facial pain (atypical facial pain)	1261
Non-sinogenic facial pain	1255	History taking in facial pain	1261
Neuralgias causing facial pain	1258	References	1263

SEARCH STRATEGY

A systematic search of the available literature was performed using Medline, Embase, Cochrane library and NHS Evidence. Search terms included facial pain, sinusitis, neuropathic pain, migraine, trigeminal autonomic cephalalgia, neuralgia, persistent idiopathic facial pain, referred pain, and medication- or analgesia-dependency headache, focusing primarily on diagnosis and management.

INTRODUCTION

The diagnosis of facial pain is complex, requiring a holistic approach to the patient. Individuals are often convinced or have been convinced, either by reading the internet or by their family doctor, that their facial symptoms have underlying sinus aetiology. Additionally, there may be a strong psychological component to the onset, severity, exacerbation and prolongation of symptoms. These consultations have a propensity to be difficult and are usually time-consuming. However, time invested at an initial consultation is often time well invested, particularly if patients are helped to understand the underlying mechanism of their pain if sinus pathology is not the cause. This chapter examines the presentation and subsequent management to the otolaryngologist of patients with the symptom of facial pain, and includes an extensive discussion on medical and adjuvant therapies currently used to treat diseases that are not isogenic in aetiology.

BACKGROUND

Reaching the correct diagnosis in patients with facial pain is challenging because many patients come with fixed ideas about the cause of their pain. The majority are convinced they have sinusitis, a not unreasonable view because the diagnosis has often been confirmed by their

general practitioner or other specialists. A proportion of patients have already undergone unsuccessful nasal or sinus surgery. If all cases of facial pain are assumed to be sinogenic in aetiology, those with other conditions will not receive the correct medical treatment and unfortunately, many patients will continue to be subjected to inappropriate surgery.

The majority of painful stimuli from the face are transmitted to the spinal tract of the brain stem via afferents in the trigeminal nerve. Pain afferents from the VIIIth, IXth and Xth cranial nerves also relay in the spinal tract. Facial pain from deep structures tends to be a dull, poorly localized ache because the afferent nerves innervating them are unmyelinated. Facial skin is supplied by myelinated nerves that produce a sharper pain. Various neurophysiological models have been proposed to explain the nociceptive inputs causing tension headache and migraine, and suggest pathogenesis similar to that of fibromyalgia and irritable bowel syndrome, conditions that frequently coexist. Experimental studies suggest that increased excitability of the central nervous system generated by repetitive and sustained pericranial myofascial input may be partly responsible, along with widespread changes in brain function and connectivity.^{1, 2} By extrapolation, facial pain is likely to be caused by central sensitization of the trigeminal nucleus by myofascial, vascular or supraspinal input, with exacerbations or provocation of pain induced by supraspinal inhibition of the trigeminal nucleus by

psychological influences.³ To add to this, surgery, trauma and inflammation may promote nociceptive stimulation of the trigeminal caudal nucleus and initiate pain.

There are many different ways of dividing the subsections in the ensuing descriptive text. However, from the perspective of the otolaryngologist the most important differentiation, perhaps, is between facial symptoms of sino-genic aetiology and those that are not. Hence, the chapter is divided accordingly, with great emphasis on the decision to operate and perhaps more important to avoid surgery. The chapter also furnishes the reader with comprehensive differential diagnoses for the patient that presents with the symptom of facial pain. In truth, the diagnoses, aetiological hypotheses and management options have not changed greatly over the last 10 years. An individual presenting with facial pain represents an extremely common encounter in both specialist rhinology and general otolaryngology out-patient clinics. A thorough grounding in what is and what is not sinus-related, understanding from where this information arises, and starting with a broad and holistic perspective in any new or complex follow-up consultation is of paramount importance to ensure that effective interventions are implemented where indicated, and withheld when they are not.

SINOGENIC FACIAL PAIN

Pain is defined as an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.⁴ Unfortunately though, discriminating between *pain* caused by sinusitis and *pain* caused by other pathologies is, perhaps, conceptually too difficult for the large majority of our patients and why, perhaps, we often hear ourselves asking questions such as, ‘Describe the pain to me’ and, ‘What do you mean by pain?’

Pain in sinusitis that is not acute or complicated is probably a misnomer. Enough evidence now exists to suggest that sinusitis per se does not cause *pain* but instead, may be associated with other more vague symptoms. Patients may complain of pressure, fullness or throbbing in the distribution of the paranasal sinuses or at the vertex of the head. Symptoms may be bilateral or unilateral, particularly if individual sinuses are affected by pathology. Examples include pathology such as pyomucocele of the maxillary antrum, or fibrous dysplasia or osteoma of the ethmoid sinus causing secondary obstruction of drainage pathways, or mucocele of the sphenoid sinus (Figures 112.1 and 112.2). Exacerbation of these symptoms on bending forwards is not, however, diagnostic or suggestive of rhinosinusitis.⁵ Furthermore, symptoms may be acute, recurrent acute (moderated by repeated short courses of antibiotics) or chronic. Associated with these symptoms may be nasal congestion and/or hyposmia, although these symptoms may be difficult for the patient to recall, particularly if the underlying diagnosis is of recurrent acute sinusitis. Clarification often requires some gentle probing. More readily detectable are the endoscopic signs of polypoid and obstruction of outflow drainage pathways, and

mucosal disease (Figure 112.3). However, these signs are frequently subtle and may, therefore, be missed. It is also highly relevant that over 80% of patients with endoscopic evidence of purulent secretions have no headache or facial pain.⁶ Moreover, if surgery is performed in cases where facial pain is the dominant symptom without firm clinical evidence of rhinosinusitis, not surprisingly, a significant proportion of these patients continue to complain of facial pain post-operatively.⁷

- Management of rhinosinusitis is initially medical, with imaging reserved for failed maximal medical therapy, complications of rhinosinusitis, or suspicion of malignancy.
- Surgery should be targeted, as good correlation between symptoms, signs and radiological findings.

NON-SINOGENIC FACIAL PAIN

The primary headaches

These are headache disorders not caused by another condition. Each is worth considering in the context of an otolaryngology out-patient setting since they are not infrequently encountered in both specialist rhinology and general situations. Some rhinologists will be very comfortable with the medical management of these headache disorders and will have a thorough understanding of the mechanisms of drug actions and their side effects; some rhinologists will rely heavily on a partnership with a neurologist and/or a colleague with a special interest in pain management. Either approach is acceptable. Not covered in this section are primary headache disorders of the stabbing, cough (precipitated by valsalva), exertional (onset during or immediately after exercise), sexual activity, thunderclap (maximum intensity reached within a minute), hypnic (waking patient from sleep), or new daily-persistent (intractable headache that persists daily for at least 3 months) subtypes.⁸ Suspicion should prompt a referral to a neurologist with an interest in headache, for an informed second opinion.

MIGRAINE

Migraine is characterized by recurrent, often unilateral, moderate to severe headaches, which may be associated with a number of symptoms attributable to the autonomic nervous system (Figure 112.4). The headache is described as pulsatile or throbbing, and may be severe enough to force the sufferer to bed in a darkened and quiet room as the pain is generally aggravated by

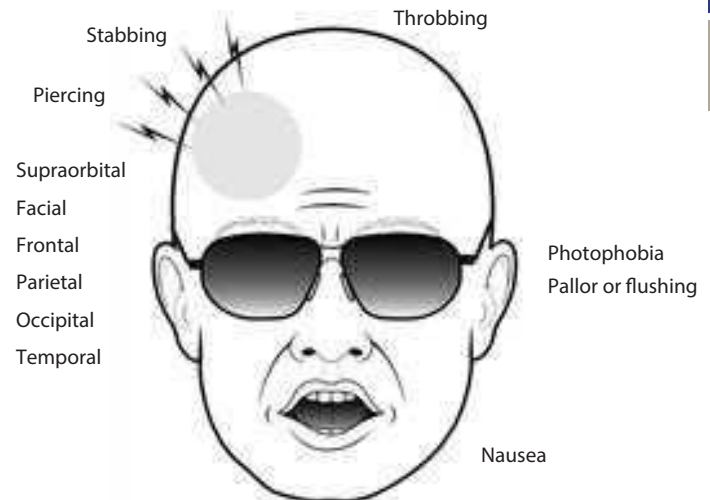

Figure 112.4 The features of migraine.

physical activity or sensory stimulation. It may last between 2 and 72 hours.

In classical migraine, accounting for 25% of cases, the associated autonomic symptoms may include one or more of nausea, vomiting, photophobia, and phonophobia. Up to one-third of classical migraine sufferers may describe prodromal aura: a transient visual (scintillating scotoma, which is an area of partial alteration in the field of vision that flickers with zigzagging lines resembling fortifications or walls of a castle), sensory (olfaction or taste), or language or motor disturbance (pins-and-needles or numbness), which signals that the headache will soon occur.⁹ Common migraine sufferers experience the same throbbing headache and nausea but without the aura associated with classical migraine.

Although previously believed to be a neurovascular disorder, the mechanism for migraine is now believed to be a disorder of the brain itself.¹⁰ Cortical spreading depression is a wave of intense depolarization that starts in the occipital lobe, propagates through the brain and is followed by a period of suppressed activity. Consequent activation of the trigemino-vascular system causes the release of neuropeptides (e.g. calcitonin gene-related peptide, substance P) from peripheral trigeminal nerve endings. It is these neuropeptides that are thought to play a role in causing and maintaining the headache. The pulsating quality of migraine is thought to be caused by a process of peripheral sensitization. The condition runs in families in approximately two-thirds of cases, is more common in women and sufferers may describe triggers, which can be encountered up to 24 hours prior to the onset of an attack.¹¹⁻¹³ Some examples of triggers include stress, hunger, fatigue, hormonal changes, foodstuffs containing tyramine (aged cheeses, smoked fish, cured meats, some types of beer), monosodium glutamate, indoor air quality and lighting, although the evidence base for all of these is poor.

Over 90% of self-diagnosed and doctor-diagnosed sinus headaches meet the International Headache Society criteria for migraines and yet 60% receive an antibiotic prescription.⁵ Furthermore, over 40% of migraine sufferers had at least one unilateral nasal symptom of congestion,

rhinorrhoea or ocular lacrimation, redness or swelling during an attack, which can confuse the picture somewhat. However, these episodes do not last longer than 72 hours and endoscopic examination during an acute episode yields no evidence of purulent secretion.

Main aspects of treatment for acute migraine

- Trigger avoidance
- Acute symptomatic control
- Pharmacological prevention.

Medications are useful if used early in an attack. For mild to moderate symptoms simple analgesics, such as non-steroidal anti-inflammatory drugs (NSAIDs) or the combination of acetaminophen, acetylsalicylic acid and caffeine, are recommended for initial treatment in acute attacks.¹⁴ Ibuprofen provides effective relief of symptoms in about half of people and diclofenac has also been found to be effective, both prescribed either with or without metoclopramide.^{15, 16} Triptans (e.g. sumatriptan, naratriptan, rizatriptan, zolmatriptan) may help individuals with moderate to severe symptoms or those with milder symptoms who do not respond to simple analgesics, and are effective in up to 75%.^{14, 17} Most side effects are mild, such as flushing, but they are not recommended for people with cardiovascular disease due to rare cases of myocardial ischaemia.¹⁴ Unfortunately though, they may cause medication-overuse headaches if used for more than 10 days per month. Older medications, such as ergotamine and dihydroergotamine, remain as effective as triptans in the management of acute migraine, are less expensive, and are associated with side effects that are typically benign.¹⁸

Preventative measures in migraine include medications, nutritional supplements and lifestyle alterations. Prevention is recommended in those that have headaches for more than 2 days a week, cannot tolerate the medications used to treat acute attacks, or those with severe attacks that are not readily controlled. Options for medical prevention include anti-epileptic drugs (e.g. topiramate, sodium valproate), beta-blockers (e.g. propranolol, metoprolol), beta-adrenergic receptor antagonists (e.g. timolol), and antidepressants (e.g. amitriptyline, venlafaxine).^{19, 20} It is important, however, to appreciate the side effects and contraindications for each before prescribing. Furthermore, it is often reassuring for patients to know that the doses of antidepressants prescribed to treat headaches and facial pain are somewhat lower than those used in the management of depression.

Botulinum toxin type A, administered intra-muscularly to between 31 and 39 sites around the head and back of the neck, has been found to be useful in those with chronic migraines (15 or more headache days per month of which at least 8 days are with migraines) but not those with episodic ones (0 to 14 headache days per month).^{21, 22} The treatment is endorsed by the National Institute for Health and Clinical Excellence.²³ Evidence for effective control of other facial pain conditions using botulinum toxin is scarce, although it has also been used for headaches of tension origin.

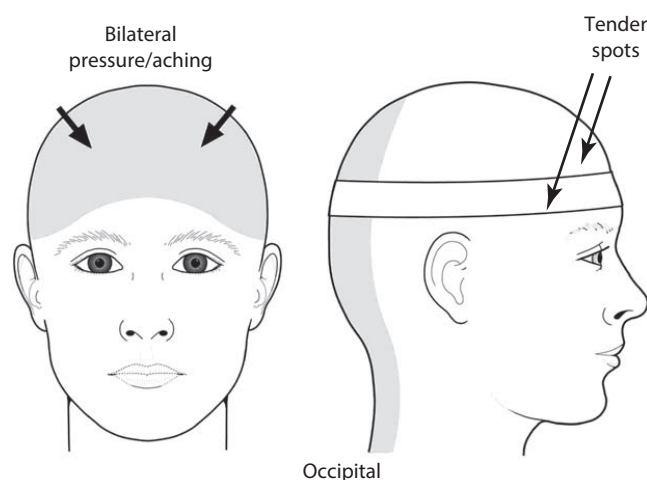

Figure 112.5 The characteristics of tension-type headache.

TENSION-TYPE HEADACHE

This is a headache that can vary in intensity in the same individual, but is usually symmetric and non-pulsatile in nature. The feeling is of tightness, pressure or constriction (vice-like) that may be confined to a small area at the glabella or extend across the whole forehead and into the temporoparietal scalp, often with a tightness or tenderness in the occiput and related trapezius (Figure 112.5). There is often some hyperaesthesia of the skin in the area giving the impression to the patient they have sinusitis, and tender trigger points can often be identified in the neck and shoulder areas. Clearly, the aggregate of symptoms suggests an underlying association with stress and tension, but depression and anxiety may also contribute.³ Furthermore, although many analgesics are being taken, the patients say they offer little relief and, in fact, analgesic-dependent headaches (see below) can complicate the picture. Despite extensive investigation, the underlying pathophysiology remains a matter of speculation, with peripheral muscular and central nervous system components both likely involved. Pericranial myofascial mechanisms are probably of importance in episodic tension-type headache, whereas sensitization of central nociceptive pathways and inadequate endogenous anti-nociceptive circuitry seem to be more relevant in chronic tension-type headache.

Relaxation training, stress management and counselling have been shown to be beneficial in the management of chronic (continuous or last for more than 15 days per month) tension-type headaches although these are, perhaps, therapeutic measures that could be implemented for all non-sinogenic headaches including, for example, temporomandibular joint disorders.²⁴ Amitriptyline is also effective in the management of tension headache and mid-facial segment pain (see below). Dosing begins at 10mg, taken once daily at night, and increased in increments of 10mg every 6 weeks until the pain is controlled. Rarely, 50mg is needed. The main side effect is sedative, which enhances quality of sleep but may cause a 'hangover' effect the following morning. Tolerance to this effect usually develops after a few days. Treatment should be continued for at least 6 weeks before judging its effect, and should

be continued for 6 months if it has helped. Alternatively, a triptan may be of value when there is overlap between headaches caused by tension and migraine.

CLUSTER HEADACHE AND OTHER TRIGEMINAL AUTONOMIC CEPHALALGIAS

The trigeminal autonomic cephalalgias are a group of primary headache disorders that include cluster headache, paroxysmal hemicrania, and short-lasting unilateral neuralgiform headache attacks with conjunctival injection and tearing/cranial autonomic features (SUNCT/SUNA).²⁵ Trigeminal autonomic cephalalgias are generally characterized by relatively short-lasting attacks of severe pain and lateralized associated features including pain, cranial autonomic symptoms and where present, migrainous symptoms, such as photophobia. Key for the otolaryngologist when diagnosing a trigeminal autonomic cephalalgia is the consideration of underlying pituitary or pituitary-region pathology, since the posterior hypothalamus is crucial in the pathophysiology of these headaches.²⁶ Although the syndromes share much in their pathophysiology and investigation paths, their treatment is distinct, so that accurate differentiation is important for optimal management. Due to the associated autonomic symptoms, there is a great propensity for the presentation to be confused with sinus pathology, causing misdiagnosis and subsequent mismanagement. It is of great value if such patients are managed in conjunction with a neurologist and/or colleague with a special interest in pain management.

Cluster headache

Cluster headaches are excruciating unilateral headaches of extreme intensity affecting the frontal and temporal regions, extending over the cheek and even into the teeth. There is often associated lacrimation, rhinorrhoea and nasal obstruction, symptoms that have led to misdiagnosis of sinusitis. The pain is typically lancinating or boring/drilling in quality, and is located behind the eye or in the temple (Figure 112.6). Descriptions range from a red-hot poker inserted into the eye or a spike penetrated from the top of the head, behind one eye, and radiating down the neck. Men are more often affected than women, primarily between the ages of 20 and 50 years. The duration of the common attack ranges from as short as 15 minutes to 3 hours or more with a rapid onset and without preliminary signs that are characteristic of a migraine. 'Side shifting' between cluster periods and bilateral headache have been described.²⁷ Clusters of headaches often continue for several weeks followed by months or years of remission. The intense pain in cluster headache is caused by dilation of blood vessels creating pressure on the trigeminal nerve. The aetiology of this process is, unfortunately, not fully understood but is, perhaps, due to an abnormality in the hypothalamus. Preventive treatment is always indicated for cluster headaches, to be started at the first sign of a new cluster cycle. Oxygen therapy, triptans, calcium-channel blockers (e.g. verapamil), and systemic corticosteroids have been found to be effective at managing cluster headaches.

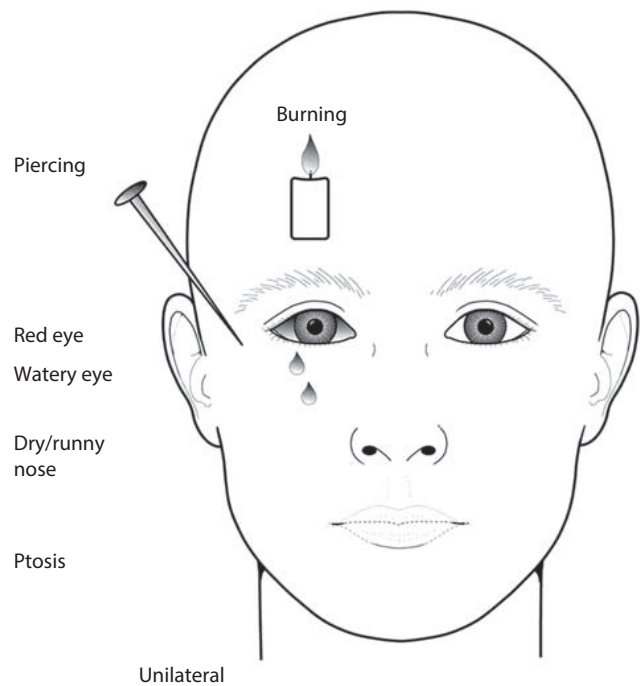

Figure 112.6 The features of cluster headache.

Paroxysmal hemicrania

This is a severe debilitating unilateral headache affecting usually the periorbital and frontotemporal regions, with an average age of onset of 30 to 40 years. Attacks are usually short-lasting, ranging from 2 to 45 minutes, and frequent, happening more than 5 times a day. Trigeminal autonomic symptoms may include nasal congestion, rhinorrhoea and lacrimation, lending itself to diagnostic confusion. The majority of patients with paroxysmal hemicrania respond to indomethacin within 24 hours. In cases where indomethacin fails to work, other drugs that have been suggested include calcium-channel blockers, naproxen, carbamazepine, and sumatriptan.

SUNCT/SUNA

Short-lasting unilateral neuralgiform headache attacks with conjunctival injection and tearing (SUNCT) and short-lasting unilateral neuralgiform attacks with cranial autonomic features (SUNA) have the shortest attack duration and the highest attack frequency. They are typified by severe, brief, unilateral attacks that usually occur in the distribution of the trigeminal nerve. SUNA differs from SUNCT in that autonomic symptoms are less prominent. Possible effective preventive drugs are carbamazepine, lamotrigine, gabapentin, and topiramate. At present, the drug of choice for SUNCT seems to be lamotrigine, whereas SUNA may better respond to gabapentin.²⁸

Hemicrania continua

This is also a strictly unilateral headache causing moderately severe pain, without side-shift, with exacerbations that can include cranial autonomic symptoms as part of the phenotype (e.g. conjunctival injection, lacrimation,

nasal congestion, rhinorrhoea, ptosis, or miosis). The headache is daily and continuous, without pain-free periods, and lasts for more than 3 months. The condition occurs more often in women and tends to present first in adulthood. Its diagnosis requires response to indomethacin but where side effects are an issue, other treatments may include gabapentin, topiramate, radiofrequency ablation of the supraorbital nerve, nerve blocks or botulinum toxin.

NEURALGIAS CAUSING FACIAL PAIN

Trigeminal neuralgia

Trigeminal neuralgia is characterized by paroxysms of brief but severe pain followed by asymptomatic periods without pain, although a constant dull ache may persist in some patients.²⁹ The pain is often described as stabbing or lancinating, burning, pressing, crushing, exploding or shooting, and patients may describe a trigger area on the face so sensitive that touching or even air currents may trigger an episode. Individual attacks usually affect one side of the face at a time, lasting from several seconds to a few minutes and may repeat up to hundreds of times throughout the day. The pain also tends to occur in cycles with remissions lasting months or even years. Vascular (arterial and venous) compression of the trigeminal nerve roots has emerged as the likely cause in most cases, with the superior cerebellar artery, the anterior and posterior inferior cerebellar arteries, and the superior petrosal vein including several of its tributaries most often implicated.³⁰ Such compression can injure the protective myelin sheath of the nerve and cause erratic and hyperactive nerve functioning. Diagnosis should be prompt as the longer a patient suffers with trigeminal neuralgia, the more difficult it may be to reverse the neural pathways responsible for pain. Magnetic resonance imaging should be performed to exclude multiple sclerosis or posterior fossa pathology. The anticonvulsant carbamazepine is the drug of choice for management. Gabapentin, lamotrigine and topiramate are useful as second-line agents. Percutaneous radiofrequency thermo- or chemical rhizotomy of the Gasserian ganglion is a valuable intervention in some cases, whilst stereotactic radiotherapy may offer relief of symptoms for others, although the effectiveness tends to decrease with time. Microvascular decompression produces satisfactory relief of trigeminal neuralgia symptoms in the majority of well-selected cases.

Post-herpetic neuralgia

This is pain following a herpes zoster infection, and is defined as pain recurring or continuing at the site of shingles after the onset of the rash. Up to 50% of elderly patients that have had shingles may develop post-herpetic neuralgia though fortunately, most recover during the first year. Antiviral agents help curtail the pain of acute shingles and they may also reduce the risk of subsequent post-herpetic neuralgia. Various medical treatments may

be helpful, particularly carbamazepine or gabapentin with or without a tricyclic antidepressant.³¹ However, management of distressing pain in these cases is often the remit of a pain specialist.

Post-surgical / traumatic neuralgia

The external portion of the nose is highly innervated by branches of the ophthalmic and maxillary divisions of the trigeminal nerve including the nasociliary nerve, external nasal nerve, infratrochlear nerve, anterior ethmoidal nerve, and infraorbital nerve. As these nerves are located on the external portion of the nose just deep to the skin, they can be easily traumatized with any impact to the nose, either following trauma or after surgery.³² The pathophysiology is unclear and may be a central, due to neuroplasticity within the trigeminal nucleus producing spontaneous firing of neurones and reverberating circuits, or a peripheral phenomenon, perhaps due to direct neural damage with fibrosis or neuroma formation, or neural entrapment. Callous formation or post-traumatic focal inflammation may exacerbate the problem.

