The trial judge may allow variation in this order of evidence, particularly in complex cases, so that witnesses for both sides are called first, to be followed then by experts. This will allow experts to hear all the evidence of fact before giving a final opinion. However, the present arrangements for disclosure of witness statements make such variation rare.

At the conclusion of the case, the judge will usually hear submissions from counsel on the law to be applied and the appropriate level of damages to be awarded if the claimant is successful. It is usual then for the judge to reserve judgement, to be delivered at a later date, as most negligence cases are complex and will require some consideration. Once judgement is given, and if the claimant is successful, the judge will indicate the level of damages to be awarded. Only at that stage is the judge informed about any payment into court that may have been made, and the costs to be awarded can then be considered.

FUNDING OF NEGLIGENCE CLAIMS

Otolaryngologists may well have been concerned at the possibility that medical negligence actions in England and Wales will follow the pattern of the United States, and that the perceived increase in the number of actions here may continue. However, with the reduction in the eligibility for legal aid, many actions that would have been funded by legal aid in the past will now have to be funded privately. The introduction of contingency or conditional fees is unlikely to assist all those who are no longer eligible for legal aid. As an incentive for the claimant's solicitor, the conditional fee system²² will allow the solicitor to claim twice the rate of fees they might have otherwise obtained in a successful action. There is a risk that the solicitor might receive no payment at all if the case is unsuccessful. As suggested above, solicitors acting for patients are therefore likely to take on fewer claims,²³ concentrating on those where liability is obvious and can be quickly established. The result is likely to be that there will be no significant increase in the number of medical negligence actions in the short term. Indeed, it is possible that there

will be a reduction at the expense of patients who might otherwise have had successful claims for compensation.

The *NHS Litigation Authority 2015/2016 Annual Report*²⁴ stated that the number of new clinical negligence claims received that year had fallen by 4.6% from 11 497 to 10 965. Damages paid out that year to patients rose from £774.4 million to £950.4 million. That is an average pay out to patients of £86 675 per claim. The provision set aside to pay agreed and estimated future damages is £56.4 billion with 75% of it due to be paid in 2021 and beyond.

DUTY OF CANDOUR

The Health and Social Care Act 2008 (Regulated Activities) (Amendment) Regulations 2015²⁵ extend the fit and proper person requirement for directors and the duty of candour to all providers from 1 April 2015. Regulation 20 defines what constitutes a notifiable safety incident for health service bodies and all other providers (such as primary medical and dental practices, adult social care and independent healthcare providers). Specifically, paragraph 8 defines the harm thresholds that trigger the duty of candour for health service bodies. Paragraph 9 defines the thresholds for all other providers.

The introduction of Regulation 20 is a direct response to recommendation 181 of the Francis Inquiry report into Mid Staffordshire NHS Foundation Trust,²⁶ which recommended that a statutory duty of candour be introduced for health and care providers. This is further to the contractual requirement for candour for NHS bodies in the standard contract, and professional requirements for candour in the practice of a regulated activity. In interpreting the regulation on the duty of candour we use the definitions of openness, transparency and candour used by Robert Francis in his report:

- Openness – enabling concerns and complaints to be raised freely without fear and questions asked to be answered
- Transparency – allowing information about the truth about performance and outcomes to be shared with staff, patients, the public and regulators
- Candour – any patient harmed by the provision of a healthcare service is informed of the fact and an appropriate remedy offered, regardless of whether a complaint has been made or a question asked about it.

This does not mean that a consultant should immediately give his version of an adverse event to a patient or relative. It does mean that the consultant should report the adverse event using standard reporting facilities within his Trust. This then allows the adverse event to be thoroughly investigated, after which the truth can be shared with the patient and their relatives. There is an inherent risk in relatives getting only a partial truth or inaccurate information should there be an immediate 'knee-jerk reaction' to tell the patient what has gone wrong. This does not mean, though, that the patient should not be told that an adverse event has occurred and is being investigated.

CONSENT

Much medical litigation is caused by the practitioner's failure to disclose adequate information about the risks inherent in a given procedure. Common law recognizes the principle that every person has the right to have his or her bodily integrity respected. There is a presumption that a person should not be exposed to risk unless he has voluntarily accepted that risk, based on adequate information and adequate comprehension.

Obtaining consent to carry out an operation is necessary to avoid three sorts of legal jeopardy. The first and second arise because any touching of another person is a potential battery. (Assault is the threat of causing physical injury. An unconscious person can be battered but cannot be assaulted.) This means that, in very exceptional circumstances, a surgeon performing an operation without consent may be prosecuted in the criminal courts for alleged criminal battery. A more likely outcome of such surgery is a civil case seeking damages for the tort (or wrong) of battery. There is no need to show that anything went wrong with the surgery, merely that it was carried out without valid consent. The third, and much the most likely legal outcome regarding consent, is that the claimant tries to show that he was not warned of the risks of a proposed therapy that resulted in harm and that, had he been warned of those risks, he would have refused the treatment. An example might be a patient with a dead ear after a competently performed stapedotomy who was not warned of that risk before surgery. He may well be able to claim damages from the surgeon because he can say that 'but for' the surgeon's failure to warn of the risk, he would not have undergone the surgery. It is immediately obvious that any careful surgeon must record what potential adverse outcomes of a proposed operation have been discussed with a patient. If it is not recorded in the notes, courts have become sceptical of a statement such as 'it is my usual practice to warn of these risks'.

The question of how much information must be given to the patient would vary from situation to situation, but was generally set by the professional standard according to the Bolam test, with doctors being arbiters of how much information should be given. This meant that, in the example above, if the defendant surgeon could assemble a responsible body of opinion whose practice would not be to warn of the risk of dead ear, his conduct did not breach a duty of care.

This was modified to a degree by the case of *Sidaway* (*Sidaway v. Board of Governors of the Bethlem Royal Hospital*)²⁷ in which the House of Lords held that where the proposed treatment involved a substantial risk of grave or adverse consequences such that, notwithstanding any practice to the contrary, a patient's right to decide whether to consent to the treatment was so obvious that no prudent medical man could fail to warn of the risk (save in emergency or some other sound clinical reason for nondisclosure), then it would be negligent not to warn. To continue the example above, the claimant could argue that total deafness in one ear is such a disability that any reasonable patient would wish to be told about it pre-operatively.

Accordingly, the right of the doctor (acting in accordance with a reasonable body of medical opinion) to decide what the individual patient should be told remained enshrined in English case law. Such medical paternalism, which may be in the best interest of some of our patients, is currently and repeatedly being questioned. The doctor should realize that in *Sidaway* when the question 'Is informed consent a part of English law?' was put to the five law lords, the answer was not unanimous. Scarman said 'yes'; Diplock said 'no'; and Bridge, Keith and Templeman said 'yes with reservations'.

In assessing which material risks should be mentioned, doctors should consider the degree of probability of the risk materializing and seriousness of possible injury if it does. A risk, even if it is a mere possibility, should be disclosed if its occurrence would cause serious circumstances (*Hopp v. Lepp*).²⁸ Medical evidence will be necessary for the court to assess the degree of probability and the seriousness. A further medical factor upon which expert evidence will also be required is to assess the character of the risk; that is, is this risk common to all surgery or is it specific to the particular operation? Special risks inherent in a recommended operation are more likely to be material.

The legal standard of disclosure required in response to direct questions is also set by the professional standard (*Blyth v. Bloomsbury Health Authority*).²⁹ Although the amount of information given must depend upon the circumstances, as a general proposition it was governed by the Bolam test (*supra*).

In Australia, the doctrine of informed consent went one stage further from *Sidaway* where the reasonable patient was considered the arbiter of what risks should or should not be disclosed pre-operatively. In *Rogers v. Whittaker*,³⁰ it is clear that the risks that must be disclosed are those that affect that one patient and not the generality of reasonable patients. To take the stapedotomy analogy one last stage further, few surgeons would warn of a dead ear risk of 1 in 2000 operations and probably the reasonable patient would be unlikely to want to know that this was a complication as it is so unlikely. The question arises of whether the patient having that operation on an only hearing ear might view the risk differently and want to be aware of it in making a decision.

In 2004, the issue of consent moved further in the patient's favour in the case of *Chester v. Afshar*.³¹ In this case whilst the injury occurred despite a competent surgical technique, the claimant argued that had she known about the risk she would have taken time to consider the risk that would have resulted in the surgery occurring at a different time and therefore the adverse outcome would not have occurred in this spinal surgery case.

*Montgomery v. Lanarkshire Health Board*³² heard in the Supreme Court in Scotland in 2016 has now shifted the requirements of what a patient should be told to 'what a reasonable person would expect to be told'. The claimant alleged that had she been told that there was a significant risk of shoulder dystocia resulting from a vaginal birth that occurred in 1999 she would have elected for a caesarean section. The law lords found unanimously in favour of the claimant, effectively ending the era of

Bolam applying to consent. This has now enshrined in law the principles laid down in the 2008 GMC guidance, *Consent: Patients and Doctors Making Decisions Together*.³³

Who can give consent?

There are three categories of patient described in the Department of Health's reference guide to consent for examination or treatment: the adult with capacity to consent; the adult without capacity to consent; and children and young people.

CHILDREN

Section 8(1) of the Family Law Reform Act 1969 provides that a person over 16 may give a valid consent to medical treatment as though he was an adult. As regards children under 16, the general principle is that laid down in the Gillick (*Gillick v. West Norfolk and Wisbech Area Health Authority*) case,³⁴ that the parental right to determine whether or not a child under 16 should have medical treatment terminates when the child achieves a significant understanding and intelligence to enable him or her to understand fully what is proposed. Until such time, the parents, or others acting *in loco parentis*, may give their consent or refusal to medical treatment. Recent case law suggests that it may still be possible to treat a seemingly competent child who is refusing to give consent, providing someone else with the capacity to consent provides consent on the child's behalf (in *Re R*, and in *Re W*).^{35, 36}

MENTALLY INCOMPETENT PATIENTS

Where a patient is unable to provide consent on his or her own behalf by reason of mental incapacity, no one else, including a court, may give consent on that person's behalf. The doctrine of necessity, however, permits a doctor to lawfully operate on or give other treatment to adult incompetent patients, provided that the treatment is in their best interest, either to save their lives or to ensure improvement in their physical or mental health (*Re F*).³⁷ However, mental illness does not mean mental incompetence as was tested in the case of *Re C* (1994),³⁸ a paranoid schizophrenic held at Broadmoor, when he refused consent to have a gangrenous leg amputated despite the wishes of his managing medical team.

The Mental Capacity Act 2005 sets out five principles on which the legal requirements are based. The principles are:

1. A person must be assumed to have capacity unless it is established that they lack capacity.
2. A person is not to be treated as unable to make a decision unless all practicable steps to help him or her do so have been taken without success.
3. A person is not to be treated as unable to make a decision merely because he or she makes an unwise decision.
4. An act done or decision made, under this Act for or on behalf of a person who lacks capacity must be done, or made in his or her best interests.

5. Before the act is done, or the decision is made, regard must be had to whether the purpose for which it is needed can be as effectively achieved in a way that is less restrictive of the person's rights and freedom of action.

That a person has been judged to lack capacity in relation to a previous decision regarding their care does not mean that they lack capacity to make decisions in all situations. Capacity of an individual to make decisions should be made on a situation-by-situation basis. Capacity can vary with the nature of the decision and may change over time.

Understanding what constitutes acting in the best interests of a patient who lacks capacity can present challenges as to what the person's best interests are. Section 5 of the Mental Capacity Act 2005 states that 'An act done or decision made, under this Act for or on behalf of a person who lacks capacity must be done, or made in his best interests'; and that 'As long as these acts or decisions are in the best interests of the person who lacks capacity to make the decision for themselves, or to consent to acts concerned with their care or treatment, then the decision-maker or carer will be protected from liability'.

In deciding the best interests of a person lacking in capacity the ENT surgeon should:

- encourage the patient to take part in the decision-making process and take all reasonable steps to improve their ability to be involved in making the decision
- identify, as far as possible, all factors that patients lacking capacity would consider, were they to decide for themselves
- make all reasonable efforts to establish the patient's views including past wishes, beliefs, behaviour, decisions and values (e.g. religious, moral, political cultural or personal) and any other relevant factors that may have a bearing on their best interests; reasonable efforts include talking to family members and, where appropriate, seeking the support of an individual mental capacity advocate
- avoid making assumptions on a person's interests based solely on factors such as age, race, gender or condition
- decide whether the person may regain capacity at a later time and, if so, whether the decision can be safely delayed till this is possible
- never be motivated in any way by a desire to bring about the death of the person without capacity in decisions concerning life-sustaining treatment
- remember that the person who lacks capacity has a right to privacy and dignity and so it may not be appropriate to share all information with everyone involved in their care or those related to them through family ties.

JEHOVAH'S WITNESSES

Certain groups of patients, including Jehovah's Witnesses, may refuse to receive blood transfusions or other life-saving therapies. The Court of Appeal has affirmed patients' rights to refuse medical treatment, even if this will result in

their death; nevertheless, for such a refusal to be effective, the court must be satisfied that at the time of refusal the patient's capacity is not diminished by illness or medication or given on the basis of false assumptions or misinformation. In the case of *Re T*,³⁹ Lord Donaldson said:

An adult patient who suffers from no mental incapacity has an absolute right to choose whether to consent to medical treatment, to refuse it or to choose one rather than another of the treatments being offered.

A decision to refuse medical treatment does not have to be sensible, obviously rational or well considered, and in the case of a competent patient, the doctor cannot override the patient's wishes because he believes it to be in the patient's best interests.

OTHER SPECIAL GROUPS

Pregnant women, patients who are human immunodeficiency virus positive or suffering from acquired immunodeficiency syndrome and the elderly do not represent special categories for the purposes of consent. Although the amount of information that has to be given to a patient varies from case to case, a decision to withhold information solely on paternalistic grounds that it may deter the patient from accepting the therapy is not justified in law.

CONFIDENTIALITY

Doctors are well aware of their duty of confidentiality, originally stated in the Hippocratic oath. What is often not appreciated is the common law and statutory basis of this duty and the circumstances in which confidential information may legally be revealed. There is a common law duty placed upon professionals to guard confidential information. A patient may sue a doctor through the civil courts if there is alleged to have been damage as a result of breach of confidentiality. The Data Protection Act (1997) places a statutory duty on anyone who holds patient identifiable data (in any form) to guard and release that information under strict controls. Any surgeon who keeps any sort of patient identifiable information at his residence (where his employer's blanket registration under the act will probably not apply) and who is not registered with the data commissioner breaches the provisions of the Act. It is particularly important to note in this context that, if disclosure is properly requested, it is an offence to fail to disclose **all** of the records, both computerized and manual.

The second statute that obliges surgeons to care for information appropriately is the Human Rights Act (1998). This enshrines in UK law the sixth clause of the European Convention on Human Rights granting citizens an absolute right to privacy and to family life.

There are a number of instances in which confidential information can be released. The first is with the consent of the patient. This is sometimes implied consent such as applies when a GP releases confidential information in a referral to a consultant (and so to both secretaries).

On other occasions, there needs to be expressed consent, for instance in release of information to insurers when a holiday must be cancelled. Sometimes a doctor is obliged to release information. The statutory examples concern the Terrorism Act 2000 and its successors such as the Terrorism Act 2006, the Counter-Terrorism Act 2008, the Abortion Act 1967 and the infectious diseases regulations. A court has power to require disclosure of records and there are several cases where disclosure is appropriate in the public interest. These are to protect the rights of others, such as reporting to prevent or detect serious crime or to prevent suspected child abuse and in reports to the Driver and Vehicle Licensing Authority. In all cases of this nature where the disclosure is not governed by the Data Protection Act, the information released must be no more than that necessary to comply with the public duty. A surgeon with any doubt as to how to resolve the conflict between duties of confidentiality and the public interest is well advised to consult his or her medical indemnity organization and to ensure that the final decision is one with which a responsible body of medical opinion would concur (*Bolam*).

The situation after the death of the patient is different. Doctors have a duty to disclose on death certificates and to national confidential enquiries as well as to the police and courts, especially the coroner. Data protection no longer applies and the relevant statute is the Access to Health Records Act 1990. This clarifies that executors or, failing them, next of kin can consent to release of medical records. It appears that anyone with a legitimate claim to view the record can see that part of the record that is relevant.

THE CORONER

The Coroners and Justice Act 2009 was implemented in 2013 and saw a change in the coroner service in the UK. Going forward, newly appointed coroners now have to be legally qualified. The Act also created the post of the Chief Coroner. The coroners' service remains a local service funded by the local authority and provides a service to the local community. There has been a dramatic reduction in the number of inquests still open after a year and it has been proposed that a system of medical examiners be introduced, which is likely to reduce the number of deaths reported to the coroner's office.

When the coroner is mentioned, most doctors ask three questions: What deaths must be reported to the coroner? What verdicts can be brought and will these criticize the doctor? And what must I do if required to write a report for or appear before the coroner?

The following must be reported to the coroner:

- violent or unnatural death
- death in custody (even if the prisoner was licensed on leave to attend the hospital)
- death where no doctor is able to issue a death certificate.

Most jurisdictions also have local agreements about the reporting of deaths within a certain period after hospital

admission and after surgical procedures. Coroners usually wish to know about deaths from notifiable diseases and industrial diseases, and deaths of those in receipt of war pensions.

The range of verdicts that the coroner can return is limited. The coroner's court (in theory at least) is not adversarial and no finger of blame should be pointed by the court. The coroner's remit is to establish the identity of the deceased, the time and place of death and the mode of death. Although death due to gross neglect is an acceptable verdict, death due to negligence is not. In practice, of course, the family of the deceased and their lawyers may use the proceedings of the coroner's court to assess whether or not an action in negligence is likely to succeed.

What about the surgeon called upon to provide a report to the coroner? The first piece of advice would be for the surgeon to contact his or her defence organization for support. The report itself should be factual, full and directed to a non-medical audience. The report should not contain opinion but just facts. In particular, a report to a coroner should never contain the words 'negligent' or 'negligence'. Not only are these a matter of opinion and not fact, but they also have special well-defined meanings for lawyers that may not be apparent to doctors.

In most cases, the report will be all that the coroner needs and the doctor will not be required to appear. If the coroner feels that the evidence that the doctor can give may be crucial to his investigations, then he will summon the doctor to the inquest. Sometimes the family of the deceased will see this as their opportunity to confront the doctor, who they see as the source of their grief. To be fair, sometimes the process works well, the family see that the doctor is not some kind of ogre and the resentment fades. Even if this does not occur, the coroner should ensure that the family do not persecute the doctor and that the proceedings remain directed towards establishing the who, when, where and how but not why the deceased perished.

If the doctor anticipates a difficult inquest, he may be accompanied by legal assistance but the solicitor may not answer for him and there is no cross-examination of the other side. Defence organizations can advise the doctor but there is always a risk that the presence of a legal advisor will make the family (and the coroner) suspect that some sort of cover-up is being attempted.

Doctors summoned to the coroner's court need to follow the usual rules of court appearances – dress smartly but conservatively and do show appropriate respect to the coroner. Bring the notes or fair copies and copies of the reports already supplied and read them through before the case opens. Remember that the doctor is a witness and not an advocate or defendant and so there is no problem in asking for a question to be repeated or for a pause while the notes are consulted before answering.

THE ROLE OF THE EXPERT

An expert medical witness is instructed by either the defence or the claimant to give his or her opinion on the medical matters pertinent to the case to the court.

This evidence is different from that of a material witness who is asked for the facts. The expert's job is to interpret the facts for the court. In simple terms, it is 'to give impartial advice and opinion'. Many otolaryngologists will be called upon to give expert opinion on personal injury cases where neither the claimant nor the defendant is a clinician. The many reports on noise-induced hearing loss that have been written by otolaryngologists are a form of written expert testimony in just such personal injury cases. A few otolaryngologists will be asked to prepare reports that assist courts in deciding clinical negligence claims and the special circumstances that pertain to these are discussed below.

Until the Civil Procedure Rules 1998 came into force, experts were retained by either the claimant or defendant's side and to some extent this remains the case. In theory, an expert's report would be the same whether he was instructed by the solicitors of the claimant or those of the defendant. The 1998 Rules have made it clear that the duty of an expert, whether he is expecting to be paid by the defendant or by the claimant, is to produce for the court an unbiased opinion. The 1998 Rules encourage a court, where practical, to appoint a single joint expert to produce such an opinion. They also give direction about exchange of reports, communication between and with experts and the expert's right to ask the court for directions.

In practice, the expert's evidence is usually contained in a report and it is rare for an expert to have to appear in court. The form and content of an expert report were previously based upon a well-known civil case.

In the *Ikarian Reefer (National Justice Compania Navies SA v. Prudential Assurance Company Ltd, The Ikarian Reefer)*,⁴⁰ Mr Justice Cresswell stated that he considered that a misunderstanding on the part of some of the expert witnesses had taken place concerning their duties and responsibilities which had contributed to the length of the trial. Although this was a shipping case, the seven duties and responsibilities laid down have equal validity for medical experts:

1. Expert evidence presented to the court should be, and should be seen to be, the independent product of the expert uninfluenced as to form or content by the exigencies of litigation.
2. Independent assistance should be provided to the court by way of objective unbiased opinion regarding matters within the expertise of the expert witness. (An expert witness should never assume the role of advocate.)
3. Facts or assumptions upon which the opinion was based should be stated together with material facts that could detract from the concluded opinion.
4. An expert witness should make it clear when a question or issue fell outside his expertise.
5. If the opinion was not properly researched because it was considered that insufficient data were available then that had to be stated with an indication that the opinion was provisional. If the witness could not assert that the report contained the truth, the whole truth and nothing but the truth, then that qualification should be stated on the report.

6. If after exchange of reports an expert witness changed his mind on a material matter then the change of view should be communicated to the other side through legal representatives without delay and when appropriate to the court.
7. Photographs, plans, survey reports and other documents referred to in the expert evidence had to be provided to the other side at the same time as exchange of reports.

More recently, the Civil Procedure Rules have modified these directions. The expert should obtain the Civil Procedure Rules [Chapter 35](#) and read sections 1.1 to 1.6, which is too extensive to reproduce here.

Before writing a report the expert should be aware of what the solicitor requires. Reports usually refer to one or more of the following six areas:

1. An initial statement on the possible merits of an allegation for a claimant before notes and other evidence are obtained
2. Liability
3. Causation
4. Current condition
5. Prognosis
6. Expert opinion on an area of medicine.

A quote should be given on the cost of the report in advance. Lawyers may have no concept of the cost in time and research to answer what to them may be the simplest of questions. The solicitor will not be pleased to receive a report of 100 pages with detailed bibliography costing £2000 when the damages sought are only £500 for a relatively minor event.

The report should be double spaced and typed on A4 paper. Each sheet should have the name of the claimant or defendant typed in the top right-hand corner and be separately numbered. It is also helpful to number the paragraphs. The names of the parties should be stated, as should the requesting solicitor or insurance company. It is inadvisable to use the word 'negligent' in the report. Negligence may be implied by using phrases such as 'falling below an acceptable standard' or 'followed a course of action that could not be supported by any body of medical opinion'. Phrases such as 'reckless action' or 'flagrant disregard' may have a special meaning and lead to criminal charges rather than a civil case.

There is always the possibility that the credentials of the expert will be tested in court. It is extremely unwise for the expert to step outside his field. Should he be forced to comment outside his field of expertise he should add the rider that he is speaking only as an average medical practitioner. The expert will need to be *au fait* with up-to-date research in his own field.

The medical expert in clinical negligence

The medical expert retained in a case of medical negligence is usually asked to elucidate the areas of medical contention within a case. He needs to be aware of the various views on current practice, even if these views are

held by a minority of doctors, provided always that the minority is a reasonable one and that the practices supported are logical (Bolitho). Although the temptation is to be an arbitrator of medical colleagues, in court, this is the province of the judge. Nevertheless, the expert will be asked to comment as to whether the claimant's complaint has merit. When acting for the defence the expert will inevitably come across cases where defence is impossible. Here it is the expert's duty to advise that a speedy settlement be made to the aggrieved patient. This will have the secondary benefit of avoiding a colleague's professional shortcomings being exposed to public criticism in court. Rarely, some doctors expect their colleagues to defend them whatever the circumstances. Hence, being an expert can lead to criticism or alienation by colleagues.

Medical negligence cases can take an inordinate amount of time. Not only may the expert have to inspect all the records, examine the claimant and prepare reports, he will have to do research, attend meetings with solicitors and counsel and attend court. A single case may, in unusual circumstances, take up to 100 hours of time or more. The expert should never take on a case if he cannot afford the time.

Subsection 1.6 of the practice direction requires that experts comply with the relevant approved expert's protocol. As might be expected, there is a detailed pre-action protocol for the resolution of clinical disputes. Although this is aimed primarily at the legal profession, it is required reading for any doctors involved in providing expert testimony in clinical negligence cases. In particular, the times allowed by the court for the completion of various stages of the claim and the defence are clearly stated.

The doctor as an expert witness in court

The purpose of expert opinion given in court is to persuade the judge that one side of a case has greater merit than the other. This does not mean that he should ignore inconvenient facts which mitigate against his argument. In persuading the judge, the expert should be seen to weigh up all the facts both in favour of his view and those in favour of an alternative view. Then he should give the reasons why the judge should favour one interpretation of the facts over another. It is the judge who will decide between the two sides of the argument. The expert should not be tempted to usurp the role of the judge for this may do untold damage to his own side or at the very least earn a rebuke which may undermine his confidence.

In court, the expert should wear conservative clothes. Evidence should be given in a straightforward, unequivocal manner. A personal view may be represented especially in response to a direct question but should always be tempered with information about acceptable alternative practice and opinion. He should always be prepared to concede points if it is appropriate to do so, and not to adhere rigidly to one view when that cannot be sustained. The expert often has difficult concepts to convey to the judge. The expert should not hesitate to use pictures, models or even video to illustrate a point but should avoid being seen as a flamboyant 'show off' lest he discredits himself by not giving due respect to the court.

The usual course of examining a witness in court is that the barrister for the side calling the witness will examine that witness and try to anticipate and pre-empt difficult questions from the other side. Counsel for the opposing side will then cross-examine the witness and may attempt to undermine the evidence given by the expert or the standing of the expert in his profession. Above all, the expert must not see this as a personal insult lest he should lose his temper and hence his dignity. After this potentially hostile cross-examination, the first barrister is permitted to re-examine the witness and try, if necessary, to restore the faith of the judge in that witness.

PERFORMANCE AND COMPLAINTS

Besides using the legal system to sue a surgeon in tort, patients have recourse to a number of mechanisms to resolve concerns about how they have been treated or managed. Some of these mechanisms have the potential to involve doctors in disciplinary or performance investigations so the two elements are considered together. A patient or a family unhappy with the outcome of a surgical process can of course sue in the tort of negligence but this is expensive and will succeed in only a few cases. Another option is a complaint to the Trust employing the surgeon. Trusts are obliged to have a complaints procedure and the patient is entitled to a prompt reply from the chief executive. In practice, the time limits are so tight that, especially when the complaint is a complex clinical one (rather than the more usual gripes about hospital food or parking for visitors), the first reply is a letter of acknowledgement. Following this the complaint should be answered point by point with an apology if appropriate. The chief executive must report to the complainant what action has been taken. Among the possible actions are Trust disciplinary procedures or referral of staff to their regulatory body. If this is rejected by the patient then the patient may request that the Health Service Commissioner investigate the complaint. This officer, also referred to as the ombudsman, can review the decisions made by the Trust. There may also be grounds for appeal to the ombudsman if there are problems with the terms of reference or the conduct of an independent review.

If the investigation of a complaint leads to further investigation of the conduct or performance of a doctor, there are a number of forms that this can take. One is an internal investigation by the doctor's Trust. Although there are regulations that govern the conduct of such investigations, there is such a variety of approaches that this chapter cannot be dogmatic. It is clear that a Trust must not unjustifiably suspend a doctor pending investigation and then drag its heels in the investigation. There may well be a case against the trust under the Human Rights Act (1998) and the doctor is probably best advised to consult his or her defence organization.

Two NHS organizations may put a doctor's reputation or right to practise in jeopardy. These are the National Clinical Assessment Service (NCAS) and the Care Quality Commission (CQC). The NCAS, which has been part of the NHS Litigation Authority since 2013, will deal with

concerns about the performance of individual doctors by investigating problems and arranging performance assessments where necessary. Memoranda of understanding have been agreed between the NCAS and both CQC and the GMC as well as some of the medical Royal Colleges so it is clear that a suggestion of deficient performance or conduct uncovered by one of the three organizations may well be reported to the other two.

The organization that these newer groups feed to and that has disciplinary control over doctors in the UK is the General Medical Council (GMC). This organization has a statutory duty to maintain standards and ensure that doctors registered with the GMC do not endanger the public. The GMC is bedevilled by lots of committees with similar acronyms but there are basically three routes through the system. The first stage is usually the reporting to the GMC by a Trust, by a member of the public, by another doctor or the NCAS.

Increasingly, the GMC is looking at reports in the media that suggest poor performance or conduct, and is initiating proceedings on the basis of these. The complaint is screened and the decision made to reject it at this stage or to refer it on for investigation. The screener decides which of the three routes – health, conduct or performance – is the most appropriate. More than one route may be pursued.

In 2012 the adjudication process was split off from the GMC and delegated to the Medical Practitioner's Tribunal Service (MPTS). If the screener at the GMC feels that the allegations against a doctor are serious or pose a threat to patient safety the doctor's case can be brought before the Interim Orders Tribunal, which can temporarily suspend or restrict a doctor's registration whilst the allegations are investigated or a performance assessment undertaken.

Health procedures are aimed at rehabilitating a doctor whose illness is affecting his or her work. The four stages of the process are: initial assessment; medical examination; then decision by two case examiners, one medical and one lay.

The performance procedures apply where there is 'a departure from good professional practice ... sufficiently serious to call into question a doctor's registration'. Referrals are examined and the doctor is likely to be asked to have a performance assessment. If he or she refuses, the Interim Orders Committee of the MPTS may order an assessment. Two case examiners consider the outcome of the assessment process.

After an investigation of a doctor's conduct, health or performance assessment the case examiners will: decide that no further action is required; agree undertakings with the doctor such as counselling, training, or that restriction of practice are required; issue a warning; or decide that the case is so serious that referral to the MPTS is required (this is also the case if the doctor has refused assessment). A Medical Practitioner's Tribunal can leave a doctor's registration intact, impose conditions, suspend or erase. A Medical Practitioner's Tribunal hearing is, to all intents and purposes, a court of law with a panel, advised by a legal assessor, sitting in judgement. The GMC and the doctor can be represented by barristers if necessary and, unlike the health process, the tone is adversarial. Formerly,

outcomes of all three processes could be appealed to the judicial committee of the Privy Council but now appeals are heard by the High Court.

Recently, the government has established the Professional Standards Authority. If it is felt that a decision of the GMC or the MPTS has been too lenient then the decision can be appealed through the courts by this commission in the interests of protecting the public.

THE HUMAN RIGHTS ACT

Perhaps the two most potentially influential recent statutes affecting surgeons are the Data Protection Act (DPA) (1998) and the Human Rights Act (HRA) (1998). The first of these is discussed under the heading of confidentiality, where its effects, although far-reaching, are relatively easy to predict. The HRA formally enshrines in UK legislation, the European Convention on Human Rights.

The European Convention on Human Rights

Many people understand this convention to be a product of the European Community and compliance with it to be a condition of membership. In reality it is a convention to which the UK government signed up in the 1950s. The requirement until the HRA became law was that national legislation should be interpreted in accordance with the convention. The HRA enshrines the rights defined in the convention in UK law, allowing UK citizens to claim in UK courts that their rights have been breached and seek damages or perhaps a stay of criminal proceedings.

A number of rights are described in the HRA and these are divided into qualified and absolute rights. The ones of most relevance to otolaryngologists are Articles 2, 3, 6 and 8.

Article 2 states the right to life. There are a number of ways in which this is relevant. Perhaps this is another route by which the family of a dead patient may seek redress if there is the suggestion that the death occurred due to corporate or individual error. The verdicts that are open to a coroner are discussed under the criminal law below, but, as described, this important field is changing. The coroner is a public body under the terms of the HRA and so must ensure that verdicts are in line with that act. Will we soon see a verdict of death in contravention of Article 2 of the European Convention on Human Rights returned as a halfway house between death by misadventure and unlawful killing? What would be the consequences for a subsequent negligence claim? If the strong lobby seeking to legalize assisted suicide in certain circumstances is successful, how will this sit with the right to life? It is not clear in the legislation how a patient can personally renounce his or her rights under Article 2.

Article 3 is the right not to be subject to torture or to inhumane or degrading treatment or punishment. This appears to influence the facilities that must be made available by hospitals for the care of patients as well as powerful

implications for the whole consent process. Surely it will not be long before a Trust is sued by a patient alleging that the wait on a trolley for 24 hours in casualty constituted inhumane or degrading treatment. There is also a suggestion that the coroner will have to pay regard to Article 3 as well if, in his view, there was inhumane and degrading treatment leading to a death.

There are two other Articles with relevance to otolaryngologists: Articles 6 and 8. These two interact with each other when the question of GMC and other legal and paralegal proceedings are considered. Article 6 affirms the right of all citizens to a fair and timely trial. A magistrate in the UK has already stayed a prosecution because he judged that the prosecution had taken an unreasonably long time to bring the case to trial. As the defendant was a doctor and now leaves the criminal court without even having been tried, let alone convicted, it is possible that this judgement will profoundly affect his treatment by the GMC.

Since GMC committees are trials within the meaning of the HRA, they are subject to exactly the same legal liabilities as courts and coroners. It is here that Article 6 may begin to conflict with Article 8, which grants the right to respect for private and family life. Consider the position of a surgeon seeking to refute at the GMC committee on professional performance an allegation that there is a consistent pattern of poor professional competence. In order to defend himself and to liaise with his professional advisers (solicitors and counsel), he would surely need access to the notes of the patients that he cared for and to whom he may have given substandard care. Also, the GMC might wish to call the patients as material witnesses to the substandard care. At present, there is no obligation on a patient, unwittingly a witness at a GMC committee, to grant consent to release of his or her confidential information to either the doctor or the GMC. The patient has rights under the DPA to know what is being done with his or her data and, except in certain circumstances, to withhold consent for release of that information. The exceptions do not seem to apply to GMC proceedings. Surely a patient who found out that a Trust had divulged notes to a surgeon and his legal advisors or to the GMC, in pursuit of a fair trial, could bring action under both the HRA and the DPA. Perhaps also, a patient or even a doctor other than the one being investigated, obliged by subpoena to attend a GMC hearing as a witness and subsequently hounded by the press, can argue that no respect has been shown to his or her privacy.