Removal of prosthetic pressure (e.g. from spectacles), drugs to treat neuropathic pain (amitriptyline, gabapentin, or pregabalin), infiltration with local anaesthetic and corticosteroid, nerve decompression and ultimately, nerve section may offer some symptom relief. These patients often suffer a degree of psychological distress following injury or are dissatisfied with the result of their surgery, and it is not uncommon for symptoms to be exaggerated if associated with ongoing litigation. It should be borne in mind that correction of an aesthetic abnormality is unlikely to alleviate pain and caution should be observed when managing such patients. Furthermore, there is the added risk of worsening the pain syndrome or causing new pain to develop after surgical intervention.

Sluder's neuralgia and 'contact point pain'

The theory that implicates mucosal contact points within the nose as a cause of headache or facial pain has, unfortunately, become firmly entrenched in otolaryngology folklore.³³ The findings have been used by some to support the notion that mucosal contact points within the nasal cavity can cause referred pain, even though the original studies did not describe contact point-induced headache or facial pain. High-quality studies now exist to support the view that the majority of people with contact points experience no facial pain.³⁴ Although Sluder's description of sphenopalatine ganglion neuralgia described a collective group of neuralgic, motor, sensory and gustatory symptoms and signs including facial pain, he did not actually describe the presence of contact points, which is all the more confusing as to why his theory has been extrapolated by some to include mucosal contact with the lateral nasal wall as a cause for facial pain.³⁵ Moreover, there is nowhere else in the body where mucosa-to-mucosa contact causes pain. It seems probable that the majority of case series in the

literature that describe surgery for anatomical variations (septal spur, concha bullosa, a paradoxically curved middle turbinate, a superior turbinate touching the septum, or a large ethmoid bulla) in patients with facial pain that responded to surgery result from the effect of cognitive dissonance or from surgery altering neuroplasticity within the brainstem sensory nuclear complex.³⁴ Benefit is more often partial than complete and relatively short-lived. Further prospective, randomized and blinded trials with a minimum follow-up period of 12 months are required to assess the place of contact point surgery.

DENTAL PAIN

Painful teeth

A frequent source of referral to a specialist rhinology clinic is the patient with vague maxillary or piriform aperture pain that has been assessed in an oral or maxillofacial surgery clinic and radiological investigation has identified mucosal thickening in the maxillary antrum. It is important to note that maxillary retention cysts are an extremely common finding in one-third of patients with no sinus complaint. Most will either shrink or remain unchanged over time.³⁶ Surgery is rarely indicated. True dental pain can often be elicited by percussing the offending tooth, although pain originating from pulp disease may be poorly localized causing misdiagnosis. This pain rarely crosses the midline but radiation to the opposite jaw (e.g. maxilla to mandible) and surrounding structures may further confuse the picture. In contrast, dentino-enamel defects will produce a sharp, well-localized pain often caused by a lost or cracked filling. Once the periodontium is involved the pain becomes localized to the affected tooth, which throbs and is tender to percussion.

Temporomandibular joint disorder

This is not an uncommon presentation in otolaryngology clinics, where muscular hyper- or parafunction may produce acute or chronic pain in the pre- or periauricular areas, deep otalgia, and tenderness in the temporoparietal and cervical regions of the scalp. Clinical findings may include scalloping of the buccal mucosa in cases of bruxism, tenderness in the muscles of mastication or in the temporomandibular joint itself, and smoothed contours of the pre-molar and molar dentition. Other causes include malocclusion, mal-alignment following dental restorative procedures, stress and anger, excessive chewing (e.g. gum), and degenerative joint disease. Treatment includes joint rest, non-steroidal anti-inflammatory analgesia, correction of aetiological factors, and an occlusal splint (e.g. biteguard) worn at night or, sometimes, longer duration can relieve inflammation in a tender joint. Use of a 'one-size-fits-all' splint can worsen symptoms in some people and so these should be custom made. Physiotherapy, temporomandibular joint injection with corticosteroid and local anaesthetic or botulinum toxin, and low-dose amitriptyline may be useful in some resistant cases.

Phantom tooth pain

Patients with unrelenting pain in the teeth, gingival, palatal or alveolar tissues often see multiple dentists and have multiple irreversible procedures performed and still have their pain. Common diagnoses include atypical odontalgia, persistent orodental pain, or if teeth have been extracted, phantom tooth pain.³⁷ One possibility is that these pain complaints are due to a neuropathic alteration of the trigeminal nerve, but more likely is a diagnosis of persistent idiopathic facial pain (see below). Treatment may include pharmacological medications that suppress nerve activity. The common medications used for atypical odontalgia and phantom tooth pain include gabapentin, tricyclics, topical anaesthetics and opioids.

OTHER CAUSES OF FACIAL PAIN ENCOUNTERED BY THE OTOLARYNGOLOGIST

Mid-facial segment pain

This is a type of tension headache that affects the mid-face ([Table 112.1](#) and [Figure 112.7](#)).³⁸ The diagnosis can be challenging as patients and their family practitioner are often convinced the symptoms are due to rhinosinusitis. However, dubious endoscopic evidence of rhinosinusitis should prompt the clinician to refute this diagnosis in support of a neurological cause. The mechanism behind tension pain and its management have been described above.

Analgesia-dependency headache or medication-overuse headache

Many headache sufferers, particularly tension-type, mid-facial segment pain and migraine, can get into a cycle of taking an excessive amount of analgesics in spite of the fact that they have little effect. Dull, diffuse and band-like headaches, usually starting in the early morning, are suggestive of drug-induced or analgesic-dependent headaches. The drugs most often used are acetaminophen,

TABLE 112.1 Criteria comprising mid-facial segment pain

- A symmetric sensation of pressure or tightness. Some patients may say that their nose feels blocked even though they have no nasal airway obstruction.
- Involves the areas of the nasion, under the bridge of the nose, either side of the nose, the peri- or retro-orbital regions, or across the cheeks. The symptoms of tension-type headache often coexist.
- There may be hyperaesthesia of the skin and soft tissues over the affected area.
- Nasal endoscopy is normal.
- Computerized tomography of the paranasal sinuses is normal (note a third of asymptomatic patients have incidental mucosal changes on CT).
- There are no consistent exacerbating or relieving factors.
- There are no nasal symptoms (note that approximately 20% of most populations have intermittent or persistent allergic rhinitis, which may occur incidentally in this condition).

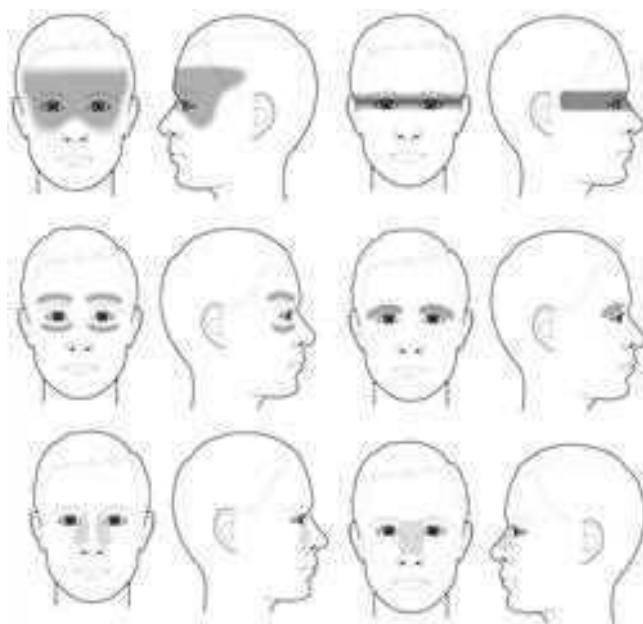

Figure 112.7 Facial map of the patterns of distribution of mid-facial segment pain.

caffeine, non-steroidal anti-inflammatory medications, codeine, ergot alkaloids, and pyrazalone derivatives.³⁹ On stopping analgesics, headaches disappear or decrease by more than 50% in two-thirds of patients, but withdrawal may be problematic as symptoms can take several weeks to disappear. Positive predictors for successful treatment are migraine as the primary headache, chronic headache lasting less than 10 years, and the regular intake of ergotamine. The underlying mechanisms behind analgesia-dependency headache remain unknown.

Myofascial pain

This is characterized by chronic pain caused by multiple trigger points in the neck, jaw or ear, and is five times more common in post-menopausal women (Table 112.2). The condition has many features in common with temporomandibular joint dysfunction, with tender points identifiable in the sternomastoid and trapezius muscles. Aetiological factors include malocclusion and poor deltopectoral posture, but stress and tiredness have a tendency to amplify the symptoms. Chronic myofascial pain may be helped by applying local heat, ultrasound therapy and often massage to relieve trigger point tenderness. Other pharmacological treatments are similar to temporomandibular joint disorders.

TABLE 112.2 Clinical features of a myofascial trigger point

- focal point tenderness
- reproduction of pain on trigger point palpation
- hardening of the muscle upon trigger point palpation
- pseudo-weakness of the involved muscle
- referred pain
- limited range of motion following approximately 5 seconds of sustained trigger point pressure

Cervical spine degenerative disease and cervicogenic headache

Cervicogenic headache is recognized as a referred pain in the head and by muscular association, to the face.⁴⁰ Primary sensory afferents from the cervical roots C1 to C3 converge with afferents from the occiput and trigeminal afferents on the same second-order neuron in the upper cervical spine. Consequently, the anatomical structures innervated by the cervical roots C1 to C3 are potential sources of cervicogenic headache. Pain may originate from different muscles and ligaments of the neck, from intervertebral discs and particularly, from the atlanto-occipital, atlanto-axial, and C2/C3 zygapophyseal joints. Treatment may include simple analgesia, physiotherapy, complementary therapies such as acupuncture or massage, cervical epidural corticosteroid injection, local botulinum toxin injection, radiofrequency ablative therapy, and surgery. Severe cases should be managed in conjunction with a spine specialist.

Temporal arteritis

This is an inflammatory vasculitis of the temporal artery. The condition usually presents to the rheumatologist or vascular surgeon but in the rare instance that an affected patient does present to an otolaryngology clinic, it is essential that a prompt diagnosis is made. Delay can, unfortunately, render a patient blind due to disease progression and involvement of the ophthalmic artery. Loss of vision in both eyes may occur very abruptly. Women over 55 years are most commonly affected, presenting with headache, fever, jaw or tongue claudication, and visual disturbance. The temporal area may be tender, with prominence of the temporal arteries, which may be thickened. Diagnosis is confirmed by raised erythrocyte sedimentation rate and a minimum 1 cm length biopsy of the temporal artery, which shows giant cells infiltrating the tissue, intimal hyperplasia and fragmentation of the internal elastic lamina. Unfortunately, a negative biopsy result does not definitely rule out the diagnosis. High-dose corticosteroids (prednisolone 1mg/kg/day) must be started as soon as the diagnosis is suspected, even before biopsy confirmation, if there is a strong clinical suspicion that the condition is present.

Pain caused by tumour

Although tumours rarely present with facial pain, nearly 80% of patients with head and neck cancers experience facial pain related to their tumour or treatment.⁴¹ Constant or progressive dull or gnawing pain, particularly if associated with other suspicious symptoms or neurological signs should alert the clinician. A past history of malignancy may raise the possibility of metachronous tumour or metastasis. A thorough examination of the head, neck and upper aerodigestive tract along with appropriate radiological imaging is mandatory to exclude the possibility of underlying tumour. Occasionally, tumours may have a long natural history of growth, such

Figure 112.8 Coronal CT image showing a recurrent left infraorbital schwannoma (arrow) causing chronic facial pain.

as a neuroma, and pain may have been present for several years (Figure 112.8).

Patients with neoplasia of the paranasal sinuses, benign or malignant, often present with advanced disease. Unilateral nasal obstruction, bloody or discoloured nasal discharge, a proptosed or displaced globe, facial paraesthesia or swelling, and a loose tooth or ill-fitting denture may represent advanced disease. Pain is usually a late feature.

PERSISTENT IDIOPATHIC FACIAL PAIN (ATYPICAL FACIAL PAIN)

This warrants special mention in its own right. A diagnosis of exclusion only, patients are all too easily labelled as suffering *atypical* facial symptoms when actually, a thorough understanding of alternative causes, mechanisms and symptoms, and appropriate management lends itself to a happier outcome for both the patient and attending otolaryngologist. It is described as a persistent facial pain that does not have the classical characteristics of cranial neuralgias and for which there is no obvious cause.⁹ The diagnosis is possible if the facial pain is localized, present daily, and throughout all or most of the day and by definition, neurological and physical examination findings in persistent idiopathic facial pain should be normal. Both the incidence and pathophysiology of the condition are unknown, and it is seen primarily in older adults.⁴² The pain does not usually stay within the anatomical boundaries of the trigeminal nerve distribution. It may move from one part of the face to another between different consultations and other symptoms, such as ‘mucous moving’ in the sinuses, are often described. A number of patients have such completely fixed ideas about their condition that they will not be convinced otherwise, whatever the weight of evidence to the contrary.⁵ Pain is often disproportionately described in dramatic terms in conjunction with an excess of other unpleasant life events. Many of these patients have a history of other pain syndromes and their extensive records show little progress despite various medications and investigations. They have often undergone previous sinus or dental surgery and may be resentful about their treatment.

Significant psychological disturbance or a history of depression may exist with the suggestion that they are unable to function normally as a result of their pain. Some project a pessimistic view of treatment, almost giving the impression they do not wish to be rid of the pain that plays such a central role in their lives.

The management of such patients is almost always challenging and confrontation is nearly always counterproductive. A good starting point is to reassure the patient that you recognize that they have genuine pain and an empathic consultation with an explanation should be conducted. Drug treatment revolves around a gradual build-up to the higher analgesic and antidepressant levels of amitriptyline (75 to 100 mg) at night. Second-line treatment includes gabapentin and carbamazepine. Patients should sympathetically be made aware that psychological factors may play a role in their condition and referral to a clinical psychologist or psychiatrist may be helpful. Attempts have also been made to further separate idiopathic facial pain syndromes according to topographical criteria. Pain clearly localized in the eye (idiopathic ophthalmodynia) or in the nose (idiopathic rhinalgia) has been described.⁴³ Whether all such focal syndromes are topographic variants of persistent idiopathic facial pain or independent disorders remains a topic for discussion.

HISTORY TAKING IN FACIAL PAIN

In an effort to draw together the breadth of descriptive text provided in this chapter, an approach to taking a thorough and accurate history is now presented since this is the crux to making a correct diagnosis in a patient that presents with facial pain. It may not be possible to make a correct diagnosis at the first visit, particularly if the patient has seen a number of physicians previously and is emotionally charged. Retaking a history at a subsequent consultation in conjunction with the evidence provided in a symptom diary may further clarify the situation.

In attempting to make a diagnosis, it is helpful to broadly classify symptoms into sinogenic and non-sinogenic in aetiology. Sinus-related symptoms (Table 112.3), coupled with endoscopic evidence of disease, should be readily substantiated. Non-sinogenic causes can be broadly classified as primary headache disorders (migraine, tension and cluster), neuralgias, pain caused by tumours, and others (mid-facial segment pain, dental, analgesia-dependency and persistent idiopathic facial pain). It is useful to have a mental algorithm to plan questions and to use these to work through a diagnostic checklist of possible conditions.

- **Where is the pain and does it radiate anywhere?**

Asking the patient to localize pain can be extremely useful in differentiating sinogenic from other causes of pain, and may differ from information contained in the referral letter. Bilateral facial pain is commonly, although not exclusively, mid-facial segment pain. Migraine, cluster and other trigeminal autonomic headaches, and temporomandibular joint disorders tend to be unilateral. The manner in which the patient outlines

their pain, and the gestures used, can inform the examiner of the emotional significance of the symptom.

- **Is the pain continuous or intermittent?**
Sinogenic pain and migraine are unlikely to be continuous or present on a daily basis. Pain of this character is more likely to represent tension headache, mid-facial segment pain, analgesia-dependency headache or atypical facial pain. Constant and predominantly unilateral pain, particularly if it is progressive, may be due to a tumour and this possibility must be considered.
- **What is the character of the pain?**
Vascular pain tends to be throbbing in nature, with cluster headaches being particularly severe. Mid-facial segment pain, like tension headache, is often described as pressure or band-like pain. Trigeminal neuralgia may cause intense stabbing pain that is initiated by a trigger.
- **What precipitates or is associated with the pain?**
Sinogenic pain is associated with adverse rhinological symptoms, but should be differentiated from trigeminal autonomic symptoms. Migraine may have preceding aura and is often associated with nausea. Trigger factors, such as certain foods, withdrawal of stress and

sleep disruption, are well recognized. Cluster headaches are frequently triggered by alcohol and wake the patient. The pain of temporomandibular joint disorder is exacerbated by chewing, and that of trigeminal neuralgia and myofascial pain is provoked by trigger points.

- **What relieves the pain?**
Sinogenic facial pain almost always responds to medical treatments such as topical decongestion, either short or long term, and antibiotics. Patients with migraine will retreat to a quiet and darkened room to lie down, which helps them to cope with their symptoms. Although mid-facial segment pain may initially respond to simple analgesics, the benefit is usually short-lived.
- **What effect does the pain have on daily life?**
Patients with persistent idiopathic facial pain often describe their pain in dramatic detail as severe and unrelenting despite sleeping well and living a relatively normal life. In contrast, some patients with this condition are unable to work and blame the pain for a breakdown in a close relationship. Severe crippling pain that wakes the patient, often a man, is typical of cluster headache.

BEST CLINICAL PRACTICE

- ✓ A careful and meticulous history is key to accurate diagnosis of facial pain, acknowledging that most patients will not have sinogenic pain.
- ✓ Examination must include nasendoscopy to assess the sinus drainage pathways, lateral nasal wall and visible anterior skull base, particularly when the patient is either symptomatic or in pain. A normal endoscopic examination in such circumstances makes the diagnosis of sinogenic pain extremely unlikely.
- ✓ Plain sinus X-rays should not be used. Computed tomography should be reserved for cases of failed maximal medical therapy, complications of rhinosinusitis, or where there

is suspicion of malignancy. Non-pathological sinus mucosal thickening is common in asymptomatic patients and management based only on radiological findings, without clinical correlation, will result in unnecessary surgery.

- ✓ Non-sinogenic facial pain should be managed medically, with complementary therapies, using cognitive behavioural therapy and rarely, with surgery if decompression or nerve section is considered. Caution should be observed if consideration is given to offering endoscopic sinus surgery or nasal plastic surgery to manage facial pain.
- ✓ A multidisciplinary approach to managing chronic non-sinogenic facial pain offers the best outcome for the patient.

FUTURE RESEARCH

- ▶ Neural pathophysiology in rhinosinusitis remains poorly understood.
- ▶ Neural pathophysiology in non-sinogenic facial pain also remains poorly understood.
- ▶ Although the psychological aspects of facial pain are well recognized, well-designed epidemiological studies to assess the incidence of anxiety-depressive disorders in patients with facial pain do not exist. Understanding this association may help to drive forward targeted therapy in such individuals.
- ▶ Future studies should focus on investigation of the source of peripheral nociception, the role of descending pain modulation, and the development of animal models for headache and facial pain to support the pathophysiologic importance of central sensitization in these conditions.

KEY POINTS

- Fundamental to the accurate diagnosis of facial pain is a comprehensive and detailed history.
- Management of patients with chronic facial pain can be time-consuming and complex.
- Facial pain may be exacerbated by an underlying psychological predilection, such as stress, depression or anxiety, or by a litigious motivation.
- Surgery for facial pain is rarely beneficial and may, conversely, either exacerbate or cause *de novo* pain.
- Rhinosinusitis, unless acute or associated with complications, does not usually cause pain.
- Genuine sinogenic pain may be complicated by non-sinogenic pain of multifactorial aetiology.
- Normal clinical examination and radiology does not usually suggest rhinosinusitis and often does not warrant surgery.
- Recurrent acute sinusitis moderated by antibiotic therapy may be the exception.
- Incidental sinus mucosal thickening on computed tomography does not automatically indicate that facial pain is sinogenic in aetiology.
- Many headache disorders may have associated trigeminal autonomic symptoms such as lacrimation, nasal congestion and rhinorrhoea.
- Many patients with chronic facial pain that is not sinogenic in aetiology benefit from drugs to manage neuropathic pain.
- It is useful to manage patients with chronic facial pain in a multidisciplinary team with neurology, pain specialty, psychology, oculoplastic and neurosurgical colleagues.

SEARCH STRATEGY

Data in this chapter may be updated by a search on PubMed and Medline which will enable the reader to identify latest information on this condition using the following keywords: nasopharyngeal neoplasms, angiofibroma, adolescent, and child', supplemented by the author's personal bibliography.

INTRODUCTION

Juvenile angiofibroma (JA) is a unique tumour presenting almost exclusively in adolescent males. The tumour is rare, with an incidence of e.g. 0.4 cases per 1 million inhabitants per year in Denmark.¹ A higher incidence has been reported in Southern Europe and even more in Asia. Although tumour biology is still not completely understood, the knowledge about JAs is increasing and the tumour is well-defined clinically. Consideration of the clinical tumour characteristics is of utmost importance in the diagnosis and treatment of JAs.

Therapeutic options for JAs include surgery, radiotherapy and, in rare cases, chemotherapy. Tumour resection is the therapy of choice. Various surgical techniques have been described previously, ranging from endonasal surgery and mid-facial degloving to approaches using skin incisions, e.g. lateral rhinotomy or infratemporal approaches. At the current time, and in the hands of experienced sino-nasal surgeons, endoscopic resection has been proven to allow successful treatment of most JAs² based on a precise knowledge of the clinical findings.

CLINICAL FINDINGS

The tumour usually arises from the lateral wall of the posterior nasal cavity close to the sphenopalatine foramen and the pterygoid base (**Figure 113.1a**). Due to its early sub-mucosal expansion towards the nasopharynx, it has frequently been termed 'nasopharyngeal angiofibroma'. Due to this location nasal obstruction and nasal bleeding may

be symptoms presented by the adolescents. Although the tumour is histopathologically classified as a benign lesion, bony erosions of the pterygoid, the clivus and the sphenoid sinus floor are common hallmarks of JAs. Bony destruction of the sphenoid sinus floor is followed by tumour extension into the sphenoid sinus. Here the tumour may fill the sinus space almost completely without infiltrating the mucosa. Furthermore, the tumour may grow along the central skull base towards the foramen lacerum. In such cases, assessment should be made of the presence, or not, of tumour tissue posterior to the pterygoid plates.

It is important to consider that JAs spread along natural foramina and fissures. Tumour tissue may extend laterally through the sphenopalatine foramen into the pterygopalatine fossa and further into the infratemporal fossa. In this case, a widened sphenopalatine foramen and an anterior displacement of the posterior maxillary sinus wall are typical radiological findings (**Figure 113.1b**).

Finger-like tumour processes may be encountered in the infratemporal fossa. A further lateral extension or tumour growth beyond the maxillary sinus will present as facial swelling. The orbit may be reached via the inferior orbital fissure causing proptosis and/or optic nerve compression with visual disturbance. Intra-cranial tumour spread is observed in advanced stages mainly through the roof of the infratemporal fossa and in some cases via the superior orbital fissure. In cases of intra-cranial tumour growth, JAs are mainly located in the extradural space. Dural infiltration or even brain involvement are rare events.

Blood supply of this highly vascular tumour needs to be evaluated carefully in order to diagnose and treat

Figure 113.1 (a) Endoscopic view of a juvenile angiofibroma (JA) in the left posterior nasal cavity (1 = nasal septum, 2 = tumour, 3 = inferior turbinate). (b) MRI of a juvenile angiofibroma (arrows) after application of contrast medium showing an enlarged sphenopalatine foramen (black arrows) and anterior displacement of the posterior maxillary sinus wall (red arrow). (c) Staining of a juvenile angiofibroma (JA) with antibodies against laminin (vascular wall, green) and the endothelial cell marker CD31 (red) demonstrates irregularly shaped vessels lined by endothelial cells only (*) in the vicinity to vessels with a regular vascular wall architecture (**).

JAs successfully. The diagnosis is based on the typical clinical and radiological findings.³ Tumour biopsy should be avoided due to the risk of severe bleeding. In its early stages, the tumour is supplied by the sphenopalatine and maxillary arteries. In advanced stages, further branches of the external carotid artery (ECA), such as the ascending pharyngeal artery, contribute to tumour blood supply. Besides the internal carotid arteries (ICAs), the vertebral arteries have to be considered as additional feeders, especially in large JAs. In view of this, a careful angiographic evaluation of ipsilateral and contralateral ECAs and ICAs is strongly recommended in all JAs, and should be accompanied by an examination of both vertebral arteries in advanced tumour stages. Pre-operative super-selective embolization of this highly vascularized tumour has attracted great attention and is recommended by most authors. Some surgeons do not ask for pre-operative embolization as they close the feeding vessels before tumour removal and have found it wise to detect possible tumour remnants by bleeding, as well as to avoid site effects of embolization e.g. brain infarction. In addition, a cell saver can be used during surgery to avoid allogenic blood donation. As well as defining the tumour feeders in JAs, the vascular tumour architecture deserves special attention, especially as the surgeon is able to reduce blood loss by respecting the unique structure of JAs.

TISSUE ARCHITECTURE

JAs are benign fibrovascular tumours with characteristic irregularly-shaped vessels, which may be lined by endothelial cells only (Figure 113.1c) or show an incomplete vascular wall architecture. Therefore, the surgeon is faced with profuse bleeding when opening these non-contractible pathological vessels during dissection of the tumour. The extreme variability in the amount of fibrous tissue and vessel density within JAs is of outstanding importance for the surgeon. The highest density of vessels, in particular those with the characteristic irregular shape, is found below a pseudocapsule at the tumour surface. Thus, the surgeon should always dissect along the pseudocapsule in order to

avoid severe bleeding. Towards the centre of the tumour, the amount of fibrous tissue increases, while vessel density decreases. Based on the clinical findings and the specific vascular architecture, JAs have been defined as vascular malformations rather than true neoplasms.⁴ Recently published genetic and molecular findings have supported this theory.⁵

JUVENILE ANGIOFIBROMA AND THE FIRST BRANCHIAL ARCH ARTERY

It has been proposed that the tumour origin is based on an incomplete regression of the first branchial arch artery.⁶ This theory is especially attractive, as it is able to explain different aspects of JAs:

Firstly, during embryological development, the first branchial arch artery finally recedes close to the pterygoid base and sphenopalatine foramen regions. Secondly, vascular remnants of this artery are incorporated into the sphenopalatine and maxillary arteries themselves. Thus, both the proximity of tumour origin to the sphenopalatine foramen and its main blood supply from the sphenopalatine and maxillary arteries in early stages of JAs can be explained by the 'branchial arch artery' theory. The fact that this embryological vessel is connected to the C4-segment of the ICA deserves special attention in this context: persistent vascular remnants of the first branchial arch artery contacting the ICA are able to account for the observation of a vascular supply from the ICA, despite an anatomical distance between this vessel and the JA. Furthermore, the 'branchial arch artery' theory elucidates the common finding of residual tumour at the pterygoid base and clivus and explains why it is necessary to drill the bone in this specific location in order to remove tumour remnants at the site of origin.^{2,7}

ENDOSCOPIC RESECTIN: SURGICAL CONSIDERATIONS

Endoscopic resection of JAs follows tumour management principles by keeping the specific characteristics of this

unique tumour in mind. Basically, the strategy of endoscopic resection takes the following considerations into account:

1. Opening of the maxillary sinus and exposure of its posterior wall are performed early during surgery. The size of the tumour dictates the size of the medial maxillectomy. The bony posterior wall of the maxillary sinus is removed with 'through cutting' punches or drills avoiding trauma to the periosteum in the pterygopalatine fossa before resection of the bone is completed. Following incision of the periosteum, the sphenopalatine and maxillary arteries are identified and clipped or coagulated. Early control of the main feeding vessel is of great value to assist further tumour resection. An alternative in early JAs is to push the tumour gently in a medial direction out of the pterygopalatine and infratemporal fossae and to identify the main feeding vessel by this manoeuvre. In cases where an extended access to the maxillary sinus does not allow exposure of the lateral tumour border within the infratemporal fossa in advanced JAs, the tumour can be pushed medially with a finger placed externally at the lateral border of the maxillary sinus below the jaw.
2. Resection of the posterior nasal septum is advised to widen the access in endoscopic tumour removal and to define tumour margins at the nasal septum.
3. The anterior sphenoid sinus wall is removed in order to expose the tumour within the sphenoid sinus. For this purpose, a bilateral opening of the sphenoid sinus is usually necessary.
4. Finally, the tumour is dissected directly off the pterygoid base and pterygoid canal regions and the clivus. Troublesome venous bleeding from the bone can be managed at this stage with drilling, chemical haemostatic agents or fine endosurgical diathermy.
5. It is of utmost importance to drill at the pterygoid base and the clivus at the end of surgery in order to avoid residual tumour.
6. Endoscopic dissection should always follow the pseudocapsule in order to avoid injury of the tumour at the surface. Finger-like extensions of the tumour can be gently pulled out along the pseudocapsule

INDICATION AND LIMITATION OF ENDOSCOPIC SURGERY

Endoscopic resection of JAs using the nostrils as natural openings is an ideal option to treat the majority of tumours successfully. Nevertheless, the endonasal approach should not be applied in a dogmatic sense. It depends on the personal experience of the surgeon to determine whether endoscopic tumour resection is appropriate in a particular JA. Each surgeon should feel free to convert to an open approach during surgery if the endoscopic resection cannot be performed in a particular situation. From the author's point of view, indications and limitations of endoscopic JA surgery will change for every surgeon with increasing experience in this field.

In general, the endoscopic resection can be used to remove JAs limited to the nasal cavity, the nasopharynx, the sphenoid sinus and the pterygopalatine fossa. With increasing experience, a surgeon might be able to perform an endoscopic resection of JAs which extend into the infratemporal fossa and to the space posterior to the pterygoid plate. With increasing experience, a surgeon will be able to remove tumour tissue from the orbit and the parasellar region in primary surgery. Generally, an endoscopic tumour resection is not recommended in situations of broad skull base infiltration, extensive blood supply from the internal carotid artery, encasement of the internal carotid artery and brain infiltration.²

Due to the importance of preserving neurovascular function, the surgeon may be forced to leave residual tumour in areas around the optic nerve, the cavernous sinus, the internal carotid artery and the dura, independent of the surgical approach selected. In cases of revision surgery for residual tumour, the surgeon should be very careful about selecting an endonasal approach, as the limitations for endoscopic approaches are different compared to primary surgery. If the residual tumour is potentially adherent by fibrosis to important neurovascular structures, it may not be possible to tease out tumour tissue as one can in primary surgery. Careful radiological follow-up of residual tumour adjacent to delicate neurovascular structures assists in monitoring potential tumour growth. Nicolai has demonstrated that residual tumour does not necessarily expand when assessed on serial MR imaging.²

BEST CLINICAL PRACTICE

- ✓ Tumour biopsy should be avoided due to the risk of severe bleeding.
- ✓ The surgeon should always dissect along the pseudocapsule in order to avoid severe bleeding.
- ✓ The endoscopic resection can be used to remove JAs limited to the nasal cavity, the nasopharynx, the sphenoid sinus and the pterygopalatine fossa.
- ✓ An endoscopic tumour resection is not recommended in situations of broad skull base infiltration, extensive blood supply from the internal carotid artery, encasement of the internal carotid artery and brain infiltration.
- ✓ Juvenile angiofibromas can be mobilized along the pseudocapsule, but are firmly fixed at the clivus and the pterygoid base.
- ✓ Dissect strictly along the pseudocapsule and avoid entering the tumour surface, as this will result in severe bleeding due to the high-density of irregularly-shaped vessels at the surface.
- ✓ Finger-like tumour extensions can be teased out gently in most cases during primary surgery.
- ✓ Knowledge of the tumour arterial feeders is essential for the surgeon, as these need to be controlled during tumour resection.

- ✓ Always check carefully for tumour extension posterior to the pterygoid plate, as residual tumour can easily be left at this point.
- ✓ Drilling of the pterygoid base and the clivus is of the utmost importance in order to avoid residual tumour at the site of tumour origin.
- ✓ Endoscopic resection has been found to be a valuable alternative to external approaches for the successful management of most juvenile angiofibromas.
- ✓ With increasing experience, endoscopic management allows the surgeon not only to resect small, but also intermediate JAs.

KEY POINTS

- At the current time, and in the hands of experienced sino-nasal surgeons, endoscopic resection has been proven to allow successful treatment of most JAs² based on a precise knowledge of the clinical findings.
- It is important to consider that JAs spread along natural foramina and fissures.
- The surgeon may be forced to leave residual tumour in areas around the optic nerve, the cavernous sinus, the internal carotid artery and the dura, independent of the surgical approach selected.
- Tumour origin is close to the sphenopalatine foramen and the pterygoid canal; bony destruction at the pterygoid base and the clivus is frequently observed.
- Widening of the sphenoplatine foramen and anterior displacement of the posterior maxillary sinus wall are typical radiological findings.
- Tumour spread takes place along natural foramina and fissures.
- The maxillary/sphenopalatine arteries are the main tumour feeders. However, the surgeon should always bear in mind that further tumour feeders may arise from the internal carotid artery.
- Tumour diagnosis is based on the typical signs on CT, MRI and angiography. A biopsy should not be performed due to the risk of severe bleeding.
- Irregularly-shaped vascular spaces, which may have an endothelial lining only, embedded in a fibrous stroma are the reason for potential profuse tumour bleeding.
- JAs are proposed to be vascular malformations originating from vascular remnants of the first branchial arch.

ACKNOWLEDGEMENTS

The author thanks Julia Długaiczek, MD for a critical reading of the manuscript and valuable suggestions.

SEARCH STRATEGY

This chapter is based on and supported by a detailed search strategy encompassing PubMed, Medline and the Cochrane Library. Searches utilized a combination of keywords associated with the endoscopic management of sinonasal tumours. These keywords included but were not limited to: paranasal sinus, endoscopy, sinonasal tumours, benign sinus lesions, malignant sinus lesions, endoscopic field control, endoscopic access, image guidance, vascular, orbital and intra-cranial extension and injury.

INTRODUCTION

With the advent of the endoscope and its early application to the management of inflammatory sinonasal conditions, surgeons identified significant advantages of endoscopic endonasal surgery over open approaches. Increasing endoscopic experience and advances in instrumentation and imaging technology have led to a natural evolution and expansion of endoscopic endonasal surgery to now commonly include the management of benign and malignant sinonasal tumours. The scope of this chapter is to provide the reader with a general overview of the approach to the endoscopic management of sinonasal tumours. Tumour specific management can be found in other chapters dedicated to the individual pathologies.

EVIDENCE BASE FOR ENDOSCOPIC MANAGEMENT OF SINONASAL TUMOURS

As surgical experience with the endoscopic resection of sinonasal tumours increases, so has the body of evidence supporting its role.¹ Systematic reviews and large case series now support the endoscopic approach as a favourable treatment option for the management of benign tumours, including most cases of sinonasal inverted papilloma,²⁻⁵ juvenile nasal angiofibroma⁶⁻⁸ and osseous tumours such as osteomas,^{9,10} ossifying fibromas¹¹ and fibrous dysplasia.^{12,13}

The application of endonasal endoscopic techniques to the management of malignant sinonasal tumours has been more controversial.¹⁴⁻¹⁶ Early concerns raised included the violation of the oncologic principle of en bloc resection, the ability to deal with vascular complications and the difficulty associated with defect reconstruction. Evidence is now emerging however that refutes such concerns, with large case series showing reduced morbidity,¹⁷ improved vascular control,¹⁸ better quality of life outcomes¹⁹ and equivalent survival outcomes to open approaches. These findings have led to the support of the endoscopic approach for the management of sinonasal tumours by a recently published European Position Paper.²⁰ Malignant pathologies successfully treated via endoscopic techniques include squamous cell carcinoma, adenoid cystic carcinoma, adenocarcinoma,esthesioneuroblastoma, sinonasal undifferentiated carcinoma and sinonasal melanoma.^{15,17-24}

SINONASAL TUMOUR EPIDEMIOLOGY

Tumours involving the sinonasal cavity are considered rare entities. They can arise from any of the structures comprising the paranasal sinuses or can involve the sinuses by direct extension from adjacent structures. Consequently, these tumours encompass a large and diverse group of lesions (**Table 114.1**). The most commonly reported benign lesion is a sinonasal osteoma, with a radiological incidence of 1%. Ossifying fibroma, fibrous dysplasia and inverted papilloma are the next most commonly reported

benign lesions of the paranasal sinuses.²⁰ Sinonasal malignancies are less common with an estimated incidence of 0.5–1/100 000.²⁵ They account for around 1% of all malignancies and 3–5% of all head and neck cancers.^{20, 23} Primary epithelial tumours are the most common type of sinonasal malignant tumour, with squamous cell carcinoma the most common subtype followed by adenoid cystic carcinoma and adenocarcinoma. Of the less common non-epithelial tumours, lymphoma is the most commonly reported tumour.²⁰

DIAGNOSIS AND PRE-OPERATIVE PLANNING

Evaluation of sinonasal masses should commence with a complete history and physical examination. In addition to a focused otorhinological examination, a complete cranial nerve assessment should be performed on all these patients. [Table 114.2](#) highlights concerning features that should be looked for on clinical examination.

Endoscopy

Nasal endoscopy forms an integral part of the rhinological assessment. Although large masses may create difficulty with respect to performing a complete endoscopic assessment, it is important to obtain as much information pre-operatively as possible. Documentation of the likely site of origin, as well as involvement or destruction of the septum, lacrimal system, orbit, palate, nasopharynx and

skull base is important and may provide useful information regarding the likely pathology, endoscopic resectability and access or approach required. Although biopsy may be performed at the time of endoscopic assessment, we recommend review of the relevant radiological investigation. This may avoid catastrophic complications including torrential bleeding or CSF leak ([Figure 114.1](#)).

Radiology

Radiological investigations in the form of computed tomography (CT) and magnetic resonance imaging (MRI) are critical in management of sinonasal tumours. Imaging not only helps characterize the tumour and assess the local and regional extension but also aids in the planning of surgery and adjuvant treatments. High resolution CT scans with contrast and slice thickness of 1 mm should be performed in all patients. CT scan permits superior assessment of osseous margins of the skull base and sinus walls which are less effectively demonstrated on MRI. Specific features to assess on CT scan and their clinical implications are shown in [Table 114.3](#).

MRI provides inherently superior soft-tissue resolution and multiplanar capabilities, rendering it superior for the assessment of soft-tissue masses and extension of infectious or malignant processes outside the confines of the paranasal sinuses. MRI facilitates the differentiation of retained secretions and haemorrhage from the tumour mass and allows a better appreciation of the tumour margin and its interface with normal tissue and critical structures. MRI of the paranasal sinuses must include

TABLE 114.2 Concerning features on clinical examination

Clinical finding	Reason for concern
Conductive hearing loss/Middle ear effusion	Obstruction/invasion of eustachian tube
Visual change/loss Visual field change Diplopia/Ophthalmoplegia Pain on eye movement Chemosis/Orbital displacement	Optic nerve involvement Intra-cranial extension, optic chiasm compression Involvement of intra-orbital contents
Clear rhinorrhea	Dural/Intra-cranial involvement with CSF leak
Facial paraesthesia	Compression/invasion of the maxillary or infraorbital nerve
Loose teeth Dental paraesthesia	Invasion of the alveolar process and dental roots
Facial asymmetry	Possible involvement of facial soft tissues
Oronasal or Oroantral fistula	Erosion of the nasal floor or maxillary sinus floor
Palpable cervical nodal disease	Possible metastatic spread
Reduced neck range of motion	Paraspinal muscle involvement

Figure 114.1 Highlights the importance of obtaining imaging prior to the biopsy of a nasal lesion. **(a)** Endoscopic Image of left juvenile nasal angiofibroma resembling a simple benign nasal polyp in the sphenoidal recess. **(b)** Coronal CT scan of left juvenile nasal angiofibroma showing characteristic expansion of the sphenopalatine foramen and **(c)** an MRI T1 with gadolinium contrast demonstrating the extensive vascularity of the juvenile nasal angiofibroma with the presence of flow voids as well. **(d)** An endoscopic image of a large left sided encephalocele presenting a left sided nasal mass. **(e)** CT and **(f)** MRI coronal images of the left encephalocele showing the clear intra-cranial origin and skull base defect. Although the pathology is suspected from the CT, MRI is needed to confirm the diagnosis prior to surgery.

high resolution (1 mm) T1- and T2-weighted images of the sinonasal cavity, orbit, skull base and the adjacent intracranial compartment. Understanding the advantage of each sequence and a systematic approach to the evaluation of the images can be extremely useful to the surgeon

in understanding the characteristics of the tumour. The use of gadolinium chelate contrast agents with fat saturation increases the sensitivity of the contrast enhancement, thereby improving the detection of local disease extent and the presence of disease beyond the paranasal sinuses such

TABLE 114.3 Radiological features on CT and their possible implications

Feature	Potential clinical implication
ORBIT	
Breach of lamina papyracea Loss of orbital fat planes Involvement of extra-ocular muscles	May indicate involvement of orbit and the need for orbital exenteration.
SEPTUM	
Erosion of septum	Important implications for surgical access and repair. Lesions crossing midline will require a septectomy and binasal approach. Gross septal involvement may preclude the use of the nasoseptal flap.
SKULL BASE	
Asymmetrical or low lying Position of anterior ethmoid arteries Skull base defect	Increase risk of inadvertent entry and CSF leak during surgery Mesentery suspended arteries are at increased risk of injury Suggestive of intra-cranial extension of sinonasal pathology or intra-nasal extension of intra-cranial pathology
SPHENOID SINUS	
Extent of pneumatization Onodi cells Location of sphenoid septations	Laterally pneumatized sinuses may place the carotid at risk May contain optic nerve and be confused with sphenoid sinus Septations may be closely related to carotid artery and optic nerve, requiring great care when removing.
PARANASAL SINUS	
Osteitic changes Widened bony foramina Tumour calcification	Possible site of tumour origin Perineural invasion of tumour Nerve sheath tumour See to varying degrees with aesthesioneuroblastoma, chondroma, chondrosarcoma, osteoma, ossifying fibroma and osteosarcoma
Expansion of paranasal sinus / fossae	Tends to indicate the presence of a mass within the space

**Figure 114.2 Coronal CT and MRI of a sinonasal tumour.**

Although the CT would suggest involvement of the extra-ocular muscles, the MRI demonstrates clear preservation of the fat plane. The MRI also facilitates a differentiation of tumour from retained secretions seen in the maxillary sinus. These images highlight the importance of obtaining both a CT and MRI for skull base tumours.

as dural involvement or perineural spread. **Figure 114.2** demonstrates the complementary features of CT and MRI in the work-up of skull base tumours.

Clinical Positron Emission Tomography (PET) relies on the preferential uptake of 18-fluorodeoxyglucose (18-FDG) by tumour cells that exhibit a higher density of GLUT1 glucose transporters. When combined with CT it can improve tumour localization, although the increased 18-FDG avidity in areas of sinonasal inflammation or infection can confound its utility in the paranasal sinuses.

In the evaluation of these tumours its usefulness is predominantly confined to the detection of distant metastases.

Biopsy

Pre-operative endoscopic-guided biopsies should be taken prior to performing the definitive surgical procedure. Biopsies should typically be performed after reviewing the relevant radiology to exclude vascular lesions or prolapsed meningo-encephaloceles. Whenever possible,

multiple deep biopsies from the centre of the tumour should be taken to gain a representative sample and avoid sampling the non-specific and necrotic superficial aspects of the tumour. Tissue should always be sent both fresh, and in formalin fixative, to allow both routine histopathology and flow cytometry. Tumour histopathology will help direct management and intra-operative decision-making.

Multidisciplinary planning meetings

All patients with malignant and complex pathology should be presented to a multidisciplinary team, comprising of surgeons, radiologists, medical and radiation oncologists and allied health professionals. Treatment recommendations made by the team should not only take into account the pathology of the tumour but also the age, health and functional status of the patients, as well as their level of home support. Although complete oncological clearance is the ultimate goal of any treatment, this may not be possible without causing significant morbidity to the patient. Patients and families should be informed of all the different treatment options discussed at tumour board meetings to enable informed consent to be made.

PRINCIPLES OF ENDOSCOPIC MANAGEMENT OF SINONASAL TUMOURS

Case selection

As experience with endoscopic cranial base surgery increases, so have the limits of what is considered endoscopically resectable. Dura, the olfactory bulbs and lamina papyracea can all be safely resected as can the entire anterior cranial base from the cribriform plate to the planum sphenoidale. Transclival approaches allow resection of tumours from the nasopharynx, clivus and the odontoid process, with the inferior limit of endoscopic resectability considered the nasopalatine line.²⁶ Endoscopic medial maxillectomy provides access to the pterygopalatine and infratemporal fossa, while the petrous temporal bone, Meckel's cave and middle cranial fossa can be accessed via the transpterygoid approach. Relative contraindications to an entirely endoscopic approach include the involvement of skin and subcutaneous tissue, the nasolacrimal sac, carotid artery, the anterior table of the frontal sinus and extensive dural and brain involvement (Figure 114.3). Like all forms of surgery, endoscopic endonasal surgery is associated with a steep learning curve. It is recommended that surgeons considering performing oncological surgery first become proficient in the surgical management of sinonasal inflammatory disease, before progressing to benign and eventually malignant tumours. Surgeons should use simpler cases to improve their familiarity with the endoscopic anatomy as well as the ergonomics involved in endoscopic surgery. The latter takes on greater importance when a second surgeon becomes involved.

Figure 114.3 Demonstrates relative contraindications to a purely endoscopic resection. (a) shows gross intra-cranial involvement necessitating a combined endoscopic and anterior craniofacial approach; (b) shows frank invasion of the extra-ocular muscles with loss of preservation of the orbital fat planes and (c) shows involvement of the lacrimal apparatus and the anterior soft tissue structures.

Optimizing the surgical field

Poor visualization due to excessive bleeding has been shown to be associated with an increased risk of intra-operative complications.^{27–30} Strategies to improve the surgical field include proper patient positioning, regulation of haemodynamic parameters, adequate topicalization and the use of electrocautery. Studies suggest that positioning a patient in 15–20° of reverse Trendelenberg can increase venous drainage without compromising cerebral perfusion. Similarly, the use of total intravenous anaesthesia to maintain a mean arterial blood pressure of approximately 60mmHg and a pulse rate below 70bpm has also been shown to decrease surgical bleeding without affecting cerebral blood flow, provided a patient does not have underlying cardiovascular disease. Pre-operative topicalization of the nasal cavity with local anaesthetic infiltration and patties soaked in vasoconstricting agents is also useful as is the intra-operative use of haemostatic agents such as Gelfoam® and Floseal®, along with the use of warm saline irrigations and cautery.³⁰ Although suction monopolar cautery is extremely useful in tumour debulking, it should be avoided near the skull base and orbit due to the theoretical risk of heat and electrical current transmission to vital structures.