The whole question of how the HRA (1998) will affect surgeons is under active consideration at present. The only guarantee in this field is that lawyers will continue to use the act to push the common law in new and unusual directions.

THE CRIMINAL LAW

Otolaryngologists rarely face criminal proceedings in connection with medical practice, but mention should be made concerning two types of criminal offence that may flow from medical treatment.

INVOLUNTARY MANSLAUGHTER

In recent years, an increasing number of doctors have faced the prospect of prosecution following the deaths of their patients, allegedly as the result of medical malpractice. The English law relating to involuntary manslaughter has been in a confused state, and clarification has only very recently been provided by the Court of Appeal. Traditionally, the test for involuntary manslaughter has been one of gross negligence. In the words of the then Lord Chief Justice, Lord Hewart, in the case of *R v. Bateman*,⁴¹ in order to establish criminal liability the facts must be such that ‘the negligence of the accused went beyond a mere matter of compensation between subjects and showed such a disregard for life and safety of others as to amount to a crime against the state and conduct deserving of punishment’. Adjectives such as ‘gross’, ‘wicked’ and ‘criminal’ were used to describe the degree of negligence required. This is effectively something of a ‘gut reaction’ test for the jury. In a crime of this nature, it is arguably best left open to the jury to make the determination of criminality.

An attempt was made to further define gross negligence by the House of Lords in the case of *Andrews v. DPP*.⁴² In that instance, ‘reckless’ was considered to be the *adjective* that most closely described the concept. In this way, the House of Lords was endeavouring to ascribe as guilty states of mind the appreciation of risk, coupled with a determination to run it, or the wilful indifference to the question of whether such a risk existed. However, ‘mere inadvertence’ was not considered to merit criminal responsibility.

The test was thrown into confusion in 1981 as a result of decisions in two cases (*R v. Caldwell*⁴³ and *R v. Lawrence*⁴⁴) by the House of Lords, which redefined the concept of ‘recklessness’. The cases concerned the offences of criminal damage and causing death by reckless driving. It was determined that the defendant would be reckless if his action created an obvious and serious risk (to a victim in the case of manslaughter) and the defendant either appreciated the risk but went on to run it or failed to appreciate the risk. This test has been criticized as being unduly harsh. It allows no realistic explanation of the defendant’s state of mind to be put forward. Thus, a doctor under pressure, perhaps through overwork and being asked to perform tasks which he or she should not otherwise have been required to do, would have no opportunity to explain those circumstances as part of defence. The mere fact that an obvious and serious risk had been created to the patient, as a result of which the patient had died, would be sufficient to secure a conviction.

The test was applied in a case of motor manslaughter (*R v. Seymour*)⁴⁵ by the House of Lords in 1983. Thereafter, however, there was significant confusion as to whether the case should extend to all cases as an involuntary manslaughter. As a result, in some cases involving doctors charged with involuntary manslaughter the traditional test of gross negligence was applied; in others the new harsh formulation for recklessness was considered appropriate. In yet other cases, attempts were made to combine the two tests.

This unsatisfactory situation has been resolved to a degree by the case of *R v. Prentice and Sulliman*.⁴⁶ The case involved two junior doctors, Dr Prentice being a pre-registration house officer who, as part of the chemotherapy treatment, injected vincristine intra-theccally in error. As the Court of Appeal observed, the mitigating circumstances in relation to both doctors were many, but a version of the recklessness test was put to the jury, resulting in their convictions. These were quashed by the Court of Appeal (*R v. Prentice and Sulliman*)⁴⁷ on the basis that the test of recklessness was not appropriate for cases of involuntary manslaughter where a breach of duty is concerned, particularly for cases involving doctors, where the court observed: ‘Often there is a high degree of danger to the deceased’s health, not created by the defendant, and pre-existing risks to the patient’s health is what causes the defendant to assume the duty of care with consent. His intervention will often be in situations of emergency.’ The traditional test for gross negligence was preferred.

The court set out the matters that need to be established for a prosecution of manslaughter, namely the existence of a duty of care, the breach of the duty causing death, and gross negligence which the jury considers justifies criminal conviction. The Court of Appeal went on to set out various states of mind that it considered could probably lead the jury to making a finding of gross negligence:

- indifference to an obvious risk of injury to health
- actual foresight of a risk coupled with the determination nevertheless to run it
- an appreciation of the risk, coupled with an intention to avoid it but also coupled with such a high degree of negligence in the attempted avoidance as the jury considers justifies conviction
- inattention to or failure to avert a serious risk that goes beyond mere inadvertence in respect of an obvious and important matter that the defendant’s duty demanded he should address.

The first three are not unduly onerous. The fourth, however, may present particular problems to medical practitioners. Medical treatment generally may be considered to amount to an obvious and important matter. Further, many serious risks are inherent in treating patients and, accordingly, medical practitioners remain in danger of falling foul of the criminal law relating to manslaughter. At the conclusion of the judgement of the Court of Appeal in the case of Drs Prentice and Sulliman, the court expressed the view that the Law Commissioners should look at the law in relation to involuntary manslaughter as a matter of urgency.

In Canada,⁴⁸ manslaughter may be committed where a doctor causes the death of a patient by, among other things, criminal negligence that may be committed where someone under a duty shows a wanton or reckless disregard for the lives or safety of others. The precise meaning of ‘wanton or reckless disregard’ is in doubt. In a recent case (*R v. Tutton and Tutton*)⁴⁹ the Supreme Court of Canada was divided between those who considered that

a defendant should have an intention to run a prohibited risk, or a wilful blindness to the risk, and those who considered that a marked and substantial departure from a standard of behaviour expected of a reasonably prudent individual would suffice. This dilemma is similar to that recently addressed by the Court of Appeal in this jurisdiction in the case of Drs Prentice and Sulliman.

In the Court of Appeal in the matter of *R v. Sellu*,⁵⁰ the conviction of Mr Sellu was quashed as being unsafe following the finding that the instructions to the jury of the trial judge on the meaning of gross negligence manslaughter were inadequate. In the judgement their Lordships made the point that ‘mistakes even very serious mistakes, errors of judgment even very serious errors of judgement, and the like, are not enough for a crime as serious as manslaughter to be committed. You must go on to consider the nature of the carelessness.’ They go on to say that ‘the key is that the breach of duty must be gross. It must have been so bad, so obviously wrong, that, having regard of the risk of death involved in it, it can be properly condemned as criminal.’

In New Zealand (*R v. Yogasakaran*),⁵¹ the test for manslaughter is that of mere negligence, and a breach of the civil standard of care resulting in the death of a patient is all that is required. Similarly in Greece, the offence under the Greek Criminal Code⁵² is of causing death by negligence, mere civil negligence being sufficient. The charge is often seen as a precursor to civil proceedings, where a victim’s family may make complaint to prosecuting authorities, effectively as part of the bargaining process for compensation.

ASSAULT, BATTERY AND BODILY HARM

Charges of assault and battery are considered very infrequently by the prosecuting authorities in this jurisdiction in relation to medical practitioners. Courts are reluctant to consider actions in tort for battery arising out of a failure to obtain consent, let alone criminal charges. Very few doctors will intend to inflict harm on a patient, the overall aim being to provide some form of therapeutic benefit. However, where the clinician performs a procedure that goes substantially beyond that to which the patient has consented and that is known to the clinician, or the clinician is reckless as to whether or not the patient’s consent will authorize the procedure actually performed, then such an offence may be made out, even if it is of therapeutic benefit. In circumstances where surgical intervention takes place, an offence of greater seriousness than mere assault may result, for example, assault occasioning grievous bodily harm.

Punitive damages

Punitive (exemplary) damages are not normally awarded in jurisdictions of the UK and Australasia but in 2002 the Privy Council heard the case of *A v. Botrill*⁵³ from New Zealand. This case involved the wholesale misreading of cervical smears by a private pathologist in Gisborne, New Zealand. Between 1990 and 1994 he examined four

smears from Mrs A. After Mrs A had a radical hysterectomy for invasive cancer the smears were reviewed and all four slides had been misread or misreported. Mrs A made a successful claim for accident compensation. Disciplinary proceedings against Dr Botrill found him guilty of conduct unbecoming of a medical practitioner. Mrs A then brought court proceedings claiming exemplary damages. Justice Young dismissed the action, applying the principle ‘exemplary damages may be awarded, but only if the level of negligence is so high that it amounts to outrageous and flagrant disregard for the plaintiff’s safety, meriting condemnation and punishment’.

Two events then occurred: Mrs A found another 10 women whose slides had been misread, and there was public concern about smear reporting in the Gisborne area. This led to a review of Dr Botrill’s slides, which showed that Dr Botrill’s false reporting rate was 50% or higher. In the light of the new evidence Mrs A applied for a retrial, which was granted. Dr Botrill then appealed this decision and his appeal was successful. Mrs A sought leave to appeal to the Privy Council, which was granted. The argument for Mrs A was that cases of reprehensible wrongdoing that are totally unacceptable to the community but arise from inadvertent negligence should not be put beyond the reach of exemplary damages. Dr Botrill’s argument was that there was no conscious, outrageous and flagrant disregard for the plaintiff’s safety. The Privy Council agreed with Mrs A and allowed her appeal on a majority decision.

Although this is a New Zealand case it now brings the possibility of punitive damages for reprehensible wrongdoing even if there was no flagrant disregard of risk. It seems that now inadvertent negligence may lead to exemplary damages in selected cases of the worst kind of professional practice.

GUIDELINES

Nowadays, many treatments are the subject of guidelines or protocols, drawn up locally or nationally from organizations such as the National Institute for Health and Clinical Excellence (NICE). These documents purport to set proper standards. Although from a litigation viewpoint they are best considered to be indicative of an accepted course of practice rather than the final arbiter of professional standards, contravention of them without good reason may make defence of a claim very difficult. Where guidelines are departed from the wise practitioner will take particular care to record the reasons in the patient records.

HOSPITAL ADMINISTRATION

A claim may arise where a patient has been lost to follow-up and only represents with an extensive recurrence of a cancer or a complication of a chronic disease such as chronic suppurative otitis media or a systemic condition such as sarcoid. Such cases may have a prospect of being

successful where the patient can establish that had there been a regular examination advancing disease would have been easily identified at an early stage.

It is therefore important that health trusts have a robust system of tracking down those patients who fail to attend for their expected appointment. Trusts should be seen to communicate with the GP in order to establish whether the address that they have is correct, and furthermore to inform the GP that the patient has not attended and request the GP to investigate the reasons why. Failure to do so may be difficult to defend, unless the trust can establish that they have emphasized to the patient the importance of regular follow-up and examination following treatment for the tumour. There is considerable

merit in a letter being sent to the patient, giving details of the diagnosis, treatment and the planned follow-up care, for the purposes of identifying early recurrence of disease. It is not uncommon for an expert to examine a claimant's notes and identify frequent non-attendance in outpatient departments of various specialties. However, the claimant usually alleges that they failed to receive the appointment in the mail. Although the treating physician may have a healthy scepticism of such allegations, it must be borne in mind that many people live in multiple occupancy dwellings in which security of mail may indeed be in doubt. As such, where follow-up is important, it is advisable that the GP is asked to investigate for repeated failures to attend.

BEST CLINICAL PRACTICE

- ✓ Where there is evidence of a flagrant disregard for safety or recklessness in performing a surgical technique, then the public may need to be protected by requesting the General Medical Council for a competency assessment.
- ✓ Where an adverse outcome of treatment has occurred, prompt offer of transfer to another department and another surgeon may assuage the patient's anger.
- ✓ Trusts should have a robust system of tracking down those patients who fail to attend for their expected appointment.
- ✓ It will be increasingly difficult to justify a single surgeon operating in excess of four hours without having a short rest.

KEY POINTS

- Clinical negligence is a matter for civil law.
- Damages awarded are general and special.
- The standard of proof is 'on the balance of probabilities'.
- There are four essential elements of the legal tort of negligence:
 - there must be a duty of care
 - there must be a breach of that duty
 - harm must have occurred
 - the breach must have caused the harm.
- The standard of care is that of the reasonably skilled and experienced doctor.
- 'It will very seldom be right for a judge to reach the conclusion that views genuinely held by a competent medical expert are unreasonable.'
- If the case for each side is evenly balanced then the claimant will fail.
- The court must award a sum of money that will, as nearly as possible, put the injured person in the same position as she would have been had she not been injured.
- The result of the introduction of contingency fees is likely to be that there will be no significant increase in the number of medical negligence actions in the short term.
- Where a proposed treatment involves a substantial risk of grave or adverse consequences such that, notwithstanding any practice to the contrary, a patient's right to decide whether to consent to the treatment was so obvious that no prudent medical man or woman could fail to warn of the risk, then it would be negligent not to warn.
- The parental right to determine whether or not a child under the age of 16 should have medical treatment terminates when the child achieves a significant understanding and intelligence to enable him or her to understand fully what is proposed.
- 'An adult patient who suffers from no mental incapacity has an absolute right to choose whether to consent to medical treatment, to refuse it or to choose one rather than another of the treatments being offered.'
- Any surgeon who keeps any sort of patient identifiable information at his or her residence and who is not registered with the data commissioner breaches the provisions of the DPA.
- The coroner's remit is to establish the identity of the deceased, the time and place of death and the mode of death.
- Articles 2, 3, 6 and 8 of the HRA are those most relevant to surgeons.
- Modifications to the law on involuntary manslaughter are awaited; currently the traditional description of gross negligence resulting in death usually applies.
- Just because a recognized complication occurs, it does not automatically mean that surgical technique has been below a satisfactory standard.

SEARCH STRATEGY

Data in this chapter are based largely on the author's long experience as an expert witness and on landmark legal judgements, some of which are alluded to in the text.

INTRODUCTION

Chapter 39a dealt with the general principles that govern legal aspects of medical practice in otorhinolaryngology. This chapter explores recurrent themes to guide safe practice and then focuses on specific scenarios that give rise to claims of negligence in general otolaryngological practice and within the subspecialties.

INTERPRETATION OF IMAGES

In many hospitals, there is no radiologist with a special interest in ENT. Consequently, the experienced consultant ENT surgeon may be just as competent at reading radiological films as the specialist radiologist. In all departments it is wise that both the clinician and the radiologist assess the radiological films within the clinical context of the patient's disease. From time to time, a difference of opinion may arise, and a failure to address this difference of opinion can lead to a delay in diagnosis, with a significant impact on prognosis for the patient. Where films have been discussed, and a difference of opinion continues, then it is advisable that a further opinion is sought from a radiologist with a special interest in the field. Nowadays, films can be easily transferred electronically and the vagaries of the postal system do not have to be endured. Where there

is a difference of opinion between the clinician and the radiologist, most patients would expect the radiological investigation to be repeated after some weeks. Although the radiologist, and indeed the clinician, may have some concerns about the increased dosage of X-rays necessitated by repeat films, where there is a possibility of malignancy, the patient will see this risk as being trivial, and would be much more concerned about obtaining peace of mind about what they see as a real and existing problem, compared to some theoretical risk of developing a malignancy in the future. Therefore, the wise clinician should argue for a repeat investigation or discuss with his radiological colleague using another imaging modality.

In the field of endoscopic sinus surgery, whether it is functional, diagnostic or treating an iatrogenic complication, it is essential to have a complete demonstration of the radiological anatomy by computed tomography (CT) scan. The nose should be scanned from its rostral extremity as far back as the basilar artery. In addition, it is essential that the window setting is such as to maximize the bony detail and also a second series should be saved with window settings to give some soft tissue information. Litigation may arise when the clinician either has not viewed the imaging or ignores a report demanding that action should be taken. For example, it is normal practice that immediate post-operative plain films of

cochlear implants are taken. In two cases, settlement had to be explored where an electrode had partially slipped out immediately following surgery, and was shown on the post-operative films but only detected by the team when the films were reviewed some months later as the patient was not doing as well as expected.

INTERPRETATION OF HISTOLOGICAL INVESTIGATIONS

Much of what has been said above on radiological investigations also applies to histopathological investigations. The wise otolaryngologist will be well aware of the pitfalls that can arise. These are especially true in salivary gland and nasal neoplasia. Also, fine-needle aspiration cytology needs to be carefully considered in the light of the clinical picture and if a lesion deemed benign on cytological examination does not appear to be behaving clinically as such, rebiopsy should be undertaken speedily.

FAILURE TO CONSIDER CONSERVATIVE TREATMENT

This issue appears to arise more commonly in private practice. It is not uncommon for the patient who has had a mishap following sinus surgery to state that conservative options for treatment, such as oral steroids and antibiotics in the case of nasal polyposis, had never been discussed, but that an immediate recommendation for surgery had been made by the practitioner. In the case of simple, benign, nasal polyposis in a fit individual, there is rarely any defence for not discussing the possibility of a course of oral steroids, with or without antibiotics. If there is doubt as to the nature of the polyps, a simple biopsy can be undertaken, followed by conservative treatment, rather than an attempt to radically clear the disease, as first-line treatment.

In those patients with nasal obstruction due to enlarged inferior turbinates, first-line treatment should normally be conservative. Adequate investigation to identify the presence of any allergy and then treatment either by allergen avoidance or topical steroid treatment would usually be first-line treatment. If the general practitioner has already undertaken this in an adequate and thorough manner, it may be reasonable to proceed with an offer of surgery. However, a significant complication occurring following turbinate surgery in the patient who has not been offered an initial trial of conservative treatment can be very difficult to defend.

PATIENT SELECTION

When a patient attends with trauma or cancer, the surgeon has little choice but to either provide the treatment that is necessary or refer on to a specialist who is more fitted to handle the case. Ultimately, the patient is going to require treatment and a failure to provide prompt treatment after diagnosis may in itself lead to litigation.

However, in the non-urgent situation, there is time for the patient to choose his surgeon and also for the surgeon to choose his patient. The wise surgeon will pay heed to features that suggest an increased risk of dissatisfaction, and will attempt to manage these before undertaking any surgical treatment. Only once the surgeon is convinced that a patient understands what the experience and the result of surgery is likely to be should the planned surgery proceed. This is especially so where there is a cosmetic element to the proposed treatment.

Beware the patient with no physical abnormality. A patient who has a physical abnormality visible to the surgeon and a clear understanding of what he or she wishes to be achieved is more likely to be satisfied with the result of cosmetic surgery than a patient with no visible abnormality. If a patient's nose is too long or too wide, the tip too bulbous or deviated, and is obviously outwith the norm, then successful surgery is possible. A patient who refuses to accept that the nose is within the range of normality and clearly believes it to be too large may be suffering from dysmorphophobia. These patients will be dissatisfied with surgery and should be referred to a psychiatrist with experience in the field for assessment and possible treatment.

Beware the patient whose appearance is at either end of the normal spectrum, obsessively neat and tidy or dishevelled and unkempt. Both types may prove difficult for the surgeon to achieve a result that satisfies the patient. The immaculate patient may be seeking a result beyond the capability of surgery, and may also find the normal scar maturation process too slow. The patient who does not care about his or her appearance may not comply post-operatively, compromising the result. If such a patient is looking for an improvement in social life, attention to personal hygiene may be more appropriate than changing facial appearance. In particular, it requires considerable tact to explain this, but undertaking a cosmetic surgical procedure on his or her face is unwise.

Beware the patient who is dissatisfied with other surgeons or the results of previous surgery. The surgeon who has refused a patient elsewhere is likely to have had good reasons for not proceeding. Furthermore, the patient's perception of these reasons will almost certainly be given with a bias that the wise would recognize. If the patient has had an unacceptable result from surgery and yet in your evaluation the result is well within the range of results produced by most competent practitioners, then dissatisfaction from further surgery is likely. However, there are those who see plastic surgery as an adjunct to all the other means of enhancing appearance, and a patient seeking another plastic surgical operation on a part of the body that has not been enhanced before should not necessarily be seen as a potentially problematical patient, particularly if the patient expresses satisfaction at previous operative procedures.

Beware the patient with the bizarre request. Occasionally, patients may present with a request that is so bizarre, the surgeon is unlikely to have come across it before. For example, a patient may believe that he or she is part-snake, part-human, and consequently requests

splitting of the tongue to give it a forked appearance. Underlying such requests may be a psychotic delusion and, whenever the surgeon is in doubt, an opinion from a psychiatrist should be sought before offering surgery.

Beware the aggressive and violent patient. Individuals who express their dissatisfaction or who fail to solve their daily problems by the spoken word and consequently resort to violence may hide an underlying personality disorder. Such people may have problems with interpersonal relationships that they have focused onto one aspect of their appearance. If this aspect is changed and their interpersonal relationship problems do not improve, they may seek retribution from the surgeon. Surgeons have been murdered by dissatisfied patients.

CONSENT TO SURGERY

Issues of consent on their own are rare in relation to sinus surgery and they are much more common when coupled with allegations of incompetent surgical technique. However, it is in the field of turbinectomy, particularly in the adolescent and young adult, that issues of consent arise. Torrential haemorrhage following inferior turbinectomy is not uncommon, probably happening in most surgeons' practice, with an incidence of between 1 in 60 and 1 in 200 cases. It does appear to be more common where a posterior turbinectomy has been undertaken, rather than removal of the anterior end of the inferior turbinates. Nevertheless, torrential haemorrhage can happen in any form of turbinate surgery. When this occurs, and the patient has undergone the usual treatment to arrest the haemorrhage and correct the blood loss, an allegation of permanent psychological damage may arise, accompanied by the allegation that the patient was not warned of the risk and had they been, then they would have refused consent for the surgery. In taking consent, the wise surgeon must assess the personality of the patient and ask himself whether they would have the mental fortitude to withstand the psychological trauma that can accompany a severe nasal haemorrhage, particularly as it may appear life-threatening to the patient and their family. If the patient, despite warning of such haemorrhage, still wishes to proceed with the surgery, then it should be carefully annotated in the notes that the warning has been given and understood.

Since the introduction of functional endoscopic sinus surgery on a wide basis, between 1988 and 1992, consent for these procedures seems, on the whole, to be well annotated in the case-notes, particularly from the point of view of the risks of injury to orbital contents and breach of the dura. However, where contention may arise, it is not that the patient was warned of these anatomical risks, but that they did not understand the consequences of these risks on their day-to-day life or that, should such risks occur, secondary complications may supervene. One patient, an intelligent banker, freely admitted that he had been warned of the risk of cerebrospinal fluid leaking from his nose, but was adamant that he had been given no warning that this could lead to meningitis and subsequent

intellectual impairment, which had occurred in his particular circumstances.

However, the claimant may find it difficult to establish in court that, had they been fully warned, they would not have gone on to subject themselves to the surgical procedure.

The landmark Australian case, *Rogers v. Whitaker*,¹ in which it was felt the risk of sympathetic ophthalmitis, with a risk of approximately 1 in 30 000, should have been explained to a patient, has not found favour in the English courts. The risk of blindness as the result of submucosal diathermy, or the use of adrenalin-containing local anaesthetic in rhinological surgery, is somewhat similar. In one case, a young woman woke up following a general anaesthetic for a submucosal diathermy to the inferior turbinates and had totally lost sight in one eye. Thorough investigation did not reveal any evidence of direct trauma to orbital or retro-orbital structures, and a literature search revealed that this can happen despite competent surgical technique. On the Bolam principle, as virtually no ear, nose and throat surgeon practising in the UK would warn of this risk, her case would fail and therefore her solicitor advised that she should not pursue the issue. A Legal Aid Certificate was not granted to test the principle that such a loss was so catastrophic that, despite its rarity, it should have been warned of and that any reasonable patient would expect that this issue be mentioned. Now in the post-Montgomery era it is likely that such a complication would meet the reasonable patient test and so the issue may be tested in the courts in the future. A major point of debate will be around just what really rare complications the consenting surgeon should actually be aware of.

Time should be spent carefully outlining: the common complications; the likelihood of them occurring; what the effects of them would be; what treatment may be necessary to correct matters should such complications arise; and, most importantly, whether such extra treatment will be charged for. Providing this free of charge goes a long way to having a satisfied patient and reduces the chance of litigation. Carefully worded patient information leaflets are helpful, either sent to the patient to read before the consultation or given for reading afterwards, but they are not a substitute for proper discussion and informed consent. The surgeon should take care to ensure that such leaflets are directly applicable to the patient's problem and to the way in which the surgeon plans to treat the patient, both at the operation and post-operatively. Some commercial leaflets are too vague or, worse, impart information that does not apply to your practice or the patient concerned. This may cause litigation problems later.

Patients should not make a final, irrevocable decision about surgery at the initial consultation. A period of time, perhaps two weeks, for the patient to reflect upon what has been said is invaluable. Many patients will undertake their own research, often using the internet or discussing matters with friends or relatives during this period. Although the surgeon may be inconvenienced or disappointed if a patient changes his or her mind and decides not to undergo a procedure, the wise surgeon will realize

that she or he has probably been saved a considerable amount of time and inconvenience by not performing the operation discussed.

TUMOUR RECURRENCE

An allegation of inadequate primary resection of a tumour, either malignant or benign, usually follows the unexpected diagnosis of a recurrence. This may seem surprising to the profession, but sadly a combination of belief in modern surgical techniques, plus the confident statement from the operating surgeon that 'all the tumour has been removed', can lead to an accusation of incompetent technique. Clearly, a confident statement on tumour resection is meant to reassure the patient and improve their psychological well-being. However, there is no excuse to take on a patronizing role, supported by frank lies. It is important that the patient is told the exact situation, as best as can be determined, and if the outcome for the future appears to be bleak, then such bad news needs to be adequately supported with appropriate psychological therapy. It is possible that any psychological damage may be looked upon seriously by the courts, and appropriately rewarded, especially when the major defence to the bulk of the claim is that 'the patient would have died anyway'.

In circumstances where resection margins are being monitored by frozen section examination during the surgery, it is vital that all specimens are sent. Thus, when a report says that the tumour is at the margin of resection, on one specimen it is useful to have a subsequent specimen indicating that there is a clearance. Obviously, where the tumour is up to, but not invading, a nerve sheath, the surgeon may have to exercise clinical judgement and decide whether to resect such a nerve sheath or not. These points should be carefully noted in the records. Thus, a histological report that indicates that the margin of resection is up to the edge of the tumour can be seen to have been acted upon appropriately.

SPECIFIC CONDITIONS AND PROCEDURES

Just because a recognized complication happens, it does not automatically mean that surgical technique has been below a satisfactory standard. A complication such as damage to the medial rectus muscle in endoscopic sinus surgery may occur, despite all care being taken by the surgeon. On the other hand, it may occur as a result of a 'gung ho' or slapdash technique, in which due respect and identification of the relevant surgical landmarks has not been attempted. For the claimant, it can be difficult, if not impossible, to prove that the damage has occurred because of the latter surgical technique, rather than the former. It would indeed be rare for a claimant to successfully identify a witness, present at the time of the surgery, who was willing to testify in court as to incompetent technique practised by the surgeon.

Increasingly, video is used in theatre and, in the case of endoscopic sinus surgery, operating via camera is a common technique. If the surgery is recorded and the tapes kept until it is established there is no significant post-operative complication, the recording may be available to both parties in which an adverse outcome to the surgery has developed.

In a recent MPTS case, examination of recordings kept on DVD by an expert was key evidence that led to the erasure from the medical register of the surgeon.

For example, in one case, a trainee undertook a difficult nasal polypectomy endoscopically. The procedure was recorded and a breach of the anterior cranial fossa, and how it was acquired, could clearly be seen on the video. In this particular instance there was a dehiscence of the cribriform plate, with absence of bone in the anterior cranial fossa. The repair was also filmed. An explanation was given to the patient, who was quite satisfied. However, his children, who lived some distance away, attended the hospital some days later. One daughter, a nurse in a maxillofacial surgical department, clearly felt that causing a cerebrospinal fluid (CSF) leak had to be negligent. Fortunately the video material was available, which was immediately shown to the family and carefully explained. This diffused the aggression and was successful in preventing litigation.

Occasionally, massive injury can be sustained in which the degree of damage is so gross that basic surgical technique has to have been ignored, or not understood. For example, in one case a patient failed to regain consciousness from the anaesthetic following intra-nasal surgery. On arrival at the intensive care unit, a 2 × 1 × 1 cm piece of cerebral cortex was retrieved from the oropharynx; subsequently an extensive resection of the anterior cranial fossa was identified, and the nose contained a huge herniation of the brain. The neuroradiological expert in the case felt that there was clear evidence of instrument tracks within the substance of the frontal lobes of the brain, suggesting that instruments had been passed repeatedly into this brain substance. In this particular case, pre-operative CT scans did not reveal any evidence of a congenital abnormality of the anterior skull base. Not surprisingly the surgeon's insurers sought a settlement early on in the process of the case.

Where the evidence is strong that the lack of standard of care would suggest a flagrant disregard for safety, or recklessness in performing the surgical technique, then the public may need to be protected by requesting a competency assessment by the General Medical Council.

RHINOLOGY AND FACIAL PLASTIC SURGERY

Negligence in general practice in relation to rhinological disease is unusual. It appears to occur mainly due to a failure in recognizing the significance of certain symptoms or signs.

One of the most common areas is in failure to arrange timely treatment for a nasal fracture. In most practices,

the best opportunity in effectively manipulating a nasal fracture is within the first 21 days of the injury. Failure to undertake timely treatment may lead to the necessity of performing a formal septorhinoplasty. The consequence of this is a longer period off work than would otherwise be necessary, as well as additional pain and suffering such as periorbital bruising. A delayed referral can rarely be defended and usually the best outcome is to seek a speedy settlement. There are exceptions and one of the most important is the cartilaginous injury of the nasal tip or septum when simple manipulation does not give the best results and a septorhinoplasty is indicated as first-line treatment.

A delay in referral of sinusitis is also a common area that leads to litigation. The general practitioner (GP) usually fails to realize when a sinus infection has spread beyond the sinus and is involving the orbit, bone, meninges or soft tissues. The most common examples of this are orbital and forehead swelling. It is only the onset of symptoms in relation to brain abscess, meningitis, blindness or severe orbital swelling that leads to a speedy referral.

The significance of unilateral nasal symptoms, such as discharge, may be ignored by the GP and so a delay in diagnosis of a tumour or foreign body occurs.

Sadly, it is not just the GP who may fall into the situation of delaying a diagnosis. Inexperienced trainees within the specialty, accident and emergency doctors, and occasionally other specialists within hospital practice, may all find themselves at the centre of litigation arising from these relatively common areas of negligence.

Inadequate pre-surgical management

Failure to investigate significant symptoms arises from time to time. Wegener's granulomatosis is a condition that regularly goes unrecognized. Often it may be mistaken for atrophic rhinitis or even industrial rhinitis, and the patient treated symptomatically, without adequate investigation. It is only when other systems are involved, such as the renal or respiratory system, that adequate investigations are triggered and the condition identified. Clearly if the condition has progressed to frank renal failure requiring dialysis before diagnosis has been made, then the patient may have a strong claim. It is common to find that other conditions, such as scleritis, flitting arthropathy or skin lesions, have not been linked to the nasal symptoms.

Circumstances arise in which the investigations for this condition, such as a raised plasma viscosity or erythrocyte sedimentation rate (ESR), which are usually raised, are within the normal range. Occasionally even the antineutrophil cytoplasmic antibody (ANCA) test is negative, and where adequate investigations have been undertaken but the diagnosis has been delayed, a reasonable defence can be mounted.

From time to time, a post-nasal space carcinoma may present as a neck lump to another specialist. Although the malignant nature of the neck lump is identified, occasionally the primary site is missed. The ear, nose and throat (ENT) expert may be asked to comment on such a delay. It is of course inappropriate for him to deal with issues of liability concerning delay in diagnosis by another specialist,

but it would be expected for him to comment on how the delay may affect the prognosis of the patient.

Similarly, a restriction in eye movement may indicate early involvement of orbital contents or a cranial nerve by a sinus malignancy. Clinical examination may not reveal an obvious restriction in movement, due to the partial nature of the malignant process. Sudden onset of double vision, without an obvious cause such as head injury, or orbital displacement should never be ignored, and requires thorough investigation to exclude a pathological cause requiring treatment.

External drainage of the frontal sinus

Frontal sinus trephine may lead to supratrochlear nerve damage and indeed supraorbital nerve damage. Where there is significant oedema in the surgical area, most surgeons could understand how the supraorbital nerve might be stretched by retractors, or indeed cut. However, in a simple drainage procedure, there can be no excuse for extending the incision so far laterally as to divide the supraorbital nerve. The Lynch–Howarth procedure gives wider access to the frontal and ethmoid sinuses. In extensive disease it may be necessary to sacrifice the supraorbital and the supratrochlear nerve. This should be anticipated before the surgery and the patient warned. In addition, the patient should be warned of the possibility of double vision post-operatively due to the detachment of the trochlea.

Caldwell-Luc procedure

Caldwell-Luc surgery is now rarely undertaken. Resting cheek retractors against the supraorbital rim in a Caldwell-Luc procedure, or similar surgery, can lead to a neuropraxia of the supraorbital nerve. This usually recovers; however, it is a well-recognized risk and adequate precautions can usually be taken to prevent it happening. On the other hand, infraorbital nerve neuropraxia in Caldwell-Luc surgery can be inflicted despite all care being taken, and does not indicate *de facto* substandard technique.

Septal surgery

A major saddle deformity of the supra tip area, following septal surgery, causes such a deformity that it can be difficult to prevent the angry and embittered patient from seeking redress. If the complication has occurred as the result of a post-operative septal abscess, and the patient has been warned of the possibility when consent was taken, then sympathetic handling can usually prevent the patient seeking redress through the court. A careful explanation that infection had destroyed the septal cartilage may suffice. Rarely the saddle could be due to a failure to recognize and diagnose disorders such as Wegener's granulomatosis, sarcoidosis or relapsing polychondritis. The wise surgeon, when presented with such an unexpected outcome, should take the appropriate tests to exclude such

disorders. Clearly the presence of an alternative explanation for a septal collapse or perforation may present an opportunity for a defence.