Image guidance technology

Image guidance technology is considered a useful aid when performing endoscopic skull base surgery. It provides the surgeon with enhanced anatomical localization and the current literature suggests that its use may decrease surgical disorientation, improve surgical completeness and potentially lower complication rates.^{31, 32} The incorporation of CT/MRI fusion is also thought to provide valuable information with regard to the extent of tumour resection and the clarification of boundaries between the tumour and normal adjacent soft tissues and neurovascular structures.³³

Principles of oncologic resection

The complete resection of a tumour with as little morbidity as possible is the primary goal of any oncological surgery. Although traditional surgical paradigm dictates that this be performed in an en bloc manner, the anatomical confines of the nasal cavity prevent this for the vast majority of endoscopic tumour resections. Fortunately, despite filling the nasal cavity, many sinonasal tumours have a small, well-defined area of origin or tissue invasion. Provided en bloc excision of this site is performed, ideally with a cuff of normal surrounding tissue, the remainder of the tumour can be selectively debulked down to attachment points, without compromising the completeness of resection or increasing the risk of recurrence.³⁴

Surgical access techniques

Prior to debulking the tumour, the initial steps of the procedure are aimed at improving surgical access. The purpose of this is twofold. Firstly it will allow the surgeon more room for instrumentation and improve the vectors needed

to approach the peripheral aspects of the tumour and secondly, it will allow early identification of tumour-free zones that can serve as margins or the limits of the resection.

IMPROVING LATERAL ACCESS

Lateral sinonasal tumours, including those involving the maxillary sinus and pterygopalatine or infratemporal fossae have historically proven difficult to access endoscopically. The introduction of angled endoscopes and instrumentation as well as the development of various approaches has meant that many of these tumours can now be resected entirely endoscopically. To access such tumours, surgeons must not only consider the lateral extent of these tumours, but the likely vectors required for instrumentation. Tumours confined to the nasal cavity with no extension beyond the infra-orbital nerve can usually be managed through the ipsilateral nostril, while those extending outside this zone will require additional lateral access. Lateral access can be improved through a transeptal approach often combined with removing varying amounts of the medial maxillary wall.

Transeptal approach

Although various transeptal approaches have been described, they are all variations of the concept of non-opposing septal incisions described by Douglas et al.³⁵ This procedure allows use of the contralateral nostril for instruments or endoscopes thereby increasing the horizontal plane of access. The additional advantage it confers is that it allows a second surgeon to be involved to provide retraction and additional instrumentation when required. Although septal perforation is a risk of this approach, it can be reduced by preserving rather than resecting septal cartilage, and ensuring that the mucosal incisions on either side of the septum are not opposing (Figure 114.4).

Figure 114.4 This image demonstrates the utility of the trans-septal approach. Here a patient with a Juvenile Nasal Angiofibroma has the mass manipulated via an instrument in the contralateral nostril placed through the transeptal incision (arrow) and the ipsilateral nostril.

Transmaxillary approaches

Surgery for lesions involving the maxillary sinus typically commences by performing a routine uncinectomy to identify the natural maxillary ostium. Depending on the size and location of the tumour, the antrostomy can then be enlarged accordingly. Posteriorly based lesions, including those extending into the pterygopalatine fossa, located medial to the infra-orbital nerve can usually be accessed with a mega-antrostomy. Lesions located lateral to the infra-orbital nerve or those involving the infratemporal fossa require more extensive resection of the medial maxillary wall. A modified medial maxillectomy allows preservation of the lacrimal duct by extending the mega-antrostomy inferiorly below Hasner's valve to the piriform aperture. This approach allows inferiolateral access to the maxillary sinus (Figure 114.5).

For more superiorly based lesions, a total medial maxillectomy is needed with transection of the nasolacrimal duct. Although this approach confers an inherent risk of epiphoria, this can be minimized with clean sharp transection of the duct followed by probing and splaying the duct open. The anterolateral area of the maxillary sinus

is considered the most difficult to access endoscopically. The pre-lacrimal approach as described by Zhou et al³⁶ is a modification of the Denker's procedure, that allows direct access to this area, with reduced alar retraction, collapse and risk to the canine root. In this procedure, following reflection of the soft tissues and mucosa of the anterior aspect of the inferior turbinate, osteotomies are used to remove a small buttress of bone at the junction of the antero-medial walls of the maxillary sinus, adjacent to the pre-lacrimal recess, with the nasolacrimal duct visualized and left intact. Through this window, the surgeon has direct access to the entire maxillary sinus including the anterior and lateral walls. Tumours can be carefully removed from these regions and sites of origin/attachment can be directly addressed (Figure 114.6).

IMPROVING POSTERIOR ACCESS

Binasal access provides the key to addressing tumours involving the nasopharynx, sphenoid sinus, pituitary fossa and the infratemporal and pterygopalatine fossae. The creation of an adequately sized posterior septectomy affords such access. Through this septal window,

Figure 114.5 (a) Coronal CT of the sinuses showing a right maxillary inverted papilloma arising from the roof of the maxillary sinus medial to the infra-orbital nerve. The area of osteitis often indicates the site of origin; (b and c) demonstrate the site of origin of the inverted papilloma prior to (b) and after (c) it has been removed, drilled down and cauterized to reduce the chance of recurrence. The black arrow indicates the infraorbital nerve.

Figure 114.6 (a) and (b) The CT scan shows the anterolateral origin of a left maxillary inverted papilloma. Note the osteitic changes at the site of origin (arrow). Despite a previous antrostomy (dotted arrow), the site of origin could not be addressed hence its recurrence; (c) and (d) Endoscopic views through the pre-lacrimal approach highlighting excellent visualization and access to the anterolateral aspects of the maxillary sinus. The nasolacrimal duct can be visualized and protected reducing the risk of post-operative epiphoria; (e) demonstrates the approximation of the inferior turbinate back to the lateral nasal wall. This technique had the advantage over the medial maxillectomy of preserving the inferior turbinate, thereby resulting in less post-operative crusting.

a two-surgeon team can utilize an endoscope and up to three surgical instruments to reach the aforementioned posterior regions.

Posterior septectomy

Before performing a posterior septectomy, the surgeon must consider whether a nasoseptal flap will be required for reconstruction. This flap is based on the posterior septal artery, a branch of the sphenopalatine artery, and runs just below the sphenoid ostium to supply the majority of the septal mucosa. If a CSF leak is anticipated, the nasoseptal flap is typically raised before performing the septectomy and then stored either in the nasopharynx or in the maxillary sinus. If a leak is not anticipated, the surgeon must still take care to preserve the pedicle in case a flap may be required later. At this stage, the sphenoid ostia are located on either side and enlarged superiorly to the skull base and laterally to the lamina papyracea. Wide exposure

allows visualization of the bony landmarks of the internal carotid artery and optic nerves and avoids inadvertent injury. With this exposure, the surgeon can then perform an appropriately-sized septectomy depending on the access required. For sellar lesions, a limited septectomy may be all that is necessary and this typically involves removing the posterior and inferior aspect of the septum with powered instrumentation or retrograde forceps. The septal window should extend anteriorly enough to enable complete visualization of the entire surgical field and limit contralateral instrument clash. An even larger septectomy will be required for surgery involving the middle cranial fossa, clivus and infratemporal fossae. Where possible, surgeons should attempt to preserve at least 1.5 cm of postero-superior septal mucosa in the region of the olfactory cleft for preservation of smell and taste (Figure 114.7). Obviously in the case of malignant tumours, surgical clearance of the tumour takes precedence but patients

Figure 114.7 (a) Shows an endoscopic view of the nasal cavity and septum via the transthmoid approach. Highlighted in yellow is the olfactory strip that needs to be preserved when harvesting the flap. The red dotted line is the area of the vascular pedicle supplying the flap. This should not be violated; (b) demonstrates the right nasoseptal flap reflected into the post nasal space. (c) shows a skull base defect of the anterior cranial fossa following resection of an aesthesioneuroblastoma. The white arrow represents the edge of the skull base defect and (d) shows reconstruction of the defect with a large nasoseptal flap.

should be warned pre-operatively of the possible loss of function of these senses.

IMPROVING SUPERIOR ACCESS

All aspects of the anterior skull base can be accessed endoscopically allowing the complete endoscopic resection of sinonasal tumours with intra-cranial extension. The anterior ethmoid artery provides a useful landmark when planning surgery for these lesions. If the intra-cranial component lies posterior to these vessels, targeted resection of the posterior skull base can usually provide adequate access for tumour removal. If however, the intra-cranial extent of the tumour lies anterior to the level of the anterior ethmoid arteries, an endoscopic modified lothrop procedure (EMLP) will typically be required to access the anterior aspect of the tumour. The EMLP also improves lateral access to lesions within the frontal sinus. Through a superior septectomy, surgeons can use the contralateral nostril to reach lesions well beyond the frontal recess and even beyond the mid-pupillary line. This not only avoids the need for external incisions, but also increases the ease of post-operative surveillance. The surgical site can be directly visualized endoscopically, reducing the need for as frequent imaging.

Tumour resection

Once appropriate access has been created, the tumour can then be debulked in a controlled manner down to its site of attachment. Debulking can be performed using various instruments including powered micro-debriders and radio-frequency ablation wands. Specimen traps should be applied to instruments, so that all of the tumour removed from the patient can be sent for histopathological analysis. Following debulking of the tumour, the site of attachment is usually visualized. The management of this region depends on numerous factors, including the age and functional state of the patient, the histology of the tumour and the location and extent of the attachment. Where possible, attainment of clear surgical margins should be attempted. Frozen sections taken from the margins of the tumour field have been shown to be reliable for ensuring complete resection of most sinonasal tumours, with the exception of mucosal melanoma and adenoid cystic tumours.³⁷ In addition to these frozen specimens, surgical margin specimens should also be sent in formalin fixative for formal histopathological analysis. Careful orientation of specimens and close discussion with the histopathologists should be undertaken for all specimens, to aid in the generation of an accurate histological report and to avoid errors such as the air-tumour interface being erroneously reported as a positive margin.

Whilst the ultimate goal of surgery is a complete oncological resection of the tumour, the nature of the tumour and the characteristics of the individual patient may, on occasion, necessitate a degree of compromise. Benign tumours may be appropriate for sub-total resections with post-operative surveillance where there is significant risk to critical structures or in the elderly frail population.

Malignant tumours may also be palliated in this fashion while limiting morbidity from the resection.

Reconstruction

Sinonasal tumour resection may result in a defect in the skull base. If the dura remains intact, and the defect is small, it may be left alone, but large defects and all breaches of the dura should be repaired to avoid meningo-encephalocele formation and ascending meningitis.

Small defects (<1cm) in the dura mater are typically amenable to a 'Bath Plug' type repair as described by Wormald.³⁸ Larger defects, however, will usually require multi-layer closure with an underlay of autogenic material such as tensor fascia lata harvested from the thigh or dural substitutes (e.g. Duragen®, Integra Life Sciences, Plainsboro, New Jersey USA), followed by an overlay which may be a free-mucosal graft or in most cases a vascularized flap. The most commonly employed vascularized flap is the Hadad nasoseptal flap,³⁹ described in the previous section, but inferior and middle turbinate flaps have also been successfully used. For very large defects (>3 cm), reinforcement of the repair site with a rigid buttress of septal cartilage or titanium mesh is also thought necessary, prior to coverage with the mucosal flap, to minimize the risk of encephalocele formation.

Complications of endoscopic techniques

Endoscopic approaches to sinonasal tumours share the minor and major complications seen in endoscopic sinus surgery. Surgeons who wish to perform endoscopic skull base surgery must make themselves familiar with these complications and their management. A thorough understanding of the surgical and radiological anatomy of the sinuses and skull base and the attendance of skull base courses may help to minimize their frequency and severity. Of all the complications, major vascular injury is one of the most serious and anxiety provoking. Through animal wet labs, Valentine and Wormald have developed and evaluated several techniques for controlling such injuries, including the use of the muscle patch.⁴⁰ They showed that the application of crushed muscle to the site of a major arterial bleed could primarily control the bleed in all cases while maintaining vascular patency. This led to reduced blood loss and overall improved survival.⁴¹ A follow-up study by the same group highlighted the benefits of surgeons undergoing training in this technique before undertaking complex skull base cases.⁴¹

POST-OPERATIVE CARE AND TUMOUR SURVEILLANCE

Once the initial perioperative period is complete, the role of the surgeon moves to one of surveillance for recurrence. Surveillance is performed with regular endoscopic examinations and serial imaging. Performance of an early post-operative CT or MRI scan within 3–6 months post-surgery provides a baseline that can be referenced,

should the patient develop clinical features suggestive of recurrence.

CONCLUSION

Published data now support the use of endoscopic techniques for the management of appropriately selected

benign and malignant tumours of the paranasal sinuses. The decision to undertake such a resection should ultimately be made by a multidisciplinary team that has considered the patient, the pathology in question and the skill set of the endoscopic skull base team. With appropriate training and surgical planning, complications can be minimized and outcomes can become more predictable.

FUTURE RESEARCH

► New technology and increased experience continues to advance the field of endoscopic sinus and skull base surgery. Although still in early development, real-time intra-operative imaging, 3-dimensional endoscopes and

remotely controlled robotic instrumentation hold promise in their application to this field. Such technology may one day further improve the safety and oncological results of endoscopic skull base procedures.

KEY POINTS

- The operating surgeon must understand the anatomy of the paranasal sinuses and the nature of the pathology to be managed.
- A comprehensive history and examination with review of radiology and biopsy specimens will enable a safe and effective plan to be formulated for the endoscopic approach to sinonasal tumours.
- The surgeon must be aware of the limitations of his or her individual endoscopic skills and the capabilities of the other teams involved to ensure that case selection is appropriate.
- Endoscopic skills and equipment are rapidly evolving, thus surgeons must remain current in their knowledge and skill development to undertake this complex surgery.

Data in this chapter may be updated by a PubMed search using the following keywords: pituitary adenoma, pituitary gland, transsphenoidal pituitary resection, sella, transsellar approach and endoscopic skull base surgery.

INTRODUCTION

History

For years, the surgical approach to the central skull base has been a challenge for surgeons given its relatively inaccessible location. A number of pathologies occur in this region and examples include pituitary adenomas, meningiomas, chordomas, germ cell tumours, and epidermoid cysts.

Sir Victor Horsley is credited with performing the first removal of a pituitary tumour in 1889, using a craniotomy with transfrontal route.¹ Shortly thereafter, Herman Schloffer² (1907) utilized a transfacial-transsphenoidal approach to the pituitary fossa, and he was followed by Oskar Hirsch³ (1909) who used a transnasal transseptal route. Another pioneer of the transnasal route was Harvey Cushing but he eventually abandoned it for open surgery.^{2, 4} Pituitary surgery continued to evolve through the 1950s as notable surgeons such as Gerard Guiot realized the merits of the transsphenoidal approach.⁵ In the 1960s, James Hardy took advantage of the increasing availability and visualization provided by use of the operative microscope to perform the first microsurgical pituitary surgery via a transsphenoidal route.⁶ This became the standard approach for pituitary and sella surgery.

In the early 1990s technological advances in optics, digital cameras, light sources, and monitors afforded surgeons a high-resolution view that was sufficient to safely perform intra-nasal surgery without external incisions. With growing experience in endoscopic sinus surgery,

efforts began to expand use of the endoscope to assist in skull base surgery. In 1992, Jankowski published the first description of a fully endoscopic transnasal technique for the pituitary gland.⁷

Microscopic approaches

The transition from open approaches to microscopic was accepted, as there was no brain retraction, decreased wound breakdown, shorter hospitalization, and no scar. The sublabial-transseptal microscopic approach is time tested and has been the standard of care for years. A sublabial incision is made followed by elevation of the septal mucosa off the septal cartilage and bones. The quadrangular cartilage is fractured laterally and bony septum removed followed by removal of the bony sphenoid face. The resulting microscopic view is straight into the sella. A variation is the transseptal approach with a hemitransfixion incision using a self-retaining retractor between the mucosal flaps. While effective, the microscopic view is limited by the speculum with an inability to visualize lateral extension of tumour.

Transition to endoscopic approaches

The use of the rigid endoscope in lieu of the microscope was initially met with resistance by some surgeons. Nonetheless, endoscopic approaches have rapidly gained popularity as experience has grown, and outcomes appear at least as favourable as microscopic approaches.^{8, 9} Proponents of an endoscopic transsphenoidal approach

to the pituitary and surrounding structures suggest that benefits over microscopic surgery include decreased pain and damage to the nasal mucosa, an improved panoramic view, and good mobility with angled views. Furthermore, there is no external incision or associated numbness which occurs with the sublabial approach. The wide angle provided by the endoscope allows the critical landmarks and tumour to be seen in the same field of view, even in regions which are difficult to see and access (Figure 115.1). This is especially helpful when tumour extends beyond the limits of the sella turcica, with an improved ability to remove these tumour extensions and decrease the risk of residual or recurrent disease.⁹⁻¹¹

Endoscopic surgery of the sellar region requires two surgeons. One surgeon holds the endoscope to provide the second surgeon an optimal view to perform the surgical dissection bimanually. Skilled endoscopic sinus surgeons have a vast experience in the approach to and operating within the sphenoid sinus and can provide fast and efficient access to the sella and skull base. Neurosurgeons with experience in pituitary surgery understand the surgical technique and complexities of operating in this region. Together, these two surgeons form an experienced team that can safely access and remove tumours of the sellar and parasellar regions. These teams should initially gain experience in the endoscopic management of pituitary tumours and learn the nuances of having two to three instruments and an endoscope in the sphenoid simultaneously. This creates challenges for the team in learning how to best prevent the crossing of instruments as well as access to tumour extensions especially in challenging areas. For this learning curve in endoscopic skull base surgery, Snyderman and colleagues described a categorization of cases into five levels of difficulty.¹² With regard to surgery of the sellar and parasellar regions, level II cases have pathology confined to the sella. Level III cases exhibit extrasellar extension but also remain extradural, while intra-dural dissection elevates complexity to level IV out of V.

Pituitary tumours make up the vast majority of endoscopic transsellar surgery,¹³ but additional skull base pathologies within the sella turcica and parasellar region can be addressed in a similar fashion.¹⁴ Other pathologies include lesions such as Rathke cleft cysts, craniopharyngiomas, fibrous dysplasia, chordomas, chondrosarcomas, epidermoid cysts, and meningiomas.

PRE-OPERATIVE ASSESSMENT

History and physical examination

Prior to embarking upon any surgery, it is critical that the surgeons understand the patient's pathology, extent of disease, neurological deficits, concurrent head and neck disease, and other co-morbidities. A comprehensive history should always be obtained with a full head and neck examination. Special attention should be paid to the cranial nerves which pass through the cavernous sinus. Visual status such as acuity, visual fields, and gaze restrictions may be best performed by an ophthalmologist. Inclusion of rigid nasal endoscopy is also warranted to determine whether sinonasal disease or anatomic obstructions are present which would need to be addressed during surgery. Particularly when pituitary tumour surgery is to be performed, an endocrinologist should be involved in the patient's care, and the patient's hormonal status and pituitary function should be determined prior to surgery.

Imaging

Radiographic imaging is critical to preparing for skull base surgery, and details of skull base and sellar region imaging are covered in detail elsewhere in this text. The primary goal of the otolaryngologist is to gain wide transnasal access to the sella (Figure 115.2). All patients require

Figure 115.1 (a) MRI chordoma axial labelled. (b) Residual tumour.

Figure 115.2 CT sella approach.

a computed tomography (CT) scan of the sinuses. Bone windows are helpful to determine presence of tumour invasion or bony remodelling. Further, review of CT scans helps delineate sinonasal disease, septal deviation (which helps with planning of a nasoseptal flap), sinus aeration, access to the sphenoid sinus, and anatomical variations such as Onodi cells, sphenoid intersinus septa, and the course of the carotid artery and optic nerve as well as potential areas of dehiscence (Figure 115.3). If there is additional concern about the carotid artery, a CT angiogram is indicated.

In addition to CT, an MRI with image guidance navigation (IGN) protocol should be obtained. This assists with pre-operative planning by differentiating tumour mass from obstructed mucus/fluid. Further, MRI is superior to CT in providing information about tumour morphology and whether dural enhancement or invasion is present. Image guidance is routinely used for all skull base cases, and this practice is widespread at large skull base centres.^{15, 16} IGN is never a substitute for thorough understanding of the patient's individual anatomy, but rather should confirm the surgeons' anatomical knowledge. It may be especially helpful for revision cases, challenging anatomy, resident teaching, expanded transsphenoidal approaches, and when extrasellar extension is present.¹⁶ Additional benefits have been reported including improved accuracy, reduced morbidity, and shorter duration of intensive care stays.¹⁷ However, there is associated set-up time and the systems require some practice to become familiar with them. The surgeons must know the limitations of IGN and realize the system is not always accurate.

ENDOSCOPIC TRANSSPHEROIDAL APPROACH TO SELLA

Pre-operative considerations

Optimizing the nasal cavity for an endoscopic approach is an important first objective of the surgery. This includes assessing the CT scan for the need to remove the lateral wall of a concha bullosa or in some cases, the entire

Figure 115.3 (a) CT intersinus septum carotid opt cor. (b) CT intersinus-septum carotid artery.

middle turbinate. Septal deviations and need for a septoplasty is evaluated. The transsphenoidal approach can be expanded to transplanum, transclival/transodontoid, and transpterygoid approaches as dictated by the size, type, and extent of the tumour.

The operating theatre is set up for a two-surgeon approach, and usually this is best accomplished by turning the table so that the anaesthetist is at the foot of the patient. The patient should be catheterized for accurate fluid balance management, especially with the risk of diabetes insipidus during pituitary tumour removal. We have found that lumbar drains are not routinely required even if a CSF leak is created during surgery. This prevents the potential complications associated with lumbar drains. Routine broad spectrum prophylactic antibiotic cover is given and the nose is decongested as for sinus surgery with topical and local vasoconstrictive agents. A surgical

preparation of abdomen or thigh as a graft donor site is performed. We prepare the abdomen to harvest fat and rectus abdominis fascia in most pituitary tumours, but prepare the right thigh for fat and fascia lata when larger defects are anticipated (craniopharyngiomas, meningiomas, chordomas, etc.). Image guidance is set up usually with a scuba head strap for the electromagnetic IGN system and then the patient is registered.

The head of bed is placed in the reverse Trendelenburg position to decrease venous congestion and bleeding in the operative field. Instruments include the standard sinus and endoscopic skull base instruments, a high-speed drill, bipolar forceps, and an endoscopic ultrasonic aspirator.

Surgical technique

The first step in the surgery is optimizing the nasal cavity. Anatomical obstructions are addressed, such as performing septoplasty and removal of concha bullosa. Eliminating these obstructions improves access and passing of instruments from both sides of the nose. This decreases the risk of striking instruments against the septum which increases bleeding, damages mucosa, and slows surgery. In extended pituitary approaches (substantial opening of the arachnoid mater), a septal flap should be raised.¹⁸ If one is unsure whether a pedicled septal flap will be required, then the vascular pedicle of the flap should be preserved on one side. This is accomplished by placing an incision from the lower edge of the natural ostium of the sphenoid and carrying this incision anterior and horizontal for about 3–4 cm. A suction Freer is used to mobilize this flap to the level of the posterior bony choana (**Figure 115.4**). This will allow the anterior face of the sphenoid to be widely opened while allowing the mobilized mucosa with the posterior nasal artery to be preserved. This ensures that should a septal flap be needed for reconstruction of the skull base or for closure of a large CSF leak, that the flap can still be raised and utilized.