Septal perforation is another common complication, especially in submucous resection of the nasal septum that causes such symptoms that a patient may seek compensation. It should always be mentioned when septal surgery is being offered. The presence of a perforation does not automatically imply a substandard technique; it is more likely to be an indicator of a severely fractured nasal septum or the presence of another disease, such as atrophic rhinitis or a granulomatous disease.

The circumstances of a submucosal resection, in which the surgeon has made an error of judgement and resected too much cartilage, are likely to be much more difficult for the patient to accept. Once more, recognition of the patient's concern is the key to good management. In addition to offering surgery to correct the deformity, it is important to recognize that the patient may no longer have confidence in the surgeon, or indeed even in the hospital in which they have been treated, and so a prompt offer of transfer to another department and another surgeon may assuage the patient's anger.

In the last few years the author has seen a rise in claims in which there has been a subtle change in the appearance of the nose following septoplasty. In these cases the surgery has clearly been performed competently but the patient claims that they were reassured that the operation would not alter their appearance.

Examination under anaesthesia and diagnostic sinus lavage

Prior to the 1980s, it was very common practice to undertake a 'proof puncture' of the maxillary antra. This would often be done at the time of a tonsillectomy or adenotonsillectomy, in older children and young adults. It was considered a legitimate investigation to detect the possibility of chronic sinus infection. Many surgeons advocated its routine use, even in the absence of any sinus or nasal symptoms. Such an invasive procedure, which carries the risk of damage to unerupted secondary dentition, the inferior orbital nerve and the orbital contents, in the absence of sinus symptoms, can no longer be justified without taking a formal consent for the procedure and offering alternative methods of investigation. In addition, several cases have arisen due to misunderstanding of the term 'examination under anaesthesia'. Some claimants who have sustained complications as a result of such procedures have asserted that they only gave consent for the surgeon to look, but not to biopsy. A typical examination would be obtaining consent for examination of the post-nasal space in a child or adult with glue ear, and then proceeding to perform an adenoidectomy having identified a significant pad of lymphoid tissue in the post-nasal space, the damage occurring usually being a secondary haemorrhage. It is important therefore, in taking consent, to include the potential risks that may arise for any additional procedure, usually a biopsy of an excisional or incisional nature.

Intra-operative monitoring

This term usually invokes thoughts of nerve monitoring in the context of ENT surgery, but it is still particularly important in rhinological surgery, although the monitoring may be purely visual in nature. In endoscopic sinus surgery, it is the orbital contents that are at risk. Clues to a significant intra-orbital incursion can be obtained by careful observation of both eyes during the procedure. This may not be possible by the operating surgeon, as it is likely that he or she will be observing the operating field either indirectly through a camera or directly through an eye-piece. However, an operating assistant, such as a scrub nurse or other colleague, should be in a position to observe both orbits and watch for the tell-tale signs of a complication arising. These may include a sudden movement of the globe of the eye, the development of proptosis or subconjunctival haemorrhage. Although in the early parts of the procedure it is important to protect the cornea from damage, at points in the surgery in which the eye may be in a critical, or vulnerable state, it is permissible for the eyelid to be opened and the globe observed for brief periods. Early identification of an incursion into the orbit is essential to reduce the risk of damage. Equally, in the recovery area, post-operative observation of the orbits and eyes is essential, particularly if a significant retrobulbar haemorrhage is to be identified, monitored and, if necessary, treated before permanent damage to the eyesight occurs.

Post-operative monitoring

Even though frontal sinus infection has been adequately drained at surgery, the patient still has the potential of developing an intra-cranial complication, though this is now much less. It is likely that the infection has spread through the venous system prior to the actual drainage of the sinuses and so the intra-cranial symptoms usually commence 24–48 hours after surgery. Complaint of severe headache that is progressive, along with drowsiness, confusion or disinhibition, should alert the wary to the onset of a frontal lobe infection. Usually the patient should be on an antibiotic with a high ability to cross the blood-brain barrier, but if this is not the case, then with the onset of these symptoms the antibiotic will need to be changed. Inadequate monitoring in the post-operative period may also lead to delay in detection of a cerebrospinal fluid leak. Although these may be blatantly obvious when there is a striking flow of clear fluid from the nose and the patient has an accompanying headache, the occasional case may be intermittent. In one case, the patient re-attended the hospital on three occasions complaining of watery nasal discharge, which was ignored. No investigations were undertaken, other than admission and observation on the ward, on one occasion only for 48 hours. On the final attendance at hospital the patient presented with a small bottle containing a sample of the CSF and symptoms of frank meningitis. The confusing issue is that nasal discharge that may be watery in nature is not uncommon following sinus surgery, or indeed may be related to the

underlying sinus disorder. It is quite likely that minor CSF leaks are probably more common than is actually realized, but fortunately they close spontaneously without any secondary damage.

Benign skin lesions

Patients often believe that small skin lesions can be removed without leaving a scar. It is very important that the inevitability of a scar, its length and width, the duration of the scar maturation process and the risk of scar hypertrophy and/or keloid formation is explained to the patient as part of the informed consent procedure.

When excising a skin lesion as an ellipse, the length of the scar will be two or three times the diameter of the lesion. Once the sutures have been removed, the scar will initially be a relatively fine line. As the proliferative phase of wound healing progresses, the vascularity increases, making the scar red and noticeable. This appearance may last for between two weeks and two months after injury.

With entry into the collagen maturation phase the appearance of the scar improves, but full maturation may take up to two years in some patients. Those with a heavy, sebaceous skin, or ginger colouring, may have a noticeable scar for longer than average. Overexposure of an immature scar to ultraviolet light from bright sunshine or from a sun bed will cause burning more easily than in normal skin or a mature scar. Patients should be advised to avoid or protect the skin from such overexposure by applying high protection factor sun cream and by keeping out of the direct rays of the sun.

The patient dissatisfied with the early appearance of a scar should be advised that early revision is rarely indicated as many scars settle without surgery being necessary. Regular communication with the patient whilst the scar matures is the keystone of treatment, as brushing off the patient or disregarding the patient's perception that there is a problem may lead to litigation. Although the scar may well settle whilst the complaint proceeds, the problems of having an ongoing case are not to be dismissed lightly. Regular outpatient consultations, encouragement that the scar is likely to settle in time and sympathy with the patient will minimize the risk of litigation.

Patients with factors known to adversely affect the final appearance of scars must be counselled about this. Adolescents with spotty, pubertal skin are best not operated on until their skin has calmed down unless there is a suspicion of malignancy. Patients with previous hypertrophic scarring, patients with coloured skin and those with lesions on areas of the face more likely to make a hypertrophic scar, such as along the line of the mandible, must be warned appropriately. In some parts of the face, particularly the tip of the nose, it is difficult to achieve a fine scar even with no adverse factors.

In trauma, the method of injury influences the final appearance of a scar. Dirty or infected wounds, traumatic tattooing, closure under tension, non-perpendicular wound edges and wounds crossing skin tension lines will

lead to poor quality scars. Trapdoor scarring is a particular problem in traumatic wounds: a flap of skin is raised, often tangentially and thus with bevelled edges, and the scar heals with contraction and localized lymphoedema within the confines of the scar. Simple excision and resuture is unlikely to resolve the problem and a patient must be advised clearly of the limited improvement that may be achieved by scar revision.

Suture marks are not acceptable and, if they occur, litigation will be difficult to defend. Careful choice of suture material and its thickness, accurate placement of the sutures and their tightness, and timing of removal are critical. It has been suggested that scar stretching can be minimized using subcuticular sutures left in place for weeks or months, but clinical experience does not generally support this.

All lesions excised should be submitted for histological examination, however benign the lesion looks, unless the patient specifically instructs that this is not to be done. In such a situation, this instruction must be recorded in the notes.

Keloid and hypertrophic scars

Both hypertrophic and keloid scars contain excess collagen. In a hypertrophic scar, the collagen remains within the borders of the scar, but in a keloid scar it extends into the surrounding undamaged skin. Hypertrophic scars usually settle spontaneously, although they may take a few years and leave unsightly scars, but keloid scars persist. Hypertrophic scarring is more common in young people, can occur on any part of the body and is more common if there has been wound infection and breakdown or healing by secondary intention. Keloid scarring may be familial, is much more common in Afro-Caribbeans than in Caucasians and has a predilection for certain parts of the body, such as in the head and neck, the ear lobes and more rarely the post-auricular skin.

Treatment of keloid scarring is difficult and often unsuccessful. Patients find it difficult to believe that simple excision will not solve the problem and that keloid recurrence is not only inevitable but may be worse. Triamcinolone injections are the mainstay of treatment, although great care must be taken that the steroid is of the correct strength (10mg/mL and not 40mg/mL) as the concentration of steroid used for intra-articular injections rapidly causes localized fat atrophy which takes two or more years to recover. Steroid impregnated tape and topical application of hydrocortisone can also help, as can pressure garment therapy.

Patients should be warned pre-operatively of the risk of keloid scarring occurring with an indication of the degree of risk for the site or procedure. For example, keloid scars developing after a pinnaplasty are rare but when they occur it is a cosmetic disaster and frequently the cause of a claim. It can be difficult when the effect of the complication is so great to defend such a claim on the grounds simply that the complication is rare and that the patient therefore did not need a warning.

Nasal trauma

DELAYED TREATMENT

Nasal fractures with bony deformity should ideally be reduced within at most 10 days following the injury to avoid callus formation and rigid bony union. Delayed treatment may lead to permanent osseocartilaginous deformity, which can only be corrected by septorhinoplasty. This may lead to a successful claim for negligence. It is essential to have a referral mechanism between accident and emergency departments and otolaryngology departments so that early assessment can take place and arrangements can be made for manipulation of a nasal fracture under anaesthesia. The decision to manipulate a nasal fracture is clinical. Plain X-rays have little to offer.

SEPTAL HAEMATOMA

Failure to recognize acute septal haematoma can lead to a permanent deformity if a septal abscess subsequently develops. In most instances of septal abscess, a doctor has not previously examined the child but occasionally a haematoma is missed or is diagnosed but not drained. The saddle nose deformity that results can be difficult to correct and as such the compensation can be relatively expensive to cover the pain and suffering of additional surgery and the cosmetic deformity.

Rhinoplasty and septorhinoplasty

The importance of proper selection of the patient and the procedure appropriate to that patient in connection with a rhinoplasty cannot be overemphasized as it is an area in which expectations are very high. It is particularly important to identify those patients who are being unrealistic. Those bringing cuttings from magazines showing the nose that they want and those with concerns about a deformity that the surgeon cannot see should make the surgeon wary of proceeding.

Pre-operative photographs must be taken and studied carefully as they may show abnormalities that the surgeon has missed on examination, or which the patient may be unaware of, such as an asymmetry that might otherwise be blamed later on the operation.

In most rhinoplasties, osteotomies are performed which narrow the nasal airway. This may cause obstructive symptoms, and assessment of the airway pre-operatively is important if nasal obstruction is to be avoided.

Patients who have a congenitally wide nose may require alar base reduction at the same time as a rhinoplasty. This will leave a permanent scar at each nostril base and patients must be warned of this.

There is a recognized revision rate following rhinoplasty, which ranges from 5% to 15% in published series. Patients must be advised that this may be required and should be regarded as normal. It is wise to include the cost of this surgery in the price quoted for the initial rhinoplasty, or to agree the cost before the first operation, as additional unexpected charges can turn a patient from accepting a less-than-perfect outcome to starting litigation.

Elderly patients with thin, fine skin are particularly difficult to manage. Any material left under the skin, such as bone dust or fragments, can easily show through once the healing process is complete. Furthermore, if the osteotomies are not carefully positioned and the bone fragments align in an unsatisfactory position, the edges of the bone or the osteotomies themselves may show through the skin. Occasionally, it may even be wise to advise a patient with such skin not to undergo a rhinoplasty procedure. Elderly skin will have lost its elasticity and will not retract satisfactorily when it is re-draped over the bony and cartilaginous framework at the end of the procedure, so resection, particularly of a bony hump, must be very conservative to avoid unsightly, redundant skin.

Tight application of a plaster-of-Paris splint against the unyielding bed when osteotomies have not been performed can lead to skin necrosis. Paper splints, such as self-adhesive dressing strips, are best used instead to prevent subdermal haematomas. Many surgeons overlap these strips and care needs to be taken that they overlap adequately otherwise a bleb of skin can herniate between them, become strangulated and lead to an ulcer and subsequently a permanent external scar.

The occurrence of unacceptable deformities, such as the pollybeak and the columella retraction deformity, do not always indicate a substandard technique and may arise from tissue loss as the result, for example, of infection. Infections must be treated promptly and with the appropriate antibiotics, either by the operating surgeon or by the patient's GP. It is important to record the treatment in the patient's records, if only to rebut a later legal claim.

The surgical technique is vitally important, not only to achieve a patient's aspirations but also to avoid complaints and litigation. A successful rhinoplasty is a balance between resection and preservation of cartilage. As the nasal skin is simply redraped over the modified cartilage framework, the cartilage left behind is at least as important as what is resected. Excision should generally err on the conservative side as a small excision can result in a significant and adequate change but a large excision can cause an unacceptable deformity, such as excessive bony hump removal.

Many changes that patients may express concern about are normal post-operative appearances and are not the result of negligent surgery. Patients will need reassurance about these changes and regular follow-up. Discharging a dissatisfied patient even though the surgeon knows that the complication is likely to resolve spontaneously may well lead to a complaint, and once this has happened the patient will be much more difficult to satisfy. These complications include particularly those occurring within the first six months after surgery, such as discolouration, loss of tip sensation and oedema. As post-operative oedema settles, irregularities of shape may appear. These may settle spontaneously but may be those that occur in the 10–15% of patients who require revision surgery. This sort of irregularity tends to be minor in size, such as a small ridge or lump on the bridge line, but a patient can become so focused on it that they feel that the deformity is noticeable to every casual observer. In most cases, any

revision rhinoplasty should be delayed until at least one year to allow the tissues to mature and soften, giving time for any resolution to occur, making the surgery easier, and giving the surgeon the best chance of rectifying the problem.

More major abnormalities, such as a saddle nose or ski-slope deformity, alar retraction, pollybeak deformity, tip and alar-columella deformities, and pinching of the lateral alar walls, are likely to be due to surgical failure. With any revisional surgery, the patient must be warned that post-operative settling takes much longer after a second operation. The final result may not be seen until a year afterwards.

A saddle nose or ski-slope deformity usually results from over-resection of dorsal bone and cartilage, but can arise after post-operative trauma leading to a septal haematoma or following an abscess, causing loss of septal support. Rarely, a granulomatous or autoimmune disease can be the cause. The treatment requires augmentation, ideally with a cartilaginous autograft. Alloplastic materials may be used as an alternative, but patients must be warned pre-operatively of the risks of infection and rejection.

Alar retraction is usually caused by excessive excision of cartilage and vestibular skin. The combination of lack of support and contraction causes retraction of the ala. These patients sometimes also get nasal obstruction due to loss of the external valve. Treatment should follow the basic plastic surgical principle of replacement of all parts of the missing tissue, and thus both cartilage and skin will be required. A composite graft, such as from the concha, will be needed and support from the graft will help to keep the external valve patent.

Causes of the pollybeak deformity, or supratip fullness, include both inadequate and excessive resection of dorsal septal cartilage, and excessive lower lateral cartilage excision, leading to loss of tip support. Despite careful surgery, however, some patients still develop a pollybeak deformity. This is commonest in patients with thick skin. Treatment is by correction of the cause with further resection or augmentation with cartilage grafts.

Tip and alar-columella deformities include bossa formation (knob-like protuberances in the region of the domes), pinching of the nasal tip, columella retraction and alar retraction. A bossa occurs after extensive lower lateral cartilage surgery or by leaving sharp or rough edges after cartilage resection. Typically, it is not evident in the early post-operative period but shows up as the swelling settles. It usually requires revision as it is unsightly. Pinching of the lateral alar walls results from over-excision of the lower lateral cartilage. It may be accompanied by collapse of the external nasal valve, causing obstructive symptoms. Cartilage grafting is needed.

Columella retraction is usually due to over-excision and is treated by a composite graft or a cartilage graft.

In a septoplasty, one particular complication is supratip depression. A careful septoplasty technique should avoid this complication but this cosmetic disaster can still occur if a septal abscess develops or the nose sustains significant trauma in the immediate post-operative period. Commonly, however, supratip depression presents

because a submucous resection technique has been used and excessive cartilage removed.

A subdermal haematoma can also occur after a septorhinoplasty, collecting underneath the dressings. Such a haematoma may go unnoticed until the external plaster or dressings are removed a week later. If this has occurred then evacuation of the haematoma is required promptly in order to try and ameliorate any adverse cosmetic result.

Pinnaplasty

There are two commonly used techniques in this surgery. One is the anterior cartilage scoring technique as described by Stenstrom. The other is the placing of permanent nonabsorbable sutures to hold the pinna back as described by Mustardé. Whichever technique is used, the patient, and the patient's parents if the patient is a child as is often the case, must be warned of the risk of recurrence of the deformity, what surgery if any will be required to correct such a recurrence, the presence of a post-auricular scar, and the rare but cosmetically disastrous risk of keloid scarring behind the ear.

In both techniques the skin and cartilage are marked with ink. It is important not to use Indian ink as this can leave permanent tattoo marks. Methylene blue is the ink of choice, but Bonney's blue and gentian violet are alternatives.

In the cartilage scoring technique the skin is elevated off the cartilage of the pinna. This can lead to haematoma collection and, subsequently, cauliflower ear deformity. Great care needs to be taken in haemostasis and the application of the dressings to prevent haematoma formation and also to ensure that the dressings do not come off prematurely in the active child. Haemostasis must, however, be achieved carefully as it is very easy to cause a full-thickness burn of the anterior pinna skin with diathermy, causing a permanent and visible scar.

Patients and parents must be warned that constant pain post-operatively, particularly if unilateral, must be reported to the surgeon who will need to remove the dressings to see if a haematoma has developed. If so, the haematoma must be drained to minimize the risk of cartilage necrosis. Once a haematoma has formed and revision surgery has been required, antibiotics should be prescribed as there is the additional risk of infection and this also may lead to permanent deformity of the pinna. Excessively tight bandages or knots from ribbon gauze placed to pull the bandages away from the eyes may cause skin ulceration and are indicative of substandard care.

In the Mustardé technique, there is a significant risk of the sutures either cutting out or becoming undone, leading to a recurrence of the bat ear deformity. In young children the cartilage may be particularly soft and so the Mustardé technique may be unsuitable. The surgeon needs to evaluate each case and decide a technique appropriate to the child.

The advantage of the Stenstrom technique is that it generally gives a good result and the ear is less likely to unfold with a return of the original deformity than in the

Mustardé technique where the recurrence rate is of the order of 15%.

Skin cancer, flaps and grafts

DELAY IN DIAGNOSIS

Despite head and neck skin cancer being one of the most common cancers in this country, cases of delay in diagnosis are unusual. The condition is more common in the elderly and occasionally diagnosis may be delayed in those that suffer from dementia, who live alone and fail to attend their GP. If there has been an administrative error within the NHS and an appointment has not been received, such patients may not seek clarification of the situation about their outpatient appointment until many months have passed.

Occasionally, an amelanotic melanoma is not recognized. It can be thought to be a benign skin lesion and may be excised in a minor surgery procedure by the family doctor or otolaryngologist. This is not a problem if the specimen is sent for histology but occasionally the excised lesion may be discarded and the true nature of the disease not picked up until a recurrence or distant metastasis develops at a later date.

In dealing with skin lesions it has been suggested that a failure to use Mohs technique for surgical excision amounts to substandard care *de facto*. However this is not the case. It is but one technique for treatment of skin cancers. Many hard-pressed histopathology departments are unable to offer the service due to shortages of staff or lack of training. In addition, in many parts of the country the histopathology department is on a different site to where the surgery is undertaken. In these circumstances it is not practicable to rush specimens by taxi from one hospital to another. Finally, there are certain parts of the face in which the technique would be inappropriate, such as the inner surface of the nasal vestibule.

Excision of the lesion with frozen section monitoring of the margins of excision is a widely used technique that is an acceptable alternative to Mohs surgery. If this is not available then excision with clinically adequate margins and repair with a skin graft rather than a flap can be carried out, the graft being removed and replaced by a flap at a later stage once histological clearance has been given and if the graft is unlikely to give an acceptable cosmetic appearance.

SKIN GRAFTS

If a patient requires a skin graft to repair a defect after trauma or excision of a lesion, appropriate pre-operative warnings must be given. Patients generally think that a skin graft looks the same as normal skin (i.e. there is an invisible mend) but it should be emphasized that this is not the case, that there may be a significant colour, texture or contour mismatch, and that other complications such as hyper- or hypopigmentation and hypertrophy may occur.

Ideally there should be 100% take of a graft. The commonest causes of graft failure are haematoma or seroma

formation, infection and shearing of the graft on its bed. Small areas of graft loss should be managed conservatively but large areas may need regrafting. In both situations the scarring is likely to be worse than if there had been normal healing.

Patients should be warned of the slight risk of graft loss and that grafts look very unsightly for several weeks after surgery. Crusting of grafts is extremely common and requires application of moisturising cream. Grafts may change colour as they heal: split grafts from the abdomen, buttocks and thighs may become yellowish, and full thickness grafts may look redder than the surrounding skin.

Split skin graft donor sites should heal within two to three weeks. If when harvesting the graft, too deep a graft is taken, healing will be longer and the eventual scarring more noticeable, particularly as it may become hypertrophic. If a full thickness cut is made whilst taking the graft this should be sutured immediately and the patient told. A linear scar which heals well will leave a scar but when the scar is fully mature 6–12 months after surgery its appearance is not likely to be as bad as might seem initially.

Full thickness grafts should be taken from an area where a good colour match is more likely, such as the post-auricular or supraclavicular regions. Unfortunately, even grafts from these areas may not match well or develop hyperpigmentation, a troublesome problem that is very hard to treat. Full thickness donor sites appear as linear scars and can undergo hypertrophy, remain narrow or stretch, all of which a patient should be warned about.

Split thickness skin grafts donor sites also become crusty for the first few months and require moisturizing cream. Milia may appear initially but these stop within a few months. Most donor sites become pale within 6–12 months but occasionally pigmentation or hypopigmentation occurs, particularly in coloured skin. Immature donor sites should be protected from excessive ultraviolet light or else they may pigment or burn.

SKIN FLAPS

A flap is needed rather than a skin graft when repairing an avascular wound, such as in an irradiated area, or to restore more tissue than can be achieved by a graft. The disadvantages of a flap are that an additional wound is made, the secondary defect, with additional scarring, that designing and raising a flap safely is technically demanding and may be got wrong, that flaps can necrose and that a flap can be too bulky, needing revision. Like grafts, the colour of a flap may not match the surrounding skin, but pigmentary changes do not usually occur.

Facelift

There are many potential problems with facelift surgery, ranging from physical complications, such as facial nerve injury and unsatisfactory scarring, to more generalized problems, such as disappointment with the rejuvenating effect of the procedure. The latter may be caused by unrealistic expectations.

The surgeon should ask why a patient wants a facelift, and look for initiating factors that might indicate the potential for dissatisfaction, such as recent occupational or marital stresses. Surgery will not alter a patient's lifestyle and will not cure failing relationships or difficulties at work. The surgical goal should be reasonable. The ideal patient will have been thinking about a facelift for some time and not just for a very short period, will have specific signs of ageing that can be seen, such as jowls or excess baggy skin under the chin, and will understand that surgery will refresh the face rather than make them look younger, particularly not taking 10 years off the appearance. Patients falling outside these groups run a high risk of being disappointed with the result of a facelift and may need to be advised against proceeding.

Patients who are dissatisfied with previous facial rejuvenation surgery, who have fallen out with other surgeons, who have a history of litigation, and who have seen several other surgeons, are very high risk medicolegally. Careful consideration should be given before accepting them for surgery.

As with other forms of facial plastic surgery, the pre-operative assessment of the patient is very important. Clinical photographs should be reviewed with the patient so that he or she has a clear indication of what might and, perhaps more importantly, might not be achieved by the proposed surgery. The patient's hairstyle and use of make-up should be noted as these may alter the placement of the incisions.

With increasing age, damage from excessive sun exposure and previous irradiation therapy, the elasticity of the skin, the flap vascularity and the skin's healing ability lessen. This will affect the result of a facelift and may increase the complication rate.

Dark-skinned patients may develop hyperpigmentation post-operatively. Specific questions should be asked about: any previous facial surgery as this will affect the site of incisions; any history of alopecia as this may herald post-operative hair loss; and whether there has been a previous Bell's palsy as this might recur. Generalized medical problems should also be enquired about, such as hypertension or other cardiovascular problems, chronic obstructive airways disease, diabetes and coagulation disorders, including anticoagulant therapy and the taking of aspirin or similar drugs that can lead to post-operative bleeding. Cigarette smoking is a relative contraindication for surgery because of the high risk of flap necrosis, particularly in the post-auricular region, and smokers should stop for at least two weeks pre-operatively.

Each part of a facelift operation has its own risks and these must be explained to the patient. Care must be taken over the amount of local anaesthetic that is infiltrated to reduce bleeding, particularly if extensive neck procedures are being performed. The maximum dose of lignocaine and/or adrenaline must not be exceeded, and care must be taken for the injections to be in the right plane to avoid injury to the frontal and marginal mandibular nerves.

Correct placement of the incision is important as incorrect siting may lead to a complaint about unsightly or particularly visible scarring, pulling forward of the tragus

to expose the external auditory meatus, or an abnormal shape of the earlobes. The incisions should be hidden within the hair as far as possible and must be made parallel to the direction of the hair follicles to prevent post-operative hair loss.

Flap elevation is in the superficial subcutaneous plane to achieve a thin flap but to retain the viability of the subdermal-dermal plexus. Haemostasis must be meticulous to prevent haematoma formation. The flap must be a consistent thickness or else post-operative irregularities in the contour will be visible. Special care when elevating the flap is needed to protect the frontal and mandibular branches of the facial nerve and the greater auricular nerve, the latter causing permanent numbness of the pinna. Dissection of the superficial musculo-aponeurotic system (SMAS) puts the facial nerve at risk, and SMAS plication may injure the buccal nerve or the parotid gland with the risk of a parotid fistula.

Draping of the skin flap after SMAS plication must be carried out with care as excessive posterior tension or failure to rotate the flap will give an unsatisfactory appearance. Excess tension near the tragus may pull it forward.

If liposuction is performed at the same time as a facelift, it is important to achieve a smooth result. The port of the liposuction tube should be held with the port away from the dermis to avoid 'buttonholing' the skin and excessive fat removal.

As with any operation, post-operative complications can occur after a facelift. Prompt and adequate treatment is required to avoid permanent unwanted effects. Haematoma is the commonest early complication. Some are minor and can be aspirated or milked after removal of some sutures but many require drainage. If untreated, at best an inflammatory response occurs leading to soft tissue irregularities, and at worst skin necrosis and infection.

Skin flap necrosis is not common, except in smokers or if the dressings are applied too tightly. It is best managed expectantly initially, but a large area will require skin grafting when the wound is clean. Careful wound care and, when appropriate, antibiotic therapy is vital. The patient will need much reassurance about the prolonged healing time and the resultant scars.

Facial nerve paralysis occurs in 0.5–3% of patients, most commonly involving the frontal and marginal mandibular branches. Most paralyse resolve spontaneously. Unless an injury is noted at the time of surgery, in which case it should be repaired, nerve injuries should be managed conservatively. Permanent paralysis may require additional surgery, such as an eyebrow lift. Sensory changes, such as hypoaesthesia of the facial skin, are common for several weeks. The greater auricular nerve may be injured. If it is noticed at surgery that the nerve has been divided it should be sutured, but otherwise treatment should be conservative. Permanent numbness will occur and a troublesome neuroma may develop.

Later complications include: hypertrophic scarring, often post-auricular and made worse by haematoma; infection and skin flap necrosis; earlobe distortion from excessive tension, a permanent deformity possibly needing further surgery such as a V-Y plasty; unfavourable

hairline changes, alopecia, permanent hair loss occurring in approximately 2–3% of patients, temporary loss with thinning more frequently but with hair regrowth within several weeks; bald scars due to incorrect bevelling of incisions; and hyperpigmentation from bruising or just spontaneous.

Mentoplasty

This is indicated as part of a rhinoplasty or as a separate procedure. A slight increase in projection of the chin is usually carried out with an alloplastic implant, usually Silastic. Projection of more than 1 cm may require a sliding genioplasty. Choosing the correct size and shape to match the shape of the patient's chin is important, particularly the curve of the implant and the length of it as it wraps round the mandible. Excessively long implants may result in the prosthesis being visible or palpable.

The surgical approach can be intra-oral or submental. The intra-oral incision is made in the labial sulcus. In a submental approach the incision must be posterior to the submental crease or else it will become visible as it is pulled forward by the implant. In both approaches a subperiosteal pocket for the implant is then created. Failure to match the size and shape of the implant exactly may lead to movement of the implant later, and great care must be taken not to damage the mental nerves. Other complications include haematoma, seroma and infection. In the long term, implants tend to give rise to some bone resorption.

Malar augmentation

Malar implants can be inserted through an intra-oral, a subciliary or a conjunctival approach. In the intra-oral route, care must be taken to avoid Stensen's duct. In the subciliary incision, a submuscular approach reduces the risk of eyelid retraction. The infraorbital nerve must be preserved. The implant is placed subperiosteally through a periosteal incision placed anterior to the orbital rim to minimize adhesions that might cause ectropion and lower lid contracture. The implant can be sutured in place to minimize the risk of movement out of place.

Eyelid surgery

A full pre-operative assessment for eyelid reduction surgery is very important. This should include assessment of the lid margin for ptosis, differences in the level of and ptosis of the eyebrows, the level of the lid creases, the degree of excess skin and the location and extent of fat pads. Lid laxity should be assessed with the snap test and the pinch test.

Pre-operative photographs are necessary in case there are minor degrees of asymmetry more visible photographically rather than clinically. These may be the cause of a complaint post-operatively if not detected.

Eliciting any pre-operative history of dry eye is very important and lacrimal secretion should be assessed by the Schirmer test if there is doubt. Patients with dry eyes

can have a blepharoplasty but artificial tears and ophthalmic lubricants will be needed. Care must be taken to limit the degree of skin excision in both upper and lower eyelids to minimize the risk of intractable dryness.

Patients should be warned pre-operatively about the recognized complications of blepharoplasty, dry eyes, haematoma, globe injury, infection, lagophthalmos and ectropion, the possibility of visual loss, irregularities in healing and the need for secondary surgery in a small percentage of cases.

A post-operative haematoma may be a cause of visual loss. It also delays resolution of periorbital oedema and can lead to subcutaneous haemosiderin deposits that cause pigmentation.

Injuries to the cornea and globe should not occur in blepharoplasty and cannot be defended. Swabs are very abrasive and easily cause corneal abrasions. Instruments should not be passed over the eyes during surgery. Corneal protectors may be used for added security but may distort the shape of the lid. The inadvertent injection of local anaesthetic into the globe can occur. This can cause a selective parasympathetic palsy with a fixed dilated pupil.

Under- or over-resection of the fat pads, particularly on the lower lids, may give a poor cosmetic appearance. Rarely, the lacrimal gland may be injured or even resected, causing dry eye symptoms.

Poor placement of lid scars is difficult to correct. If the upper lid incision goes too far medially, an epicanthal web may develop needing a Z-plasty to correct it. If the upper lid incision is too close to the lid margin or too high, the scar will be visible. Correction is difficult. In the lower lid, the incision should be made close to but not involving the eyelashes or else permanent loss of the lashes will result.

Great care must be taken over the amount of skin that is excised. Lagophthalmos, incomplete upper eyelid closure, is a normal occurrence in the first 48 hours after surgery. It usually resolves spontaneously but a large lagophthalmos (greater than approximately 3 mm), or if it persists, indicates overexcision of upper eyelid skin. If left untreated, dry eye symptoms and corneal exposure occur. The best treatment is replacement of the excised skin, providing that this has been stored in a refrigerator at the time of the operation, as this provides the best match. Ectropion is often due to excessive removal of skin but may be due to other causes such as scar contracture or a lax lid margin. Taping of the lower lid, and if necessary a support stitch, for a few weeks may resolve the problem but permanent ectropion will require skin grafting that will leave additional scars.

Loss of vision is the most feared complication following blepharoplasty. It is very rare but, because it is such a serious complication, all patients considering a blepharoplasty should be warned of the risk of it happening. The mechanism of action is not clear but it may be due to acute elevation of intra-ocular and intra-orbital pressures due to retrobulbar haemorrhage from a bleeding artery retracting into the retrobulbar space. The elevated intra-orbital pressure leads to optic nerve head ischaemia and central retinal artery occlusion. Meticulous haemostasis is the best prevention.

Laser skin resurfacing

Lasers are commonly used for reducing wrinkles around the mouth and eyes, ablating areas of actinic damage and generally 'tightening up' the skin due to elastosis. The two lasers used are the pulsed carbon dioxide (CO₂) and the erbium:yttrium-aluminium-garnet (Er:YAG). The CO₂ laser removes 50–100 µm of tissue with each pass of the laser, whereas the Er:YAG laser removes only 25–30 µm of tissue. There is less collateral dermal energy with the latter and adverse effects, such as the risk of scarring, may therefore be less. Pre-operative assessment must include careful assessment of the skin, including photographs. Contraindications to surgery include active acne, recent retinoid treatment and an active herpes lesion.

Post-operative infection, including fungal and viral infections, will cause scarring and must be treated early. Post-operative pigmentation problems are most likely to be troublesome in patients with type IV and type V skin. Patients with black skin should not be treated because of the likelihood of hypopigmentation. All patients will experience some erythema after treatment but more unwelcome complications are persistent hypopigmentation and hyperpigmentation. Hypopigmentation may respond to topical treatment. For several weeks after treatment, exposure to bright sunshine may cause hyperpigmentation.