Access to the sella should be created bilaterally to increase the working space for the binasal two-surgeon approach. Wide access yields improve visualization and

Figure 115.4 Septal flap.

allows space for the endoscope to be placed out of the way of the suction and dissecting instruments during surgery. The middle corridor of the nasal passage is widened by lateralizing the middle turbinates to expose the sphenoidal recess and superior turbinate. The inferior half of the superior turbinate is removed flush with the face of the sphenoid sinus (**Figure 115.5a**). In many patients, the sphenoid ostium is clearly identified medial to the superior turbinate at the junction of the lower third and upper two-thirds of superior turbinate.¹⁹ If the natural ostium is not visible the blunt end of the 4 mm microdebrider blade can be used to measure 12 mm from the posterior choanae.²⁰ A blunt Freer elevator is used to palpate the sphenoid face and identify the ostium. Entry with a Freer has a low risk of injuring the critical structures housed within the sphenoid sinus. The sphenoid ostium is widened and the posterior ethmoids opened so the sphenoid ostium can be widened to the lamina papyracea (**Figure 115.5a**). The final size of the sphenoidotomy should be from septum to lamina laterally, and from the roof of sphenoid to the floor of the sphenoid vertically. The Hajek-Koffler and Kerrison punches are ideal to for this purpose. While the bites are aggressive enough to make rapid progress, the biting mechanism minimizes the risk of inadvertently damaging the optic nerve and carotid artery (**Figure 115.5b**). At this point the mucosa of each side of the sphenoid should be elevated from medial to lateral leaving the lateral mucosa still attached to the bone (**Figure 115.5c**). This provides two mucosal flaps that can be used to reconstitute the anterior face of the pituitary fossa at the end of surgery. However, these mucosal flaps are removed if a pedicled septal flap is utilized.

To maximize access and to prevent the posterior edge of the septum being pushed into the endoscope thereby limiting visualization, a posterior septectomy is performed. This can be completed with the microdebrider, scalpel, or large backbiting forceps. If the microdebrider is used, care is taken to protect the pedicle of the septal flap and therefore the septectomy is only performed above the previously mobilized pedicle. Usually about 1–1.5 cm of the posterior edge of the septum is removed (**Figure 115.5d**). Intersinus septations are carefully removed using a rongeur or diamond drill, being conscious that septations frequently veer towards the carotid artery and/or optic nerve (**Figure 115.5f**). Septations are removed flush with the face of the sella. The medial²¹ and lateral opticocarotid recesses are identified along with the anterior genu of the carotid arteries and both optic nerves (**Figure 115.5f**). Confirmation of these structures is obtained by using the image guidance suction probe. These limits define the planned bony exposure of the sella and identification reduces the likelihood of damaging them during the bone removal.

In most patients with a pituitary macroadenoma, the sellar face will be soft due to tumour expansion and pressure on the bone. A Freer elevator is used to gently fracture the bone giving an edge for placement of the 2 mm forward biting Kerrison punch. Alternatively, if the bone is hard (often seen with microadenomas), a diamond burr is used to “eggshell” the bone so it can be gently fractured

Figure 115.5 (a) Sphenoid os. (b) Opened sphenoid. (c) Sphenoid mucosa. (d) Septectomy. (e) CT Onodi pituitary. (f) Opened sella. (g) Onodi.

and removed. The Kerrison punch is used to remove the bone off the dura exposing the underlying dura from one cavernous sinus to the other and from the pituitary fossa floor to just below the tuberculum sella (**Figure 115.5f**). Once bone removal is complete the surgeon must be able to easily pass instruments below the pituitary fossa and from one sphenoid wall to the other. Creating this large space allows significant freedom of movement for the instruments without the bony walls of the sphenoid limiting access to any part of the sellar or parasellar region.

The dura is opened with a retractable blade or a number 11 blade in a U-shaped incision placed a few millimetres medial to each cavernous sinus and joined at the floor of the sella. This produces a superiorly based U-shaped flap which gives the best possible exposure of the fossa (**Figure 115.6a**). Cruciate incisions are no longer used as the visualization after such an incision is poor compared to the U-shaped incision.

In patients with macroadenomas the tumour should be immediately apparent and tissue is taken and sent for histology (**Figure 115.6b**). In patients with microadenomas, the MRI scan and image guidance can be helpful in

identifying the tumour. An attempt is made to complete an extracapsular resection of these tumours thereby improving the chances of complete resection. Tumours have varying consistency from soft to firm, and the best instruments for removal will depend on the consistency. They may remain confined to the sella turcica or may extend into the parasellar and suprasellar regions. In cases of parasellar extension, a 30° angled endoscope is very useful to access tumour under vision and appreciate the full extent of the disease. This visualization is paramount to ensuring comprehensive removal, and achieving such views is not possible with microscopic approaches. **Figure 115.1b** is an example of a tumour that has grown laterally and behind the cavernous segment of the carotid artery. This extension would have been impossible to see with the microscope. It has been established that extrasellar extension is a risk factor for persistent disease;²² thus, we aggressively chase tumour extensions in secreting tumours. However, our philosophy regarding extrasellar extension in cases of non-secreting adenomas is to resect what is relatively easy to remove without putting the patient at undue risk.

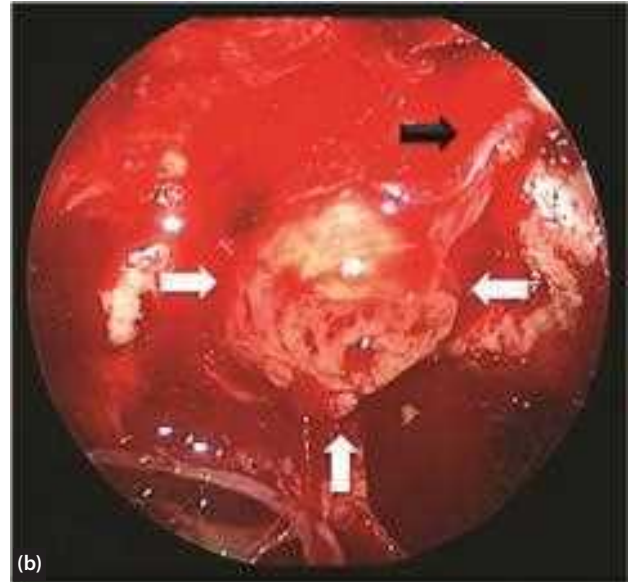

Figure 115.6 (a) Dural incision. **(b)** Tumour exposed.

After complete tumour removal, haemostasis is ensured using Gelfoam paste (made up of Gelfoam® powder (Pfizer Inc, New York, NY) and saline) and pressure from neuropathies. The pituitary fossa is gently filled with the paste and the dura placed over the paste. The sphenoid mucosal flaps are placed over the dura, secured with Surgicel® (Ethicon, Somerville, NJ) and fixed with a layer of fibrin glue. No packing is placed in the sphenoid sinus.

If a cerebrospinal fluid (CSF) leak is created during tumour removal, the diaphragm sellae defect is identified and a small triangle of fat placed into the defect ensuring cessation of the leak. An additional small piece of fat is placed in the sellar fossa with a layer of fascia over the fat. The dura and sphenoid mucosa are draped over the fascia followed by Surgicel® and fibrin glue. A layer of Gelfoam® is then placed over the glue followed by a ribbon gauze pack soaked in bismuth iodoform paraffin paste (BIPP) or antibiotic ointment. This is removed on day 3 post surgery. For large CSF leaks or in patients who have had an extended approach with a defect in the arachnoid mater, the pedicled septal flap is raised.¹⁸ The fascia (or dural substitute such as DuraGen™ (Integra LifeSciences Corp., Plainsboro, NJ)) is placed as an underlay intra-cranial graft with the pedicled septal flap placed over this graft onto

the bone of the defect. The edges of the flap are secured with Surgicel® and fibrin glue and the repair covered with Gelfoam® and the sinus packed with ribbon gauze soaked in BIPP for 3 to 7 days depending on the size of the defect.

SURGICAL APPROACH FOR PARASELLAR (CAVERNOUS SINUS) EXTENSION

Parasellar extension beyond the pituitary fossa is initially dealt with as above. In some cases, tumour may extend anterior to the carotid before entering the cavernous sinus (**Figure 115.7a**). As per our philosophy, such tumour extensions are only addressed in secreting tumours as the risks outweigh the benefits in benign non-secreting tumours.

When lateral access is required, bone anterior to the anterior genu of the cavernous carotid artery is very gently removed. It is often safest to perform osteotomies with a 2 mm diamond burr on this bone and then to use a blunt hook to dissect the carotid from this bone before fracturing this bone (osteotomies control the fracture points) and removing it to expose the carotid artery. After complete

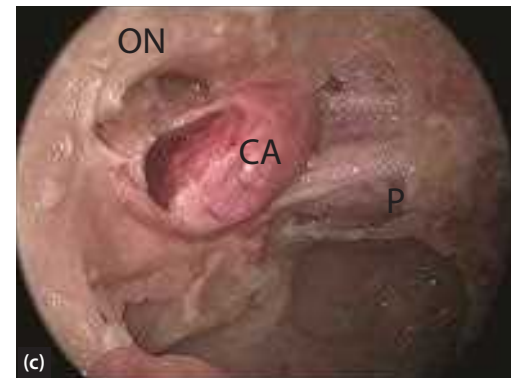

Figure 115.7 (a) MRI tumour encase L carotid. **(b)** Lateral to carotid intraop. **(c)** Far lateral approach.

exposure of the anterior genu of the artery, the cavernous sinus can be approached from anterior and lateral to the carotid (Figures 115.7b and 115.7c). Post-tumour removal, the exposed carotid artery should be covered by the pedicled septal flap.

COMPLICATIONS

Delayed complications

The most common complication is CSF leak. Our philosophy is not to limit tumour resection because of fear of creating a CSF leak. We feel that we can successfully deal with any CSF leak at the end of the surgery. However, a post-operative CSF leak is a complication, and while this does occur the accepted rate of post-operative CSF leaks should be less than 5%. We use a multilayer closure including use of fibrin glue and a sphenoid sinus pack to maximally bolster the skull base repair and prevent a post-operative leak. Currently our post-operative CSF leak rate is under 5% with this protocol. Should a post-operative CSF leak occur, the patient is kept on bedrest and a lumbar drain is placed. If, despite these measures, the leak does not cease within 24 hours the patient returns to theatre for a formal closure. Other more common complications include mucosal scarring, hyposmia or anosmia, nasal crusting, and sinusitis.

Immediate complications

Immediate complications other than CSF leak include vision damage and both venous and arterial bleeding. The pre-operative imaging is very useful in preventing devastating complications; therefore, anatomical variations such

as an Onodi cell (sphenoidal cell) should be identified pre-operatively (Figures 115.5e, 115.5f). The Onodi cell pneumatizes lateral and superior to the sphenoid sinus and the optic nerve often runs within it. Failure to identify this ahead of time places the optic nerve at risk. Similarly, the medial location of the carotid artery (Figure 115.1a) or an intersinus septum that attaches to the carotid artery is identified on imaging (Figures 115.3a and 115.3b).

Carotid artery injury is a devastating complication with up to 30% of patients having neurological sequelae and an approximate 20% mortality rate.²³ Carotid injury is one of the most challenging endonasal situations requiring both calmness and skill from both surgeons.²⁴ Recently, an animal model has been created by our group to provide skull base surgeons with a realistic model where techniques of how to manage high-flow bleeding can be taught and these surgical skills can be practised. This model almost exactly replicates both significant cavernous sinus and carotid artery bleeding.²⁵ We have used this model to assess the best way to handle such a complication and recommend the use of crushed muscle as a patch on the bleeding vessel as the quickest, safest, and most effective way to handle such a complication.²⁶

CONCLUSION

The endoscopic transsphenoidal approach is a safe and effective means to remove many tumours within the sellar and parasellar regions of the central skull base. With improvements in technology, combined with greater surgical experience, the boundaries of safe and effective endoscopic removal of tumours will continually be pushed with the goal of improving patient care.

KEY POINTS

- The endoscopic approach to sellar and parasellar lesions has benefits over the microscopic approach including angled visualization and a dynamic, mobile view. However, this approach requires two surgeons and the image is only in two dimensions.
- An endoscopic skull base surgery team consisting of a neurosurgeon and otolaryngologist should be formed to perform these cases. They should start on easier pathologies before advancing to more difficult cases such as laterally based tumours and those that are adjacent to critical structures.
- Wide nasal access is critical to facilitate visualization and complete tumour removal, which is best accomplished with a binaural approach.
- It is important to salvage the posterior nasal artery so that a nasoseptal flap can be used to cover this defect if a cerebrospinal fluid leak is encountered.

SEARCH STRATEGY

Data in this chapter may be updated by Medline and PubMed searches using the following keywords: anterior skull base, craniopharyngioma, endoscopic endonasal surgery, meningioma, nasal dermoid, pituitary adenoma and sinonasal malignancy.

INTRODUCTION

A paradigm shift has occurred in skull base surgery over the last two decades with the introduction of endoscopic techniques for sinus surgery. Endoscopic techniques have been widely adopted for surgery of the pituitary gland and endoscopic endonasal surgery (EES) has been extended to include extrasellar regions of the ventral skull base. EES encompasses parasellar regions for the treatment of sellar pathology that extends to the cavernous sinus and suprasellar area, as well as the anterior cranial base.

The primary principle of EES is not endoscopic visualization but rather utilization of the endonasal corridor to provide optimal access with the least morbidity for the patient. For many tumours that are bounded by the neural and vascular structures of the cranial base, the endonasal corridor allows complete resection while minimizing manipulation of uninvolved cranial nerves, blood vessels, and brain tissue. In comparison to the microscope, the endoscope provides superior visualization with the capability of panoramic views and angled visual pathways. EES is team surgery, requiring the coordination of two specialties to achieve operative goals. Skull base team surgery is a dynamic process that results in enhanced visualization, increased efficiency, and improved communication and problem-solving.

CLASSIFICATION OF APPROACHES

Endonasal approaches to the ventral skull base are classified based on their orientation in sagittal and coronal radiological planes relative to the sphenoid sinus ([Table 116.1](#)).¹ The sphenoid sinus is the epicenter of endonasal skull base approaches since it is often the starting point for endoscopic skull base experience (pituitary surgery) and it is the location of critical anatomical structures (optic nerves, internal carotid arteries). Sagittal plane surgical modules extend from the frontal sinus to the sella, and from the sella to the upper cervical spine (C1/2). Coronal plane modules extend laterally, in correspondence with each cranial fossa (anterior, middle, and posterior).

The anterior cranial base extends from the sella to the frontal sinus in the midline plane and laterally across the orbital roof. Discrete sagittal plane modules include transfrontal, transcribriform, and transplanum approaches. These can be combined to provide complete access to the anterior cranial fossa for large intra-cranial tumours or excision of sinonasal malignancy that involves the skull base. For example, an endonasal resection of an aesthesioneuroblastoma includes transfrontal (Draf 3 frontal sinusotomy), transcribriform, and transplanum modules. Lateral margins of the anterior cranial base may be extended to the midline of the orbits by removal of the medial orbital roofs.

TABLE 116.1 Classification of endonasal approaches to the skull base

Infrapetrous	
Parapharyngeal space	

INDICATIONS

Pathologic processes may arise from intra-cranial, cranial, or extracranial structures and include a diversity of benign and malignant pathologies (Table 116.2). Isolated transfrontal approaches are primarily performed for inflammatory sinus disease (chronic frontal sinusitis, mucocele) and benign tumours (osteoma). The intra-cranial component of a nasal dermoid can be removed by following the tract through the foramen cecum, anterior to the crista galli.

Isolated transcribriform approaches are used for meningoencephaloceles that typically involve the lateral lamella of the cribriform. Rarely, tumours may arise from the olfactory nerves (olfactory schwannoma, olfactory hamartoma, aesthesioneuroblastoma). The most common indication for a transcribriform approach is for olfactory meningioma or sinonasal malignancy with skull base involvement. A transcribriform approach is usually combined with transfrontal and transplanum approaches to obtain adequate access and resection margins.

TABLE 116.2 Indications for endoscopic endonasal surgery (by surgical approach)

Transfrontal	chronic sinusitis, mucocele, osteoma, nasal dermoid
Transcribriform	meningoencephalocele, olfactory groove meningioma, olfactory schwannoma, olfactory neuroblastoma, sinonasal malignancy
Transplanum (suprasellar)	Pituitary adenoma, craniopharyngioma, meningioma
Transsellar	Pituitary adenoma, Rathke's cleft cyst, craniopharyngioma
Supraorbital	osteoma, meningioma, sinonasal malignancy

Sellar pathology includes primary pituitary adenomas (functioning and non-functioning) and Rathke's cysts. Large macroadenomas may extend to the suprasellar area and require a combined transsellar-transplanum approach for exposure and removal. A combined approach is also used for craniopharyngiomas and tuberculoma meningiomas.

A supraorbital approach augments transcribriform and transplanum approaches by providing access to the roof of the orbit and associated dura. Usual indications for a supraorbital approach include a dural tail for meningiomas and dural margins for sinonasal malignancy.

For patients with sinonasal malignancy, oncological principles can be preserved with EES.² The goal of surgery is complete oncological resection with the least morbidity. With such cases, the endoscope is only a surgical tool and resection margins should not be compromised in order to perform an endoscopic resection. Although it is often promoted, en bloc resection is not achievable with an 'open' approach in many patients, due to proximity of the tumour to critical neural and vascular structures and fracturing of the tumour specimen. There is also abundant evidence that en bloc resection is not necessary as long as final resection margins are negative (e.g., inverted papilloma, Moh's surgery for skin cancer, and laser resection of pharyngeal and laryngeal squamous cell carcinoma). For sinonasal malignancy that involves the cribriform plate with risk of intra-cranial extension along olfactory filia to the olfactory bulb, bilateral wide resection of the anterior cranial base is recommended including dura, olfactory bulbs, and olfactory tracts.³ Potential benefits of endoscopic surgery include better visualization of resection margins with better local control, no transgression of normal tissue planes with risk of tumour seeding, absence of frontal lobe manipulation, and faster recovery with early institution of adjunctive therapies.

A wide variety of sinonasal neoplasms are suitable for EES if properly selected. These include olfactory neuroblastoma (aesthesioneuroblastoma), neuroendocrine carcinoma, sinonasal undifferentiated carcinoma (SNUC), squamous cell carcinoma, adenocarcinoma, adenoid cystic carcinoma, and melanoma. Operability is determined by the biological behaviour of the tumour (diagnosis), stage (extent), and patient factors (age, medical co-morbidities). Surgery is generally preferred as the first treatment option for resectable tumours that do not have a high risk of distant metastases. Brain invasion is not necessarily a sign of inoperability. If a pial or cortical margin of brain tissue can be removed to achieve a negative margin without sacrificing major cerebral vasculature, then the tumour is operable. If there is tumour involvement of cerebral vessels, then the goal of surgery is no longer cure but palliation. Such patients usually receive radiochemotherapy first and surgery is reserved for salvage treatment of residual disease. For tumour with aggressive biological behaviour and increased risk of metastases (SNUC, melanoma), systemic therapy (chemotherapy, immunotherapy) is considered first. Even though the prognosis remains poor for cure of mucosal melanoma, EES is considered for local control.

The endoscope provides additional treatment options in patients with malignancy. In addition to performing a

Figure 116.1 Pre-operative (a) and post-operative (b) MRI of a complete oncological resection of an adenocarcinoma of the left olfactory cleft with cranial base involvement.

Figure 116.2 Debulking of unresectable squamous cell carcinoma of nasopharynx prior to radiochemotherapy. The patient presented with a VIth nerve palsy that resolved with surgery. (a) Pre-operative MRI with tumour encasement of both internal carotid arteries (arrows). (b) Post-operative MRI with fat graft (FG) and residual tumour surrounding the internal carotid arteries (arrows). The patient had a complete response to radiochemotherapy and remains disease-free more than 10 years later.

complete oncological resection (Figure 116.1), debulking of tumour prior to radiochemotherapy (Figure 116.2) may be considered in order to relieve symptoms such as bleeding, infection, pain, or compression (brain, orbit, cranial nerves). In addition, potential benefits of debulking prior to radiotherapy include accurate assessment of tumour margins and areas of invasion, modification of radiation ports to spare uninvolved tissues (optic nerves), and improved therapeutic response. The endonasal approach is ideal for palliation of symptoms in patients with unresectable recurrences (Figure 116.3). The morbidity of EES is minimal in such cases and affords the opportunity for

multiple outpatient surgeries. Palliative surgery may also be considered for prevention of complications related to continued tumour growth (e.g., visual loss).

Pre-operative planning

The pre-operative evaluation of patients with tumours involving the cranial base starts with a detailed history and thorough physical examination. Presenting symptoms are often minimal and non-specific. Sellar and suprasellar tumours may present with headache, endocrine dysfunction, or visual loss. Intra-nasal tumours may present with

**Figure 116.3**

(a) Unresectable olfactory neuroblastoma with complete encasement of the right orbital apex and cavernous sinus. (b) Palliative EES with limited resection of residual tumour was performed to limit spread of tumour to the uninvolved eye and preserve vision (MRI is 2 years following radiochemotherapy and 1 year following surgery).

nasal obstruction, olfactory loss, epistaxis, or rhinorrhea. Tumours that extend laterally to the orbit may cause diplopia from displacement or invasion of orbital tissues. Intra-cranial tumours are often silent but subtle changes in personality and memory loss may become evident with further questioning.

Physical examination includes nasal endoscopy to assess the location and extent of tumour. Origination medial to the middle turbinate is typical of olfactory neuroblastoma. Coexistent sinus pathology may include infection, mucocoele formation, and nasal polyposis. Olfaction may be assessed using available ‘scratch and sniff’ tests (Sensonics, Inc, Haddon Heights, NJ). Assessment of orbital function includes examination of extraocular motility and visual acuity. Visual field testing can provide evidence of early visual compromise and topographic data (tumour location relative to the chiasm). If there is concern about brain function, neurocognitive testing of executive functions can be performed. Pre-operative testing of visual and brain function is valuable for comparison with postoperative function.

Radiological imaging is essential for proper diagnosis as well as surgical planning. Both computed tomographic (CT) scan and magnetic resonance imaging (MRI) are obtained in many cases due to complementary information. CT is better for demonstrating bone erosion and sinus anatomy and MRI is better for delineating soft-tissue invasion and differentiating tumour from obstructed secretions. Scans are obtained using a skull base format with intra-operative navigation in mind. CT angiography is useful for identification of the internal carotid artery (ICA) or anterior cerebral arteries both pre-operatively and intra-operatively using navigation.

SURGICAL TECHNIQUES

EES is performed in an operative suite that is dedicated to endoscopic procedures. The room is organized around the patient with multiple monitors for viewing

endoscopic images. The operative set-up is as shown in **Figure 116.4**. Following induction of anaesthesia, the head is immobilized with 3-point fixation in a Mayfield clamp. This allows precise positioning of the head for endoscopic access and facilitates intra-operative navigation. It also prevents inadvertent movement of the head during periods of critical dissection. The head is extended to increase anterior access and slightly rotated and laterally flexed to align the surgical corridor with the surgeon. Intra-operative navigation is registered and neurophysiological monitoring electrodes are placed. Cortical function (brain ischaemia) is monitored during every case using somatosensory-evoked potentials. If dissection of cranial nerves (III, IV, VI) is anticipated, electromyographic (EMG) monitoring of extraocular muscles is performed.

The nasal mucosal tissues are decongested with pledgets soaked in 0.05% oxymetazoline and the nasal vestibule and midface are prepped with betadine solution. Antiseptic rinses of the nasal cavity are not used due to

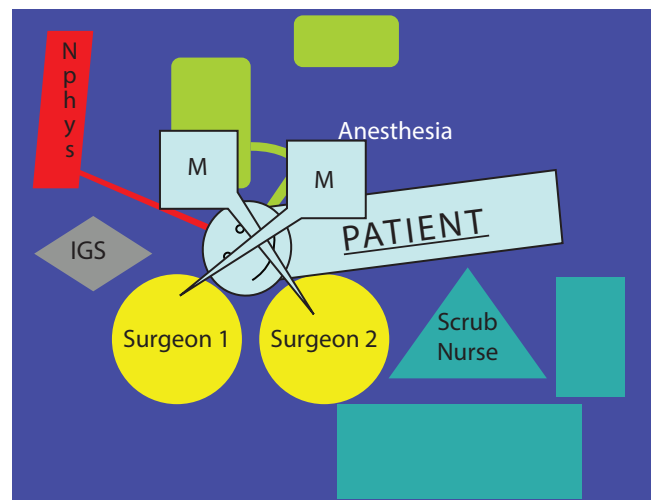

Figure 116.4 Operating room set-up. IGS: image-guidance system; M: monitor; NPhy: neurophysiology.

their deleterious effects on mucociliary function. A third-generation cephalosporin antibiotic is administered intravenously for perioperative prophylaxis.