Rhinophyma

Rhinophyma is a bulbous enlargement of the nose and is caused by hypertrophy of the sebaceous glands, soft tissues and blood vessels of the nasal tip. If large, it can lead to obstruction of the nares. Misdiagnosis by assuming that the bulbousness is due to the underlying nasal cartilage may make the surgeon excise nasal cartilage instead of the soft tissues, leading to an abnormal shape of the nasal tip. Rhinophyma is usually treated by direct excision with a scalpel or by dermabrasion, but laser excision or cryotherapy can be used. Great care must be taken not to excise or dermabrade too deeply or else the area will heal slowly and by secondary intention, leading to unsightly scarring. If the patient develops an infection in the excised area, deepening of the skin loss may occur, leading to additional scarring which the patient may find unacceptable. Full thickness excision of all the rhinophymatous tissue followed by skin grafting has been advocated in the past but this is not considered now to be an acceptable procedure because of the extensive resultant scarring.

OTOLOGY AND NEURO-OTOLOGY

Hearing disorders

DELAYED DIAGNOSIS

Although parents may be convinced that there has been a significant delay in the diagnosis of a child with profound hearing loss, it is often difficult for them to prove this. Often the child will have passed the health visitor screening tests early in life; the claimant may find it difficult to establish

that these were improperly undertaken and led to the wrong conclusion. A child may be born with a mild to moderate hearing impairment, which gradually deteriorates.

A delay in diagnosis of meningitis may also account for a claim for profound hearing impairment. In the case of pneumococcal or meningococcal meningitis this may amount to only a matter of hours, and there is often dispute as to whether the signs and symptoms of meningitis were evident at the time when the first doctor missed the diagnosis at the onset of the illness. This is especially so in babies. If not, a case can be defended successfully as there is evidence that the onset of profound deafness is early in the course of the disease, especially in pneumococcal cases. In one case, tuberculous meningitis was misdiagnosed as a viral infection, despite the fact that at the same time the child's mother had just been diagnosed with open tuberculosis. Nobody had linked the presence of the tubercular cough as being a likely source of infection and cause of the baby's ill health.

ESTABLISHING DAMAGES

Even if there is clear evidence from GP records that a child's mother attended on frequent occasions complaining about the child's ability to hear, the mother may have grave difficulties in establishing that the child has been damaged by any delay that may have occurred. The problem becomes more difficult if the child has other developmental abnormalities, particularly if they affect language development. A child in whom the diagnosis is delayed until the age of, say, two-and-a-half years may then be fitted with hearing aids and it is uncertain what deleterious effect the delay brought about. If the child is older and the optimum time for fitting a cochlear implant has been missed, then the prospect of the child developing the ability to understand spoken language and to communicate orally may have been lost. With a trend towards earlier implantation it has become more difficult to argue that diagnostic delay did not bring about adverse consequences.

NEGLIGENT CAUSATION

Profound deafness at birth may arise from a negligent act in the antenatal period. For example, in one case a mother was established as lacking immunity to rubella following the birth of her first child. The hospital failed to arrange a rubella vaccination, as did the GP. A year later the mother attended at nine weeks gestation with her second pregnancy, having just contracted rubella. The GP reassured her that, as it was coming to the end of her first trimester, there was no risk to the foetus of damage from the maternal rubella infection. As a result of this advice, the mother decided not to pursue a termination of the pregnancy, which had been her original intention. The child was born profoundly deaf. Judgement was in the claimant's favour.

DEAFNESS WRONGLY DIAGNOSED

Litigation may also arise due to decisions made on the false assumption that the child has a profound hearing impairment. In the young infant and toddler, a detected

hearing loss assessed by brain stem evoked response audiometry may give thresholds in the region of 80 dB. The child may be fitted with hearing aids, and educational decisions based on a hearing difficulty may lead the child to be placed in a school for children with special needs. Such a child may also have a fluctuating conductive hearing loss, due to otitis media with effusion, and the true sensorineural thresholds may only become established when the child reaches the age of 5 or 6. At this point, it may become clear that the hearing impairment is only in the order of 30–40 dB, and that placement in a mainstream school can be considered. The parents of such a child often feel aggrieved.

They may feel that their child is being disadvantaged educationally and attempt to seek compensation. Although the diagnosis in such circumstances of the degree of hearing loss may have been incorrect, it is a challenge for the claimant to establish that alternative management would firstly have been instituted, and secondly would have led to a materially different and improved outcome.

Congenital fixation of the stapes

Rarely, a child may present with a conductive hearing loss and no middle ear effusion or significant past history of middle ear suppuration. This may be misdiagnosed in the older child as otosclerosis and surgery recommended. In these circumstances a range of congenital abnormalities can be present and not be recognized by the inexperienced. When a stapedotomy is attempted, the result is frequently a dead ear secondary to a perilymph 'gusher'. Problems may also arise from attempting to perforate a mobile thin footplate. This happens when the anterior crus is attached to the promontory rather than to the footplate. This abnormality, rather than a fixed footplate, accounts for the conductive loss. Correct management is to either divide the anterior crus alone or else close the ear. It is rare that poor outcomes from stapes surgery in children can be defended. Not only do surgical errors occur, but also often the consent has been inadequate, not taking into account the special problems of such surgery in children. Where a stapedectomy is planned in a child under 10, most experts in the field would expect that high definition CT scans of the cochlear and vestibular aqueducts had been obtained beforehand. Congenital abnormalities of the inner ear are a specific contraindication to such surgery.

Matters become more complex in the case of the adult with congenital fixation of the stapes, as not surprisingly there are often no records from childhood. The past history of childhood hearing loss can be then erroneously ascribed to otitis media with effusion.

Ear syringing

Nearly all of the cases of negligent ear syringing take place in general practice.² The first common failure is failure to take an adequate history, asking in particular for previous ear surgery or ear infections with perforation of the eardrum as contraindications to undertaking the procedure.

The advent of the pulsed jet of water produced by a device connected to a simple pump has, in recent times, reduced the number of injuries sustained as a result of faulty bulb or barrel ear syringes disassembling during syringing.

Occasionally, irrigation fluid at the wrong temperature can cause the patient to move suddenly. This can happen either because excessively hot or cold liquid surprises the patient or, more commonly, a marked caloric effect with dizziness causes the patient to become stressed. Rarely, a sudden movement may lead to trauma of the external auditory canal.

Failure to ensure that all the wax has been removed can lead to a soggy mass of wax and dead skin left in the external auditory canal. This almost inevitably leads to an external ear infection and a dissatisfied customer. If the eardrum is perforated through trauma then it is probably wise to give a short course of prophylactic antibiotics to reduce the risks of otitis media. The presence of a perforation of a traumatic type following ear syringing does not automatically imply negligence: a perforation of the eardrum can still happen even if an adequate history has been taken and the procedure was performed competently. This usually happens in those patients who have had a previous perforation in the past, which has healed by a thin two-layer repair. The patient may not be aware that this has happened in the past and consequently have failed to declare the problem. However, a defence is unlikely to be successful if there is clear evidence in the GP's records of a previous acute otitis media that settled following an episode of aural discharge.

Otosclerosis

It should always be remembered that a bilateral conductive audiogram is a common finding in assessing a patient for surgery in otosclerosis. This presents the dilemma of wondering whether it is a true bilateral conductive hearing impairment or whether the phenomenon of central masking has led to the failure to detect a dead ear on one side.³ In the patient who has had no previous surgery and appears to derive benefit from a single hearing aid worn in either ear, it is reasonable to assume that the patient does have a bilateral conductive hearing impairment. The problem arises in those patients who have had a stapedectomy on one side that has been unsuccessful, in that the hearing has not improved and the audiogram is showing a bilateral conductive hearing impairment. These patients would usually confirm that wearing a hearing aid in the operated ear provides no benefit. However, the only reliable way of determining whether there is inner ear function in both ears is to undertake pre-operative electrocochleography. In one case in which the patient had had several procedures on one ear it was decided that a stapedectomy should be undertaken on the ear that had never had any previous operations because his audiogram showed a bilateral conductive hearing loss. When the patient awoke following this surgery he had no hearing left whatsoever and subsequently had to be managed with a cochlear implant (unpublished data*). Electrocochleography should

be seriously considered in those patients who detect no improvement in hearing from a hearing aid worn in one ear, or where a previous stapes operation has been performed without apparent benefit.

Having established that the patient has a true bilateral conductive hearing impairment then the process of consent for surgery commences. It is important that the patient clearly understands that a hearing aid is a valid and relevant treatment. Once the patient has been counselled of the risks of stapedectomy including loss of hearing, balance dysfunction and tinnitus, the patient should be asked once again whether they are absolutely sure that they do not wish to consider at least a trial of wearing a hearing aid. It should be clearly documented in the notes that the patient has refused to either continue using a hearing aid or is absolutely refusing a hearing aid trial despite counselling.

Stapedotomy is the preferred operation in managing otosclerosis for more than 35 years. Stapedectomy is rarely indicated and is probably only appropriate as a management in certain complications of the stapedotomy operation. There are two basic techniques in stapedotomy: the first is where the fenestra is closed with a vein graft prior to positioning the prosthesis; and the second is where the fenestra is closed directly by the prosthesis itself. Both techniques are still widely practised and, despite the arguments put forward by the proponents of each, both techniques are still acceptable practice.

Complications may arise directly relating to the prosthesis itself. In the type of prosthesis in which the barrel is made of Teflon attached to a piece of wire, there have been incidences of the Teflon barrel becoming detached from the wire during the operation. In one case the Teflon barrel fell through the fenestra into the inner ear. In these circumstances probably the wisest thing to do is to close the fenestra with a vein graft but sadly, in this case, the surgeon attempted to remove the Teflon barrel and the patient subsequently developed a total loss of hearing (unpublished data*).

Litigation may arise post-operatively where a dead ear is the result of either a perilymph fistula or granuloma formation. Prompt diagnosis of a suspected stapedectomy granuloma with urgent exploration of the ear does have a reasonable chance of saving some inner ear function. This can also occur in sudden significant perilymph fistula. However, the patient with the suspected minor perilymph leak that is being treated conservatively is a much more difficult management problem from the point of view of choosing the optimum time for surgery. In many instances it can be reasonably demonstrated that even if surgery had taken place promptly there was still a likelihood that a total loss of hearing would occur. If conservative management is advocated with bed rest then it is essential to monitor the hearing daily and if the sensory thresholds are falling exploration and sealing any perilymph leak is required.

Iatrogenic facial nerve damage

This is a rare complication and is probably sustained as a result of negligence in about 1 in 600–1500 major ear operations. In the author's hospital there have been

only two cases of permanent inadvertent iatrogenic facial nerve damage in middle ear surgery over a 20-year period, which gives an approximate incidence of 1 in 2000 cases of middle ear surgery excluding minor procedures, such as ventilation tube insertion and procedures on the external auditory canal (in which there were no palsies). In 1982, Wiet⁴ estimated the risk of iatrogenic damage as being 0.6–3.6% in the USA, which is considerably higher than in the UK, but not all cases of iatrogenic damage are due to negligence. It has been reported in operations such as stapedotomy, but is so rare that it was doubtful that even despite the devastating effect that a palsy has, it was not a requirement to warn patients as part of the consenting process. This may no longer be the case in this post-Montgomery era. In the UK in 2016 the patient should be advised about the risks to the facial nerve from cholesteatoma surgery even if the surgeon has evidence from personal audit that it is not a common risk in their hands.

The occurrence of a facial palsy following an ear operation does not *de facto* indicate that a negligent surgical technique has been employed. In cases where the disease has exposed the nerve or where the nerve is covered in granulation tissue as a response to infection, facial palsy can occur despite the fact that all care has been taken. Also in cases where the nerve is found in a congenitally abnormal position⁵ and is injured as a result then often a defence can be mounted. However, in these rare situations it is advisable to make detailed records supplemented by verification by another surgeon or photography if at all possible.

There are several common errors made in ear surgery that account for a facial palsy that are usually impossible to defend:⁶

- thermal injury as a result of drilling with inadequate irrigation
- failing to find the nerve in an area of normal anatomy and following it into the area where the pathology lies
- inexperience in recognizing the cardinal anatomical landmarks in a normal temporal bone.

This final situation is most common in trainees and usually occurs when undertaking a cortical mastoidectomy and the descending portion of the nerve is injured.

Injury to the facial nerve is much more common in parotid surgery and also joint replacement surgery on the temporomandibular joint.

Sadly, although the cause of the injury may be defensible, it is all too often that the management of the injury is substandard. The unexpected facial palsy that does not recover in a few hours goes unexplored, even though it is clear from the notes that the surgeon has no idea how the nerve has been injured. When an unexpected facial nerve injury occurs, the wise surgeon seeks guidance from a colleague and the patient is reassured that the injury is being taken seriously. Where neuronography indicates that a serious injury has been sustained, then urgent exploration of the facial nerve with repair is required.⁷

Settlements in the United States for facial nerve damage are much higher than in the UK. Wiet⁸ quotes settlements of between US\$200 000 and US\$1.6m, whereas the largest settlement excluding loss of earnings in the UK is £40 000 (US\$62 000). Dr Yeager of the Medical Inter-Insurance Exchange of New Jersey reported that in the 10 years from 1977 to 1987 they settled a total of 79 cases (four were iatrogenic facial palsies) arising from ear surgery.⁹

Nerve monitoring has now become widely available. Facial nerve monitoring has the ability to give the surgeon warning of proximity to the nerve in those cases where the nerve is dehiscant or in an abnormal position. However, such cases are usually defensible anyway. As yet, it is not standard practice to use a nerve monitor in major ear surgery, such as for cholesteatoma. In all the cases of iatrogenic facial nerve palsy that I have opined upon, only one case was the result of surgery by a consultant, with the rest due to operations performed by various grades of trainee or non-consultant career grade doctors. Usually the injury was gross with complete transection of the nerve and one of the circumstances indicated in the records is a failure to identify the major landmarks that indicate the position of the nerve. In the case of a trainee, there was usually no direct supervision. In all cases that are indefensible, adherence to the cardinal rules of mastoid surgery and adequate supervision by a trainer would have prevented the accident. It is debatable that these cases can be prevented by the use of facial nerve monitoring. A large prospective series of monitored mastoid procedures undertaken by trainees would probably be enough to convince the profession or, even better, a randomized controlled trial, but this is unlikely to happen for some time given the UK's track record on multicentre studies of otological surgery. Interestingly the last six cases of iatrogenic facial nerve injury that I have opined upon were all fitted with a facial nerve monitor.

Cholesteatoma

DIAGNOSTIC OR TREATMENT DELAY

Delay in diagnosis usually occurs due to a failure of the GP to refer a patient with a chronic aural discharge. Occasionally, particularly in those cases of congenital cholesteatoma with an intact eardrum, a mother may have attended either the GP, and/or the hospital, complaining that their child has a unilateral hearing impairment. It is quite permissible in those children under the age of 8, particularly if the tympanogram is abnormal, to wait the usual three months for a middle ear effusion to resolve. If the condition has not resolved, then serious consideration should be given to an examination of the ear under anaesthesia, and if there is any doubt, a CT scan. Plain radiography often gives a clue in these cases, due to the loss of the septae in the air cell system, as well as the cloudiness due to the presence of the cholesteatoma.

Although parents may be aggrieved by the delay in diagnosis, they are usually unable to establish that any additional damage has occurred as a result of the delay, unless there has been an intra-cranial complication.

If patients have been referred and diagnosed and placed on the waiting list for excision of a cholesteatoma, complications such as facial nerve paralysis, meningitis or other intra-cranial sepsis may occur whilst the patient is on the waiting list. In these cases it is rarely possible to prove negligence, as it is difficult for the claimant to establish that the waiting list has been managed such as to amount to providing substandard care. However, whether increased delays to some patient's treatment caused by prioritizing 'long waiting' patients amounts to negligence has not been tried in the courts. Cholesteatomas are often large in children despite a relatively short history and consequently it is probably only a matter of time until there is a challenge to waiting list management arguing that a child with a cholesteatoma should be given priority over an adult who may have waited longer. This may be especially so today as waiting list management is increasingly being taken out of the hands of consultants who know the patients and is being controlled more by hospital managers. As such managers are not medically qualified, there is an argument that the Bolam principle should not apply.

The cornerstone of the argument that is usually advanced in cases that develop intra-cranial complications while on the waiting list is that the patient should have been given priority over routine mastoid surgery. For example, in one case a patient lost all hearing in their only hearing ear while waiting for excision of cholesteatoma in that ear and the consultant and defence argued that all cholesteatomas were potentially life-threatening and as such should be treated in the order that they presented. The claimant argued that the fact he had such poor hearing in the other ear meant that should he lose all hearing in the diseased ear then he was going to have a greater loss than the other patients on the waiting list. The defence also was on Bolam. The case settled out of court in favour of the claimant (unpublished data*).

NEGLIGENT MANAGEMENT

As yet no litigation has arisen as a result of creation of an open cavity. However, patients are becoming increasingly sophisticated in their expectations and demanding of being involved in choices concerning their health, which has been upheld by the Montgomery case.¹⁰ Having an open cavity effectively bars the patient from many jobs and, in particular, from joining the armed forces. In areas where the armed forces are major employers of young men who have little prospect of any other employment, choice of ear operation to eradicate cholesteatoma is important. Patients have been angry to discover that there was a choice of either canal wall up surgery or canal wall down surgery, and had a canal wall up procedure been undertaken there would have been a prospect of passing an army medical. They were angry that an open cavity had been created and as such there was now a considerable restriction on job opportunities. It is only a matter of time until this point is litigated.

Technical errors in performing mastoid surgery are still all too common. In one case, an aural polypectomy was

performed that revealed cholesteatoma. Several months later, an atticotomy for cholesteatoma was undertaken on the same ear. Five days following surgery the child was admitted to another hospital with meningism and cerebritis. An exploration of the ear was undertaken by an experienced ear surgeon who found that extensive cholesteatoma still remained. This was despite the operation note for the atticotomy indicating that all cholesteatoma was removed. The case was settled for an interim payment of £15 000 as fortunately, the child had made a full recovery from the brain infection, but should epilepsy subsequently develop then further compensation would be paid.

Ossiculoplasty

Ossicular reconstruction appears to attract remarkably little litigation. This suggests that in everyday practice not that many cases of ossicular reconstruction are being undertaken, or else those that are doing them are not making errors. The key to a satisfied patient is to manage their expectations. The patient with normal hearing in the other ear needs particularly careful handling. In these circumstances, for the patient to appreciate a significant improvement, the operated ear will need to reach within about 20 dB in the important speech frequencies of the other ear for the patient to notice a benefit. Consequently, if there is a significant sensorineural component on the side with the conductive loss, it may be impossible to give the patient a noticeable hearing benefit. To offer ossicular surgery in these circumstances would generally be considered substandard care. Fortunately, litigation in these circumstances is rare as even if the operation is successful all the patient feels is that the operation did not work. It usually requires a loss of amenity for the patient to seek redress, such as the development of chronic discharge, pain, tinnitus or altered taste sensation.

Rarely, serious damage can occur during ossicular surgery. This has included gluing an instrument to the stapes with histoacryl glue with accidental removal of the stapes on removal of the instrument.

Recently two cases have occurred where a prosthesis with a shoe that rests on the footplate has given trouble. In this design there is a central wire core to the prosthesis. This wire has gone through the shoe and penetrated the footplate causing a perilymph leak.

Sudden sensorineural deafness

From time to time, a patient will attempt to litigate following a sudden loss of hearing. This usually arises when the patient presents to a specialty other than ENT, such as general practice or orthopaedics. Examples include patients told by their GPs that they had colds with middle ear effusion, although they had no cold symptoms, and patients awaking from non-otological surgery with total hearing loss in one ear. Cases that subsequently litigate have usually been told to consult their GP. There can be trouble if they are subsequently told that prompt treatment with a vasodilator or steroids would have restored

their hearing. These cases can usually be defended as there is no evidence that any therapy is effective in acute sudden sensorineural deafness apart from acyclovir in herpetic infection and perhaps steroids in acute autoimmune cochleitis and tertiary syphilis.

Dizziness

Failure to diagnose a cause of dizziness can lead to litigation, but the likelihood of success usually depends on the final diagnosis. Vestibular schwannoma appears to be the number one disorder for which the public will attempt litigation if diagnosis has been delayed. However, cases are rarely successful due to the slow growth rates of the tumour and difficulties in establishing that any damage has been caused by the delay. It is in those disorders where there is an effective, reliable treatment that litigation is likely to be successful.

A good example is provided by the failure in one case to diagnose bilateral labyrinthine failure in a young professional. The patient attended her GP with acute rotatory vertigo and was seen by her local ENT surgeon. Following a history, and a brief clinical examination with audiometry and a magnetic resonance scan, the surgeon diagnosed acute vestibular neuronitis and reassured the patient that she would get better. Six months later the patient was still off work despite having seen her local physiotherapist. The patient then went privately to see another ENT surgeon with a special interest in balance dysfunction. By the end of a half-hour consultation that impressed the patient, the surgeon diagnosed bilateral vestibular failure, which was confirmed by caloric tests, and instituted Herdman exercises. The patient was back to work within six weeks and felt considerably better. She litigated for the six months' loss of salary and brought a complaint against the original specialist through the NHS complaints procedure (unpublished data*).

Benign paroxysmal positional vertigo is another disorder that if missed may lead to a prolonged period off work but there has not yet been litigation for failure to diagnose and treat this condition as far as I am aware.

Dizziness can be the presenting symptom for a number of serious conditions. Failing to be suspicious of cardiac causes and undertaking a basic examination in a patient presenting with dizziness can lead to allegations of negligence. Checking someone's pulse will detect arrhythmia and heart block. Failing to identify such serious disorders will depend on the circumstances and the symptoms complained of but could lead to litigation. Similarly, failing to diagnose and act on severe untreated hypertension or marked hypotension can lead to a successful claim.

Menière's disease

Failure to diagnose Menière's disease is unlikely to succeed as the patient would have to establish that they would have been successfully treated within the time frame of the delay. Litigation therefore tends to arise because of side effects of the treatment that the patient was not expecting.

SACCUS DECOMPRESSION SURGERY

The structures that are at risk of damage in this procedure are the facial nerve, posterior semicircular canal, the dura and the lateral venous sinus. Damage to the facial nerve or the posterior semicircular canal is usually indefensible unless the nerve is in a congenitally abnormal position. Opening the dura with cerebrospinal fluid leak is an inherent risk of many of the advocated procedures on the sac, such as excision, insertion of a valve, and so on, and so a defence can often be mounted. In one case the lateral sinus was injured and led to major complications. During the procedure a cutting burr opened the sinus. The surgeon chose not to repair the sinus but to pack it. Before doing this he chose not to refer to the scans that had been done to exclude a vestibular schwannoma. Following the procedure, the patient developed bilateral VI nerve palsies and chronic headache due to packing of the only lateral sinus, as there was a congenital absence on the other side. This may be seen as incredibly bad luck, but it is a complication that could have been foreseen and prevented by the simple measure of having the scans in the theatre and checking them before deciding on how to manage the complication (unpublished data*).

The unusual

Occasionally the bizarre turns up. The following are some of those cases that have occurred that could not be foreseen by most experts in the field of otology.

HYPERSALIVATION

The patient complained of having excessive mucus and saliva at the back of the throat. She was a senior executive in a stressful occupation with an introspective personality. Despite normal sinus radiology the surgeon undertook a range of sinus procedures including washouts and intranasal antrostomies, none of which produced any long-term resolution of her symptoms, which she was beginning to dwell on. He then diagnosed 'hypersalivation', even though the patient was not on any medication known to cause this, and advocated a tympanic neurectomy, which was duly carried out and produced no benefit. He then persuaded her to have a tympanic neurectomy on the other side, which did not help either. At this point, the patient sought a second opinion.

SHAM SURGERY

A patient with Menière's disease attended an otologist privately and after a consultation and discussion it was agreed that a saccus decompression should take place. After the operation the patient was no better and thus sought a second opinion. On this occasion, a computed tomography scan was undertaken as part of the investigations, which revealed that no saccus decompression operation could have taken place as the mastoid air cell system was present and normal. The patient had not received the operation for which she had paid and, as such, had been defrauded. The patient chose to treat this as a criminal

matter and reported it to the police who subsequently took action against the doctor concerned. It is essential when billing a patient that they are billed for exactly what they received.

Causation of loss of hearing

From time to time, expert opinion is sought on the matter of causation of deafness, where the alleged injury has been perpetrated by a doctor from another specialty. There are some areas of practice in which this happens again and again.

FAILURE TO DIAGNOSE MENINGITIS

Usually the doctor involved is a paediatrician, accident and emergency specialist or GP. In most circumstances, the date and time when the disease should have been diagnosed can be established with some certainty. It is usually easier to express an opinion if the infecting organism is known. Placing the hearing loss in the context of other neurological damage is much more difficult. In other words, it may be possible to state with some conviction that hearing would have been saved, but it is much more difficult in some cases to assert that the interpretation of sound would have been normal, especially if it is likely that other central neurological damage would have occurred. In expressing an opinion on such matters, it is useful to discuss the hearing loss and neurological damage with a neurologist. This is particularly important if requested to give an opinion on the management of the claimant's current condition with a cochlear implant and the claimant also has a severe neurological deficit.

OTOTOXICITY

It is unusual for the claimant to allege that the negligence occurred at the hands of an otolaryngologist, but from time to time indiscriminate use of ototoxic ear drops are accused of causing deafness. Establishing causation can be difficult. First, it may be claimed that the deafness has occurred because of chronic suppuration. Second, there is nothing in the medical literature that establishes beyond doubt that topical ear drops are ototoxic when used in short courses. Third, it may be argued that when used to treat Menière's disease, buffered gentamicin does cause deafness and the literature gives many accounts of this; however, the counter-argument is that topical gentamicin ear drops are not buffered and therefore do not act in the same way as buffered gentamicin. Nevertheless, where a patient has been using ototoxic ear drops in the presence of a perforation or mastoid cavity on a daily basis for many months or years contrary to the advice in standard texts, it is a real possibility that having heard the scientific argument a judge will give the benefit of the doubt to the claimant.

Ototoxicity is much more common where the drug has been administered parenterally. Consequently, where the drug is an aminoglycoside, knowledge of renal function

and inspection of the drug charts and any blood levels usually makes it clear at what point the ototoxic deafness occurred. Rarely, the doses and drug levels appear to be within the therapeutic range, yet there appears to be no other explanation for the deafness occurring other than ototoxicity. In these circumstances the possibility of synergy between drugs causing an ototoxic effect has to be considered. Common synergistic combinations are furosemide and/or vancomycin with an aminoglycoside. Also a rare genetic predisposition to ototoxic effects of aminoglycosides could explain deafness where drugs have been used within recognized therapeutic parameters. Opinion from a clinical pharmacologist may be valuable in trying to determine the possible cause of the claimant's deafness.

Dermatological products containing steroid and aminoglycoside may cause sensorineural deafness after prolonged usage on inflamed skin. Any patient presenting with symmetrical deafness should be asked about usage of skin preparations. A typical situation may be prolonged usage of Betnovate® with neomycin to manage generalized eczema. The patient should be advised of the possible cause and, after excluding other causes, it is reasonable to attribute the hearing loss to the obvious. As usage has been prolonged, often over many years, it is much more difficult to advise the court at what point the hearing loss started as opposed to when the claimant noticed a problem. The easiest way may be to quantify the hearing loss and then divide it by the number of years over which the product was used. However, this may not be fair as the history of usage of the product is not likely to indicate even consumption but variation as the underlying skin disorder waxes and wanes.

The court, however, needs a practical solution, which may often be reached following discussion with the expert for the other side. Both experts need to demonstrate that they have considered all reasonable ways of calculating the onset of the hearing loss and why they have discarded some methods in favour of another.

POST-SURGICAL LOSS OF HEARING

Very rarely, sudden sensorineural deafness can occur as a result of surgery in the posterior cranial fossa. The otologist may be asked to give an opinion as to the likely cause. This may be a 'fishing expedition' on behalf of the claimant by their lawyers. Any operation in the posterior cranial fossa can cause deafness. The cause may be obvious, such as vestibular schwannoma surgery or a meningioma involving the VIIth and VIIIth nerve. On the other hand, it may be something unrelated to the VIIIth nerve such as a microvascular decompression of the Vth nerve for trigeminal neuralgia or VIIth nerve for hemifacial spasm. The cause of the deafness is frequently not clear. Each case has to be considered individually but in most cases the answer comes down to vasospasm, embolism, thrombosis, dividing the blood supply or venous drainage surgically, or cutting the VIIIth nerve.

Embolism causing deafness is rare but it occurs most commonly on heart bypass surgery and following major

limb injury when it is believed to be fat embolism in the presence of a right to left cardiac shunt, say through an atrial septal defect.

PAEDIATRIC OTOLARYNGOLOGY

Tonsillectomy and adenoidectomy

DENTAL DAMAGE

Most anaesthetists will advise that loose milk teeth are removed prior to surgery and consequently inhalation of a milk tooth is unusual. Occasionally, secondary dentition can get chipped in the older child or adult. Many hospitals now have speedy internal access to dental services to effect a repair, which often forestalls litigation.

CONSENT AND BLEEDING

One of the commonest sources of complaint revolves around post-operative haemorrhage. Many parents when they are giving consent do not grasp that a haemorrhage can be large, require a blood transfusion and even become life-threatening. Most parents will acknowledge that they were warned that bleeding could occur, but most do not have in their mind a collapsed, shocked child with a young doctor desperately trying to get venous access – or even worse, medical and nursing staff showing signs of panic as they realize they are losing control of the situation. Parents who have come through this scenario with their child almost all say that they would not have consented had they known of this risk. Actual haemorrhage rates are between 5% and 10% with severe bleeds happening in approximately 1–2%. A landmark case in October 2004 in the House of Lords¹¹ now means that it is no longer necessary for the claimant to establish that had they known of the risk they would not have had the surgery; it is just necessary to establish that they would have delayed surgery whilst they sought further advice. This effectively means that it is now essential that every parent be warned of the risk of major haemorrhage and blood transfusion.

Occasionally, the haemorrhage can go unrecognized by nursing staff. This can happen when nursing staff do not follow post-operative instructions on monitoring or, worse, carefully chart a rising pulse in a restless child up to the point that the child has a massive haematemesis or even loses consciousness.

Errors in the resuscitation of the shocked child may be less common now with the introduction of paediatric life support and advanced paediatric life support training courses.

POOR SURGICAL TECHNIQUE

Diathermy burns in the mouth and on the lips are still produced. Considerable care needs to be taken especially if using diathermy dissecting instruments or scissors as these can cause large burns, particularly on the tongue. It is generally impossible to mount a defence.

Perforation of the palate – deemed to be due to negligent surgery – has been reported with diathermy dissection.

Excessive resection of the soft palate leading to velopharyngeal incompetence can occur. Where these changes in speech and swallowing reverse within a few weeks a defence can usually be mounted. However if the changes due to nasal escape persist beyond two years the loss of soft palate tissue is usually so excessive that a defence is impossible.

Acute epiglottitis

Since the introduction of haemophilus influenzae B (HiB) vaccination, epiglottitis is on the decrease. No child died from epiglottitis in England and Wales in 2013 while there were nine adult deaths, all aged over 45. In the recent past it was failure to diagnose or suspect the condition that would lead to a patient being sent home only to return hours later with grave breathing problems or even to die at home. Not only may it be a failure to recognize clinical symptoms and signs, but also the classical radiographic appearance can go unrecognized, thus leading to an indefensible claim.

Acute airway obstruction is more commonly due to acute laryngotracheobronchitis (ALTB or croup), especially in infants. If an artificial airway is needed this is now best managed by intubation. The anaesthetist may wish to have an ENT surgeon standing by to undertake a tracheotomy should intubation be impossible and the airway become compromised. Emergency tracheotomy in this situation is nowadays extremely rare. If the airway is not quickly secured, brain damage ensues. Whether sub-standard care is deemed to have occurred will depend on each individual case.

Tracheotomy

Problems with the operation being undertaken as a planned procedure are unusual. Rarely, in very young children a pneumothorax can develop as can injury to the brachiocephalic vein. In the immediate post-operative period, should the tracheostomy tube become dislodged then there can be problems with maintaining the airway. This is why the tube may be sutured to the skin or stay sutures placed on either side of the tracheal incision to help find the opening should the tube be dislodged.

Most litigation relating to tracheotomy surgery can be attributed to complications arising from poor nursing care. Many patients who have tracheotomies have been long-stay patients on intensive care. These patients frequently have chest infections with production of thick secretions. The secretions leading to acute airway obstruction can block the tracheostomy tube. Speedy identification of the problem by close monitoring of the patient usually results in aggressive suction of the airway with saline lavage or bronchoscopy with lavage if necessary. If this does not cause a rapid relief of the problem, the tracheostomy tube can be removed altogether. Unfortunately problems arise on general wards where the nursing staff may have many patients to look after and are unfamiliar

with tracheostomy care. Ward nurses on ENT and neurosurgery wards are often experienced in nursing tracheotomies patients but this cannot be said for the other wards. The timid nurse is often frightened to introduce a suction catheter deep into the lungs. In fact it is failing to pass the catheter right through the tube into the trachea that leads to the deep part of the tube obstructing with dried secretions. Also, these nurses may not have been trained to undertake bronchial lavage to loosen secretions and so bronchial plugging happens, which reduces the patient's oxygenation.

When the patient's airway obstructs, speedy removal of the 'inner' tube and aggressive suction is required. If there is no inner tube then rapid removal of the whole tracheostomy tube and insertion of a clean tube is required. The tracheotomy tube is then connected to an Ambu-bag for inflation of the lungs. Despite the obvious fact that the tracheotomy was undertaken for obstruction to the airway above the stoma, there have been cases where the nursing staff attempted ventilation via the mouth with a facemask and ignored the tracheostomy. It was only when the cardiac arrest team arrived that the blocked tracheostomy was dealt with, but by then severe brain damage had been sustained.

Foreign bodies

THE EAR

The safest way to deal with a foreign body in the ear of a small child is under a general anaesthetic. Attempts to remove a foreign body from the ear without a general anaesthetic by syringing or the use of a strong electromagnet are often successful and carry a low risk of injury. However, instrumentation of the ear in a fractious child can lead to serious injury; such an action can only rarely be defended. Fortunately the injury is usually just limited to laceration of meatal skin, but perforation of the eardrum, ossicular injury and even complete avulsion of the stapes has occurred.

THE NOSE

Failure to diagnose a foreign body is a common cause of complaint and even litigation. The presence of a unilateral or even bilateral foul nasal discharge, which does not settle, should alert the otolaryngologist to the possibility of a foreign body in the nose in a child. In most cases the mother has attended on several occasions at the GP, the accident and emergency department and the ear, nose and throat department where a junior doctor has failed to realize the significance of the problem.