Standard equipment for endonasal surgery includes a full set of endoscopic sinus surgery instruments including frontal sinus instruments, endoscopic bipolar electrocautery with exchangeable tips, endonasal drill with 4mm coarse (hybrid) diamond bits, an array of angled Frazier and Fukushima suctions, pistol-grip extended microscissors and fine-tip extended dissectors for microvascular dissection. A nerve stimulator is used to aid identification of cranial nerves and a Doppler probe is used to identify and measure blood flow in major vessels.

Surgical approaches

TRANSFRONTAL APPROACH

The transfrontal approach provides access to the skull base anterior to the cribriform plates. It includes the floor of the frontal sinuses and the foramen cecum and crista galli in the midline. With drilling of the 'beak' of the frontal bone, the majority of the posterior table of the frontal sinus is accessible. Key landmarks and limits of the transfrontal approach are noted in [Table 116.3](#).

A Draf 3 frontal sinusotomy is the foundation for the transfrontal approach ([Figure 116.5](#)). The nasofrontal recess is identified bilaterally by following the uncinate process and opening the anterior ethmoid air cells. The anterior ethmoid artery is identified at the posterior limit of the nasofrontal recess. The anterior tip of the middle turbinate is resected to the first olfactory fibre. The mucosa and periosteum of the olfactory sulcus can be elevated to assist in identification of the anterior margin of the cribriform plate and olfactory fibres. A superior septal window is created between the nasofrontal recesses to provide binarial access and improved angles for instrumentation. With visualization of the frontal sinuses on both sides, the floor of the frontal sinuses is then drilled in a curvilinear fashion anterior to the crista galli. Additional bone is drilled anteriorly in the midline (frontal beak) to increase access superiorly. Intersinus septations are drilled as necessary to provide a wide drainage pathway.

TABLE 116.3 Key landmarks and limits of the transfrontal approach

Key landmarks

The posterior table of the frontal sinus is thinned with a drill and then elevated with dissecting instruments to expose the dura. The crista galli can be exposed in the midline and partly removed by drilling.

CASE EXAMPLE: NASAL DERMOID

A 5-year-old boy presented with a history of recurrent inflammation of the nasal dorsum despite prior transcutaneous excisions of a dermoid cyst of the nasal dorsum. A well-healed scar of the nasal dorsum was present without active inflammation. Nasal endoscopy revealed swelling of the superior nasal septum. CT and MRI demonstrated swelling of the superior nasal septum with a sinus tract extending through the foramen cecum to a small intra-cranial but extradural collection ([Figure 116.6](#)). Following frontal sinusotomy, the septal portion of the dermoid cyst was opened and contents were removed. The sinus tract was followed through the skull base by drilling the surrounding bone. The sinus tract was resected to the surface of the dura without a CSF leak. The defect was left open to the nasal cavity to prevent recurrence.

TRANSCRIBRIFORM APPROACH

A transcribriform approach provides access for tumours that arise from the cribriform plate area such as olfactory neuroblastomas and olfactory groove meningiomas. It is also a common site for meningoencephaloceles with spontaneous CSF leaks. A transcribriform approach is often combined with transfrontal and transplanum approaches for complete resection of the anterior cranial base in patients with a sinonasal malignancy. Key landmarks and limits of the transcribriform approach are noted in [Table 116.4](#).

A Draf 3 frontal sinusotomy may be necessary to provide access to the anterior limit of the cribriform plates and also avoids problems with post-operative obstruction

Figure 116.6 Pre-operative axial (a) and sagittal (b) MRI demonstrate a dermoid cyst extending from the superior nasal septum (arrow) through foramen cecum (arrows) to the surface of the dura. (c) Endoscopic view of healed defect of superior septum following surgery.

TABLE 116.4 Key landmarks and limits of the transcribriform approach

Key landmarks	
	Crista galli

	Anterior: frontal sinus
	Posterior: planum, posterior ethmoid artery
	Medial: crista galli
	Lateral: orbit

of the frontal sinuses. Bilateral ethmoidectomies are performed and the middle turbinates are resected. It may be necessary to debulk large intra-nasal tumours first in order to delineate the margins of the tumour and expose the area of skull base involvement (Figure 116.7a). Devascularization of intra-nasal tumours can be achieved by bipolar electrocautery of the tumour surface and ligation of feeding vessels. The anterior and posterior ethmoidal arteries may be identified where they cross the skull base lateral to the tumour. The paired vessels diverge from each other as they pass medially. The anterior ethmoidal artery is located between the 2nd and 3rd ethmoid lamella just posterior to the nasofrontal recess. Navigation can also be used to locate the artery; it exits the orbit in a coronal plane that is tangential to the posterior surface of the globe. The anterior and posterior ethmoidal arteries are best transected on the orbital side of the skull base. The lamina papyracea is partially removed and the orbital periosteum is dissected from the orbital roof. The periosteum is tethered where the vessels enter the foramina. The vessels are cauterized with bipolar electrocautery prior to transection. It is important to leave a small stump for cauterization so that the vessel does not retract into the orbit and cause a retro-orbital haematoma.

The bone of the skull base is then thinned with the drill and elevated to expose the dura to the margins of resection. If dural margins are important, it is helpful to elevate the dura from the orbital roof; this makes it easier to resect additional dural margins later, if needed. The dura is incised laterally with a retractable sickle knife and the incisions are extended with micro-scissors, taking care to avoid injury to cortical vessels. In the midline anteriorly, it is necessary to detach the dura from the crista galli. The base of the crista galli is removed with the drill prior to dural opening so that the attachment of the falx can be cauterized and cut once the dura is open (Figure 116.7b). Transection of the falx is directed posteriorly towards its free edge. This releases the dural specimen anteriorly and the remaining posterior dural cuts can be made. Additional intra-cranial tumour is dissected as needed.

CASE EXAMPLE: OLFACTORY SCHWANNOMA

A 12-year-old male presented with headaches and altered personality. Imaging revealed a large intra-cranial tumour arising from the olfactory area (Figure 116.8). A bilateral transcribriform approach was performed with complete intra-dural excision of the tumour. Histological examination confirmed an olfactory schwannoma.

TRANSPLANUM APPROACH

A transplanum approach provides access from the cribriform plates anteriorly to the tuberculum posteriorly (Figure 116.9). The planum forms the roof of the sphenoid sinus and is bounded by the optic canals posterolaterally. Most commonly, an isolated transplanum approach is used for access to intra-cranial tumours such as meningiomas. It may be combined with a sellar and suprasellar approach for suprasellar lesions such as pituitary tumours and craniopharyngiomas. Meningiomas that extend into the optic canals can be completely removed by decompressing the optic canals medially out to the optic strut.

Figure 116.7 (a) The tumour is debulked and surrounding bone landmarks of the skull base are exposed. CG: crista galli; E: ethmoid roof. (b) The falx (F) is transected to release the dural specimen anteriorly. CG: site of crista galli.

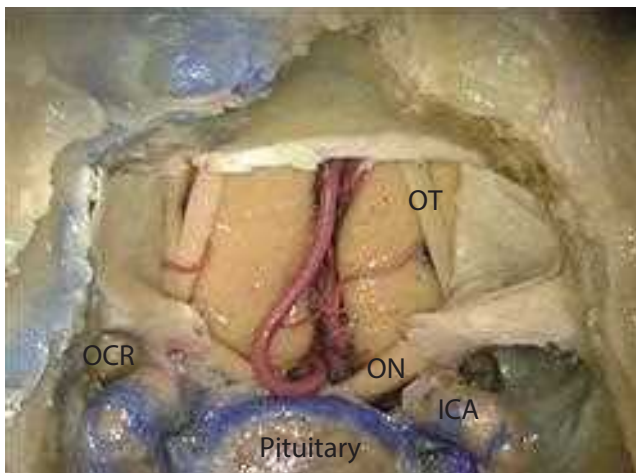

Figure 116.9 Anatomical dissection of a transplanum approach demonstrating key landmarks. ICA: internal carotid artery; OCR: optic-carotid recess; ON: optic nerve; OT: optic tract. The transplanum approach is bounded by the cribriform plates anteriorly.

Key landmarks and limits of the transplanum approach are noted in [Table 116.5](#).

Bilateral ethmoidectomies and a wide sphenoidotomy are necessary to provide visualization of the planum. The rostrum of the sphenoid is resected to provide binarial access. It is important to avoid aggressive resection of the septal attachment superiorly due to risks of olfactory injury or cerebrospinal fluid leak from the cribriform plates. The sphenoid sinus landmarks are identified and mucosa is stripped from the bone. The posterior ethmoid

TABLE 116.5 Key landmarks and limits of the transplanum approach

	Posterior: superior intercavernous sinus
	Posterolateral: optic canals
	Lateral: orbital apex

arteries are variable in location and diameter but are generally found near the junction of the planum sphenoidale and roof of ethmoid sinus. The foramina are approximately 4–7 mm anterior to the optic canal.

The bone of the planum is outlined with the drill and fragments of bone are dissected from the underlying dura in an anterior to posterior direction. Posteriorly, the optic canals are kept in sight. If tumour dissection from the optic canals is necessary, a 3 mm coarse diamond bit is used to thin the overlying bone. Copious irrigation is used to prevent thermal injury to the optic nerves. The thinned bone is carefully elevated with fine dissectors to avoid compression of the optic nerves. The posterior ethmoid arteries are cauterized and transected on the orbital side of the bone. Excessive bone removal beyond the anterior margin of the tumour should be avoided so that normal brain tissue does not descend and obstruct the view.

The dura is incised with a retractable sickle knife and the incisions are extended with micro-scissors, taking care to avoid injury to cortical vessels. Tumour dissection is performed using standard microsurgical techniques with internal debulking followed by extracapsular dissection. If the dura is incised to the optic canals, care should be taken to identify and preserve the ophthalmic artery, which is often inferior and medial to the optic nerve as it branches from the ICA (**Figure 116.10**).

Figure 116.10 Intra-operative view of an aneurysm arising from the right ophthalmic artery.

CASE EXAMPLE: MENINGIOMA

A 45-year-old female presented with headaches and vision loss. MRI revealed a large suprasellar tumour with compression of the optic chiasm and tumour extension into the optic canals (**Figure 116.11**). Gross total excision was achieved using a transplanum approach. The dura of the optic canal was opened medially just above the optic nerve and tumour was dissected without injury to the ophthalmic artery.

Figure 116.11 Pre-operative (a) and post-operative (b) MRI of a planum meningioma. GTR was achieved using a transplanum approach with decompression of the optic canals.

SUPRAORBITAL APPROACH

The supraorbital approach is a coronal plane approach that provides access to the orbital roof. The maximal limit of exposure is the mid-sagittal plane of the orbit. This approach is used to remove tumour-involved bone (osteomas, meningioma) and to chase dural margins for sinonasal malignancy or meningiomas. It is often combined with transcribriform or transplanum approaches. The supraorbital approach is bounded anteriorly and posteriorly by the ethmoidal arteries. Key landmarks and limits of the supraorbital approach are noted in [Table 116.6](#).

Following a complete sphenoidectomy, the medial wall of the orbit is removed to the level of the skull base. The anterior and posterior ethmoidal arteries are identified and transected following cauterization. Periorbital is then dissected from the orbital roof to the mid-plane of the orbit. Access is greater in the middle and posterior orbit due to the trajectory of the surgical corridor. A binarial approach with a superior septal defect greatly enhances the exposure for instrumentation and minimizes contact of powered instrumentation with the orbital tissues. While the orbital tissues are protected with a suction or retracting instrument, the medial orbital roof is drilled and removed with rongeurs to the margin of resection. Posteriorly, removal of bone can extend to the anterior clinoid and facilitate 270° decompression of the optic canal.

CASE EXAMPLE: SINONASAL MALIGNANCY

A 52-year old man presented with nasal obstruction and a unilateral nasal mass involving the skull base with dural thickening over the medial orbit ([Figure 116.12a](#)). Biopsy confirmed a diagnosis of undifferentiated carcinoma and resection of the tumour and skull base was performed, including removal of the medial wall of the orbit. The initial dural incision did not provide an adequate resection margin ([Figure 116.12b](#)) and additional bone was removed from the orbital roof ([Figure 116.12c](#)) to achieve a negative dural margin.

SUPRASellar APPROACH

A suprasellar approach is combined with transsellar and transplanum approaches to gain access to suprasellar pathology. The most common indications include pituitary macroadenomas with suprasellar extension, craniopharyngiomas, and meningiomas. It is bounded by the

TABLE 116.6 Key landmarks and limitations of the supraorbital approach

The edge of the resected bone is highlighted with asterisks. (c) Additional bone is removed from the orbital roof with retraction of orbital contents. The initial dural incision is highlighted with asterisks. AEA: anterior ethmoid artery.

optic chiasm superiorly and pituitary stalk or membrane of Lillequist posteriorly. Key landmarks and limits of the suprasellar approach are noted in [Table 116.7](#).

Following a wide sphenoidotomy with opening of posterior ethmoid air cells, the landmarks of the sphenoid sinus are identified ([Figure 116.13](#)). This includes the sella, optic canals, lateral optic-carotid recess, and parasellar ICA. The medial optic-carotid junction or recess (mOCR) is an important landmark where the ICA courses medially before it passes under the optic nerve. The medial clinoid is a small bony projection below the medial OCR that provides a medial point of attachment of the dural rings next to the anterior genu of the cavernous ICA. In some cases, this can be calcified to form a complete ring around the ICA.

The bone of the sella is first thinned with the drill and removed to the margins of the cavernous sinus superiorly and laterally. Bone rongeurs are used to lift the thinned bone rather than bite the bone due to risk of injury to the ICA, especially at the medial optic-carotid junction. Anteriorly, the bone of the posterior planum is thinned with the drill until dura is exposed. The tuberculum strut (bone between the optic canals) is then disconnected laterally with a drill just medial to the optic canals ([Figure 116.14](#)). Then the entire tuberculum strut can be dissected free as a single piece of bone.

TABLE 116.7 Key landmarks and limitations of the suprasellar approach

Key landmarks	
	Optic canals
	Tuberculum

	Lateral: optic canals, paraclinoidal ICA

Figure 116.13 Key landmarks of the suprasellar approach. CR: clival recess; ICA: internal carotid artery; latOCR: lateral optic-carotid recess; MC: middle clinoid; ON: optic nerve.

Figure 116.14 The bone cuts (lines) for a suprasellar approach for resection of a pituitary tumour (Pit Tumour) with suprasellar extension are shown. The lateral cuts are made with the drill medial to the optic nerve (ON) canals. Removal of the tuberculum allows descent of the suprasellar component of the tumour.

The dura is then incised above and below the superior intercavernous sinus (SIS). The location of the optic chiasm should be ascertained from pre-operative imaging in case it is prefixed or displaced anteriorly by tumour. The SIS is then cauterized with bipolar electrocautery and transected. Bleeding from the cut edges is controlled with application of Floseal® or Surgifoam®. Dural cuts are extended as necessary to the margins of the tumour.

CASE EXAMPLE: CRANIOPHARYNGIOMA

A 44-year old man presented with progressive vision loss, headache and fatigue. Imaging showed a heterogeneous, partially cystic suprasellar lesion involving the pituitary stalk and elevating the optic chiasm ([Figure 116.15](#)). Hormonal evaluation revealed hypogonadism, hypothyroidism and borderline adrenal insufficiency. The patient underwent an endoscopic endonasal suprasellar approach with complete resection of the tumour that was histologically confirmed to be a craniopharyngioma. The tumour extensively involved the pituitary stalk, which was transected as part of complete removal. The patient's vision improved significantly post-operatively and he was treated with oral replacement for panhypopituitarism with the new addition of diabetes insipidus.

Reconstruction (nasoseptal flap, pericranial flap)

Prior to dural reconstruction, it is imperative to have good haemostasis. Bipolar electrocautery is used for bleeding dural edges and small arterioles. Cavernous sinus or venous bleeding can be controlled with application of haemostatic materials such as Surgifoam® or Floseal®. Mild oozing from the surface of the brain or residual tumour can be controlled with copious irrigation of warm saline (40°C).⁴ It may take 10 minutes or more of continuous irrigation to confirm that all bleeding is controlled.

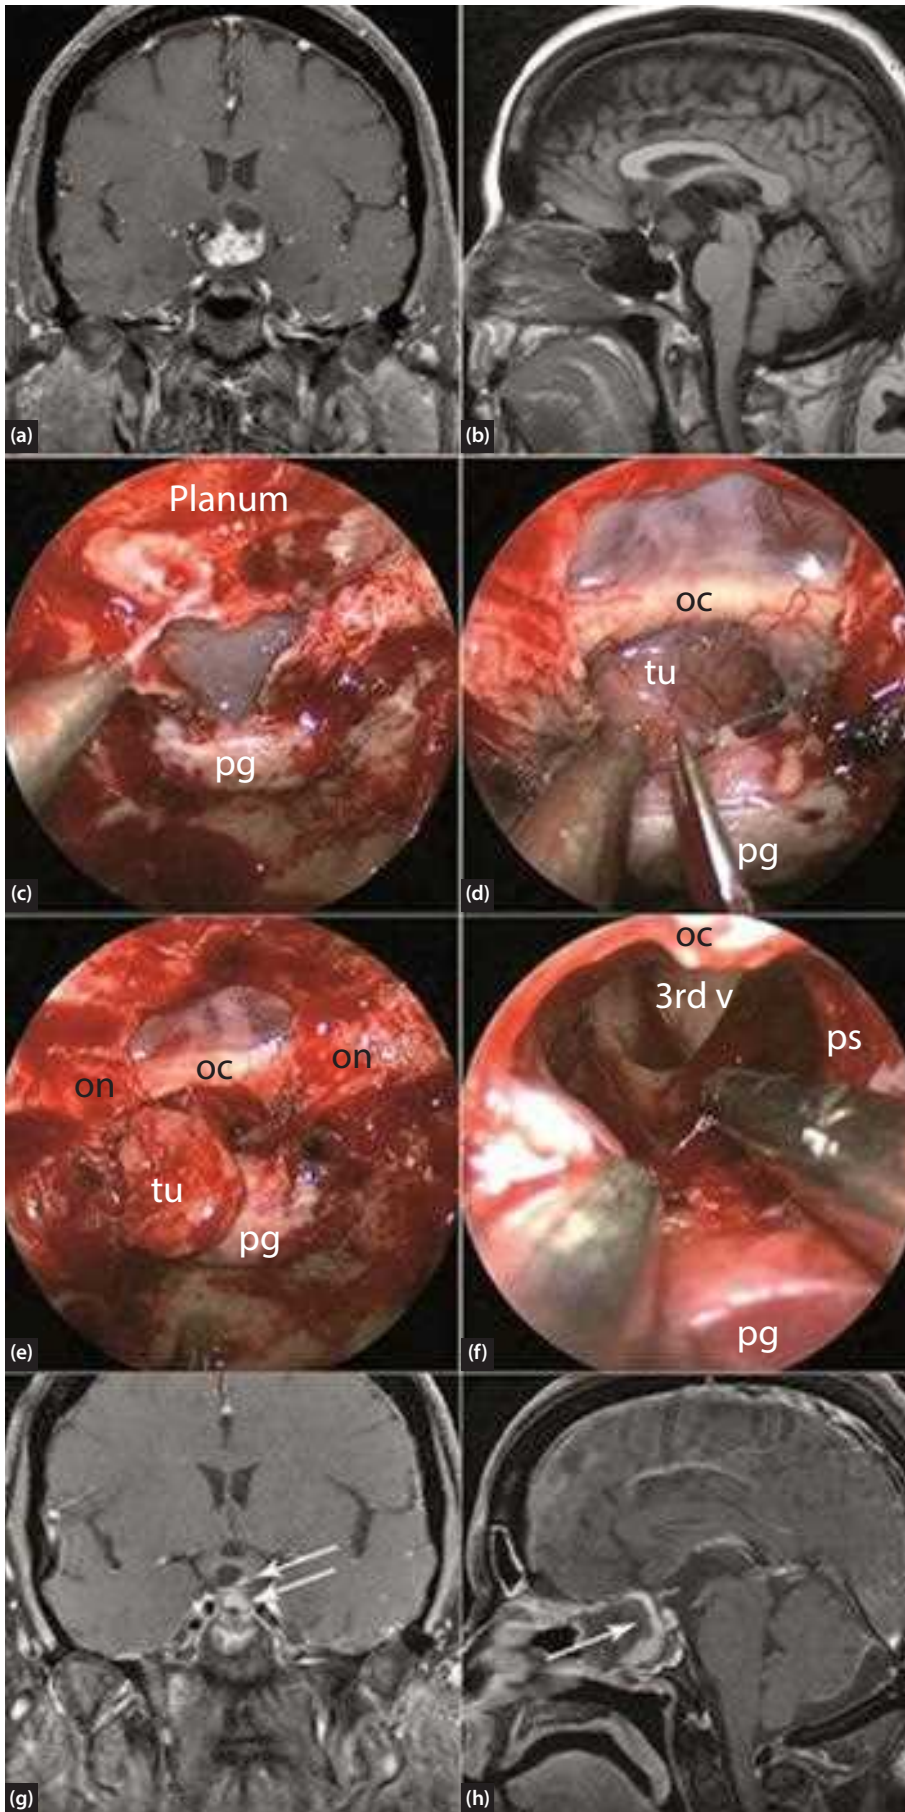

Figure 116.15 Craniopharyngioma.

Pre-operative, intra-operative and post-operative images of a suprasellar craniopharyngioma with intraventricular extension that underwent GTR with EES. **(a, b)** Pre-operative MRI demonstrates a mixed solid and cystic suprasellar tumour that invades the floor of the 3rd ventricle. **(c)** Intra-operative view with a 0-degree endoscope after bony resection of the planum, tuberculum and anterior wall of the sella with exposure of the pituitary gland (pg). **(d)** After opening the suprasellar arachnoid, the optic chiasm (oc) is identified and the solid compartment of the tumour (tu) is visualized between the optic chiasm and the pituitary gland (pg). **(e)** The tumour (tu) is dissected and removed from the suprasellar cistern. The dura over the optic nerves (on) remains intact. **(f)** A closer view with the 0-degree endoscope provides direct visualization of the 3rd ventricle (3rd v), the floor of which was eroded by the tumour. Having removed the tumour, the pituitary stalk (ps) is identified with deviation to the left. The optic chiasm (oc) and pituitary gland (pg) remain intact. **(g, h)** Post-operative MRI with contrast confirm GTR of the craniopharyngioma. The pituitary stalk can be seen on the coronal image (upper arrow) deviated to the left, just above the pituitary gland (lower arrow). The linear contrast-enhancing area on the sagittal MRI (arrow) represents the vascularized nasoseptal flap that was used for skull base reconstruction and the enhancing spot behind the flap is the intact pituitary gland.

Reconstruction of dural defects of the anterior cranial base is ideally performed using vascularized tissue.⁵ Although small dural defects are effectively repaired using a variety of techniques and materials, the use of vascularized tissue is associated with significantly lower post-operative CSF leak rates for larger defects. Local vascularized flaps include middle turbinate, inferior turbinate, and nasal septal flaps, all of which are based on terminal branches of the sphenopalatine artery. Regional vascularized flaps include pericranial and temporoparietal fascial flaps. Of these, the nasal septal flap and pericranial flap offer the best coverage and are preferred for reconstruction of large defects of the anterior cranial base.