It is a common practice to wrap the small child in a blanket, then to remove the foreign body. However, if this method is employed, it is vital that all care is taken to avoid injury and the practice should not be used on those at risk of atlanto-axial subluxation. Injury occurring in these circumstances is difficult to defend when it could be argued that a general anaesthetic carries less risk.

THE OESOPHAGUS

Problems usually only arise with sharp foreign bodies. The main risk is of perforation but often this can be defended with a sharp foreign body. However, litigation is more likely to arise when there is a delay in recognizing the perforation or inappropriate management once recognized.

THE AIRWAY

Occasionally an inert foreign body can be present for some time before it is recognized. Complaint usually only arises when a significant symptom such as stridor is ignored and then subsequently it is found to have been due to a foreign body.

An unjustifiable delay in undertaking an examination where a foreign body has been inhaled may lead to problems. Any history of a suspected inhaled foreign body accompanied by a severe bout of coughing or noisy breathing mandates an examination of the airway and bronchoscopy. This is especially so when the foreign body is of a vegetable material such as a peanut. The delay can lead to swelling of the peanut with subsequent obstruction to that lung segment and bronchiectasis or lung abscess.

It should always be remembered that a normal chest radiograph does not exclude a foreign body and is not a defence against neglecting to undertake a bronchoscopy.

BUTTON BATTERIES

These modern foreign bodies can cause considerable damage if left in place for any length of time. If they are left in place in the nose or oesophagus they cause caustic burns with marked swelling and a risk of subsequent stenosis. Litigation may arise if a child is not treated as an emergency but is left until the next available routine list.

IATROGENIC FOREIGN BODIES

My experience of this includes a nasal splint retained for 17 years, a guidewire left in the airway for several weeks after a percutaneous tracheotomy and swabs left in the airway after adenoidectomy.

Cervical lymphadenopathy

Once a patient presents with a neck lump, delay in referral is rare. When it occurs it is nearly always in young adults or children.

Once a patient is referred there can be a preoccupation with investigating for cancer rather than on some of the more esoteric conditions such as infections, for example tuberculosis and cat scratch fever. History taking may be inadequate so that exposure to an infection is missed and investigations are not considered. Fortunately, investigating for cancer does usually bring to light the alternative diagnosis.

Surgery may be considered to establish a histological diagnosis in persistent cervical adenopathy. Trauma to the accessory nerve with resultant shoulder drop can arise as a result of dissection in the posterior triangle. Patients need

to be explicitly warned of this risk and its consequences prior to surgery. Ultrasound imaging may avoid the need for surgery in some neck masses. Proper surgical technique will avoid injury to the accessory nerve. Firstly it is usually best to undertake the open biopsy under a general anaesthetic without muscle relaxant or infiltration of local anaesthetic. The accessory nerve should be found in an area of normal anatomy and traced towards the node that is being biopsied. Traction should be used judiciously and use of the diathermy kept to a minimum and always where the tissue being cauterized is seen. On completion of the surgery it is well worthwhile assessing accessory nerve function and recording it.

If an injury to the nerve is identified then it should be thoroughly assessed. If neuronography suggests a major lesion then exploration of the nerve should be undertaken and a repair effected if necessary. If a lesion is detected after some months then EMG evaluation can be useful to predict likely recovery or to indicate a major lesion. Discussion can then take place on the pros and cons of late exploration of the injured nerve.

Salivary gland tumours and congenital anomalies in children

This is a complex group of disorders. Claims usually arise because of delay in diagnosis or facial paralysis. Adverse outcomes occur especially where a surgeon is persuaded to manage a condition that he has little or no experience of rather than insisting the child is seen in a tertiary referral centre.

Epistaxis

In children, the commonest site for repeated epistaxis is the nasal septum. Cautery with silver nitrate is still commonly practised. This rarely causes a problem, but excessive use on both sides of the nasal septum at the same time can lead to a septal perforation. This can also occur when hot wire cautery is used. In occasional circumstances, a severe vestibulitis following the cautery may be a significant contributory factor. Usually, such a complication cannot be defended.

Trichloroacetic acid is rarely used nowadays in the UK to cauterize the nasal septum. However it is now more commonly seen being used as a chemical peel agent in facial plastic surgery. This needs to be handled very carefully as if too much or the wrong concentration is applied it can run on to the upper lip and cause a permanent scar.

Complicated sinusitis

The usual practice is to treat the frontal and ethmoidal sinusitis with decongestants and antibiotics, which is often successful. However, if there is a failure to respond or there is evidence of infection spread beyond the sinus, then drainage of the sinus is required. Failure to recognize that the infection beyond the sinus can lead to orbital abscess and intra-cranial infection. Within the hospital setting,

spread of the infection should be recognized within 24 hours of the first signs or symptoms of this complication developing.

If the infection spreads beyond the frontal sinus, then infection of the bony walls of the sinus can be inferred, as well as thrombosis of the venous channels through the bone. This infection is difficult to eradicate and requires prolonged use of antibiotics in the order of 8–12 weeks. When a patient presents with marked swelling of the soft tissues of the forehead, perhaps with a subperiosteal abscess, there may be an initial settling of the symptoms with a two-week course of antibiotics. The dramatic improvement in the patient's condition may lull either doctor and/or patient into a false sense of security and the antibiotic course is terminated as a result. Then, weeks later, the features of chronic osteomyelitis develop or even secondary intra-cranial sepsis. It is indefensible not to give a prolonged course of antibiotics where there is a significant risk of osteomyelitis.¹²

Atlanto-axial instability

Children with trisomy 21 (Down syndrome) have a high risk of atlanto-axial instability. This can result in excessive movement of the odontoid process during anaesthesia, such as to cause pressure on the spinal cord and neurological dysfunction, including permanent tetraplegia. It is often the anaesthetist who is blamed, especially if the induction has been fraught and the parent was present. However, it is more likely that it is the surgeon and the theatre team who cause this event by over-vigorous movement of the head while the child is hypotonic under the anaesthetic, often with muscle relaxants. High-risk children should be assumed to have the disorder. The practice of ordering routine plain radiographs of the cervical spine prior to surgery on Down syndrome children is outdated and no longer appropriate. It is more important to ensure that all theatre personnel move the child's head with extreme care. There is a salutary lesson to be learned with reference to this: a case was brought after a myringoplasty from which the child awoke with a partial tetraparesis. Post-operative radiology indicated that it was a rotational injury probably caused by the surgeon pushing the head away from himself to get a view of the anterior margin of the perforation whilst trying to position the graft. The mother dropped the case when she learned that it was more likely that the surgeon rather than the anaesthetist had caused the injury, as she liked the surgeon and thought he was a kind and caring doctor.

HEAD AND NECK SURGERY

Thyroid surgery

In times gone by it was standard practice to leave a clip remover attached to the end of the bed of any patient that had thyroid surgery so that, should a haemorrhage arise,

rather than the patient having an airway obstruction with death or brain damage, they just got a bad scare. I was surprised only this year to have two cases where no clip remover was present. In one the patient died; in the other, by the time the sutures were released the patient had sustained a major brain injury. This should not happen and I would suggest that this misadventure would be a good candidate to join the list of never events.

Recurrent laryngeal nerve injury remains the mainstay of clinical negligence in thyroid surgery. The key to preventing litigation is to ensure that training covers the techniques of finding the recurrent and superior laryngeal nerves; the key to defending litigation is a good operation note that details how the recurrent laryngeal nerves were identified and protected during the surgery. Monitoring can also be used and can be especially helpful where the gland is grossly enlarged and in supervising trainees. It is extremely unusual to find a claimant who alleges they had no warning of recurrent laryngeal nerve injury and the risk of change of voice; however there appear to be occasions when the risk of bilateral recurrent nerve palsy and its consequences has not been mentioned. It is such a devastating injury that a claimant having surgery for a benign condition has a good chance of persuading the court that they would have postponed surgery or considered an alternative treatment such as radio iodine. In operative cases where the vagus nerves and/or the recurrent laryngeal nerves are at risk it is wise to record vocal cord function found at a pre-operative laryngeal examination as occasionally a patient will be found to have an unrecognized cord palsy.

It is essential that all thyroid specimens are subject to histology. This also goes for thyroglossal cysts as rarely a malignancy may be found.

Acute loss of parathyroid function can occur. In some cases it can even be predicted, such as the risk occurring after removing a functioning parathyroid tumour or after a total thyroidectomy for cancer. It is the unsuspected case that catches out the unwary. As a general rule if both lobes of the thyroid have been disturbed and not necessarily at the same operation then it is wise to monitor calcium function and blood levels at least once in the post-operative period. The same holds true in laryngectomy surgery even if a thyroid lobe with its parathyroids has been preserved.

Submandibular gland surgery

STONES

The main issue with stones is failing to warn of the risk of leaving a stone behind when opening the duct in the floor of the mouth to extract stones. Usually there is a floor of mouth radiograph to compare the extracted stones with. It is also wise to lavage the duct after removing the stones just to wash out any grit that might be present. However, despite these steps, occasionally a stone will be encountered that will not come out easily. If the patient has been duly warned there is rarely a problem. However, if there

is a post-operative infection secondary to a retained stone litigation can follow.

SUBMANDIBULECTOMY

If a discrete lump can be felt within the gland then it is malignant until proven otherwise. Fine-needle aspiration cytology can be of particular help when it confirms a malignancy but if it is equivocal or even if a report of a benign condition comes back, the wise surgeon should still treat the gland as potentially containing a cancer. Stones and sialectasis can usually be confirmed radiologically.

It is essential to warn of the risks of marginal mandibular branch of the facial nerve palsy, lingual, and hypoglossal nerve injuries. Anaesthesia of the skin over the gland post-operatively is common.

Some series quote as many as 30% of excisions as being accompanied by a nerve injury with mandibular branch of the facial leading the way with an external excision technique and the lingual with an intra-oral approach.

There are two techniques for managing the marginal mandibular branch of the facial and the technique used should be recorded. In the first technique the lower border of the gland is identified and the capsule incised. The capsule of the gland is left attached to the skin and subcutaneous tissues, in which will be the nerve. The dissection is performed in the subcapsular plane. This is also the quickest technique. The other way is to actually find the retromandibular vein and follow it superiorly to locate the nerve and then dissect the nerve. In this way the nerve is always kept in view and the risks of injury reduced. Care has to be taken to dissect close to the gland in benign cases to reduce the risk of injury to the hypoglossal and lingual nerves on the deep aspect of the gland. Injury to the nerve is not *de facto* evidence of poor surgical technique but to convince a court that the operation was done competently, a good note dealing with how these nerves were protected is important.

Parotid disease

Management of chronic sialadenitis leads to litigation as it is often underestimated by both surgeon and patient. Problems arise when the patient has unrealistic expectations of the surgery. The risk to the facial nerve is extremely high when attempting a total resection of the gland. Opinion is divided as to whether total excision is required of the whole gland. As a general rule if any glandular tissue is left behind there is a risk of further active infection but radical excision of the gland carries high risk of facial nerve injury. The golden rule is always to try and treat conservatively. If a point comes where there is no choice but to operate then it is essential that the patient accepts that they will probably have some degree of loss of facial movement.

Salivary gland fistulae if persistent can lead to allegations of substandard care. It is generally accepted that botulinum toxin injected into the remaining gland is first

line treatment. Should this fail, ligation of the fistulous tract is worth a try. In recent times histoacryl glue has been used to block the fistula and the National Institute for Health and Clinical Excellence (NICE) has produced guidance on this technique. Once again litigation can be avoided by managing patient expectations from the outset. It is a risk that should be mentioned at consent and when it occurs the patient needs to understand that they can be troublesome to stop. However, leaving the patient to leak saliva from the incision with only reassurance is unacceptable care.

PAROTID TUMOURS

If the histology of a tumour has not been revealed by a fine-needle aspiration cytology then the lump needs to be excised with a substantial cuff of tissue around it. This is because, should the tumour be malignant or a pleomorphic adenoma, then local recurrence is a real risk and will be difficult to defend. Occasionally a GP will remove a parotid lump, often expecting it to be a benign skin lesion such as a sebaceous cyst, and get a surprise when the histology of a pleomorphic adenoma comes back. If such a patient is referred, the hospital consultant has a choice as to what to recommend to the patient. The choices are radiotherapy, revision superficial parotidectomy or watch and wait. There is no right thing to do and each case has to be weighed up, taking into consideration the size of the specimen removed and the age of the patient. Should the tumour be a low-grade malignancy then total parotidectomy with facial nerve preservation is usually the treatment of choice but all such cases now should be managed through a multidisciplinary team (MDT).

Where a tumour is located hard up against the skull base at the stylomastoid foramen it is substandard to try and locate the main trunk of the facial, as the tumour will for sure have moved the nerve to an abnormal anatomical position. The nerve should always be located in an area of normal anatomy. If the tumour is known to be benign then it best to identify a peripheral branch such as the marginal mandibular branch of the facial nerve and trace it back towards the main trunk and the tumour. This will usually effect a successful excision without a nerve palsy. Where the tumour is malignant then it is best to open the mastoid and identify the descending facial nerve and follow it towards the tumour. This has the advantage that in a low-grade malignancy the nerve can usually be kept intact but if that is not possible grafting is permitted.

With an increasing interest in patient outcomes it is wise for the ENT surgeon to keep a record of all his salivary gland surgery and the outcomes and complications so that he can defend his position if there is any argument about his competency.

Chronic laryngitis

Poor outcomes of surgery lead to litigation especially in the professional voice user. One of the commonest

allegations is lack of conservative management in the early course of the condition and going for a surgical option without trying alternatives. In some instances this can be defended, especially where the patient abuses tobacco and alcohol and cancer is suspected. Nevertheless the wise surgeon should explain his reasons for recommending biopsies in the larynx and counsel on any long-term risk to the voice.

The main reason for a poor result is post-operative tethering of the mucosa, often as a consequence of stripping away too much tissue and damaging the underlying vocal ligament.

Another reason for litigation is misdiagnosis or failure to make a diagnosis at all of rare neurological conditions that can affect the voice and larynx. Such conditions include Shy Drager syndrome, laryngeal dystonia, motor neurone disease, neuroferritinopathy and neuroacanthocytosis. These conditions usually present with such a range of symptoms that affect other parts of the body as well as the larynx that they rarely present in an ENT department and when they do the systemic nature of the disorder is usually spotted. In the early stages they can just present with voice and laryngeal symptoms or the ENT surgeon fails to ask about any general symptoms. I have seen a case of delayed diagnosis of Shy Drager syndrome in which the ENT surgeon completely failed to appreciate the significance of the patient's fainting episodes and chronic diarrhoea. She went into a crisis requiring an emergency tracheotomy after six months of progressing problems and subsequently successfully litigated.

DELAY IN DIAGNOSIS

Delays in diagnosing cancer rarely occur in general practice these days. Prompt referral of patients with a greater than six-week history of voice change to the two-week wait clinic is the norm, meaning that more than 90% of patients in the two-week wait clinic do not have cancer. Problems arise when biopsies come back showing dysplasia or just chronic inflammation. Discharge of patients back to the GP or on to speech and language therapy for a course of treatment can only be justified if there are no 'red flag' symptoms suggesting cancer, such as persistent unilateral earache in a normal ear or intractable pain in the throat. A good rule for patients who smoke and/or drink who have symptoms of cancer but a negative biopsy is that they have cancer but just require more in-depth urgent investigation. A three-month wait in a smoker with intractable earache and evidence of laryngitis cannot be justified. Rebiopsy, PET scanning or CT scanning should be seriously considered on receipt of a negative biopsy and tests ordered even before discussion at an MDT.

Rare tumours or common cancers with unusual presentation can be diagnosed late. Examples of these include sarcomas, malignant tumours of blood vessels and locally

destructive tumours such as ameloblastoma. There is no doubt that if the patient sees someone inexperienced, such as a young consultant or trainee, then there is an increased risk of delay. In the cases where litigation is successful there has usually been a reluctance on behalf of the managing practitioner to bring the case to a more experienced colleague or to discuss the case at an MDT. In addition there is often a series of errors. Another common error is in the management of the case with an unusual presentation. In such cases, it is important to go back to first principles taught at medical school and take a thorough history followed by detailed examination. If the surgeon does not go back to first principles, important steps that may give key clues to the diagnosis may get missed. Examples include failure to palpate the tongue, transilluminate or auscultate a lump.

Delays in diagnosis have differing consequences. The commonest allegation is that a resection would have been smaller, which may lead to allegations that a different less disfiguring reconstruction would have been used, a prosthesis would have been avoided or neurological deficits would not have occurred.

The next allegation is that surgery would have been avoided and another treatment modality would have been used such as radiotherapy in cancer of the larynx.

Conversely, allegations may include that chemotherapy and side effects such as ototoxicity would have been avoided or that radiotherapy with consequent scarring, stricture formation or xerostomia would have been avoided.

SURGICAL INFECTION

Allegations of substandard surgical technique in the management of head and neck cancer are unusual and mainly revolve around salivary gland and thyroid surgery. Where allegations occur is in the ward management of the post-operative patient. These usually revolve around the management of infection. MRSA (methicillin resistant *Staphylococcal aureus*) infection can lead to the claimant alleging failure to adhere to Trust policies on infection control. Nowadays with the emergence of resistant strains of bacteria there is wisely an increasing reluctance to use antibiotics, especially where wounds are dirty or contaminated, but there is little indication of systemic or spreading infection. Not surprisingly, getting such wounds to heal especially if there are salivary fistulae can take many weeks. Claimants can make allegations that but for the failure of prescribing antibiotics they would have been discharged earlier and with less scarring.

Conversely, allegations arise in the case of hospital-acquired infections (HAI) such as *C. difficile* and their consequences, which would not have occurred but for the injudicious use of antibiotics in the post-operative period. This can be difficult to repudiate if the claimant has been on an antibiotic for weeks with no evidence of review.

BEST CLINICAL PRACTICE

- ✓ Sudden onset of double vision should never be ignored.
- ✓ It is wise that both the clinician and the radiologist assess the radiological films, within the clinical context of the patient's disease.
- ✓ In the field of endoscopic sinus surgery, it is essential to have a complete demonstration of the radiological anatomy by CT scan.
- ✓ If a lesion deemed benign on cytology does not appear to be behaving clinically as such, rebiopsy should be undertaken speedily.
- ✓ In the case of simple, benign, nasal polyposis, there is rarely any defence for not discussing the possibility of a course of oral steroids, with or without antibiotics.
- ✓ A post-operative saddle nose deformity could, rarely, be due to a failure to recognize and diagnose disorders such as Wegener's granulomatosis or sarcoidosis. In such an event, the appropriate tests to exclude such disorders should be taken.

KEY POINTS

- Ear syringing and stapes surgery are the commonest procedures leading to litigation in otology.
- The only reliable way of determining whether there is inner ear function in both ears is to undertake pre-operative electrocochleography.
- The argument that is usually advanced in cases that develop intra-cranial complications while on the waiting list is that the patient should have been given priority over routine mastoid surgery. Disease in the other ear with hearing loss is usually given as the reason for priority.
- Cases of failure to treat sudden deafness can usually be defended as there is no evidence that any therapy is effective except acyclovir in herpetic infection.
- Establishing that sensorineural deafness is caused by ototoxic ear drops can be difficult.
- Wegener's granulomatosis is a condition that regularly goes unrecognized.
- Issues of consent on their own are rare in relation to sinus surgery.
- Where contention may arise is not that the patient was warned of anatomical risks, but that they did not understand the consequences of these risks on their day-to-day life, or that, should such risks occur, secondary complications may supervene.
- Infraorbital nerve neuropraxia in Caldwell-Luc surgery can occur despite all care being taken and does not indicate de facto substandard technique
- A decision not to investigate is probably only best confined to those patients who have such gross comorbidity that no surgeon or anaesthetist would consider them for surgical management.
- Unless progressive sensorineural deafness in a young adult is investigated, cases of treatable disease such as neurofibromatosis will be missed.
- Failure to act on a unilateral sensory neural deafness is rarely defensible.
- Misinterpretation of brainstem-evoked responses can lead to a failure of instigating radiological tests and subsequently a delay in diagnosis of a vestibular schwannoma.
- Failure to diagnose an olfactory groove meningioma usually occurs when there is another plausible explanation for the loss of smell.
- Meningitis is such a devastating disease when it occurs that clearly a degree of risk has to be considered acceptable when undertaking the investigations for a suspected CSF leak.
- In lateral skull base surgery, every surgeon should now give careful consideration as to which lower motor cranial nerves should be monitored.

SEARCH STRATEGY

The information described in this chapter comes directly from the NOTSS project, with details in the reference section. Further details can be found at www.rcsed.ac.uk/professional-support-development-resources/learning-resources.

All tables provided in this chapter are based on those developed in the NOTSS project but adapted for use by ENT surgeons.

INTRODUCTION

Technical skills in ENT surgery relate to the hand-eye coordination that enables the surgeon to move the scalpel or drill exactly, to cut with the correct pressure to a precise depth without injuring adjacent structures; to hold the tissues gently; to create the space to work and to diathermy only the bleeding vessel, keeping collateral damage to a minimum. Technical skills are the craftsmanship of surgery.

Non-technical skills relate to those additional abilities of situational awareness, decision-making, communication and teamwork, and leadership that allow the technical work to proceed efficiently, safely and calmly, and are equivalent, in aviation, to crew resource management skills, which are part of the human factors well known in aviation circles. The influence of these skills in healthcare on both good and poor performance is now well recognized. Surgery is particularly susceptible to complications and these adverse events are much more likely to follow failures in non-technical rather than technical skills.¹ It has been estimated that adverse events, not directly related to the underlying condition, occur in 10–15% of hospital admissions. Half of these occur in surgical patients and around half are avoidable.²

Despite the introduction of the World Health Organization (WHO) peri-operative surgical checklist, which reported significant reduction in morbidity and

mortality,^{3, 4} there remains an alarming rate of ‘never events’.⁵ The problem, until recently, was that the surgical fraternity did not know much about these so-called ‘non-technical’ skills,⁶ what they were and how they could be observed, taught or even assessed. These skills are not new or mysterious behaviours; they represent what the safest and most efficient surgeons do on a consistent basis. In ENT, training in ‘theatre behaviour’ was given only by example, both good and bad, was incomplete, was random and depended on the awareness and perspective of the training consultant. It is now clear that these skills underpin everything surgeons do, supporting technical and clinical excellence, reducing errors and improving outcomes. In a reply to an anonymous postal survey in South East Scotland, 68 consultant surgeons from all specialties identified 70 skills that they considered important to be a successful surgeon.⁷ Only 19 (27%) of these were technical and 22 (31%) clinical; 29 (41%) related to communication, teamwork and the application of knowledge. Problems with decision-making, communication and teamwork have been shown to be related to surgical failure.^{8–10}

Following the example of civil aviation and other high risk industries (e.g. offshore oil exploration and nuclear power generation) that have developed training and assessment of non-technical skills,¹¹ surgery has developed its own ‘non-technical skills for surgeons’ (NOTSS) that are required in the intra-operative environment to support the surgeon’s technical expertise. These were identified in a joint project between

Aberdeen University and the Royal College of Surgeons of Edinburgh,¹² and an associated classification was developed along with good and poor behavioural markers, which can be used to assess surgeons. Several studies have now demonstrated that these are usable, reliable and reproducible, and can be informative for trainee feedback.^{12–14}

BEHAVIOURAL MARKERS

Observational methods for identifying and rating non-technical skills in medicine were first developed for anaesthetists,¹⁵ now called anaesthetists' non-technical skills (ANTS). Other studies have explored team factors, which support good surgical performance.^{16–18} NOTSS is a system designed 'by surgeons for surgeons' to observe and rate individual surgeons. Subsequent phases of the NOTSS project have used the classification for debriefing trainees after surgery,¹² in surgical simulation, and as a central part of a master-class to train surgeons to observe and rate non-technical skills.¹⁹ NOTSS has also been subject to an independent trial of workplace assessment systems along with procedure-based assessment (PBA) and objective structured assessment of technical skill (OSATS),²⁰ with encouraging results in the operating room.²¹ NOTSS has been adopted by the Royal Australasian College of Surgeons as part of their competence assessment and recommended by the Accreditation Council for General Medical Education (ACGME).²² A large-scale trial in Japanese hospitals is also underway.²³ A similar system has subsequently been developed for theatre scrub practitioners: scrub practitioners list of intra-operative non-technical skills (SPLINTS).²⁴

THE NON-TECHNICAL SKILLS FOR SURGEONS (NOTSS) SYSTEM

The aim of the NOTSS project was to develop a non-technical skills classification, with associated behavioural markers, which could be used in the training and assessment of surgeons during the intra-operative phase of surgery. The resulting NOTSS classification is made up of four main skills categories, each with three levels of associated elements as shown in [Table 40.1](#).

Skill category	Level	Element
Situational awareness	I	Gathering information
	II	Understanding information
	III	Projecting and anticipating future state
Decision-making	I	Considering options
	II	Selecting and communicating options
	III	Implementing and reviewing decisions
Communication and teamwork	I	Exchanging information
	II	Establishing a shared understanding
	III	Coordinating team activities
Leadership	I	Setting and maintaining standards
	II	Supporting others
	III	Coping with pressure

It is important to understand that this is not about personality, but about observable characteristics within the operative environment. For training purposes, to provide feedback, and to assess surgeons, behaviours associated with each element may be scored as follows:

- **Good** (score 4): Performance of a consistently high standard, enhancing patient safety, which could be used as a positive example for others
- **Acceptable** (score 3): Performance of a satisfactory standard, but could be improved
- **Marginal** (score 2): Performance indicated a cause for concern, considerable improvement is needed
- **Poor** (score 1): Performance endangered, or potentially endangered, patient safety; serious remediation is required.

Sometimes a particular behaviour is not required, or not relevant, in a particular situation. In this case 'Not Applicable' or 'N/A' is recorded. This is not to be used if the behavioural skill is lacking. If the skill is lacking then a score of Poor (score 1) or Marginal (score 2) is recorded.

Although these elements appear distinct, several of the elements may occur at the same time during a particular event. For example, gathering information about a developing, urgent, life-threatening situation, such as worsening stridor, will require good communication, exchanging information about all possible options and potential outcomes, establishing a shared understanding, and leading to a balanced decision on the next best step to take to maintain standards and safety, all the time coping with the stress. Although NOTSS relates to the intra-operative environment, these skills are also important in all aspects of surgical care, on the wards, in the clinics, and when dealing with managerial and secretarial staff. For each category, shown in [Tables 40.2–40.13](#), a selection of 'good' and 'poor' behaviours associated with each of the three elements within that category, relevant to ENT surgeons, will be discussed, though the broader picture may be applied to all surgeons. Examples from aviation and industry may be used for comparison or illustration.

SITUATIONAL AWARENESS (SA)

Situational awareness is the ability to develop and maintain a dynamic awareness of the present situation based on fitting together environmental information, understanding its meaning and thinking ahead to what might happen next. Good SA in the operating theatre is essential for all the other non-technical skills and comprises three distinct levels, which may be inferred from the above definition: Level I – gathering information; Level II – interpreting the information, which requires understanding; and Level III – projecting and anticipating future states based on this information.²⁵

Level I – gathering information

The information gathered relates to ensuring the safety of both patients (clinical information) and staff (non-clinical information), and forms the foundation of forward

TABLE 40.2 Situational awareness Level I. Gathering information – examples of good and poor behaviours

Good behaviours	Poor behaviours
<ul style="list-style-type: none"> • Has reviewed patient in the clinic and explained relevance of investigations to surgery: begins consent process • Carries out pre-operative checks of patient notes, especially previous surgery • Ensures that all relevant imaging/investigations are available and have been reviewed in detail, e.g. CT sinuses before FESS • Identifies hazardous anatomy on CT, e.g. sloping skull base (Keros I), Onodi cells; exposed ant. ethmoid artery and optic nerve • Liaises with anaesthetist about comorbidities affecting anaesthetic plan, e.g. hypotension and tolerable blood loss • Monitors staff well-being • Asks anaesthetist for regular updates on e.g. blood loss 	<ul style="list-style-type: none"> • Has not seen the patient before the day of surgery • Doesn't see the patient pre-operatively, but expects the trainee to have done so • Reviews results superficially at the last minute, or does not review them at all • Is unaware of the pressures on the operating theatre staff, e.g. numbers, skill mix, impending urgent cases • Does not listen to the concerns of the anaesthetic team, e.g. about using hypotension during FESS or ear surgery to reduce bleeding in a patient with cardio-vascular disease • Asks theatre staff to read from patient notes during procedure because surgeon has not read notes pre-op. • Fails to review pertinent information collected by the operating theatre team • Ignores the assistant/nurse who may be struggling to assist, or standing for long periods of time, for reasons unknown to the surgeon • Ignores anaesthetic or theatre alarms • Is unaware of patient's allergies

planning to make the surgical procedure as efficient and free of complications as possible. If information is poor or absent, all future planning will suffer. This information may be obvious, or subtle. Obvious information should be noted by all but the most obtuse; subtle information may be observed only by the experienced (e.g. a past history of significant peri-operative bleeding, despite all blood and clotting parameters being normal, may indicate a rare platelet malfunction under certain surgical conditions).

In order to gather information the surgeon needs to be able to manage mental focus. Focus, or level of concentration, may be classified as broad or narrow, external or internal, and the agility to move observational abilities from broad to narrow focus, and vary the intensity of the focus, as the situation demands, is an important skill for situational awareness and other non-technical skills. Managing focus is important in managing fatigue.

A broad external focus, which may be thought of as a relaxed focus with reduced concentration, would best be used when all appears to be going well. This may be thought of as 'scanning the horizon' for signs of trouble, for gathering less critical information, such as the number of medical and nursing staff available and their skill mix with respect to the complexity of an oncoming difficult procedure, and observing any staff health issues, both emotional and physical, that may reduce their resilience under pressure. A narrow external focus, which may be thought of as intense focus, would best be used when absolute concentration is needed for the moment, such as decompressing a facial or an optic nerve, or placing a stapes prosthesis, or carving an incus for a transposition ossiculoplasty. The operating theatre is often a busy and noisy place, but during these moments of intense focus, distractions must be reduced to a minimum, since all the surgeon's senses will be heightened, especially hearing. Background conversation, or music, or both, must be stopped, no doors allowed to slam and telephones switched to silent. All this must be communicated to the surgical team at the WHO pre-op team briefing as a 'critical step', so that all who are present in the operating theatre are prepared for 'silent running' (a maritime term used to

describe submarines in stealth mode), and the surgeon is freed from distraction and able to concentrate wholly on the critical task. In aviation this 'silent running' is called 'sterile cockpit', used during take-off and landing, or in an emergency, when non-essential communication or distractions cease, and messages are confirmed by repeating the message back.²⁶

Equally, due to the intense concentration of narrow external focus, which is tiring, the surgeon may either miss other information, or miss its importance. This is termed 'inattentional or perceptual blindness'.²⁷ It is important to recognize the psychological draining effect of prolonged intense concentration and a mid-procedure break is wise, especially during long cases using the microscope. A 5-minute break in a 2–3-hour operation speeds up the procedure significantly. It gives time to review progress, to plan the rest of the operation, to relieve the nurses and to have a hot drink. This broadens the focus, de-stresses the mind and facilitates 'coping with pressure' (*vide infra*), and is why all craftsmen have a tea break. Clearly, the surgeon must focus on the task in hand, but must also realize constantly, perhaps at a subconscious level, that important information might be missed. The most perfectly placed stapes prosthesis would be to no avail if the patient was arresting under the hypotensive anaesthetic. During such an event, even when locked within the high concentration of narrow focus, the surgeon must listen to the theatre environment and secure the operating field as quickly as possible, get away from the patient and hand over control to the anaesthetic team. Even in less dramatic circumstances, such as a disconnected monitor lead, stopping the procedure to reassess the situation and discuss progress with colleagues will help regain Level I situational awareness. In these examples, decision-making and communication and teamwork also play a large part in the NOTSS.

Level II – understanding information

After all the relevant information has been received, the surgeon must understand its significance, which requires training and experience. Inexperienced surgeons may

TABLE 40.3 Situational awareness Level II. Understanding information – examples of good and poor behaviours

Good behaviours	Poor behaviours
<ul style="list-style-type: none"> • Changes surgical plan in proportion to the patient's condition, when appropriate • Acts according to information gathered from previous investigations • Studies the CT scan and points out important features • Reflects and discusses significance of information with team, e.g. links stridor and tracheomalacia in a child with a trachea-oesophageal fistula (TOF) • Discusses surgical priorities 	<ul style="list-style-type: none"> • Overlooks or ignores important results until hazard encountered peri-op, e.g. history of bleeding • Asks questions that demonstrate a lack of understanding or preparation • Poorly coordinates investigation: essential blood tests done in theatre • Flicks through the CT scan and misses hazardous anatomy • Fails to prepare, e.g. a ventilating bronchoscope for MLTB in a patient with a TOF and tracheomalacia • Reads the summary of the radiologist's report, not the report detail • Discards rather than discusses results that don't 'fit the picture'

be unaware of the significance of certain facts and may not respond, or respond differently, from more experienced surgeons. This process is dynamic, since new information will require processing within the context of established information, and different interpretations may lead to different actions. When interpreting information, it is important that the surgeon avoids 'confirmation bias', whereby ill-fitting information is filtered out, since it does not fit with the surgeon's established view. Yet ill-fitting information may suggest an alternative path and require an unpleasant course of action, which must be faced. This error may be avoided by analyzing all the available information (co-morbidities, blood results and imaging) with the anaesthetic, radiological and surgical teams in their turn, and discussing what actions or precautions are required (e.g. an unusually low or perhaps dehiscent skull base, unreported on the scan, may indicate a surgical hazard).

Level III – projecting and anticipating future state

After receiving and understanding the information available, the surgeon must then anticipate what might happen next and this will help to decide on the best plan of action. Incorrect anticipation can be avoided by discussing possible future situations with colleagues and reviewing alternative strategies. A good example of this would be management of a difficult airway problem in theatre, depending on the urgency. The team briefing would extend the 'critical steps' discussion and include various 'what if' events, such as a failure to intubate,

tracheal bleeding after removal of a foreign body or tracheal biopsy, or a peanut splitting in two and blocking each main bronchus. For each potential situation, the surgeon rehearses what they would do and tells the team. Each member of the team can then rehearse what they would do for each situation and three levels of situational awareness repeated until all are content. Although this process improves situational awareness, it relies on good communication and teamwork (see below). In this example, the anaesthetist would plan, with the operating department practitioner (ODP), which methods she might use to intubate and the equipment needed, and define what parameters determine failed intubation, so the surgeon knows when to act. The surgeon would go through, step by step, what facilities need to be ready and in place for a swift tracheostomy: position of the patient, surgical instruments and suction ready and working before intubation is attempted. This rehearsal is especially important when transferring responsibility of the airway between the anaesthetist and the surgeon in paediatric cases using the ventilating bronchoscope, or for peanut recovery, or to prevent both lungs filling with blood after a tracheal biopsy. In aviation, and in the film industry, this process is called 'pre-visualization' and improves situational awareness by predicting difficult or unexpected circumstances. Pre-visualization enables all in the team to plan and to know their role, so the team can act swiftly in a coordinated fashion, should such disasters occur. Making 'pre-visualization' a habit helps prepare for complications with routine surgery too (e.g. excessive bleeding from adeno-tonsillectomy).

TABLE 40.4 Situational awareness Level III. Projecting and anticipating future state – examples of good and poor behaviours

Good behaviours	Poor behaviours
<ul style="list-style-type: none"> • Has contingency plans for peri-operative complications: requesting required equipment to be available: cerebrospinal fluid (CSF) repair kit, fibrin glue, Floseal® • Keeps anaesthetist informed about procedure progress, e.g. exposed dura or venous sinus, and estimated finish • Verbalizes what may be required later in operation • Anticipates post-op problems: a tracheostomy tube placed in the TOF 	<ul style="list-style-type: none"> • Overconfident attitude and continues with no regard for what may go wrong • Does not discuss potential problems with team • Tells the anaesthetist about excessive bleeding late, or not at all • Fails to anticipate a predictable problem and responds late • Does not plan ahead, assuming 'all will go well', rather than 'all will go ill' • Fails to tell the anaesthetist about potential problems in recovery; tracheomalacia in the presence of a TOF which may require an ITU bed post-operatively • Failing to plan (= planning to fail)

Projecting and anticipating the future state is fluid and dynamic and will change many times during the course of an operation. Surgeons with good situational awareness will regularly stop what they are doing (even if only mentally) to avoid ‘inattention blindness’ and reassess how the operation is progressing, asking themselves the question: are we where we expect to be at this time? If not, what needs to be done to get the operation back on track? This will undoubtedly require the ability to collect all the relevant information including non-verbal clues (anaesthetic activity, scrub nurse concerns and monitor warnings), understanding what they all mean and what is likely to occur later. Non-operating observers with a broad focus can often see a problem developing, which operating surgeons would recognize if they were not locked within intense concentration. In this situation, the scrub nurse should be informed and she would look for a safe opportunity to alert the surgeon, allowing action to be taken well before the inevitable ‘event’ occurs.

DECISION-MAKING (DM)

Decision-making may be defined as the thought process of selecting the best logical choice of an appropriate course of action from the available options. This means considering all the alternatives and weighing the positives and negatives of each option. To be effective, the surgeon must also be able to forecast the outcome of each option and determine which would be best for a particular situation. This skill requires thinking time, which is dependent on the understanding gained through surgical experience and the urgency of the situation. Although experience helps, it does not create expertise, and expertise is not infallible: sometimes the decision made, on the information available at the time, is not the best when viewed leisurely with hindsight.

Although the various types of decision-making have been much studied and written about, the simplest model is that described by Daniel Kahneman²⁸ in his book *Thinking Fast and Slow*. Fast thinking, also known as *System 1* thinking, is quick, automatic, requires little or no effort, and has no sense of voluntary control. *System 1* decisions, often made in stressful situations, reduce threats and can be both instinctive, such as fear of blood loss, and learned through prolonged practice and experience, such as recognizing the subtle change in pitch of the drill when it touches the *tegmen tympani*: the sound moving away from the rumble and towards the scream as the thin plate of bone vibrates under the touch of the burr; or the glimpse of the whiter bone of the skull base; or the yellow tinge of the *lamina papyracea* during endoscopic sinus surgery. *System 1* thinking may be thought of as intuitive, and instantly tells the experienced surgeon to hold back and proceed cautiously, and is used when the risk is high and time is short; however, it is not always correct. The pallor of the skull base, seen in the distance, may be a simple mucous retention cyst,

yet it could be a meningocele, or an encephalocele. In these situations the main consideration is safety; danger is recognized and disaster averted. Fast, *System 1* thinking can also be called *recognition-primed DM* (RPD) and is a type of pattern recognition that experts use to make satisfactory decisions under times of high stress or time-pressure.²⁹

Slow thinking, or *System 2* thinking, also termed *analytical DM*, is more familiar and is the type of thinking used to check the validity of a complex logical argument. *System 2* thinking allocates mental processing capacity or focused attention to the effortful analysis of a situation; assessing options, weighing up the pros and cons and deciding on a course of action. Often this produces a better course of action than *System 1* thinking and is used when risk is low and time is available. Clinically, *System 2* thinking would be used to diagnose and treat, for example, a patient with complex balance problems. In theatre, *System 2* thinking would be used to plan the next few steps of an operation, with diversion options in mind if the plan fails, and alternative reconstruction methods if the pathology is not as expected, as used in head and neck surgery, or in otology, for example following a cholesteatoma avoiding dehiscent structures while considering primary or staged hearing reconstruction possibilities.

Analytical DM requires more focused concentration than recognition-primed DM. In times of stress, when an individual’s working or short-term memory is overloaded, ‘freezing’ can occur, which is the inability to make any decision at all. In this situation, someone else can help by taking on some of the mental workload, freeing up working memory and allowing the individual to think about what to do next (see below). One recent study demonstrated that during the intra-operative phase of surgery, surgeons use analytical DM in around 50% of cases.³⁰

There is another main form of decision-making, which is *rule-based*, and is somewhere between fast and slow thinking in terms of the working memory required. It is particularly useful in times of stress when ‘thinking’ is more difficult. It is used by both trainee and expert surgeons and follows the algorithmic process of ‘if X occurs then I’ll do Y’. This is usually based on well-known guidelines and protocols; for example, when a cerebrospinal fluid leak occurs during sinus surgery, while the fibrin glue is defrosted, the bleeding is stopped, the area is cleaned, fat is harvested and mucosal flaps lifted in preparation for repair. An injured dural sinus during mastoid surgery is covered immediately with a damp swab, the head lowered to prevent air embolus, followed by a muscle graft, or haemostatic gelatin (FloSeal®), or occlusive BIPP packing: all these critical events having been discussed at the WHO pre-op team briefing.

For completion, DM that relies on creating brand new solutions in theatre should only be a last resort when the above three methods fail, and, in general, it requires an inordinate amount of time and does not work well. Pre-visualization works better.

There are three elements of decision-making: Level I – considering options; Level II – selecting and communicating options; and Level III – implementing and reviewing decisions.

Level I – Considering options

When the situation is urgent and high risk, and a decision is needed swiftly, there may be only one option. When there is more time and less risk, alternative options may be weighed in the balance.

Level II – Selecting and communicating options

This should progress naturally from considering alternative options, but one option can only be selected if the surgeon appreciates the alternatives. Ignoring valid alternatives ensures an easy decision, but which sometimes is wrong. Telling the team which option has been selected is a ‘sense check’ and strengthens the team’s cohesion.

Level III – Implementing and reviewing decisions

Once a decision has been made and acted upon, reviewing progress should run in parallel to monitor if all is going well, or badly, so that alternative choices can be made in a timely manner; for example, the decision to carve an incus remnant, for a transposition ossiculoplasty, may be abandoned in favour of a prosthesis or a bone chip, if the incus remnant proves to be too small or too crumbly. In this situation the three levels of decision-making are repeated, but this can be done only if the original decision is reviewed.

Situational awareness and decision-making represent the two cognitive non-technical skills in the NOTSS classification: the skills that require ‘brain power’. In aviation, these are reduced to the more rapid process of observe; interpret; decide; act (OIDA) and this pattern is followed repeatedly, so the pilot’s mind flies ‘in front of the aircraft’. Surgeons work in the same way when concerned with patient care, thinking ahead to the next step. The next two non-technical skills are the social skills of communication and teamwork, and leadership.

TABLE 40.5 Decision-making Level I. Considering options – examples of good and poor behaviours

Good behaviours	Poor behaviours
<ul style="list-style-type: none"> • Weighs the chances of success of primary or staged reconstruction • Considers changing list order for clinical need • Considers autograft versus prosthetic ossicular reconstruction with respect to comorbidities • Considers asking for help if in difficulty • Considers early start to list to prevent late finish • Considers an alternative instrument to do the same manoeuvre • Is open to new options suggested by others 	<ul style="list-style-type: none"> • Reconstructs the same way regardless of the clinical situation • Reconstructs in suboptimal conditions, e.g. myringoplasty in presence of <i>pseudomonas</i> infection • Fails to consider changes to list order, e.g. for diabetics, young children, anaesthetist’s request • Considers it a failure to request help with a procedure/list • Fails to consider alternatives when new information becomes known • Does not consider any alternative • Insists on a particular instrument when another would work almost as well, e.g. periosteal elevators • Ignores alternative suggestions made by others

TABLE 40.6 Decision-making Level II. Selecting and communicating options – examples of good and poor behaviours

Good behaviours	Poor behaviours
<ul style="list-style-type: none"> • Tells the team the decision in an urgent situation (<i>System 1</i> thinking) • Requests a moment to think when decision is complex (<i>System 2</i> thinking) • Verbalizes options, with associated pros and cons • Absorbs information provided by others to refine selected option 	<ul style="list-style-type: none"> • Selects an option but does not tell the team, e.g. decides on an ossicular prosthesis but gives no prior warning • Is unable to make a selection of a technique, an instrument set, or tool, so requests everything • Does not select an option when there are clear alternatives and ignores resources: skill of a colleague, nurse/anaesthetist. • Uses information unrelated to patient care to select an option

TABLE 40.7 Decision-making Level III. Implementing and reviewing decisions – examples of good and poor behaviours

Good behaviours	Poor behaviours
<ul style="list-style-type: none"> • Makes a decision and sets a timescale for review of progress, e.g. estimates duration of operation and updates anaesthetist peri-operatively • Checks a decision is acceptable, e.g. changes in list order • Reviews the quality of the decisions/work in progress; is flexible 	<ul style="list-style-type: none"> • Does not make a clear decision and continues with no clear direction • Makes a decision and carries on regardless of new information • Ignores poor progress, or the poor outcome of a decision made, when re-evaluation may improve matters • Assumes repair is satisfactory when it could be tested peri-operatively, e.g. ossicular reconstruction or a repaired CSF leak (with an anaesthetic Valsalva)

COMMUNICATION AND TEAMWORK (C&T)

Communication skills, and working as part of a team, are important skills for the surgeon that underpin and link the other non-technical skills of situational awareness, decision-making and leadership. Being able to communicate clearly and succinctly, and hear others' perspectives, ensures the team has a shared understanding of the situation, of the challenge to be faced and the overall objective, so that individuals can complete their tasks by working together effectively. These skills are important throughout the peri-operative period, but particularly so during the WHO pre-op team briefing. Knowing each team member by name improves prompt information exchange and efficient working when under pressure. Communication and teamwork may be divided into three levels: Level I – exchanging information; Level II – establishing a shared understanding; and Level III – coordinating team activities.

Level I – Exchanging information

This is the free exchange of information pertinent to the situation, from all members of the team, and a complete picture is best gained if the atmosphere is easy and unstrained. This is not the didactic surgeon telling the team how it is and who should do what in a bombastic way, brooking no argument. Each member of the team brings a personal understanding of what might be required of them, but not how that might fit in with other members of the team; therefore, individuals tell the rest of the team their thoughts, concerns and impressions, that they feel are important to their role in the team. Clarity is achieved by questions and answers; however, reticent members of the team may need to be 'drawn out' and asked directly if there is anything they would like to say, or ask. Information given by one member of the team may trigger further information or questions from another and sufficient time needs to be allocated for this. All relevant concerns should be shared. Holding back information, or minor concerns, because these are thought to be unimportant, may not be helpful, since a situation may arise when these concerns become highly important. Experienced professionals develop a 'sixth sense' when something is

about to go wrong and sensing this may initiate checking emergency equipment, such as additional means of intubation, or that the crash trolley is well stocked and has serviceable defibrillators. This process of exchanging information is necessary to develop a 'shared mental model' of the situation.

The exchange of information is not confined to the WHO pre-op team briefing. It is also a crucial part of the communication between the scrub nurse and the surgeon to avoid misunderstanding and increase efficiency, especially during critical phases of the operation. In aviation, during critical phases of the flight, instructions from Air Traffic Control (ATC) are repeated back to ATC by the pilot, for example take-off and landing. This confirms to ATC that the pilot has received the message correctly. If the pilot makes an error, the word 'correction' is used and the process is repeated. Although this sounds like practising to be a parrot, and seems to be a waste of time, it is the most efficient way to communicate when misunderstanding could be fatal. In surgery, this method is used, especially for critical moments of the procedure, for example, the surgeon requests an instrument by name: 'micro-scissors'. The scrub nurse hands over the instrument and repeats back the name: 'micro-scissors'. If the surgeon initially asks for the wrong instrument, for example, the surgeon says: 'Knife, correction, Beaver Blade', the nurse diverts to the correct instrument and passes this to the surgeon and repeats back: 'Beaver Blade'. This discipline reduces the chances of a wrong instrument being used at a critical moment and is good practice at all times when using sharp instruments.

Level II – Establishing a shared understanding

Once there has been a full exchange of information, each individual has a greater appreciation of the whole situation, its challenges and objectives, and how they, as individuals, might contribute to achieving the objectives by working with other members of the team; how they might help others, and in turn, be helped by others to ensure the work progresses in a coordinated fashion. This is especially important for the surgeon, anaesthetist, scrub nurse and ODP, for example, in the case of an airway emergency when time is of the essence. Prior practice and pre-visualization promotes performance. Once a shared

TABLE 40.8 Communication and teamwork Level I. Exchanging information – examples of good and poor behaviours

Good behaviours	Poor behaviours
<ul style="list-style-type: none"> • Has a relaxed attitude allowing individuals to speak • Asks if anyone has any questions/concerns at the end of the WHO team briefing • Explains need for 'silent running' during times of intense concentration at briefing • Encourages scrub nurse to repeat back instrument names, especially sharp instruments • Is clear about when the operation is paused and control is handed over to the anaesthetic team, e.g. during a cardiac arrest 	<ul style="list-style-type: none"> • Overconfident attitude and disregards others' concerns • Does not communicate with, or consider the pressures on, the operating theatre staff, e.g. numbers, skill mix. • Intimidates colleagues/juniors, allowing no-one else to raise concerns about clinical safety • Shouts/speaks harshly to theatre staff to be quiet during the procedure • Shouts/speaks harshly to scrub nurse because she misheard the name of the instrument requested

TABLE 40.9 Communication and teamwork Level II. Establishing a shared understanding – examples of good and poor behaviours

Good behaviours	Poor behaviours
<ul style="list-style-type: none"> • Checks everyone understands what needs to be done • Checks that objectives are clear • Pre-visualizes alternative situations and rehearses what each person would do, e.g. in an airway emergency • Communicates clearly to all when the situation has changed, so all understand an alternative route is underway • Re-explains patiently if someone in the team is unsure 	<ul style="list-style-type: none"> • Does not communicate with anaesthetist, especially, e.g. over a shared airway during a laryngeal procedure, or blood pressure control during FESS or ear surgery • Does not ensure all team members are clear what needs to be done if things do not go as planned • Assumes all can tell when things are not going well and ignores the resources and help of the anaesthetic and nursing team • Is intolerant of inexperience

TABLE 40.10 Communication and teamwork Level III. Coordinating the team – examples of good and poor behaviours

Good behaviours	Poor behaviours
<ul style="list-style-type: none"> • Fits in when other team members lead when appropriate • Coordinates with scrub nurse when setting up, each doing separate things for efficiency, e.g. surgeon sets the endoscope demister, nurse sets the diathermy • Tells the nurse when ‘silent running’ is needed peri-operatively • An unscrubbed surgeon follows theatre communication etiquette when another surgeon is operating 	<ul style="list-style-type: none"> • Insists on being in command at all times • Positions the patient after towelling up, when it would have been easier to coordinate before • Fails to warn staff of the procedure duration, so staff are unprepared for the next case • A visiting surgeon speaks directly to an operating surgeon without waiting for the scrub nurse to indicate a good time to speak

understanding has been established, potential changes to that situation, causing diversions from the plan, are readily apparent to all and the team can change direction as one with little disturbance to the smooth running of the case.

Level III – Coordinating the team

This is more likely to be successful once Levels I and II have been followed, but coordinating the team does not fall to one person at all times. There will be times when the anaesthetist and ODP coordinate activity, such as transfer of the patient to and from the operating table when the surgeon may act as a helper. During patient positioning, the anaesthetist and ODP help the surgeon. During towelling up, the surgeon and the scrub nurse work together with the anaesthetist to ready the patient for surgery. During times of ‘silent running’, when the surgeon is in intense concentration and fully occupied, the scrub nurse coordinates the (silent) theatre, but in a medical emergency, such as a cardiac arrest, the anaesthetist takes command. This flexibility of hierarchy, like the Knights of the Round Table, uses the skill mix of the team to maximum effect and is most efficient when teams work together regularly.

Not surprisingly, problems with communication are usually associated with the most adverse events.^{8, 10, 31} When communication improves between members of the team, the shared mental model will undoubtedly be better and overall teamwork and performance will benefit.

LEADERSHIP

There are many industrial definitions of leadership, but in the operating theatre the skill of leadership may be considered as: ‘a social process of influence that ensures

the best work of the theatre team to achieve the objective of safe, high quality patient care’, in other words, a successful operation. Leadership skills are essential for the efficient and safe performance of the surgical team and require emotional intelligence.

Leadership is not an inherent part of seniority, associated with fancy titles or domineering or charismatic personal attributes, and it is much more than the ability to command or to realize a vision: it incorporates the ability to earn respect and trust. Respect and trust may be earned by maintaining high standards of clinical care, being considerate to others and being calm under pressure.

During the NOTSS development process, the leadership behaviours were grouped into three elements: Level I – setting and maintaining standards; Level II – supporting others; and Level III – coping with pressure. These social leadership skills were more reliably rated than the cognitive skills in NOTSS.³² Leadership skills may be divided into those related directly to the *team* and those related to the *task*.³³ There is a degree of overlap between these three levels. For example, by reviewing blood results and scans, and setting up the microscope before an otological procedure in good time, the surgeon sets an example for trainee surgeons, supports the nursing staff by being ready and eases the stress of last minute or peri-operative microscope adjustments.

Level I – Setting and maintaining standards

In theatre, this includes adhering to theatre protocols of sterility, communication and etiquette, and respecting the high standard of care given by the anaesthetist, the nurses

TABLE 40.11 Leadership Level I. Setting and maintaining standards – examples of good and poor behaviours

Good behaviours	Poor behaviours
<ul style="list-style-type: none"> • Endorses the WHO checklist • Changes gloves/gown when advised sterility has been compromised • Follows theatre etiquette • Allows for inexperienced team members • Respects seniority 	<ul style="list-style-type: none"> • Arrives late, or has to be searched out by theatre staff • Does no pre-op planning, delegates the briefing to a junior • Disregards theatre protocols • Is impatient with inexperienced staff • Does not use facial nerve monitor appropriately when it is available

TABLE 40.12 Leadership Level II. Supporting others – examples of good and poor behaviours

Good behaviours	Poor behaviours
<ul style="list-style-type: none"> • Supports trainees appropriately for their surgical skill level • Liaises with the anaesthetist and accepts constraints associated with comorbidities • Is approachable, takes heed of staff well-being • Is tactful and discreet when supporting those having a tough time. 	<ul style="list-style-type: none"> • Leaves trainee to 'go solo' with an operation beyond their skill level • Intolerant of anaesthetic constraints, fails to suggest requesting more senior help, if appropriate • Is bullish, unapproachable and intolerant of staff 'excuses' • Is tactless and indiscreet, so is denied knowledge useful for the smooth running of the operating list.

and the ODP. Although the most important person in the theatre is the patient, the surgeon and anaesthetist are close behind: the operating surgeon holding the knife or drill, and the anaesthetist for keeping the patient alive despite, on occasion, the activities of the surgeon. Theatre personnel rely on the surgeon to set an example and also for guidance, for doing the right thing and upholding the culture of safety, for example endorsing the WHO checklist as an important method of preventing errors and maintaining standard of care.

Checklists have been used in aviation for decades and have been honed and refined to prevent basic errors of omission, manage complex technology and free up mental processing capacity (working memory) to focus on the current task. Once the checklist is complete, the surgeon (and pilot) can relax, knowing nothing has been missed, and can concentrate on operative planning.

In the UK, personal attributes of politeness and good manners are respected and rudeness and bad manners are not; however, what is polite in one culture may be considered rude in another and, in certain company, it would be respectful to be culturally aware.

Level II – Supporting others

A team works well because the strength of one team member makes up for the weakness of another. In the operating theatre, all are trained, or are being trained, to the high standards essential for safe patient care. In those being trained, technical and knowledge deficiencies are expected, and they are supported by further training and study to improve deficiencies until the trainee can 'go solo'. Supporting anaesthetic and surgical colleagues in theatre, by being receptive to the anaesthetic constraints of comorbidities, and to the skill needs of trainees, has been written into the traditions of operating theatre culture since surgery began; however, not all traditional surgeons have been receptive, approachable and willing to help secure patient safety by supporting others.

Supporting others in non-technical terms is a social skill, which, for some, can be difficult to master in the cut and thrust of the operating theatre. Not all members of the team are strong at all times, and most will not complain if they are feeling unwell, or are dealing with stressful issues away from the operating theatre. Most people do not allow personal difficulties to interfere with their professional work; they 'keep calm and carry on'. To support those going through a tough time, it is a social skill to be aware that all is not well, yet not to enquire too deeply into personal matters.

An approachable surgeon is more likely to be advised of such a situation, since it is likely that he will adjust his mental model of the team's strengths and weaknesses and ensure the team is able to make allowances and cope with the pressures of the operating list. This becomes important when the team is under pressure and good judgement is required to know how far someone can be pushed without buckling, or if that person needs some time out, or even time off work.

An unapproachable surgeon, insensitive to the needs of others, bullish in manner or both, is unlikely to listen to any excuse for poor work and is likely to be intolerant in the operating theatre, which puts the rest of the team under greater pressure. The work must go on, the operation takes priority and supporting others can be a delicate business and difficult to get right every time. It is also linked with how well the surgeon can cope with the pressure of operating (see below) when she depends on the strength of the team supporting her.

Level III – Coping with stress

Potential stressful situations can be countered before they escalate by making a practice of assessing situational awareness, decision-making, communication and teamwork; however, coping with stress can be difficult and depends on the degree of stress. Forward planning and training can mitigate most stressful situations by having the resources and the ability to deal with the situation.

TABLE 40.13 Leadership Level III. Coping with pressure – examples of good and poor behaviours

Good behaviours	Poor behaviours
<ul style="list-style-type: none"> • Has pre-assessed the situation and is aware of potential difficulties • Carries out a ‘stress assessment’ and raises concerns pre-operatively (WHO checklist) • Rehearses dealing with potential complications (pre-visualization) • Forward-plans equipment needs • Calls for help appropriately • Mentally checks I’M SAFE and makes adjustments 	<ul style="list-style-type: none"> • Is unaware of potential difficulties • Is unprepared for the operation and unaware of potential complications • Tackles an operation outside comfort zone without asking for help from a colleague • Is unprepared for an operative complication • Is unable to remain calm under pressure • Blames others for personal failings

Confidence in your technical ability to complete the surgery to a high standard reduces the stress of complex procedures and is learned through focused training. In most theatre lists this is the normal situation. There are, however, technical and non-technical factors that increase the stress, which vary in number and severity. Many small stressors may be equivalent to one big stressor. As a general rule, more than two big stressors are too many and steps need to be taken to reduce the number and severity of the stressors. In the same way that risk is assessed by a risk assessment, it is wise for the operating surgeon to do a ‘stress assessment’ pre-operatively, even if this is just mentally rehearsing the procedure and dealing with potential peroperative complications. This surgical pre-visualization may be done whilst scrubbing up and uses a narrow internal focus (see above). Often this will bring to mind the need for additional equipment, for example, fibrin glue and the Rhoton® neurosurgical micro-dissectors to facilitate the repair of a cerebrospinal fluid (CSF) leak occurring during FESS, which may have been forgotten during the WHO pre-op team briefing.

If a procedure is outside your comfort zone because you supra-specialized (e.g. an otologist tackling a neck stabbing), then swallowing your pride and calling for help from a friendly colleague reduces stress. Your colleague provides more than technical know-how; they also provide support that is emotional, practical, informative (advice) and provides companionship (EPIC), and all these ease the stress significantly.

Sometimes a case is especially tricky and having the support of a well trained, familiar theatre team is essential. Confidence in the nurse’s ability to provide the exact instruments in a timely manner ensures a flowing, relaxed procedure, and knowing the anaesthetist and ODP will keep the patient safe, and asleep, during surgery is quite calming. Unfortunately, this is not always so. If the case is complex and high risk, such as a third revision mastoid exploration in an only hearing ear, in which the lateral semi-circular canal, facial nerve and dura are exposed, and the nurse is new to the procedure and has not memorized the instruments, some of which may be missing or damaged, and you are expected to train an inexperienced registrar, and explain the procedure to medical students, and your new anti-hypertensive medication is associated with postural hypotension, there are too many stressors,

especially when a peri-operative complication occurs and you are being handed the wrong instruments.

It would be wise to explain, at the team briefing, that this case is complex, delicate and requires your full concentration. Politely request the help of an experienced scrub nurse; ask the registrar or the anaesthetist, or both, to teach the students quietly, outside theatre if possible; request more instruments and a comfortable chair to sit on during the procedure. Warn the theatre staff that there will be episodes of ‘silent running’ (i.e. when dissecting matrix off the lateral semi-circular canal, facial nerve and dura).

It would be unwise to get deep into the procedure before requesting these things; it would be even wiser to arrange all this before surgery after your assessment of the situation is complete (situational awareness), and perhaps quietly tell a friendly colleague of the situation so your mind benefits from EPIC support, even if this is remote.

A surgeon’s ability to cope with stress is also proportional to his well-being and this was alluded to above when mentioning the surgeon’s hypertension. A surgeon who is hydrated, fed and rested is more likely to operate more skilfully (and be less stressed and less grumpy) than a dehydrated, hypoglycaemic and tired surgeon. In aviation safety, to check if a pilot is fit to fly, the well-known personal mnemonic: I’M SAFE is used and we can use this in surgery to check if we are fit to operate. This is a quick check-list to cover:

- Illness (Am I well? Is my angina under control?)
- Medication (Are there side effects?)
- Stress (Feuds and performance targets?)
- Alcohol (No alcohol in the bloodstream is the only safe option)
- Fatigue (Enough sleep, well rested?)
- Eating (Had something suitable and nutritious to eat before operating?)

This self-assessment would be an example of broad internal focus (see above).

A responsible surgeon with such insight will know when he is unsafe and, if unsure, will discuss with a trusted colleague. Better this than the patient coming round to discover he is being intubated by the anaesthetist while the ODP bounces on his chest underneath an arc of spurting blood coming from his carotid.

THE SURGICAL CHECKLIST AND NOTSS

As discussed throughout this chapter, the WHO introduced the concept of the 'surgical checklist' in order to provide a final error trap before surgery.³ In addition to providing a final 'check' before surgery, it has undoubtedly contributed to the improvement of the various non-technical skills required for better team-working in the operating room. *Situational awareness* around the diagnosis and procedure, along with the instruments/equipment required and possible difficulties that may be encountered (projection/anticipation), are all discussed. *Decision-making* is improved by early identification of possible difficulties and *communication* throughout the team is expressed out loud and acknowledged. *Teamwork* has to be improved by the knowledge of all the names of people in the operating room. Good *leadership* can be observed by completing the checklist in the appropriate manner, demonstrating a commitment to patient safety and both recognizing the roles, and supporting other members, of the operating team.

KEY POINTS

- Good surgeons have good 'non-technical skills' which support good operative performance and better outcomes for patients.
- These non-technical skills for surgeons (NOTSS) have now been identified as Situational awareness, Decision-making, Communication & Teamwork and Leadership
- Using the NOTSS taxonomy these skills can be observed, assessed, rated and taught.
- Better understanding of these skills will improve overall clinical performance and outcomes for patients with reduced adverse events.

Practising these skills in the day to day running of the operating theatre will ensure they become habitual and instinctive, so that during an urgent surgical emergency the pre-visualized processes can be followed swiftly and smoothly, reducing the likelihood of error.

SUMMARY

This chapter has described those non-technical skills that have been identified by experienced surgeons as being important for safe and successful surgery, recognizing that technical proficiency alone is not enough. These skills are both cognitive and social and can be observed by the demonstration of good and bad behaviours, as outlined in each section of the chapter. As surgeons strive to improve their operative performance, they will need the support of the whole operating team. Only with good non-technical skills will errors and adverse events be reduced and outcomes improved. Now that these skills have been recognized the challenge in the future is to incorporate them into undergraduate teaching as well as post-graduate training and assessment.

ACKNOWLEDGEMENTS

The authors recognize the enormous work carried out by Dr. Stephen Yule and Prof. Rhona Flin on the NOTSS project along with the support of Aberdeen University, NHS Education Scotland (NES) and the Royal College of Surgeons of Edinburgh.

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: epidemiology; public health; clinical trials; research; research design; patient outcome assessment; statistics; epidemiological studies; methods; data interpretation; sample size; evidence-based medicine; bias (epidemiology) and confounding factors (epidemiology).

INTRODUCTION

This chapter presents epidemiology as a methodological discipline that provides important principles for clinical and health services research. It introduces the 'determinant-occurrence relationship' as a key epidemiological concept. On the basis of this concept, we will demonstrate how epidemiological methods and techniques can be used to address a wide range of questions. This chapter is intended to inform those who want to read the medical literature and evaluate research evidence. In other words, it has been written especially with the needs of the 'consumers' of research in mind.

We will concentrate on the choice of a study design for different types of research questions with the ultimate aim of developing a study that produces results that are relatively precise (free of random error) and accurate (free of systematic error or bias). An additional consideration is that the study needs to be efficient (affordable in terms of time and money). Strengths and weaknesses of study designs will be discussed as much as possible on the basis of examples related to diseases of the ear, nose and throat.

This chapter is not based on a specific literature search strategy. It amalgamates information and points of view as can be found in major textbooks and reviews of epidemiology, methods of health services research and evidence-based clinical practice.

Example: The indication for tonsillectomy

Simple, but well-designed, epidemiological research can be of great importance for clinical practice. A recent systematic review indicated that the effectiveness of tonsillectomy in adults is uncertain (although modest in children)¹ and in turn, that the indications for tonsillectomy are controversial. Nevertheless, tonsillectomy is one of the commonest surgical procedures carried out in children as well as in adults.

In the 1930s, an estimated 200 000 tonsillectomies were performed annually in England and Wales, a huge number compared to an annual number of approximately 40 000 in the year 2000. In the pre-war period, tonsillectomy had become popular to the point of being fashionable, and there was marked variation in its frequency according to geographical location, social class and sex.² It was estimated that at least 85 children lost their lives each year as a direct result of tonsillectomy.

Another study, carried out in the 1940s, demonstrated that there was great uncertainty about effectiveness and indications,³ as cited in a book by Sackett and co-workers.⁴ Among 389 11-year-old schoolchildren with intact tonsils examined by a group of clinicians, tonsillectomy was recommended in 174 (45%). A second opinion was requested in the 215 schoolchildren for whom tonsillectomy was

not recommended, and tonsillectomy was recommended for 99 (46%). The remaining 116 children, in whom on the two previous occasions tonsillectomy was not recommended, were then examined for the third time, and tonsillectomy was recommended in 51 (44%) of them. The most remarkable finding is that tonsillectomy was recommended in each of the three cycles for approximately 45% of the children.

These historical examples illustrate that uncertainty about diagnostic and management decisions can lead to overtreatment, which may have serious consequences for patients. Given the fact that there is still no high-quality evidence on the effectiveness of tonsillectomy more than 50 years later, the same problem may still exist, albeit to a lesser extent. The only published study on the effectiveness of tonsillectomy that could be included in one systematic review studied 91 children and was affected by important baseline differences in the characteristics of the surgical and the control group.¹ It is obvious that this kind of clinical uncertainty can only be solved by epidemiological evidence of high quality.

WHAT IS EPIDEMIOLOGY?

Epidemiology is a relative young discipline, but during its short life many definitions of epidemiology have emerged.⁵ Many of these describe epidemiology in terms of its subject matter. The perhaps most frequently cited definition in this context states that epidemiology is the study of the distribution and determinants of disease frequency in human populations.⁶ These three closely related components – distribution, determinants and frequency – encompass many epidemiological principles and methods.⁷ For example, an epidemiological study that would fit perfectly within this definition is that of the frequency of head and neck cancer in a certain geographical area. This study could also consider the distribution of the disease among different subgroups. The determinants of disease occurrence would then derive from these two.

Although this definition has its merits in that it covers many epidemiological studies, some of which attracted large media attention (for example, smoking and lung cancer, cholesterol and heart disease, effect of diethylstilbestrol on offspring, unprotected sex and the acquired immune deficiency syndrome), a growing number of epidemiologists feel that the above-cited definition does not cover their work. The reason is that the subject matter of what can be considered epidemiological studies has become rather heterogeneous. Attempts to produce a definition of epidemiology based upon its subject matter therefore produce confusion rather than clarity.

The concept of the determinant-occurrence relationship

In the last two decades, an alternative definition has arisen that defines epidemiology as a discipline that studies the

functional relationship between the occurrence of disease (or related health outcomes) and its determinants.⁸ This may seem a trivial step, but this focus on the concept of the ‘determinant-occurrence relationship’ rather than the subject matter has considerably broadened the scope of epidemiology in medicine.