The nasal septal flap⁶ is raised at the beginning of the procedure to preserve the vascular pedicle. The superior incision runs parallel to the skull base approximately 1 cm below the skull base. If there are concerns about tumour involvement of the septum, clear margins are assessed by frozen section or reconstruction with a pericranial flap is considered. The inferior incision runs from the posterior choana along the posterior edge of the nasal septum to the junction of the nasal septum and nasal floor. If a wider flap is needed, the nasal floor can be incorporated into the flap. The anterior incision connects the superior and inferior incisions at the junction of the septal mucosa and skin of the nasal vestibule. It is important to include the most anterior-superior septal mucosa that is anterior to the attachments of the middle turbinate in order to harvest a maximal flap. After the flap is elevated from the underlying septal cartilage, it is displaced into the nasopharynx during the remainder of the procedure.

When it is time to repair the dural defect, an inlay fascial graft is placed between the brain and the dura. The septal flap is then transposed to cover the entire defect. All surrounding mucosa should be removed so that the entire flap is in contact with bone or dura. If the flap is not long enough, the reach of the flap can be extended by drilling the sphenoid floor or filling the clival recess with autologous fat grafts. The margins of the repair can also be augmented with onlay fascia grafts placed under the flap or fat grafts placed over the edges of it as needed. The donor site on the anterior nasal septum is covered with a free mucosal graft when available, and Silastic® nasal splints are placed.

An extracranial pericranial flap provides maximal vascularized tissue for reconstruction.⁷ After the intradural fascial graft is placed, the flap is harvested using a bicoronal scalp incision. The scalp is elevated to the level of the nasion and supraorbital rims with preservation of the supraorbital neurovascular bundle on one or both sides. The bone at the level of the nasion is then drilled to create a window (approximately 2.0 cm × 0.5 cm) into the nasal cavity that is below the level of the skull base (Figure 116.16). The pericranial flap is then dissected from the scalp in a subgaleal plane and passed through the bony defect into the nasal cavity. Rotation of the flap is facilitated by sacrificing the vascular pedicle on one side. Endonasally, the flap is spread out to cover the dural and bony margins of the defect. If possible, the flap pedicle is displaced to one side to prevent obstruction of the drainage

Figure 116.16 An extracranial pericranial flap requires drilling (a) of a bone window (arrow) at the nasion that extends from orbit to orbit below the level of the skull base (b). The pericranial flap (PF) is pedicled on one or both supraorbital vessels and passed through the bone window into the nasal cavity (c).

pathway of the Draf 3 frontal sinusotomy. Care should be taken to ensure the proximal flap is in contact with the anterior aspect of the skull base defect or the bone of the posterior table of the frontal sinus.

The reconstructive flap is then covered with layers of Surgicel®, tissue glue, and Gelfoam®. Support of the reconstruction is provided by a Foley catheter inflated with saline or Meroce® tampons. Tampons are preferred

for large anterior defects and when the optic nerves are exposed and susceptible to compression.

CASE EXAMPLE: PERICRANIAL FLAP

A 79-year-old female underwent EES for an olfactory neuroblastoma. Because of septal involvement by the tumour, reconstruction of the anterior cranial base defect with a nasoseptal flap was not possible (Figure 116.17). An extracranial pericranial flap was harvested using a bicoronal scalp incision and was passed into the nasal cavity inferior to the skull base using a bony window at the level of the nasion and covered the defect widely, including the medial orbits. The post-operative course was not complicated by a CSF leak and sensory and motor function of the frontal scalp was preserved.

Figure 116.17 A nasoseptal flap was not available for reconstruction of this dural defect. (a) Following endoscopic endonasal excision of an olfactory neuroblastoma. (b) An extracranial pericranial flap provided ample coverage of the defect (original dural defect outlined). Note drainage pathway (arrow) for the frontal sinuses to the side of the flap pedicle.

Post-operative care

Patients are monitored for signs of intra-cranial complications and a CT scan of the brain is performed within 8 hours to look for evidence of intra-cranial haemorrhage or tension pneumocephalus. Visual outcomes are assessed if dissection included the optic nerves/chiasm. If a suprasellar approach is performed, patients are also at risk for diabetes insipidus and are managed in conjunction with the endocrinology service. Antibiotic prophylaxis is continued for the duration of nasal packing. After 24 hours, patients can be switched to an oral cephalosporin (Ceftin). Lumbar drainage is used in patients with significant arachnoidal dissection (i.e. high-flow leaks), but there is limited evidence to support this practice.

Nasal packing is removed in 5–7 days; this can be done in the outpatient clinic. Nasal splints are maintained for 1 week if a pericranial flap is used and for 3 weeks if a septal flap is used. This facilitates mucosalization of the septum. Nasal irrigations with saline are performed daily and periodic endoscopic debridement of the nasal cavity is performed until healing is complete.

OUTCOMES

We have successfully treated several nasal dermoids with intra-cranial extension (extradural) through foramen cecum using an endonasal approach. Review of the literature demonstrates minimal data regarding endoscopic endonasal resection of nasal dermoids.⁸ The initial experience is positive, however, and suggests that equivalent outcomes can be achieved with these techniques.

Oncological outcomes for sinonasal malignancy are limited. A meta-analysis of 23 studies (361 patients) of treatment for olfactory neuroblastomas demonstrated a higher published survival rate for endoscopic surgery when compared to open surgery, even when stratifying for year of publication. Although endoscopic series had similar follow up, they had earlier stage (Kadish) disease, suggesting a treatment bias. Data are even more limited for other sinonasal malignancies such as squamous cell carcinoma, adenocarcinoma, and sinonasal undifferentiated carcinoma. Early results suggest that comparable results can be achieved using endoscopic techniques.

The optimal approach for olfactory groove meningiomas remains controversial, but there is a role for EES for debulking large tumours in the elderly and avoiding frontal lobe retraction. In a review of 44 patients who underwent EES for olfactory groove meningiomas (unpublished data), 55% underwent gross total resection, 16% near total and 30% subtotal. In 16 patients, tumours were removed in two stages, both to allow tumour descent/ collapse and as part of the endoscopic learning curve. Overall, the CSF leak rate was nearly 40%, but this decreased throughout the series as reconstructive techniques evolved. As a result, 6.8% of patients suffered post-operative meningitis. As experience improved, the gross total resection rate increased to almost 70% in the last 3 years. No patients had worsening of vision and 64% of those with pre-operative visual impairment improved.

Suprasellar meningiomas often present with visual impairment. In a review of 75 patients with suprasellar meningiomas, visual impairment was the most common presenting symptom in 81%. Following EES, complete resolution or improvement of visual symptoms was seen in 86% of patients with deterioration in only 4% (2 patients). These results compare favourably to the literature for open approaches and suggest that preservation of small vessels of the optic chiasm are better visualized and preserved with EES. Gross total resection (GTR) was achieved in 79%. GTR was limited by large tumours (>3 cm), multi-lobulated tumours, and those with vascular encasement but not by optic canal involvement. CSF leak was the most common complication in 25% of patients but has decreased to 16% since the introduction of the nasoseptal flap for reconstruction.

Craniopharyngiomas are well suited for an endonasal approach. We performed a retrospective review of 64 patients (47 adults, 17 children) with craniopharyngioma who underwent EES.⁹ The most common presenting symptom in adults was visual loss (81%); headache was most common in the paediatric population (65%). Resection >95% was achieved in 72% of patients; the resection rate was significantly better in the paediatric population. Of those patients presenting with visual impairment, vision was improved or normalized in 86%. In patients with normal pituitary function ($n = 24$), new pituitary deficit occurred in 14 (58%). Other than pituitary dysfunction (hypopituitarism and diabetes insipidus), CSF leak was the most common complication (23%) but decreased to 11% following introduction of the nasoseptal flap for reconstruction. Treatment options for recurrent disease (34% of patients) included repeat EES in 55% of recurrences. With the goal of gross total or near total resection, EES can be employed for the treatment of every craniopharyngioma regardless of the location, size and extension (excluding purely intra-ventricular tumours) and can provide acceptable results, comparable to traditional craniotomies. This surgical technique is not limited to adult patients, actually showing higher resection rates in the paediatric population.

In patients undergoing EES of the skull base, excellent QOL scores are noted using the anterior skull base questionnaire.¹⁰ One area of relative deficiency is in specific symptoms, such as olfactory loss. Limited data suggest that QOL is superior to open transcranial approaches for tumours involving the anterior cranial base. Nasal morbidity has

been assessed in the endonasal surgical group using the SNOT-22 questionnaire, a validated instrument.¹¹ The use of a nasoseptal flap for reconstruction had a limited negative impact. As expected, increasing nasal morbidity (decreased QOL) has been noted in the expanded (non-transsellar sagittal plane and coronal plane) surgical modules compared to transsellar surgery.¹²

COMPLICATIONS

Complications may be categorized in multiple ways, by location, type, or time period. Intra-operative complications are rare and depend on the type and extent of pathology and the surgical approach.^{13, 14} The most serious intra-operative complications are injuries to the optic nerves or carotid arteries. Meticulous surgical technique, familiarity with endoscopic anatomy, and good visualization are key factors in avoiding injury. With a transcribriform approach, the frontopolar vessels are at particular risk and the dura should be initially incised laterally to avoid injury. Visual loss may result from direct trauma to the optic nerves or from loss of vascular supply (branches of superior hypophyseal arteries).

Post-operatively, the most common complication is CSF leak. Potential risk factors include the size and location of the dural defect, patient factors (prior treatment, obesity), reconstructive technique (materials, vascularized flap, packing), and perioperative care (patient activity, lumbar drain, debridement). Most leaks are small and are related to insufficient coverage by the reconstructive tissues. In most cases, endoscopic repair supplemented by a lumbar spinal drain is successful. Intra-cranial infection is rare and is usually associated with a post-operative CSF leak. Prompt repair of CSF leaks and limited use of lumbar spinal drains is encouraged to limit the risk of infection.

Sinonasal complications include sinusitis, epistaxis, synechiae, chronic crusting, cosmetic deformity, and loss of olfaction. Delayed epistaxis is usually due to a branch of the sphenopalatine artery. A saddle-nose deformity can result from loss of septal support. Even if the olfactory nerves are preserved, some loss of olfaction is common and may be due to altered airflow patterns, mucosal oedema and crusting, post-operative irradiation, or direct damage to the olfactory epithelium or olfactory tracts. Fortunately, QOL studies demonstrate that overall sinonasal morbidity is low.

KEY POINTS

- The anterior cranial base from the frontal sinus to the sella and from orbit to orbit is accessible using EES.
- These techniques can be applied to a wide variety of lesions including meningoencephaloceles, benign tumours (nasal dermoids, meningiomas, craniopharyngiomas, pituitary adenomas) and malignant tumours (sinonasal malignancy) with preservation of microsurgical and oncological principles.
- Many of the challenges of endonasal surgery have been solved and large dural defects can be reconstructed effectively using vascularized flaps.
- Oncological and functional outcomes are comparable or superior to other approaches with the potential for decreased morbidity.
- Proper training in endoscopic techniques and adherence to the principles of team surgery is necessary to avoid complications and achieve superior outcomes.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: sinonasal, paranasal, and diagnostic imaging with cross-referencing from the papers thus identified.

INTRODUCTION

Modern imaging has come to occupy a pivotal role in the pre-/post- (and intra-) operative depiction of patient anatomy and disease localization in the sinonasal region, and can, on occasion, provide insights into pathology. The principal modalities used in sinonasal imaging are CT and MRI, and their role (as outlined in the examples that follow) is frequently complementary. PET-CT, a technique combining anatomical information with metabolic information (by virtue of uptake of the glucose analogue ^{18}F -FDG), is increasingly utilized in head and neck cancer imaging in general (for example, in the investigation of the unknown primary), although its role in sinonasal imaging is still emerging.

Plain film imaging is now largely obsolete (except in the context of trauma or, perhaps on the rare occasion when an AP frontal sinus radiograph may be used in template planning for osteoplastic flap surgery). In one study, comparing plain radiographs and coronal CT scans in a paediatric population with recurrent sinusitis, there was an almost 75% discordance between plain film and CT findings.¹ Plain radiographs are neither necessary nor sufficient to either exclude or confirm sinus disease. This advice may be modified, however, in healthcare systems where access to modern cross-sectional imaging is limited.

IMAGING MODALITIES – TECHNICAL ASPECTS

Computed tomography (CT)

Multi-detector row CT (MDCT) enables a patient to be rapidly scanned in the supine position, resulting in submillimetre slices that can be reformatted, in high resolution, in axial, coronal or sagittal planes.

The main drawback with CT is that it involves ionizing radiation. Radiation dose to the lens of the eye is a specific concern in relation to sinonasal imaging and work has focused on the potential for reducing the dose of radiation whilst still maintaining diagnostically satisfactory images.²

With CT, high-attenuation ('white') bone contrasts against low attenuation ('black') air and intermediate ('grey') soft tissue and fluid. In terms of providing contrast between different soft tissues or fluid, intravenous iodinated contrast can be of assistance, to some extent, although MRI is superior and usually to be preferred (particularly in the assessment of neoplastic disease where contrast between tumour and secretions/inflamed mucosa is desirable).

Magnetic resonance imaging (MRI)

Having the advantage of no ionizing radiation and superior soft tissue contrast, the imaging sequences employed

usually involve a combination of T1- and T2-weighted images with Gadolinium contrast agents being employed to assess complications of inflammatory disease or to assess spread of neoplasms (particularly to assess perineural tumour spread and dural invasion).

Note that in comparison to CT, no (or very little) contrast is seen on MRI between air and cortical bone (both low signal, or 'black', thus CT more optimally depicts the intricacies of bony anatomy), between cortical bone and fast-flowing blood (for example, between the wall of the sphenoid and the internal carotid artery), or between air and dessicated secretions (both signal voids on T2-weighted images, see below). Thus, there are pros and cons to both CT and MRI and frequently both are needed – particularly in assessing disease involving the skull base.

A particular feature of MR imaging of the paranasal sinuses is the effect that increasing viscosity and protein concentration within secretions has on T1-weighted and T2-weighted images signal intensities – a source of potential confusion. As protein concentration (or viscosity) increases, the signal intensity on T1-weighted images (which for water is low to intermediate) increases and then falls (becomes bright and then dark). For T2-weighted images (starting with bright 'water' signal) there is a gradual decrease in signal intensity³ (Figures 117.1 & 117.2).

At the extreme end of the spectrum, with markedly viscid and dehydrated secretions, a signal void is produced on all imaging sequences.⁴ If MRI is the initial investigation then this could be mistaken for air, although a clue to the presence of dessicated secretions may be the finding of expansion of the affected sinus (a mucocoele) (Figure 117.3). CT will clarify by demonstrating intermediate or high attenuation contents ('grey') within the sinus (as opposed to air which would appear 'black').

MRI Signal Intensity of Proteinaceous Secretions		
	T1W	T2W
'Water'		
'Syrup'		
'Paste'		
'Solid'		

Figure 117.1 MRI of sinus secretions. Note, as the concentration of sinus secretions increases the signal intensity on T1-weighted images goes from intermediate to high to low, whereas on T2-weighted images the signal intensity progressively decreases.

Positron-emission tomography/computed tomography (PET-CT)

A technique fusing the anatomical information of CT with metabolic information provided by uptake of the glucose analogue ¹⁸F-FDG (fluoro-deoxy-glucose) and predicated on tumour (or inflammatory) tissue having increased metabolism and thus increased glucose uptake in comparison to normal tissue. As indicated, its potential role in sinonasal imaging is gradually being appreciated but we will return to this topic towards the end of this chapter.

Figure 117.2 MRI of sinus secretions (olfactory neuroblastoma).

A large nasal cavity olfactory neuroblastoma causing obstruction of the frontal and maxillary sinuses (T1-weighted image on left, fat-suppressed T2-weighted image on right). Note the differing signal intensities of secretions in the affected sinuses depending on their concentration. Mucosa lining the right maxillary sinus (arrows) is of a similar signal intensity to the aqueous humour (equates to water) in the globe above. Within the right maxillary sinus (arrowheads) the concentration of secretions begins to increase and, as a result, the signal begins to increase on T1-weighted images and decrease on T2-weighted images. Compare with the left maxillary sinus (large arrows) where, as the concentration increases still, the signal on T1-weighted becomes markedly high whilst continuing to reduce (although remaining fairly high) on T2-weighted images. With increasing thickness/concentration of secretions in the frontal sinuses (stars), the signal remains high on T1-weighted images but has now dropped out on T2-weighted images.

Figure 117.3 Mucocoeles containing signal voids. Dessicated secretions can produce a signal void that can be confused for an air-filled sinus, particularly on T2-weighted images. The expansion of the sinus walls hints at a mucocoele and in both cases CT confirmed an opacified sinus.

IMAGING – APPLICATIONS

Depicting anatomy

Sinonasal anatomy is subject to tremendous variation and is virtually unique to any one individual such that plain radiographic and, more recently, CT assessment of sinus anatomy are well-recognized techniques for victim identification in forensic investigation.⁵

Some anatomic variants are relevant in terms of potential risk of surgical complications: for example, asymmetry of the anterior skull base (in particular the fovea ethmoidalis) or the presence of an Onodi cell (or sphenothmoidal cell—a posterior ethmoid cell projecting posteriorly and laterally to, or more commonly above, the sphenoid sinus to be related to the optic nerve).⁶

There are also a number of anatomic variants which have a close relationship to the drainage pathways of the paranasal sinuses. It is controversial as to whether any of these (other than maybe nasal septal deviation) have an aetiologic role in the development of sinusitis.⁷ However, an understanding of these variants remains necessary to safe and effective sinus surgery. The reader will be familiar with most anatomic variants including the concha bullosa (pneumatized middle turbinate) and the Haller cell (an air cell located below the ethmoid bulla, inferomedial to the orbit).

More complex are the variants of anatomy occurring in the frontal recess region. This area is of particular concern as this is a difficult area to operate in and as the frontal sinus is an area prone to sinusitis recurrence following FESS.⁸

In understanding frontal recess anatomy, it is useful to start with the basic template of frontal sinus, frontal sinus ostium, frontal sinus drainage pathway, agger nasi cell and ethmoid bulla (Figure 117.4). To this template we can consider the various potential frontal recess cells in three groups: medial, anterior and posterior. The medial group consists of the interfrontal sinus septal cell which is best seen on coronal images and easily appreciated as an air cell arising within the interfrontal sinus septum.

The anterior group of frontal cells are classified into types 1 to 4 (Figure 117.5).⁹ Note that in Kuhn's original classification a type 4 cell is an isolated cell in the frontal sinus. However, Wormald⁶ has modified this classification describing both type 3 and 4 cells as frontal cells which pneumatize through the frontal sinus ostium and extend cephalad to a height either less than (type 3) or more than (type 4) 50% of the height of the frontal sinus.

The posterior group consists of the suprabullar cell and the frontal bullar cell, the differentiating characteristic of the latter being that it extends beyond and above the frontal sinus ostium in contradistinction to the former (Figure 117.6).

Also belonging to the posterior group, and the hardest cell to illustrate conveniently in a single image (requiring study of both coronal and axial images), is the supraorbital cell.¹⁰ The opening is usually found anterior to the canal for the anterior ethmoidal artery and it extends laterally to pneumatize the orbital plate of the frontal bone, its distinction from the frontal sinus made clear on axial images, where a bony septum can be seen between the two.

Figure 117.4 Typical frontal recess anatomy as demonstrated in parasagittal section. Frontal sinus ostium (dotted line) runs from frontonasal beak (interrupted arrow) anteriorly to anterior skull base posteriorly. Frontal sinus drainage pathway (dashed line). Note wide superior compartment leading into narrow inferior compartment. Agger nasi cell (small arrow). Ethmoid bulla (large arrow). (Note small suprabullar air cell).

Figure 117.5 Type 1 frontal cell. Type 1 frontal cell (large arrow) sitting above agger nasi cell (small arrow). Note relationship to frontonasal beak. Note the frontal sinus ostium (interrupted line). In a type 2 configuration there are two cells above the agger nasi cell but below the frontal sinus ostium. In type 3 and type 4 configurations a large frontal cell extends through the ostium into the frontal sinus for a variable distance of either <50% (type 3) or >50% (type 4) of the height of the frontal sinus.

Figure 117.6 Suprabullar cell (star). Note relationship to anterior skull base and frontal sinus ostium (dashed line). A frontal bullar cell extends above the dashed line into the frontal sinus.

Sinus inflammatory disease

INCIDENTAL FINDINGS

Mucosal thickening, fluid-filled sinuses and retention cysts are common findings in asymptomatic patients imaged for other reasons: for example, patients undergoing MRI of the head/brain for neurological symptoms,¹¹ or of the internal auditory meati,¹² or cone-beam CT for orthodontic patients.¹³ It has been said that incidentally found mucosal thickening up to 3mm is of no clinical significance and that in the ethmoid sinuses 1–2mm of mucosal thickening occurs in 63% of asymptomatic patients.¹⁴ The concept of an ‘incidental’ Lund score, with 0–5 considered ‘normal’, has also been suggested.¹⁵ As regards retention cysts (recognized as dome-shaped, smoothly margined opacities on CT with high (fluid) signal on T2-weighted MR; [Figure 117.7](#)), the natural history is that the majority either regress or remain unchanged.¹⁶

Figure 117.7 Maxillary sinus retention cyst. High signal on T2/fat-saturated images. Typically smooth outlined, ‘dome-shaped’ lesion.

The relevance of these incidental findings depends on correlation with clinical findings.

RHINOSINUSITIS (TYPICAL)

The diagnosis of rhinosinusitis is largely a clinical/endoscopic one. Whilst a negative CT is useful to rule out rhinosinusitis and provoke the search for an alternative diagnosis (particularly where the predominant symptom is facial pain¹⁷), the role of CT when sinusitis is diagnosed is largely one of demonstrating the bony anatomy prior to surgery and defining disease extent ([Figure 117.8](#)). Disease extent can be quantified through the use of one of a number of staging systems of which the Lund-Mackay system¹⁸ is perhaps the best known. CT acquisition is also needed

Figure 117.8 Rhinosinusitis. OMU pattern. A case of rhinosinusitis conforming to an ostiomeatal unit pattern of disease involving frontal, maxillary and anterior ethmoid sinuses. Whilst this pattern of disease suggests obstruction at the level of the middle meatus, the CT appearance of the affected sinuses is non-specifically bland.

where the operating surgeon employs a surgical navigation system in theatre.

In terms of diagnostic information, whilst sinus wall sclerosis serves as a pointer to chronicity of disease, the plain CT imaging findings are, for the most part, banal. CT (and MRI) become of more crucial use diagnostically in the investigation of the complications of sinusitis, particularly subperiosteal orbital abscess and intra-cranial infective complications.

FUNGAL SINUSITIS

Fungal sinusitis is a disparate group, with disparate imaging features (Figure 117.9), which can be classified into invasive and non-invasive forms:

Invasive (IFS)

Acute invasive fungal sinusitis (AIFS) AIFS usually occurs in immunocompromised patients and is a rapidly progressive, potentially fatal condition. Findings on CT such as bone erosion and mucosal thickening may be subtle.¹⁹ The finding of extrasinus extension (or perisinus soft tissue infiltration)²⁰ is described as an early and characteristic finding suggesting AIFS (with MR said to be more sensitive in this regard).²¹ However, a larger retrospective review²² found that the commonest early findings on CT in this condition were severe, unilateral, nasal mucosal inflammatory changes (marked mucosal thickening or complete nasal cavity opacification) and that these were found much more frequently, and earlier, than osseous erosion or extra-sinus extension. More recently, the finding on post-contrast MRI of foci of non-enhancement in the nasal cavity (the so-called 'black turbinate' sign—non-enhancing devitalized tissue contrasting with the typical mucosal enhancement normally seen in sinusitis, Figure 117.9) has been described in two patients with mucormycosis.²³ In the correct clinical context this finding has the potential to alert the radiologist and surgeon to the correct diagnosis.

Chronic invasive fungal sinusitis (CIFS) Affected patients are usually immunocompetent or have a mild degree of immunocompromise (such as diabetics).