One of the major reasons why epidemiology has gained such far-reaching importance lies in the nature of medical knowledge. Medical knowledge is, to a large extent, derived from the experience obtained in groups of similar patients. Medicine is therefore an empirical science, and many of the empirical relationships in medicine can be considered as determinant-occurrence relationships. It is especially this realization on the basis of which epidemiology has become a basic science in medicine.

Epidemiology as a methodological discipline

An alternative approach to clarify the definition of epidemiology is to consider it as a methodological discipline. From this perspective, the subject of epidemiological inquiry is not so much the determinants of the occurrence of disease and other health outcomes, but the principles and methods for the study of determinant-occurrence relationships.

As a methodological discipline, epidemiology allows a large number of different questions to be answered. As explained earlier, it may play a role in describing the distribution of health and disease in a population. Who is affected? Where and when does this health problem occur? Why does it occur in a particular population?

However, other questions can be considered as well. Once a health problem occurs, epidemiology also provides methods for monitoring the course and outcome of a health problem. What is the outcome of the health problem? It may answer questions regarding the outcomes of interventions. Is intervention A more effective than intervention B? How well does a diagnostic test distinguish between people with and without the target disorder?

Epidemiological research is also essential for the assessment of the burden of disease and the need for health services and evaluation of the access to services. How much suffering does this health problem cause in a population? How many people need a certain intervention? Who uses the intervention? What factors explain differences in healthcare use?

‘STREAMS’ OF EPIDEMIOLOGY

Given the extension of the boundaries of epidemiology – based on the introduction of the determinant-occurrence relationship as the key epidemiological concept and the realization that epidemiological principles provide the methodological underpinning for the study of a wide range of questions – one can recognize several ‘streams’

of epidemiological research. These streams differ largely according to the types of questions they address, but they share most of the methodological concepts and principles.

Classical epidemiology

The first stream of research is ‘classical epidemiology’, sometimes referred to as ‘aetiological epidemiology’ or ‘risk factor epidemiology’, of which the ultimate goal is ‘the elaboration of causes that can explain patterns of disease occurrence’.⁵ The geographical distribution of a disease, the variations in its frequency over time, and the special characteristics of people affected by it, are typical objects of study.

There is often a natural progression in this type of epidemiological research.⁷ First, there is a concern about the possible influence of a particular factor on the occurrence of disease. This suspicion can have many origins – clinical practice, laboratory research, theoretical speculation – but it often arises from examination of disease distributions, and leads to the formulation of a specific hypothesis about its causes. It can then be further explored in studies of individuals that include an appropriate comparison group. A systematic collection and analysis of data may reveal that a statistical association exists. It is then essential to assess whether random errors or systematic errors might be responsible for the findings. Finally, a judgement needs to be made about whether an observed association represents a cause-effect relationship.

An otolaryngological example of this type of epidemiological research is the study of the distribution of head and neck cancers and the association of the occurrence of this disease with traditional risk factors such as diet, smoking and drinking habits or socioeconomic status. Another more specific example is the testing of the hypothesis that there is a link between human papillomavirus and the occurrence of a subset of these cancers. The result of aetiological research may guide the first steps towards the development of primary prevention that keeps disease from occurring at all.

However, the reductionist nature of classical epidemiology has been criticized. It has been argued that epidemiological studies often ignore ‘the interdependence of multiple agents and how human populations become exposed and susceptible to them’.⁹ Epidemiological research that focuses on the effect of risk factors measurable at the level of the individual neglects the population context and the social and cultural determinants that act at population level.

Clinical epidemiology

The second stream of research is ‘clinical epidemiology’. The adjective ‘clinical’ is added because clinical epidemiology ‘seeks to answer clinical questions and to guide clinical decision making with the best available evidence’.¹⁰ Clinicians are mainly concerned with problems of individual patients. It may seem paradoxical that

results of epidemiological studies that are derived from groups of patients should be applicable to the problems of individual patients. It is obvious, however, that this is because the best evidence to solve a clinical problem is derived from the experience of a large number of similar patients.

Advocates of evidence-based medicine have addressed this paradox directly. They state that clinicians need to carry out ‘the particularization, to the individual patient, of our prior experiences (both as individual clinicians and collectively) with groups of similar patients’.⁴ A good clinician should therefore use the best available external evidence together with his own unsystematic clinical experience and intuition – based on a blend of knowledge derived from anatomy, physiology and other basic sciences.¹¹ Evidence alone is never sufficient to make a clinical decision. Decision-makers always trade the benefits and risks, inconvenience and costs associated with alternative management strategies, and in doing so should especially consider the patients’ values and preferences.

The significance of the definition of epidemiology as a methodological discipline that addresses determinant-occurrence relationships is based on the reach of the concept of determinant-occurrence relationships in itself. If one considers the presence of disease as the outcome and the diagnostic information as the determinant, then this represents a diagnostic problem. The object of study is, in this case, the functional relationship between diagnostic information and the presence of disease. If one considers the occurrence of a disease or a health-related event in the future as the outcome and the presence of certain patient characteristics as the determinants, then this represents a prognostic problem. One of these patient characteristics can be the use of a specific therapy, and in that case, this represents a therapeutic problem. In the latter case however, to achieve accurate results the ‘*ceteris paribus* principle’ – the condition that all other determinants are equal – is a fundamental notion that we will explicitly address in the section ‘Randomized controlled trials’ below.

A study of the diagnostic accuracy of fine-needle aspiration as a test for malignant disease in patients with nodular thyroid disease is an otolaryngological example of diagnostic research. The influence of the age of patients with an oropharyngeal carcinoma on long-term survival constitutes a prognostic research question. The effect that early surgery compared with watchful waiting for glue-ear has on language development in pre-school children represents a therapeutic research question.

It is useful at this point to distinguish between the epidemiological terms, ‘incidence’ and ‘prevalence’. Incidence is defined as the number of new cases that occur in a specific time period. Prevalence is defined as the proportion of the population that actually has a disease, or condition, at a specific point in time. Unlike prevalence, incidence is a true rate because it includes a measure of time. Prevalence on the other hand is a ‘snapshot’ of a situation at a single point in time and for this reason is sometimes also called the ‘point’ prevalence.

Epidemiology and health services and public health research

Epidemiology is also one of the core disciplines of health services research and public health. Whereas classical epidemiology and clinical epidemiology focus largely on determinants of health and disease and related conditions in individuals, health services research is more directed towards questions addressing the quality and organization of healthcare systems and public health research towards the health and healthcare problems in communities. One could consider this as a third stream of epidemiological research.

Important questions for health services research are those that address the variations in processes and outcomes of healthcare services, as well as the determinants of these variations. Research in public health may be concerned with the influence of environmental factors, socio-economic conditions and health services on health in the community. It will be clear by now that many of these questions take the form of determinant-occurrence relationships, which again confirms the crucial role of an epidemiological approach.

A study comparing the outcome of thyroid surgery performed by experienced surgeons and surgeons in training is an example of an epidemiological study directly addressing a determinant of the quality of otolaryngological care.¹² Another example is a study of the impact that the publication of a guideline on the treatment of persistent glue-ear in children had on the rate of surgery.¹³ A systematic review of studies addressing the effectiveness of screening young children to undergo early treatment for glue-ear is a third example of public health research.¹⁴

THE 'ANATOMY' AND 'PHYSIOLOGY' OF EPIDEMIOLOGICAL RESEARCH

We cannot discuss the different study designs before we have examined what epidemiological research is made up of and how it works. The easiest way to do this is to describe the components of a study protocol and the way results are used to draw inferences from the study results about the truth in the universe. The following sections are based largely on the introductory chapters of a recent book by Hulley and colleagues about designing clinical research.¹⁵

Essential components of a protocol for an epidemiological study

A research protocol is a document that provides all essential details of a study. A protocol is necessary for guiding all the decisions that need to be made in the course of the study. The process of writing a protocol itself helps the investigator to enhance the scientific rigour and efficiency of the project. Most research involves teamwork and a written document ensures that all members know how the study should be implemented and what they are

expected to contribute. A good protocol provides answers to a number of essential questions.

WHAT QUESTION WILL THE STUDY ADDRESS?

The research question defines what you want to achieve. Many experienced researchers will agree that formulating a question that can be translated into a feasible and valid study can be surprisingly hard. What often happens is that instead of a 'research question', a 'topic' is formulated. 'Framing' the research question is the first step for every new project, of which the importance cannot be overestimated. Conversely, many studies fail not so much because the study design is flawed or the execution of study is poor, but because the question was not formulated adequately in the first place.

An otolaryngological example of such a 'topic' that needs further research is the concern about the rising complication rate after tonsillectomy in the UK. It is clear that we need to provide more detail and structure before we are able to formulate a relevant and answerable 'research question'. The concept of the determinant-occurrence relationship may provide some guidance in this context. In other words, we need to be specific about what outcomes we want to study as well as what determinants we want to consider. Finally, we need to specify the target population, the kind of people for whom the study should provide answers.

In epidemiological research, a good research question therefore has four components, which can be summarized by the acronym PICO:

1. the target population or participants (P);
2. the intervention (I);
3. the comparison or control group (C), at least if there is any;
4. the outcome(s) of interest (O).

An example of a 'good' research question for a study addressing the complication rates after tonsillectomy could be: 'In patients undergoing tonsillectomy for recurrent tonsillitis, does the use of the bipolar diathermy forceps increase the occurrence of tonsil bleeds severe enough to require return to theatre in the first 28 days after surgery, compared to other tonsillectomy dissection types?' Admittedly, this is a rather convoluted sentence, and is only given here to illustrate how the four components of a research question can be covered in one question. In practice, the question will be shortened to 'Does bipolar diathermy increase the haemorrhage rate after tonsillectomy', but in that case the details that define the target population, intervention, comparison and outcome of interest need to be provided separately.

WHY IS THE STUDY QUESTION IMPORTANT?

Good epidemiological research should also pass the 'so what' test. In the Introduction or Background section of a protocol, it should be argued that answering the research question will provide a significant contribution to our

state of knowledge or, in other words, add to what is already known about the problem. It is therefore important to be on top of the published literature before developing a study. It should also be clear that the results of the proposed study will help to resolve current uncertainties, which may lead to new scientific understanding and influence clinical and public health policies.

It is often ‘scholarship’ that will identify the gaps in the current knowledge and how these can be addressed in an optimal way by learning from the work of others. For example, a recent systematic review of the literature on the effect of tonsillectomy in patients with chronic or recurrent tonsillitis concluded a lack of evidence to guide decision-making for this surgical intervention in adults or children.¹ More importantly in this context, the authors of the systematic review also concluded on the basis of the results of their review that future trials should address the effectiveness of tonsillectomy in subgroups according to age, severity and disease frequency, and that patients should be followed up for at least one year to assess outcomes such as general well-being, behaviour, growth, sleep and eating patterns in addition to severity and frequency of infections. These conclusions based upon a systematic review provide powerful arguments for the direction of future research.

HOW IS THE STUDY STRUCTURED?

Choosing the study design is a complex issue. The actual choice depends strongly on the research question. The study should be designed in such a way that it produces results that are relatively precise (free of random error) and accurate (free of systematic error or bias). An additional consideration is that the study needs to be efficient (affordable in terms of time and money).

A simplistic ‘taxonomy’ of study designs, presented in [Figure 41.1](#), shows that two fundamental decisions have to be made. First, the investigators have to decide

whether they want to assign the determinants themselves in an ‘experimental study’, or whether they want to examine events as nature takes its course in an ‘observational study’. Second, if an observational study design is chosen, the next step is to decide whether the study needs a comparison or control group. If so, the study is often called ‘analytical’. If not, it is a ‘descriptive’ study. Descriptive studies are often used as a first step into a new area of study – the scientific ‘toe in the water’,¹⁵ and followed by analytical studies to answer questions that can address determinant-occurrence relationships.

A more detailed presentation of study designs follows under the section ‘Choosing the study design’ below.

WHO ARE THE STUDY SUBJECTS AND HOW WILL THEY BE SELECTED AND RECRUITED?

A good choice of the study subjects ensures that the results of the study will accurately represent what is going on in the population of interest, the target population, the set of people best suited to the research question (for example, patients with early laryngeal squamous cell carcinoma for a study comparing radiotherapy and surgery for laryngeal cancer). The protocol must also specify the study sample, which is the subset of the target population available for study (for example, all consecutive patients with this disease condition referred to a regional head and neck cancer centre in a defined period of time). The study sample should be a subset of the target population that can be studied at an acceptable cost and is large enough to control random error and representative enough to control systematic error.

In many cases, controlling both random error and systematic error sets conflicting demands, which is sometimes referred to as the ‘precision–bias’ dilemma. For example, a study that aims to evaluate the usefulness of the endoscope compared to the headlamp for sinonasal surgery should carefully consider which patients to include.

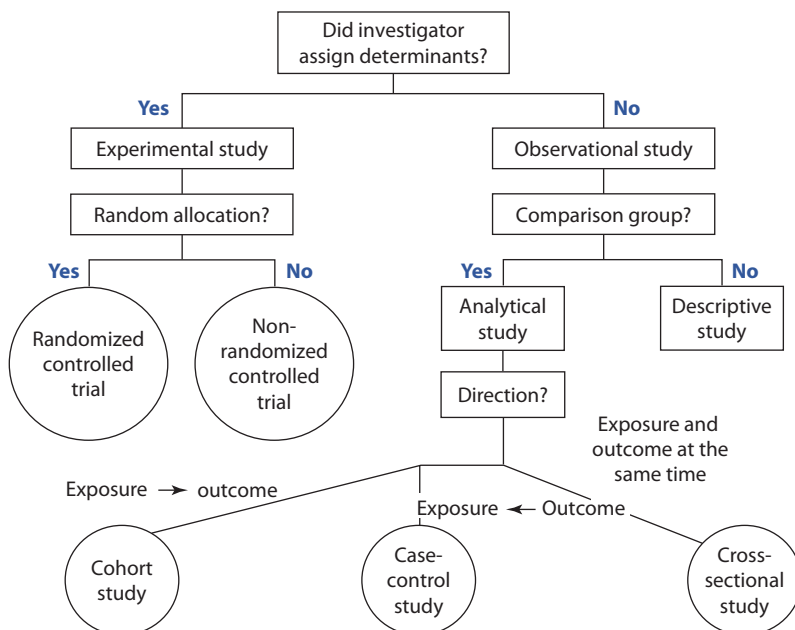

Figure 41.1 Algorithm for classification of types of clinical research. Reproduced from Grimes and Schulz, 2002,¹⁶ with permission from Elsevier.

It is highly likely that the results of the study will differ according to the extent of the surgery. The comparison might be most relevant for patients who undergo surgery for procedures around the middle meatus and the anterior ethmoid. Including patients who undergo only simple polypectomy, who comprise approximately 50% of the total number of patients who undergo a form of sinonasal surgery, may seem an attractive option because it will double the size of the study. However, including these patients will diminish the extent to which the study sample represents the population for which the research question is of interest.

In an ideal world without practical and financial limitations, we would study the entire target population. Often, if not always, the target population is too large and the study will be carried out in a sample. Earlier, we gave as an example the study comparing radiotherapy and surgery for early laryngeal carcinoma that was carried out in consecutive patients visiting a regional centre in a defined period of time. This type of sampling, including patients that are easily accessible to the investigator, is called ‘convenience sampling’. It is very frequently used in clinical research. It has obvious advantages in terms of costs and logistics, but its drawback is that it might not sufficiently represent the target population. Consecutive sampling, including without interruption all accessible people, is especially useful in this context given that it reduces the possibility that selection either by the investigators or self-selection by the subjects influences the results. Probability sampling is the gold standard for ensuring that the study sample is representative of the target population, except for the effect of chance variation. There are several probability-sampling methods. With simple random sampling, every individual in a population has the same chance of being included. However, in some cases, a form of stratified sampling (random sampling with a known sample size within subgroups) is desirable. For a study of patient satisfaction of patients visiting an otolaryngology outpatient clinic, for example, the investigators may wish to divide patients in ‘strata’ according to their diagnosis or the procedure that was being carried out, and then sample specified numbers from each stratum.

The choices made about the selection of the study subjects (the intended sample) are important as they have an impact on the extent to which the study findings can be generalized. The sampling procedures can affect the generalizability of the results in a number of ways. First, the actual sample might be different from the intended sample. For example, people who were eligible for the study might have refused, and people who participated might be different (more or less healthy, dependent on the study context) from those who did not. Second, the study sample should be sufficiently similar to the target population. For example, the ‘spectrum’ of disease in patients with laryngeal squamous cell cancer might differ from one centre to the next, and in turn the effects of radiotherapy and cancer might differ as well. Third, the investigator must form an opinion about whether the results can be generalized to people outside the target population. In terms of our example, do radiotherapy and surgery have

similar effects in other countries, in patients with more advanced disease, or in patients who are on average older or younger? This will always be a subjective judgement that depends on findings in other studies, more general scientific knowledge, and what is sometimes called ‘a feeling for the organism’. It is not a yes-or-no decision, and may trigger debate among experts. This debate may be informed by the study itself if the study population is diverse enough to explore the constancy of effects in different subgroups within the study.

WHAT MEASUREMENTS WILL BE MADE?

The quality of a study depends on how well the variables measured in the study represent the phenomena of interest. Another concern is how the variables of interest can be measured as precisely (free of random error) and accurately (free of systematic error) as possible without making the study unreasonably expensive.

It is important to have some understanding about the types of variables that are encountered in epidemiological research, and how they can be measured. Any variable can be considered to be of one of two basic types: continuous variables and categorical variables. This distinction determines the way in which these variables should be measured as well as analyzed. As a general rule, with categorical variables, the analysis will involve a description or comparison of the proportion of subjects falling into the various categories. With continuous variables, the descriptions or comparisons are most often presented in terms of average values or medians if the sample is small and the average value is considered to be inappropriate to describe the ‘midpoint’ of the variable’s distribution.

Theoretically, continuous variables can take all possible values on a continuum along a specific range. Many clinical parameters are continuous. Variables, such as blood pressure, body weight, body temperature, are not restricted to particular values and are only limited by the accuracy and precision of the measuring procedures. The units in which a continuous variable is expressed specify a uniform difference along the entire length of the scale. A difference in blood pressure of 10 mmHg has the same interpretation irrespective of whether it occurs at the lower or the upper end of the blood pressure scale.

Discrete variables can only take certain numerical values – in most cases only integers (whole numbers). If discrete variables have a considerable number of possible values, they can often be treated as if they were continuous. Examples of these ‘quasi-continuous’ variables are counts (such as the number of cigarettes smoked, number of episodes of acute tonsillitis in last year, or number of days spent in hospital) or scores on ‘clinimetric scales’ (such as the 20-item Sino-Nasal Outcome Test) that measures symptom severity of sinonasal conditions on a scale with discrete values ranging from 0 (no symptoms) to 100 (very severe symptoms)¹⁷ or the Epworth Sleepiness Scales, used in patients with obstructive sleep apnoea, that can take discrete values from 0 (no daytime sleepiness) to 24 (very severe daytime sleepiness).¹⁸ Strictly speaking, considering

scores on a clinimetric scale as continuous is somewhat problematic, as the interpretation of a difference of one unit may vary along the length of the scale. For example, does an increase from 5 to 10 on the Epworth Sleepiness Score correspond to an increase from 15 to 20?

Phenomena that cannot be measured quantitatively can often be measured by classifying them into categories, and then counting the number of subjects that fall within the defined categories. In its simplest form, there are only two categories (such as man/woman, or dead/alive), and these variables are called dichotomous or binary variables. When there are more than two possible categories, the variables are termed poly- or multichotomous variables. Polychotomous variables can be further classified into those that are ordered, called ordinal variables, and those that are not, called nominal variables. Socioeconomic status, ASA grades describing fitness to undergo surgery,¹⁹ and degree of pain are examples of the former, and race, marital status and blood type are examples of the latter.

As a general rule, continuous variables are more ‘informative’ than categorical variables. It is therefore advisable to use continuous variables as much as possible. For example, ‘body temperature’ as a continuous variable should be preferred to a categorical variable dividing patients into those with a temperature below and above a certain threshold.

Good measurements are precise and accurate. There are largely three sources of random and systematic error: (i) variability due to the observer; (ii) variability due to the subject; and (iii) variability due to the instrument used.

A number of strategies can be followed to increase simultaneously both precision and accuracy of the measurements. First, the measurement procedures should be standardized and clearly described in the study protocol. Second, those who are involved in taking the measurements should be trained and their performance monitored in the course of the study. Third, the measurements should be carefully chosen in terms of what is known about their performance. Fourth, calibration procedures should be carried out against a ‘gold standard’. This is especially essential for mechanical devices such as weighing scales, thermometers and blood pressure measuring devices. Furthermore, a simple and rather effective approach to increase measurement precision is to repeat the measurements and to use the mean of two or more observations. The latter approach is commonly used in studies measuring blood pressure. An important approach to reduce systematic error is blinding, which conceals information about determinants, or in some cases outcomes, to the observers and/or subjects. This reduces the possibility that the observers or the study subjects distort the overall accuracy of the measurements, consciously or unconsciously. Blinding, however, does not ensure overall accuracy of the measurements, but it may eliminate ‘differential bias’ that affects one study group more than another. Blinding is especially relevant for measurements that incorporate some subjective judgement. For example, a study comparing early surgery with watchful waiting

for glue-ear in pre-school children used a tester of language development who was unaware of what treatment the children had received.²⁰

HOW WILL THE RESULTS BE ANALYZED?

The main statistical methods that are going to be used to analyze the results should be defined in the study protocol. Choosing the statistical methods after the results have become available will increase the likelihood of finding associations between determinants and outcome on the basis of chance alone.

An important element of the analysis plan is the description of how the outcome variable is going to be analyzed. For example, a trial on early surgery for glue-ear that measured language development with the Reynell development language scales (a test of expressive language and verbal comprehension abilities in children aged 6 months to 6 years) could analyze the Reynell data as a continuous variable.²⁰ Conversely, it could define groups with normal language development and with delayed language development by dichotomizing the Reynell data, and use this categorical variable as the main outcome measure.

If a categorical variable is used as the outcome measure, the ‘denominator problem’ should be considered. **Figure 41.2** summarizes the questions that have to be answered in this respect. The first question asks whether the numerator is going to be included in the denominator. If the answer is yes, the next question is whether time is included in the denominator or not.

Let us first consider the case when the numerator is included in the denominator, but time is not. A first example of this would be a measure of the occurrence of sensorineural hearing loss in neonates. One could simply report the proportion of neonates with hearing loss: the numerator would be the number of neonates with hearing loss and the denominator would be the total number of

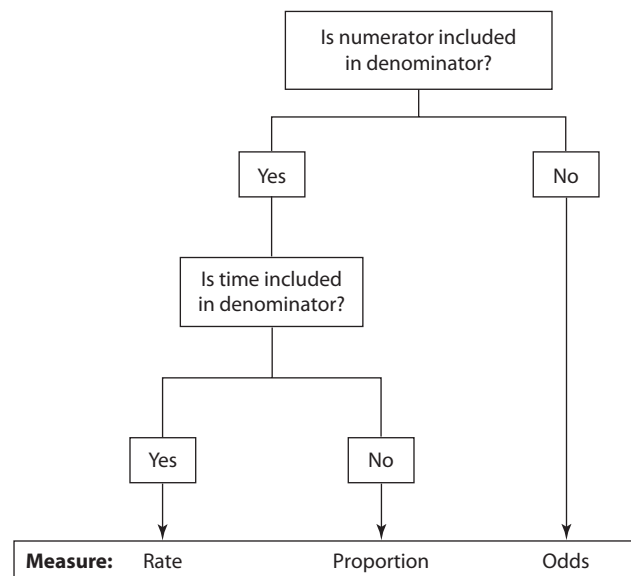

Figure 41.2 Algorithm for distinguishing rates, proportions and odds. Adapted from Grimes and Schulz, 2002,¹⁶ with permission from Elsevier.

neonates included in the study. This proportion is often referred to as *prevalence*. A second example would be a measure of the occurrence of head and neck cancer in people, initially free of the disease, who developed the disease within a specified time period. The numerator would be the number of subjects who developed the disease during follow-up and the denominator would be the total number of subjects at the beginning of the study. This proportion is often referred to as *cumulative incidence*. Suppose that 1000 smokers are followed up during 5 years and that 15 develop head and neck cancer, the cumulative incidence would be 1.5%.

The calculation of a proportion as an estimate of disease occurrence, as described above, assumes that the entire study sample has been followed up for the specified time period. This is often not the case. Some subjects might enter the study later, and others might be lost to follow-up. An alternative way of measuring outcomes that takes these varying follow-up time periods into account is to include time in the denominator. The numerator would be exactly the same as for proportions, but the sum of the time that each individual was followed up and at risk of becoming a case would be used as the denominator. In this case, an incidence rate (also called incidence density, force of morbidity/mortality, hazard) could be calculated that is equal to the number of people who develop cancer divided by the total person-time at risk during follow-up. For example, on the basis of the previous example of the occurrence of head and neck cancer in smokers, one could have expressed the incidence rate of cancer as approximately 3 cases per 1000 people per year (or 15 divided by approximately 5×1000 years of person-time at risk). Because the incidence is very low, a simple relationship holds: cumulative incidence \approx incidence \times average follow-up time.

Many epidemiological studies report, in some form or other, outcomes expressed as 'odds'. It is important to distinguish odds from probability. A probability can be estimated as the proportion of people in whom a particular characteristic, such as the presence of disease, is present. The larger the group of people under study, the better the observed proportion of people with the disease reflects the 'true' probability. Odds, on the other hand, represents the ratio of two complementary probabilities. For example, if the probability of disease is 0.20, then the odds are $0.20/0.80 = 1:4 = 0.25$. Another way of calculating the odds is by dividing the number of subjects with the characteristic by the number without it. In other words, the numerator is not included in the denominator (Figure 41.2).

Most frequently, it is not the odds itself that is reported in epidemiological studies, but the odds ratio – the ratio of odds in different groups. This can be the 'outcome odds ratio', or the ratio of the odds of the outcome of interest in the group with the determinant to the odds of the outcome in the group without the determinant. Conversely, this can also be the 'determinant odds ratio', or the odds of the determinant in the group with the outcome compared to the odds of the determinant in the group without the outcome of interest. One reason why epidemiologists find odds ratios so attractive is that 'outcome odds

TABLE 41.1 'Outcome odds ratios' and 'determinant odds ratios' – fictitious example of complication rates after tonsillectomy

Dissection instruments used	Post-operative complication					
	Yes		No		Total	
Bipolar diathermy	36	a	264	b	300	a+b
Other	24	c	676	d	700	c+d
Total	60	a+c	940	b+d	1000	

ratios' are equivalent to 'determinant odds ratios', which is a fact used in the analysis of case-control studies (see 'Case-control studies' below). For example, Table 41.1 presents fictitious findings of a study on risk factors for post-operative complications after tonsillectomy. The outcome odds ratio is the same as the determinant odds ratio, which can be easily understood as both odds ratios simplify to the 'cross product' of the cell frequencies of a 2×2 table. The 'outcome odds ratio' can be calculated as

$$\frac{\frac{a}{a+b} / \frac{b}{a+b}}{\frac{c}{c+d} / \frac{d}{c+d}} = \frac{a/b}{c/d} = \frac{a \times d}{b \times c} = \frac{36 \times 676}{24 \times 264} = 3.8.$$

Similarly, the 'determinant odds ratio' can be calculated as

$$\frac{\frac{a}{a+c} / \frac{c}{a+c}}{\frac{b}{b+d} / \frac{d}{b+d}} = \frac{a/c}{b/d} = \frac{a \times d}{b \times c} = 3.8.$$

When a dichotomous outcome variable is used (for example, alive/dead, or disease present/absent) 'risk differences' and 'risk ratios' are commonly used as 'measures of effect'.¹⁰ The 'risk' in this circumstance can represent 'prevalence', 'cumulative incidence', 'incidence' or even 'odds', as described above. One might ask, 'What is the additional risk of head and neck cancer in people who smoke, over and above that in people who do not?' The answer to this question is obviously a risk difference. In a previous fictitious example, we supposed that we followed up 1000 smokers for a period of 5 years and that we found that 15 of them developed head and neck cancer. The cumulative incidence of cancer in this group is therefore 1.5%. We can also suppose that we did the same in 1000 non-smokers and that we found cancer in 7 of them. The cumulative incidence in non-smokers is 0.7%. The risk difference attributable to smoking is therefore 0.8% ($= 1.5 - 0.7$). On the other hand, one might ask, 'How many times are smokers more likely to get head and neck cancer compared to non-smokers?' Following our example, we could calculate the risk ratio as 2.1 ($= 1.5/0.7$). In other words, smokers are approximately twice as likely to develop head and neck cancer over a 5-year period as non-smokers. This risk ratio does not tell us anything about the magnitude of the risk difference. Even for large risk ratios, the risk difference might be quite small if the

outcome is uncommon. As a rule of thumb, risk differences are more meaningful as a measure of effect in clinical situations, because it represents the actual additional probability in those exposed. On the other hand, relative risks are more meaningful as effect measures of a causal relationship in aetiological studies.

HOW LARGE IS THE STUDY GOING TO BE?

A major problem of many studies is that the study size is too small. Small studies lead to imprecise results. Small studies often increase, rather than reduce, the scientific and clinical uncertainty in a specific area. Although one might argue that small studies have a value of their own because they might be included in a systematic review and meta-analysis, which would mimic the results of a larger study, it should be the goal of every study to include a number of subjects that would in itself produce 'meaningful' results. A considerably less frequent problem is that of a study that is larger than necessary to be meaningful. Larger studies are more difficult to carry out and may be more costly than necessary. The most important issue in this context is of course to determine what can be considered meaningful.

How can the appropriate size of a study be determined? This question is most commonly answered on the basis of a statistical 'sample size calculation'. Although the answer of a sample size calculation is exact (for example, the number of subjects to be included in a study), in many cases it depends on a number of rather subjective choices. The way that the sample size of study is to be calculated depends on whether it is an analytical study (study with a comparison or control group) or a descriptive study.

For analytical studies, a research hypothesis should be formulated that further refines the study question. This hypothesis sets out the basis for statistical significance testing. Because this hypothesis guides the statistical analysis, it should be simple (addressing one determinant or comparison and the occurrence of one outcome) and specific (defining unambiguously the target population, the control and comparison group, and the outcome of interest). For the purpose of statistical significance testing, this hypothesis should be given in the form of a 'null hypothesis' that states that there is no association between the determinant and the outcome. A statistical test helps to estimate the probability that an association observed in a study is due to chance (the ' p -value'). The 'alternative hypothesis' states that there is such an association. Sometimes, a distinction is made between one-sided and two-sided hypotheses. Two-sided hypotheses state only that an association exists between determinant and outcome, whereas one-sided hypotheses specify the direction of the association. For example, the null hypothesis of a study comparing early surgery with watchful waiting for glue-ear in pre-school children could be that there is no difference in the language development in the two treatment groups. The one-sided null hypothesis would state that language development with early surgery is poorer than with watchful waiting. One-sided p -values are appropriate in selected circumstances, when only one direction

of the association is important. One-sided p -values may seem attractive as, generally speaking, with a one-sided significance test the p -value would be half the size of that with a two-sided test, but, on the other hand, if the results of the study would suggest that the language development is indeed poorer with surgery, then this would produce a large p -value as it is likely to observe a result like that given that the null hypothesis (language development with surgery is poorer) is true. For this reason, it is convention to use two-sided hypotheses when planning the size of a study as well as two-sided p -values when analyzing the results, unless there are well-argued reasons for the contrary.

When developing a study protocol for an analytical study, the investigator does not know the size of the effect that the determinant of interest has on the outcome, as one of the objectives of the study is to estimate it. For example, the investigators of the study of the effect that early surgery has on language development in children with glue-ear had to decide the smallest effect of surgery that in their view would be of clinical importance. This quantity is often called effect size or target difference. Determining this effect size is the most arbitrary step in a sample size calculation. The smaller the effect size, the larger the study needs to be, other things being equal. Previous studies could help to make a guess about what can be expected, but they do not provide any guidance about what is an important difference and what is not.

Before a sample size can be calculated, two further arbitrary choices need to be made. First, the 'alpha level' or 'significance level' has to be chosen that defines the cut-off point for the p -value – conventionally 0.05 – to classify a result either as 'significant' (if p -value \leq cut-off), in which case the null hypothesis is rejected, or as 'not significant' (if p -value $>$ cut-off), in which case the null hypothesis is not rejected. Second, the 'power' of the significance test has to be chosen – commonly used values are 0.80 or 0.90 – that defines the probability to obtain a significant result if we assume that the defined effect size or target difference would be the 'true effect' or 'true difference'.

Finally, and only if a continuous outcome variable is going to be analyzed, a measure of the variability (spread) of that outcome – standard deviation or variance – is needed. The greater the variability in the outcome variable among the subjects, the more difficult it will be to demonstrate a difference between two groups, and the larger the study needs to be.

The required sample size can be obtained on the basis of the above-described ingredients either by using the formulae presented in statistical textbooks, from published tables or by using commonly available statistical software packages. The ingredients and the formulae for study size are purely technical. They do not take into account the value of the information obtained in the study. The most important decision is to determine the 'right balance' between the value of greater precision in study results against the greater costs. Essentially, this decision boils down to a cost-benefit analysis in which the benefits are more difficult to quantify than the costs.

For descriptive studies, concepts such as null hypothesis, effect size, alpha level and power do not apply. Instead, descriptive statistics, such as means and proportions, are presented. The sample size of descriptive studies depends on how precise the investigator wants these descriptive statistics to be. Confidence intervals, such as 95% or 99% confidence intervals, are commonly used to represent the precision of the estimates. For example, a study of the 5-year survival after surgical treatment in 228 patients with hypopharynx carcinoma found that the survival was 27.2% with a 95% confidence interval ranging from 21.5% to 33.5%.²¹ This interval indicates that we can be 95% confident (which can be considered more or less the same as saying that there is 95% chance) that the 'true' 5-year survival probability lies within this interval. When estimating the sample size for descriptive studies, the investigator specifies the desired width of the confidence interval, and the sample size derives from that and can be read from tables or obtained from statistical software packages. This approach can be followed for any type of descriptive variable for which confidence intervals can be calculated.