Chronic granulomatous invasive fungal sinusitis (CGIFS) CGIFS usually occurs in Africa (Sudan) or South Asia, is usually caused by *Aspergillus* species, and occurs in immunocompetent individuals. It is considered by some not to be a separate entity but to be a subset of chronic invasive fungal sinusitis.

On CT, chronic (granulomatous) invasive fungal sinusitis tends to display homogeneous soft tissue opacification with no focal hyperdensities (in contrast to allergic fungal sinusitis). Disease tends to be limited in extent or unilateral, sinus expansion is not a feature, focal bony erosion is limited to areas of extra-sinus extension and the burden of disease is often more outwith the sinuses (for example, intra-orbital) than within.²⁴

Non-invasive

Allergic fungal sinusitis (AFS) Typically, affected patients are immunocompetent with a history of atopy. A characteristic finding at endoscopy is the presence of so-called 'allergic mucin'.¹⁹

The typical imaging findings at CT are those of unilateral or bilateral opacification of multiple sinuses, with sinus expansion, bony erosion of the sinus walls, and areas of intra-sinus high attenuation (due to heavy metals, calcium and inspissated secretions).²⁵

An important point to note is that whilst AFS is classified as non-invasive (in histopathological terms), advanced disease with sinus expansion and bony erosion can result in extensive intra-cranial and/or intra-orbital 'invasion' with an aggressive appearance on imaging which can mimic malignancy.

Also, it should be noted that the presence of intra-sinus high attenuation is not specific to AFS but can be seen with desiccated secretions in chronic rhinosinusitis. In this case the imaging features of sinus expansion and bony

Figure 117.9 Fungal sinusitis. (a) is a case of acute invasive fungal sinusitis (mucormycosis) with cribriform plate extension and dural enhancement as demonstrated on MRI. Note also the non-enhancement of the left middle turbinate and adjacent ethmoid air cells (the so-called 'black turbinate' sign) due to the presence of devitalized tissue. Compare with the normally enhancing right middle turbinate. (b) is a case of non-invasive mycetoma or 'fungal ball' on plain CT. The 'ball'-like nature of this condition containing punctate hyperdensities is difficult to appreciate on a non-contrast CT where there is no discrimination with the adjacent inflamed mucosa. (c) is a case of allergic fungal sinusitis with the ethmoid sinuses filled with high attenuation material and with expansion of the sinus causing lamina papyracea remodelling. More typically allergic fungal sinusitis is diffuse and bilateral as in (d) where there is remodelling of the skull base in the region of the sphenoid. Part (a) is reprinted from The Otolaryngologist, Vol 1(1), Fraser L, McGarry W. Core knowledge and literature review, p. 5. 2006 Copyright with permission from Rila Publications Ltd, London.

thinning point to the former whereas the latter is more characterized by thickening and sclerosis of sinus walls.

The MR appearance is typically low to signal void on T2-weighted image (due to heavy metals and desiccated secretions) and more variable on T1-weighted image.¹⁹

Fungal ball/ mycetoma A fungus ball is a tangle of fungal hyphae within a sinus, but with no allergic mucin (compare with AFS) and no evidence of submucosal invasion (compare with IFS).¹⁹ Affected individuals tend to be older and immunocompetent.

Typically a single sinus is involved, and on a non-contrast CT, an iso- to hyper-attenuating soft tissue mass is seen, frequently containing punctate or nodular calcifications. In contrast the inflamed mucosa lining the sinus is hypo attenuating on CT, hyper intense on T2-weighted image MRI and demonstrates contrast enhancement.

The fungus ball is low signal on T1-weighted and T2-weighted images as it contains little or no free water. Contained calcifications or heavy metals (iron and manganese)²⁶ produce a characteristic signal void on T2-weighted image.²⁷

Granulomatous inflammation

Covering a range of disorders, this subset is characterized by the common imaging features of nasal septal perforation and destruction of the midline sinonasal skeleton including turbinates and hard palate.

The differential diagnosis for septal perforation and mid-face destruction not only includes the various granulomatous disorders but also neoplasia (for example, squamous cell carcinoma), infection (leprosy, syphilis, tuberculosis, actinomycosis, rhinoscleroma) and cocaine misuse (Figure 117.10).

Figure 117.10 Cocaine-induced nasal cavity destruction. Note the mucosal thickening accompanying destruction of the right inferior turbinate and lower aspect of right middle turbinate. Unusually the process is unilateral and the nasal septum is not involved.

Of the granulomatous disorders, Wegener's granulomatosis has a particular propensity for involvement of the nasal cavity and paranasal sinuses.

The early features of the disease may be non-specific (mucosal thickening, sinus opacification) but with disease progression, bony destruction occurs involving nasal septum and turbinates initially. Neo-osteogenesis (to the extent of sinus obliteration) is also a feature on CT, and one which is exacerbated by surgery.²⁸

On MRI, as on CT, the early manifestations of sinonasal Wegener's may be non-specific and indistinguishable from sinusitis. In the later stages granulomatous inflammation is depicted as low-signal intensity lesions, best depicted on T2-weighted images. Orbital involvement may occur.²⁹

The imaging features of cocaine misuse are similar to Wegener's but at initial presentation the extent of mid-face destruction is usually greater (perhaps reflecting a delay to presentation).³⁰

Sarcoidosis shares similar imaging features with other granulomatous disorders, but a feature which is said to be characteristic is the finding of soft tissue nodules on the septum or turbinates.³¹

NK (natural killer cell)/T-cell lymphoma (formerly known as lethal midline granuloma) shows a tendency to spread as a thin sheet of tumour enveloping turbinates and septum³² and may extend into the nasopharynx³² or paranasal sinuses.³³ Nodal involvement is not usual. Interestingly, a recent study has shown a majority in their cohort presenting as unilateral nasal cavity disease.³³ However, the imaging findings are not diagnostic and the finding that is most characteristic for this disease is Southeast Asian ethnicity.^{32, 33}

Miscellaneous

The imaging features of a miscellaneous group that includes antrochoanal polyp and silent sinus syndrome are virtually diagnostic (Figure 117.11a and 117.11b). In the maxillary sinuses, a possible odontogenic cause of sinusitis (Figure 117.11c) should always be considered and one should consider also odontogenic cysts (Figure 117.11d) in the differential diagnosis of the 'opacified maxillary sinus'.

Sinonasal neoplasms

It is rare (if ever) that imaging will be able to definitively diagnose a sinonasal lesion without the referring clinician ultimately having to make recourse to biopsy. Conversely, however, the radiologist and clinician must be alert to those occasions when it is mandatory *not* to perform a biopsy (for example highly vascularized tumours, sphenoid sinus internal carotid artery pseudoaneurysm).³⁴

But for the most part, the purpose of imaging the sinonasal neoplasm is to delineate the extent of the tumour, both in terms of differentiating tumour from secretions or mucosa (Figure 117.12) within the sinonasal compartment (where MRI is of particular use), and in terms of defining extent outwith the sinonasal compartment.

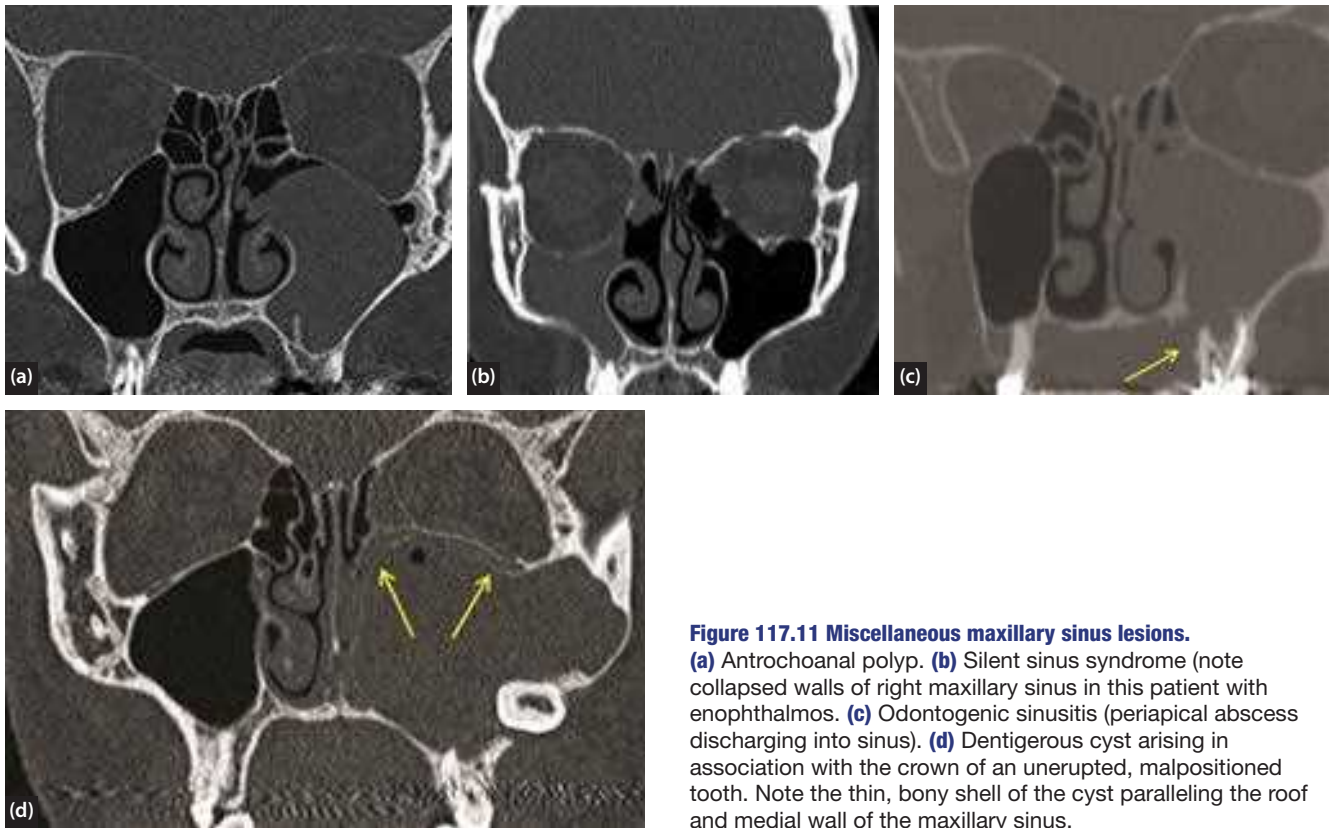

Figure 117.11 Miscellaneous maxillary sinus lesions.

(a) Antrochoanal polyp. (b) Silent sinus syndrome (note collapsed walls of right maxillary sinus in this patient with enophthalmos). (c) Odontogenic sinusitis (periapical abscess discharging into sinus). (d) Dentigerous cyst arising in association with the crown of an unerupted, malpositioned tooth. Note the thin, bony shell of the cyst paralleling the roof and medial wall of the maxillary sinus.

Figure 117.12 Tumour vs. obstructed secretions. MRI sharply defines the extent of this tumour in the anterior ethmoid sinus contrasting with obstructed secretions in the posterior ethmoids and sphenoid.

SPECIFIC TYPES OF NEOPLASMS

Inverting papilloma

A unilateral mass commonly originating in the lateral nasal wall and involving middle meatus and maxillary sinus, although less commonly the site of origin will be

the maxillary sinus itself, the anterior ethmoid sinus or, rarely, the sphenoid, frontal or posterior ethmoid sinuses. Though benign, these lesions commonly recur and are associated with squamous cell carcinoma. CT features include internal calcification, and bony erosion or bowing. Focal hyperostosis (Figure 117.13c) is a finding which has been said to correlate with the site of origin of this neoplasm – a finding which has potential relevance in planning the extent of surgery needed to achieve extirpation.³⁵ On MRI a characteristic convoluted, cerebriform pattern (Figure 117.13a and 117.13b) is said to be highly suggestive of this diagnosis, with the concomitant finding of necrosis suggesting a coexistent focus of carcinoma.³⁶

Sinonasal carcinoma

These include the common squamous cell carcinoma and the less common adenocarcinoma. Neither have specific imaging characteristics and the purpose of imaging is to define tumour extent.

Adenoid cystic carcinoma is given particular attention because of its poor prognosis, in part because of its propensity for perineural spread. However, this mode of tumour extension will be more frequently encountered in squamous cell cancer simply because the latter is much more common. Thus imaging of all forms of carcinoma must include post-contrast MR sequences with particular care given to examining the cranial nerves (Figure 117.14), pterygopalatine fossa, skull base foraminae and the intracranial compartment.

Figure 117.13 Inverted papilloma. Note the striations ('cerebriform' pattern) visible on T2 FS (a) and post-contrast (b) MRI and the focus of hyperostosis in the lateral wall of the maxillary sinus on CT (c) suggesting the site of origin of this growth.

Figure 117.14 Perineural tumour spread (recurrent SCC). Note enhancement of left maxillary nerve (also right). (a) Pre-contrast; (b) post-contrast.

Sinonasal melanoma

Sinonasal melanoma is infrequent and whilst these lesions may demonstrate high signal on T1-weighted images, presumably because of the paramagnetic effect of melanin³⁷ or haemorrhage,³⁸ a number may be amelanotic in which case the imaging features are non-specific.

Bone and cartilage tumours

In contrast to the non-specific imaging features of sinonasal disease in general, imaging (in particular, CT) of lesions arising from bone or cartilage plays a central diagnostic role in concert with pathology.

Benign lesions include osteoma, which can appear as dense cortical bone or ground-glass,³⁹ and fibro-osseous lesions (fibrous dysplasia or ossifying fibroma). Fibro-osseous lesions are readily recognizable on CT although biopsy may still be required to refine the diagnosis. In contrast, the MRI appearance of fibrous dysplasia can be misleading and may be a trap for the unwary (Figure 117.15).

Of the malignant lesions primarily arising from bone, chondrosarcoma is perhaps the most common in the paranasal sinus region and can be suggested on CT by matrix calcification (Figure 117.16a) and on MRI by high signal on T2-weighted image (as a result of a high matrix

water content) and by curvilinear septal enhancement on post-contrast images (Figure 117.16b and 117.16c).^{40, 41}

Vascular lesions

These include haemangioma, haemangiopericytoma, angiomatous polyp and the juvenile nasal angiofibroma (JNA). The clues to the vascular nature of a nasal mass include the finding of flow voids and avid enhancement with contrast (Figure 117.17). The location of the lesion is an important feature of the JNA, which characteristically expands the pterygopalatine fossa.

Lymphoma

T cell lymphomas characteristically affect the nasal septum (see above) whilst B cell lymphomas typically arise in the maxillary sinus with an epicenter close to the lateral sinus wall and tumour on either side of the sinus wall.³⁹

Neuroendocrine tumours

This is a group of tumours including olfactory neuroblastoma (Figure 117.2) and sinonasal undifferentiated carcinoma (SNUC) which tend to arise in the superior nasal fossa but which otherwise frequently have non-specific imaging features.

Figure 117.15 Fibrous dysplasia. (a) On MRI it is very easy to confuse fibrous dysplasia (in this case involving sphenoid) with tumour. (b) On CT the diagnosis is straightforward.

Figure 117.16 Chondrosarcoma. (a) Note calcified matrix of a chondrosarcoma of the nasal septum. (b) Internal septal enhancement on post-contrast MRI. (c) High signal on T2-weighted image resulting from high water content of chondroid matrix.

Figure 117.17 Juvenile angiofibroma. Note flow voids ('black dots' and curved black lines) within this brightly enhancing tumour indicating that this is a highly vascularized lesion.

Predicting dural invasion

Skull base invasion by (with or without intra-cranial extension of) a sinonasal malignancy has important implications in assessing the feasibility and extent of surgical resection and in deciding between an endoscopic or open approach to the tumour. Whilst CT is important to assess the integrity of the bony skull base owing to the contrast between bone and soft tissue, MRI becomes essential for assessing tumour relationship to dura and brain parenchyma.

Whilst a tumour with clear evidence of intra-cranial extension associated with brain oedema on MRI is generally considered to imply that the tumour has breached the leptomeninges to involve the brain parenchyma (Figure 117.18),⁴² the use of MRI in predicting earlier degrees of dural invasion has also been studied. Pial enhancement, nodular dural enhancement and dural thickening of more than 5 mm have been found to be predictive of dural invasion. A linear pattern of enhancing dura was more commonly associated with, or interpreted as, reactive inflammation adjacent to tumour.⁴² Further, where linear dural enhancement is separated from tumour by a thin hypointense zone this suggests reactive inflammation. In contrast, areas where tumour cannot be

Figure 117.18 Brain parenchymal invasion. Vasogenic oedema in the left frontal lobe implies that this tumour (an olfactory neuroblastoma) has transgressed the dura and is now invading brain.

Figure 117.19 Alveolar rhabdomyosarcoma. Note the thin linear dural enhancement (yellow arrows) representing reactive inflammation interrupted by nodular tumour tissue, indistinguishable from enhancing dura. This corresponds to the nodular enhancement described by Eisen⁴² or the focal interruption of linear dural enhancement by tumour as described by Ahmad^{43, 44} and is a marker for dural invasion.

visually separated from enhancing dura, or where there is a focal interruption of linear dural enhancement by tumour (Figure 117.19), suggest dural invasion.^{43, 44}

CSF leaks

CSF rhinorrhoea is most commonly post-traumatic in origin (frequently post-surgical), less commonly non-traumatic (tumours, infection or congenital lesions), and occasionally spontaneous. In most cases, non-contrast CT of the skull base is the only imaging investigation required to identify a skull base defect (Figure 117.20).⁴⁵

MRI should be performed in cases where a skull base defect found on CT is associated with opacification in the nasal cavity or sinus below the defect, to exclude an encephalocele or meningoencephalocele (Figure 117.21).

More advanced techniques include non-contrast MR cisternography (heavily T2-weighted with fat suppression), which relies on the detection of a continuous, bright CSF column from the subarachnoid space to the nasal cavity or sinus below⁴⁶ or, in cases where there remains a diagnostic dilemma, then more invasive cisternography (radionuclide or CT) may be considered.

MR cisternography using intrathecal Gadolinium has been used to detect CSF leaks with reported success,⁴⁷ however, its widespread acceptance has been delayed (partly due to a lack of FDA approval) and some have sounded caution regarding the lack of data confirming an absence of neurotoxicity over the long-term.⁴⁸

Figure 117.20 Arachnoid granulations. Spontaneous CSF fistula. Arachnoid granulations (yellow arrows) eroding roof of sphenoid sinus with fluid noted in the sinus below. Note extent of lateral pneumatization of the sinus. Non-contrast CT is frequently the only investigation needed to identify the site of a CSF leak.

An alternative to cisternography is the use of intrathecal fluorescein injection coupled with the endoscopic detection of fluorescein-stained CSF leaking through a skull base defect (Figure 117.22).

Figure 117.21 Encephalocele. (a) Note the defect in the lateral wall of sphenoid and the contiguous opacification within the sinus on this non-contrast CT. MRI is mandatory subsequent to this. (b) Note herniating brain tissue through the defect. The converse situation, the finding of a sinus 'polyp' or fluid adjacent to the skull base on MRI, may require a subsequent CT to more clearly depict the bony defect.

Figure 117.22 Endoscopic detection of CSF leak following intrathecal injection of fluorescein. Note skull base defect with fluorescein leakage adjacent to tip of probe. (Courtesy of Gerry McGarry).

IMAGING – NEW DEVELOPMENTS

The roles of PET-CT and DWI (diffusion-weighted imaging) are as yet not clearly defined but are beginning to emerge.

PET-CT

As sinonasal malignancies are rare, and are heterogeneous in terms of pathology, the role of PET-CT has been slow to emerge. Where PET-CT has been used in the staging or re-staging of sinonasal malignancy it has been seen to have a role in altering treatment course, particularly in the detection/exclusion of distant metastases (where consistently high negative predictive values have been demonstrated).^{49, 50} However, caution should be exercised

regarding the number of false positive studies (24%),⁵⁰ which may lead to unnecessary interventions (biopsies), and with regard to the occasional false negative study (for example, in intra-cranial disease where the normal metabolic activity of the brain may obscure disease).

It is unlikely that PET-CT will obviate the need for conventional imaging (in particular, MRI – although PET-MRI has been shown to be feasible), it is being more frequently used as an important adjunct – especially in the settings of advanced disease (where the finding of distant metastases may avoid major, potentially mutilating surgery) and in recurrent disease (where the effects of treatment, residual masses and recurrent disease are difficult to differentiate on conventional imaging).

In the setting of sinonasal papillomas PET-CT has been explored for its potential in identifying co-existent malignancies but with disappointing results.⁵¹

PET-MRI

This development has so far only been explored in terms of its feasibility but has the potential to improve soft-tissue contrast and reduce radiation exposure compared with PET-CT. Whole body imaging is feasible using this technique although the technique is not widely available and its role remains uncertain.⁵²

Diffusion-weighted imaging (DWI)

Essentially, this is an extension of MRI predicated on the degree to which free water molecules diffuse in tissues. In general, the more cellular the tissue the less extracellular space available for water to diffuse. The degree to which diffusion occurs in tissues can then be expressed in terms of the apparent diffusion coefficient (ADC). The more cellular the tissue the lower the ADC and therefore it might be hoped that measuring the ADC of a tumour might help distinguish benign tumours from, usually more cellular, malignancies. Unfortunately, the picture is complicated by factors such as tumour necrosis and the presence

of keratin, collagen or debris. A considerable overlap in ADC values has been observed between benign sinonasal tumours and malignancies⁵³ although other observers report improved differentiation between inflammation, benign lesions and malignancy through the use of ADC mapping (a visual map of ADC values assigned to individual pixels rather than an overall ADC)⁵⁴ particularly if interpreted alongside the analysis of time-signal intensity curves generated from dynamic contrast-enhanced MRI (DCE MRI).⁵⁵

Cone beam CT

A low-cost, compact technology used widely in dental practice, as yet the image quality (particularly soft-tissue contrast) does not compare with conventional CT. However, the potential for significant radiation dose-reduction exists and its role in sinonasal imaging could

include intra-operative imaging (for example, assessing adequacy of resection).⁵⁶

CONCLUSION

Modern cross-sectional imaging plays a central role in the diagnosis and assessment of sinonasal disease. Whilst MRI and CT are the key imaging modalities it is likely that the use of PET-CT will continue to expand as its role becomes clearer, particularly in the setting of sinonasal malignancy.

This is a complex area, both in terms of the anatomy of the sinonasal region and anterior skull base and in terms of the heterogenous pathologies presenting here. Increasingly therefore, there is a need for increased subspecialization by dedicated head and neck radiologists working closely with head and neck surgeons in the best interests of this patient group.

BEST CLINICAL PRACTICE

- ✓ Radiologists should work closely with clinicians and pathologists in an MDT setting.
- ✓ Radiologists should aim to subspecialize in this challenging area.
- ✓ Audit results.

FUTURE RESEARCH

- New techniques are being developed in CT to reduce radiation dose whilst maintaining high-quality images.
- Anticipated developments in cone beam CT are expected to include improved image quality and potentially intra-operative use.
- The role of Diffusion-weighted MRI is expected to be refined.
- Advancements in PET MRI are expected.

KEY POINTS

- There is virtually no role for plain radiography in the investigation of sinus disease.
- Radiation to the eyes is a particular concern with CT.
- CT and MRI differ in the contrast demonstrated between different tissues. Thus these two modalities are often complimentary.
- Sinus anatomy is subject to extreme variability between individuals.
- Mucosal thickening, fluid-filled sinuses and retention cysts are common incidental findings.
- In inflammatory disease, imaging is useful to exclude sinusitis as a cause of symptoms, to provide an anatomical roadmap to the surgeon, and to provide diagnostic information.
- In neoplastic disease, the purpose of imaging is to alert the surgeon when not to perform a biopsy and to delineate the extent of the tumour in relation to secretions and inflammation, and spread outwith the sinonasal compartment.
- The role of PET CT is an evolving one but it is of particular use in staging cancer patients with advanced disease and in detecting recurrence.