CHOOSING THE DESIGN STUDY

The taxonomy of study designs presented in [Figure 41.1](#) provides a simple decision aid for choosing the most appropriate design. A number of questions have to be answered with the ultimate goal being to create an affordable study that provides results that are relatively precise (free of random error) and accurate (free of systematic error or bias). A first distinction that has to be made is that between studies in which the investigator actively assigns the determinants (experimental studies) or those in which this is not the case (observational studies). A second distinction that has to be made is that between observational studies that do or do not have a comparison or control group. If so, the study is called analytical, if not, descriptive.

The following sections are largely based on a series of short essays on clinical research published in the *Lancet*,¹⁶ and chapters of recent books about designing clinical research by Hulley and colleagues¹⁵ and clinical epidemiology.¹⁰ We start this section by describing observational studies and will end with the description of experimental studies (randomized controlled trials).

Levels of evidence

Individual studies are frequently graded according to a hierarchy whereby those at the top are considered to provide stronger evidence than those lower down the scale. The Oxford Centre for Evidence-Based Medicine has provided one such framework as shown in [Table 41.2](#).

Caution, however, is recommended in exercising such a rigid hierarchical approach to all studies. Thus, randomized controlled trials (RCTs) for a particular intervention are not always available and not all interventions can be evaluated in RCTs; a lack of RCT evidence does not equate to a lack of evidence. In addition, although guidelines are

TABLE 41.2 Oxford Centre for Evidence-Based Medicine – classification of levels of evidence

Level	Evidence
1a	Systematic review of RCTs; meta-analyses
1b	Individual RCT
2a	Systematic review of cohort studies
2b	Individual cohort study
2c	'Outcomes' research
3a	Systematic review of case-control studies
3b	Individual case-control study
4	Case-series (and poor quality cohort and case-control studies)
5	Expert opinion, anecdotal evidence, case reports or based on physiology, bench research or 'first principles'

Modified from <http://www.cebm.net/oxford-centre-evidence-based-medicine-levels-evidence-march-2009>

based on the best available published evidence, not all evidence makes it into the literature. Finally, this approach fails to take into consideration the quality of individual studies. A well-designed and properly conducted cohort or case-control study may provide better evidence than a small or poorly conducted RCT.

An alternative approach is to classify studies not only by their *design* but also according to the *quality of evidence* they provide. For example, The Grading of Recommendation, Assessment, Development and Evaluation Working Group (GRADE Working Group) has developed a system for grading the quality of evidence.²²

Minimizing bias and confounding

We indicated earlier that the precision of study results depends mainly on two factors: the size of the study design and the methods used to obtain the measurements. Furthermore, a study should be designed in such a way that it avoids systematic error or bias. A great number of different types of bias have been documented but it is not a major simplification to consider all these types of biases in three categories: selection bias, information bias and confounding.

To examine whether selection bias would introduce systematic error in the study results, two questions need to be answered: 'Do the sample of study subjects sufficiently represent the population of interest?' and 'Are the groups that are going to be compared similar in all important respects apart from the determinant(s) of interest?' The first question is especially relevant when designing a randomized controlled trial, because trials usually enrol patients who tend to be different (often healthier) from the target population and the results tend to overestimate the effects compared to what they would be in routine practice. This contributes to the differences between the efficacy of a therapy observed in the highly controlled circumstances in selected clinical settings and the effectiveness

of a treatment in actual practice. The second question refers directly to the comparability of the groups. In other words, do the groups differ importantly aside from the comparison that is being studied?

Information bias results from incorrect information about the determinant or the outcome or both. The important question that has to be answered is: 'Has information been gathered in the same way?' In cohort studies (see 'Cohort studies' below), information about the outcome should be obtained in the same way for those with and without the determinants under consideration. Also, those who collect the information about the outcome should be unaware of ('blind to') the determinant status of the subjects as much as possible. In case-control studies (see below), information about the determinant status should be collected in the same way for cases and controls.

Confounding occurs when two determinants or risk factors are associated with each other. In that case, the effect of one is confounded with, or distorted by, the effect of the other. Confounding can occur because of selection bias, by chance, or because the two determinants are really associated in nature. Selection bias and confounding are not mutually exclusive, but they are often presented differently as they represent problems at different stages in a study. Selection bias is an issue when the sampling procedures for patients are determined during the design phase of a study, whereas confounding is an issue to consider during the analysis phase.

Often in the same study more than one bias operates, as in the following example. Imagine a study that compared the effect that surgical and non-surgical management had on speech and language development in children with persistent otitis media with effusion. In this example, selection bias could have been present if the children who received surgical treatment came from a different background and had parents who were on average of higher socioeconomic status, or if they had a family history of chronic ear infection. Information bias could have occurred because the assessment of language development might have been influenced by the fact that those who were applying and interpreting the speech and language tests knew the treatment the children had received. Finally, the conclusion that surgical treatment improved speech and language development might have been the result of confounding if the children who received surgical treatment had had more serious or more frequent ear infections. The latter bias is often referred to as 'confounding by clinical indication'.

When designing studies, investigators should try as much as possible to rule out bias. The concerns about bias need to be thought through very carefully. This relates directly to the three components of a good research question, and these components should be represented adequately in the study design. First, the study sample should adequately represent the target population. Second, the measurement of the determinants should adequately represent the comparison of interest. Third, the measurements of the outcomes should adequately represent the outcome(s) of interest.

When confounding is anticipated, the investigator should consider design and analysis strategies to control its

influence on the outcomes. The simplest approach in the design phase is restriction or specification. For example, investigators could decide to include only non-smokers in a study on the effect of human papillomavirus and oropharyngeal cancer. The disadvantage of this strategy is that it reduces recruitment and prohibits generalization of the results to smokers. Another potential approach in the design phase is matching, which means that subjects with matching values for the confounding variables are included. This can be done individually (pair wise matching) or in groups (frequency matching). However, the use of matching has many disadvantages. The recruitment process can become rather cumbersome. Special analytical techniques are required that represent the fact that the subjects are not sampled independently. There is also the danger of overmatching – matching on the basis of a variable that is not a confounder, which would reduce the study's power. Given these disadvantages, matching should be avoided if other strategies could provide sufficient control for confounding.

In the analysis phase, the investigator can use either stratification or adjustment. Stratification ensures that the analysis compares like with like, first by comparing subjects within a group (or stratum) of subjects with similar values of one or more confounding variables and then, in a second step, by calculating an overall estimate by pooling the stratum-specific results. The most important disadvantage of this approach is the limited number of variables that can be controlled for. Adjustment on the basis of a statistical multivariate model does not suffer from this limitation, but its effects depend on the adequacy of the model fit. Both approaches depend on the completeness, precision and accuracy of the measurements of the confounders.

Observational studies

DESCRIPTIVE STUDIES

Descriptive studies can describe the experience in only one individual, a case report, or a report on a series of individual cases, the case-series report. Case series are the most frequently published studies in surgery. An important function of descriptive studies is that they can describe the distribution of diseases or disease-related conditions and events in a specified population.

Good descriptive research should address the five 'W' questions – who, what, why, when and where – although as soon as these questions are addressed on the basis of the data, the distinction between descriptive studies (no comparison) and analytical studies (comparison between groups essential) starts to disappear; but a distinctive characteristic of descriptive studies is that they cannot directly quantify the risk that can be attributed to a specific determinant. For example, a series of three cases was published recently of perichondritis of the pinna as a result of 'high' ear piercing, and was used to focus attention on the risks of body piercing.²³ The study also presented the increasing trend in the number of hospital admissions for perichondritis of the pinna in the UK and Wales from

approximately 600 in 1990–91 to approximately 1200 in 1997–98. The latter is an example of a surveillance study, which is another important type of descriptive study. A surveillance study is an ongoing and systematic collection, analysis and interpretation of health data essential to the planning, implementation and evaluation of health services and public health practice. The fact that this particular descriptive study cannot quantify the attributable risk might not be a weakness as most cases of perichondritis of the pinna may be due to piercing practices in the first place.

The strength of descriptive studies is that they often use existing data and thus are inexpensive and efficient to carry out. Furthermore, few ethical limitations exist. The disadvantages are that there is a danger of over-interpretation. For example, in early 2001 the UK government recommended that single-use instruments should be used for adenotonsillectomy to minimize the risk of transmission of variant Creutzfeldt-Jacob disease (vCJD). In the course of the same year, suspicion was raised about the post-operative haemorrhage rate. It was thought that the increase in the haemorrhage rate was due to the poor quality of the single-use instruments and, in late 2001, the UK government recommended the reintroduction of reusable instruments. The need to consider alternative explanations arose later as more detailed analyses of hospital admission data revealed that there also had been a gradual increase in the post-tonsillectomy complication rate from 3.9% in 1995–96 to 7.3% in 2000–01.²⁴

Analytical studies

An important distinction that is often made with respect to observational studies that are analytical is whether the determinants and outcomes relate to phenomena that occur at the same time. If so, it is called a cross-sectional study. If not, it is either a cohort study (looking forward in time from determinant to outcome) or a case-control study (looking backward from outcome to determinant).

CROSS-SECTIONAL STUDIES

The single most important characteristic of cross-sectional studies is that the determinant(s) as well as the outcome(s) measured occur at the same time, and that there is no follow-up period. Cross-sectional designs are very well suited to describe the prevalence of health and disease-related conditions and their distribution patterns. For example, a study was carried out in 864 school children in the UK to investigate the effect of parental smoking on middle ear disease.²⁵ Data on parental smoking were collected with a questionnaire and glue-ear was considered to be present in children with a flat tympanogram. The study identified 82 cases in total, 45 in the 407 households with at least one smoker and 37 in the 457 households with no smokers, and a risk ratio of 1.4 (=11.0%/8.1%, with a 95% confidence interval ranging from 0.9 to 2.1) could be calculated.

The major strength of cross-sectional studies is that they examine the presence or absence of an outcome and

determinant at the same time. Cross-sectional studies are therefore fast, relatively cheap, and there is no 'loss to follow-up'. A major disadvantage of cross-sectional studies is that they provide only a snapshot of complicated temporal relationships between determinant and outcome. Parental smoking, for example, is likely to be persistent, but chronic middle ear infection in children is an intermittent disease. As a consequence, causal relationships are difficult to establish with cross-sectional studies. For the same reasons, they are not suitable for producing information on prognosis or the natural history of a condition.

Studies of the accuracy of diagnostic tests are a special case of cross-sectional studies. A key feature of such studies is that the diagnostic test results and 'gold standard information' or reference test results about the presence or absence of the conditions of interest are collected at the same time. The subjects should have both undergone the diagnostic test in question (for example, ultrasound-guided fine-needle aspiration to diagnose malignant disease in patients with nodular thyroid disease), as well as the reference test (histology after surgical resection). The results of one test should not be available to those who are carrying out the other. In terms of the example, the pathologist examining the surgical specimen should be 'blind' to the results of the fine needle aspiration. Another important criterion for a valid evaluation of the diagnostic accuracy is that the diagnostic test is evaluated in 'an appropriate spectrum of patients' (such as those in whom we would use it in practice).

The accuracy of a diagnostic test, a measure of how well the test results help to distinguish between individuals with and individuals without the disease or target disorder, is often expressed in terms of sensitivity and specificity. However, it is important to realize that this is, in most cases, a simplified representation of the diagnostic accuracy. Sensitivity and specificity can only be calculated for a test with dichotomous results, often called 'positive' if the result suggests that the disease is present and 'negative' if it suggests that disease is absent. The sensitivity is estimated as the proportion of individuals with the disease who have a positive test result. The specificity corresponds to the proportion of individuals without the disease who have a negative test result. The sensitivity and specificity of a 'perfect' test are 100%. The sum of the sensitivity and specificity is sometimes used as a single measure of the diagnostic accuracy. The sum of the sensitivity and specificity for a 'worthless' test, a test that would perform no better than tossing a coin, is expected to be 100% and for a perfect test 200%.

In many cases, however, relying on sensitivity and specificity as measures of diagnostic accuracy is too simplistic. For example, many tests, if not all, have more than two possible outcomes, and dichotomizing the results in a positive and a negative test result reduces the amount of diagnostic information that a test can provide. Furthermore, if one would like to dichotomize the test results, it is not immediately obvious what the cut-off value between positive and negative results should be. Lastly, the actual aim of performing a diagnostic test is

not to distinguish between individuals with and without the disease, but to identify those individuals for whom the expected benefit of treatment outweighs the expected harm. This indicates that the classic diagnostic ‘stepping-stone approach’, jumping from signs and symptoms to diagnosis and then from diagnosis to treatment, is rather artificial in many cases. This should be reflected in studies assessing diagnostic tests. They should focus on clinical effectiveness (effect on patient outcomes) rather than on diagnostic accuracy alone (for a comprehensive review of methods for the evaluation of diagnostic technologies, see Knottnerus).²⁶

COHORT STUDIES

Cohort studies follow groups of individuals over time. The word ‘cohort’ originates from the Latin word for a group of 300 to 600 soldiers in a Roman legion. This is appropriate as the same rule applies for epidemiological cohorts as once for Roman cohorts: if a person joins a cohort, he will be a member of that cohort forever, which emphasizes the need for the completeness of follow-up. Most follow-up studies are analytical (comparing the occurrence of outcomes according to presence or absence of certain determinants), but they can be descriptive as well.

The design of many cohort studies is relatively straightforward. A group of people is assembled, none of whom have experienced the outcome of interest, but all of whom could experience it. On study entry, people may be classified according to the determinants of interest. These people are then observed over time to see in which of them the outcome of interest occurs. Despite this simple design, the terminology used to describe these studies can be confusing. For example, terms such as ‘longitudinal study’, ‘prospective study’ or ‘incidence study’ are often used interchangeably. The only real problematic issues in this respect is the use of the term ‘prospective study’, as cohort studies can consider data that are collected prospectively as well as retrospectively.

The terms ‘retrospective’ and ‘prospective’ refer to the way that the data have been collected rather than to the study design. The essential characteristic of prospective data collection is that data are being collected on determinants and outcomes that manifest themselves after the establishment of a study protocol. In all other situations, the data collection should be considered to be retrospective. Retrospective data collection can be based on data recorded in the past for other purposes or on the memory of the study subjects, investigators or other parties. It is obvious that the precision and accuracy of prospectively collected data can be expected to be better than retrospectively collected data. Cohort studies can be based entirely on retrospective data (using retrospective data on both the determinants and the outcome), based entirely on prospective data (using prospective data on both the determinants and the outcome), or based on a mix of retrospective data on determinants and prospective data on the outcome.

Cohort studies have many attractive features. They are the best way of ascertaining the incidence of a disease or health-related event or condition, as well as the

natural history of a disorder. They also provide insight into the temporal order of determinants and outcome, which strengthens the inferences that can be made about whether an observed risk factor is a cause of the outcome. Furthermore, multiple outcomes can be considered, which is especially relevant if cohort studies are compared with case-control studies (see ‘Case-control studies’ below). However, the dangers of considering multiple outcomes are also obvious since testing many hypotheses may lead to misleading results. Lastly, prospective cohort studies are especially valuable for the study of fatal diseases, or more general studies of the occurrence of disease-related conditions with a short duration. When these kinds of conditions are studied retrospectively, the observed occurrences may be an under-representation of all occurrences.

The major drawback of cohort studies is that they are relatively expensive and therefore an inefficient way to study rare outcomes. Cohort studies become more efficient as the outcomes become more common. Another disadvantage for cohort studies that collect outcome prospectively is that the results may not be available for a long time. A prospective study of the effect of passive smoking on the head and neck cancer incidence may take more than 10 years to come up with relevant results.

However, not all prospective cohort studies need to take a very long time to complete. A cohort study could be used, for example, to study the risk factors for complications after tonsillectomy. Such a study could prospectively collect patient characteristics as well as data on surgical technique, instruments used and experience of the surgeons. Every patient could be followed up for a certain period, say one month, and the occurrence of complications could be registered. Such a study would provide insight into the incidence of complications – it might even distinguish between primary haemorrhage, secondary haemorrhage as well as infection, and also in the way this incidence depends on relevant risk factors.

CASE-CONTROL STUDIES

Case-control studies can be considered as ‘research in reverse’.¹⁶ Many epidemiologists consider them as one of the most important tools in their armamentarium. The design of case-control studies can be appreciated by again considering the example of the study on risk factors for complications after tonsillectomy. For this study, we could also use a case-control design. All the patients who experience a complication in the first month after surgery could be considered as ‘cases’, and patients without post-operative complications as ‘controls’. The investigators then have to look back in time to find data on the patient’s risk factors that were present at the time of surgery.

The essential feature of a case-control study is that not all controls need to be included but that a selection would suffice. Many case-control studies include only one control for each case, whereas others included more but hardly ever more than four or five. The reason that the number of included controls per case is seldom higher is that including more controls will have only a small effect on the power of the study and on the precision of

the estimates ('law of diminishing returns'). The fact that only information has to be collected for a selection of the controls makes that, in many circumstances, case-control studies are the most efficient design in terms of time, effort and therefore money. Hence, case-control studies are especially relevant if the occurrence of the outcome of interest is low. However, if the frequency of the determinant of interest is low, case-control studies might become inefficient. For example, if the frequency of a certain risk factor of post-tonsillectomy complications is low, investigators have to examine many cases and controls to find some who have been exposed. Some have advocated a 'rule of thumb' stating that cohorts are more efficient than case-control studies if the occurrence of the outcome is more frequent than that of the determinant and vice versa.

Unlike cohort studies, case-control studies cannot produce an estimate of the occurrence of the outcome of interest since we lack information about the denominator. A case-control study of post-tonsillectomy complications will neither provide information on how many patients underwent the operation nor on what their risk factors were. The relevant effect measure that a case-control study can provide is the odds ratio for a determinant, derived from the proportions in cases and in controls (more precisely, the odds) in whom the determinant is present. Earlier, we referred to this odds ratio as the 'determinant odds ratio'. This determinant odds ratio is equivalent to the 'outcome odds ratio' and the odds ratio obtained from a case-control study can therefore be used as a measure of relative risk.

The advantage of case-control studies (efficiency in time, effort and money) comes at a price, however, because two methodological issues may introduce major systematic errors: selecting the control group and obtaining information about the determinants. The selection of cases is relatively straightforward provided that the definition of the outcome being studied (the 'case definition') is clear. The selection of the control group is more problematic. Two criteria need to be met. First, controls should be representative of the population at risk of becoming cases. In other words, the controls should have been selected as cases had they developed the disease or outcome of interest themselves. Second, selection of the cases should be independent of the determinant(s) being investigated. Therefore, a case-control study of risk factors for post-tonsillectomy haemorrhage should include as controls only patients who underwent a tonsillectomy themselves. Furthermore, it seems inappropriate to select as controls all patients who underwent a tonsillectomy immediately after patients who developed complications. If that were the case, it would be very likely that the same surgeon using the same technique and the same type of instruments treated these patients. It is left as an exercise for the reader to decide what an appropriate strategy to select controls would be.

RANDOMIZED CONTROLLED TRIALS

Randomized controlled trials are cohort studies with prospective data collection. Their distinctive feature is

that they use a random allocation scheme to assign the determinant. With randomization, you can expect that the prognostic characteristics of the randomized groups or 'arms' of the trial are similar except for differences due to chance variation. Randomization eliminates the influence of both known and unknown confounders that are present at the time of randomization. Without randomized treatment allocation, it cannot be excluded and is in practice very likely that imbalances in prognostic factors between the groups occur that are the result of selection bias – a type of bias often called 'confounding by clinical indication'.

The ethical argument in favour of a random process deciding what intervention patients receive is that there is equipoise, or a state of genuine uncertainty on the part of the clinical investigator regarding the comparative merits of each intervention. If there is genuine uncertainty about which treatment is best, it is not possible to recommend one over the other, which justifies that a random process decides. The problem, however, is that equipoise depends on subjective judgements and that therefore experts may disagree. Furthermore, preferences of patients or those who are candidates to receive the intervention have to be taken into account. The process of informed consent should address all these issues to ensure that patients can evaluate the potential risks and benefits of the study from their own perspective before they agree to participate.

It is important that the randomization process is 'concealed' from the investigators who include the participants into the trial. Proper allocation concealment requires that the investigators do not know the arm to which a participant will be allocated until the participant has definitively been recruited and included in the study. Concealment of the randomization is the only way to prevent the investigators influencing the balance of the prognostic characteristics between the groups that are being compared. For example, prior knowledge of the next allocation may allow investigators to exclude certain candidate participants from the trial because they are perceived to be allocated to an inappropriate group. More directly, the investigators may try to influence the order of inclusion. Concealment of treatment allocation is so important that with inadequate concealment a randomized controlled trial should be considered non-randomized. Empirical studies have shown that trials with inadequate concealment overestimate the treatment effect by as much as 40% on average.

Another important feature of many randomized controlled trials is the use of a form of blinding, which prevents the participants and the investigators who are in contact with the participants from being aware of which treatment has been offered. Blinding can help to prevent bias in a number of ways. First, if participants do not know what treatment they are receiving, it is less likely that their perceptions and expectations of the treatment that they receive can influence their compliance and the physical and psychological response to the intervention. For example, most patients expect that a new treatment is better than an existing one. Second, blinding investigators is important, as this would prevent them consciously or unconsciously managing the participants in

the trials differently. Also, their attitude towards the treatment can influence how patients respond to the treatment. Third, blinding participants and investigators will prevent outcomes from being assessed differently. The terms 'single-blind' and 'double-blind' are often used to indicate trials in which only the participants or both the participants and the investigators are blinded.

Double blinding is impossible in almost all surgical trials. To avoid biased management, the investigators should then try to standardize other potential treatments as much as possible. Approaches to minimize biased assessment of outcomes could include the use of a third party who is unaware of the treatment originally given. When blinded assessment is not possible, one should try as much as possible to use 'hard outcomes' (based on measurements resistant to bias). Another alternative includes the use of standardized outcome measurement scales that can be completed by the participant. This approach is likely to produce less biased outcomes than the judgement of an investigator.

Many people also consider the use of a placebo treatment as an essential feature of a randomized controlled trial. Placebo treatment is a form of treatment indistinguishable from the 'active treatment' under study, but it does not have a specific known mechanism to influence a patient's health. Blinding often requires the use of placebo treatment. Apart from that, the choice whether to use placebo treatment depends on the question that the trial tries to answer. First, if the question is whether intervention A is better than intervention B, then it is obvious that one should compare the effects of A and B with each other and not against placebo treatment. Second, if the question is whether intervention A is better than no treatment at all, the answers may be different for researchers and clinicians. Researchers are likely to be more interested in the specific effects – effects that can be attributed to the 'active component' of an intervention. Clinicians are likely to be more interested in the combined effects of the active and placebo components. On the other hand, it is always useful to know what part of the total effect is due to the active component and what part to the placebo when balancing the potential benefits against potential harms and costs, which are likely to differ between the active and placebo components. It is obvious that placebo treatment is rarely an option for randomized controlled trials in surgery. For example, in a trial comparing tonsillectomy with non-surgical management, it would require a form of 'sham surgery' to provide a placebo treatment. It is left to the reader to decide what the advantages and disadvantages of using such a form of placebo treatment in this context would be.

If a substantial number of participants do not receive the study interventions, do not comply with the study protocol or are lost to follow-up, the trial is likely to be underpowered and its results biased. Strategies to maximize compliance and follow-up should therefore be an integral part of every trial protocol. An obvious strategy is to make participation in a trial as convenient, painless and enjoyable as possible. Some trials have a 'run-in period' that can be used to 'screen out' patients who may

not adhere to the study protocol and the follow-up procedures. It is essential to ascertain that compliance and completeness of follow-up do not differ between the trial arms as this could lead to biased estimates of the effects of the interventions.

The results of trials can be analyzed in two ways. First, the comparison of the intervention can be carried out according to the intervention to which the patients were randomized ('intention-to-treat' analysis) or according to the treatment they actually received ('per protocol' analysis). The advantage of an intention-to-treat analysis is that the question that is being addressed corresponds exactly with the one clinicians and patients try to answer in clinical practice. The disadvantage is that if many patients do not receive the treatment they were randomized to, this would obscure the difference between the trial arms. Per protocol analysis, on the other hand, addresses which intervention is better more directly. With this form of analysis, the treatments are being compared according to the treatments that the patients actually received. The problem with this approach is that if many patients do not receive the treatment to which they were randomized, the study no longer represents an experimental study.

The analysis should focus on a single outcome – often referred to as the 'primary endpoint' – to avoid the problems of interpreting the outcome of multiple hypothesis tests. This primary endpoint should also be used for the power calculation in the design phase of the trial. It is often desirable to consider a number of secondary endpoints – outcomes that represent different aspects of the outcome of interest – to provide a more detailed picture of the effects of the interventions under study. For example, a randomized controlled trial of tonsillectomy and non-surgical management could consider the reduction in the number of episodes of tonsillitis or sore throat as primary endpoint, but could also collect information on post-operative complications, reduction in time off work and reduction in the use of certain drugs, such as analgesics and antibiotics.

Subgroup analyses are comparisons between randomized groups in a subset of the patients with specific characteristics. The most important question that subgroup analyses try to answer is whether the effect measure is different in different subgroups by carrying out a statistical test for interaction (or 'effect modification'). For example, one could investigate – when analyzing the results of the trial on tonsillectomy – whether the effects of tonsillectomy on recurrence of tonsillitis are different in children younger than 5 years compared to children of 5 years and older.

Subgroup analyses can be dangerous and misleading, but they can also provide an important extra insight into the generalizability of the results. One danger arises from the fact that multiple comparisons are carried out, which increases the risk of producing false-positive results. To avoid this risk, only a limited number of subgroup analyses should be carried out and they should be specified in the study protocol, in other words, before the results of the trial are known and on the basis of patients characteristics that are measured before randomization.

Furthermore, the actual number of subgroup analyses carried out should be reported. Another approach to minimize the risk of false-positive results is to reduce the significance level of the statistical tests for interaction (for example, from the conventional 0.05 to 0.05 divided by the number of tests carried out as specified by the Bonferroni method). A further danger is the limited power of the subgroup analyses, because the group size is, by definition, smaller than that of the original trial population.

An important problem of randomized controlled trials is that of generalizability. Most trials are carried out in highly controlled conditions in a selected group of patients. Their results therefore provide evidence about the efficacy of an intervention (does the treatment work under ideal circumstances?) and not about the effectiveness (does the treatment work in actual practice?). It depends on the question that needs to be answered as to what extent the design of a trial should focus on efficacy or on effectiveness. An explanatory trial (addressing the efficacy question) is needed in the early stage of a new intervention. However, a pragmatic trial (addressing the effectiveness question that aims to create study conditions that reflect as much as possible actual practice when effectiveness is more important) is more appropriate to answer whether an intervention should be included in the 'repertoire' of available services.

The Consolidated Standards of Reporting Trials (CONSORT) statement has been developed to alleviate the problems arising from inadequate reporting of randomized controlled trials.²⁷ The CONSORT statement is an evidence-based, minimum set of recommendations for reporting randomized trials and offers a standard way for authors to prepare reports of trial findings, facilitating their complete and transparent reporting, and aiding their critical appraisal and interpretation.

It is obvious that not all questions about the effectiveness of surgical procedures can be addressed with a randomized controlled trial.²⁸ A number of obstacles have been identified that make randomized controlled trials inappropriate (outcome of interest relatively rare, relevant outcomes far in the future, or randomization affecting the effectiveness of a procedure), impossible (refusal of clinicians or patients to participate, ethical obstacles) or inadequate (low generalizability of experimental studies).²⁹ As an example, the EaStER trial (Early Stage glottic cancer: Endoscopic excision or Radiotherapy) was closed early with recruitment of only 17 patients. Four principle reasons were found to contribute to poor recruitment into the trial: (i) surgeons and nurses involved in the trial were not in equipoise between the two trial arms and did not fully agree with the trial protocol; (ii) surgeons differed about primary outcome measures; (iii) recruiters focused on the treatment process rather than treatment per se; (iv) logistical issues in some centres made trial participation difficult.³⁰ If the obstacles are insurmountable, carefully designed observational studies should be considered.

Studying surgical innovation

Innovations are essential to the advancement of otolaryngology. However, the overall number of RCTs in surgical innovation remains small compared with the number of RCTs evaluating medical interventions. On this backdrop, The IDEAL Collaboration was set up in Oxford, UK. They concluded that innovation in surgery follows a different pathway to that of pharmacological developments and that a different approach was needed. The collaboration proposed a framework for the stages in surgical innovation (idea, development, exploration, assessment, and long-term study) and developed a set of recommendations on how evaluation should be conducted at each stage.³¹

Schwartz described three categories of surgical innovation: practice variation (minor changes to routine surgical practice); experimental research (formal trials); and a 'transition zone' between the two.³² She outlined the ETHICAL model for studies in this 'transition zone' (expertise, technical skill, hazard awareness, informed consent, conflict of interest avoidance, analysis of results, and literature publication). This seeks to protect patients and surgeons, guides decision-making and assists in the generation of scientific hypotheses, without unduly hampering surgical progress.

CONCLUDING REMARKS

This chapter introduces the 'determinant-occurrence relationship' as a key concept for medical research, and epidemiology as a methodological discipline with immediate relevance for otolaryngological research. A basic understanding of epidemiological principles is therefore essential for all people who are involved in clinical research and desirable for all clinicians who want to read the medical literature critically.

We have only presented a broad picture of epidemiological concepts and principles, but it will be clear to the reader that studies vary according to the likelihood that their results are accurate (free of systematic error) and precise (random error). For this reason, a 'hierarchy of evidence' has been suggested.¹¹ For therapeutic issues, this hierarchy ranges from well-conducted randomized controlled trials at the top – preferably summarized in a systematic review and meta-analysis – to case-reports and expert opinion at the bottom (used throughout this book). For diagnostic and prognostic issues, very different hierarchies are necessary. These hierarchies of evidence are not absolute. If the therapeutic effects are very large in comparison to the potential effects of bias – for example, effects of insulin in ketoacidosis – a description of a series of cases may already provide compelling evidence. Nevertheless, it should be a leading principle that users of research try to look for the best available evidence from this hierarchy.

KEY POINTS

- Epidemiology is a methodological discipline. Epidemiological concepts and principles will help to design empirical studies that are relatively precise (free of random error), accurate (free of systematic error or bias) and efficient (affordable in terms of time and money).
- The 'determinant-occurrence relationship' is a key epidemiological concept, and many clinical research questions can be 'framed' as determinant-occurrence relationships.
- Epidemiological studies can be distinguished into experimental studies (investigators assign the determinants themselves, e.g. randomized controlled trial) and observational studies (investigators examine events as nature takes its course). Observational studies without a comparison or control group are called descriptive studies.
- A research protocol is a document that provides all essential details of a study. It should contain information on:
 - research question
 - study design
 - selection and recruitment of the subjects
 - measurements
 - statistical analysis
 - sample size calculation.
- A 'hierarchy of evidence' has been suggested on the basis of the likelihood that results are accurate and precise. For therapeutic issues, this hierarchy ranges from well-conducted randomized controlled trials at the top – preferably summarized in a systematic review and meta-analysis – to case-reports at the bottom.

SEARCH STRATEGY

There is a vast literature on this subject, so there was no formal literature search.

AIM OF CHAPTER

The aim of this chapter is to explain the background to patient-based outcomes research. The emphasis is on instruments relevant to otolaryngology. The instruments described are simply examples for the reader. The authors do not suggest that these are the best instruments in their subject area. A list of recommended reading is included for readers who wish further information.

INTRODUCTION

Clinical outcomes research examines the outcomes of treatment or of disease. Traditionally outcomes of medical care are based on clinical observations or laboratory measurements. While these measures provide useful information for the clinician, they are often of limited interest to patients. There is often poor correlation between clinical outcomes and functional capacity and well-being, which are the areas of most interest to the patient. There has been increasing recognition that traditional measures need to be complemented by some measure reflecting the impact of the intervention on the patient in terms of health status and health-related quality of life. These terms refer to experiences of illness such as pain, fatigue, disability and broader aspects of the individual's physical, emotional and social well-being. Medicine, in particular surgery, formerly had the principal objective of reducing

mortality and morbidity. These objectives are usually straightforward to assess. Nowadays, a large proportion of clinical practice is either cancer or chronic disease. There has been little improvement for some time in survival in cancer while treatments often have associated side effects and functional impairment that significantly affect the patient's quality of life. There is an increasing prevalence of chronic diseases with an ageing society and here the aims of treatment are to arrest or reverse decline in function.¹ These factors have led to an increased interest in patient-based outcome measures.

At the same time, increased attention is being given to patients' opinions and wishes in relation to their health. Patients should be involved in decisions about their treatment. To contribute usefully, they need information about the outcomes of treatment, not just in terms of surgical results but in terms of the possible effects on their quality of life. Financial resources limit healthcare around the world, and increasingly the distribution of these resources is influenced by the benefits perceived by patients, their carers and society as a whole.

WHAT ARE PATIENT-BASED OUTCOME MEASURES?

Patient-based outcome measures are, in general, questionnaires that ask patients about their perception of their health. Usually these instruments are made up of

a number of items or questions. These items are linked in a number of domains or dimensions. A domain refers to an area of behaviour or experience, such as mobility, self-care, depression, pain, social functioning and general well-being. Many questionnaires focus on physical function, such as the patient's ability to walk, climb stairs, wash and dress themselves. Others ask about the impact of health on various areas of an individual's life, such as ability to socialize with members of their family and friends. These are aspects of health-related quality of life (HRQoL). Overall quality of life is influenced by many factors other than health, such as social, financial and physical factors. Patient-based outcome measures assess only one aspect of quality of life and are not measures of overall quality of life.

Patient-based outcome measures assess some aspect of the patient's subjective experience of health and the consequences of illness – and of treatment. As these experiences are those of an individual patient with an individual personality and lifestyle, they cannot be objectively verified. This point is sometimes raised as a criticism of patient-based outcome measures, but it should be borne in mind that many clinician-based outcomes are the subjective opinion of the clinician.

WHY USE PATIENT-BASED OUTCOME MEASURES IN RESEARCH?

In the early days of research, few if any studies included assessment of health-related quality of life. It is increasingly argued now that clinical trials should include patient-based outcome measures except where it is clear that these are not relevant outcomes. The UK Medical Research Council (MRC), the European Organisation for Research and Treatment of Cancer (EORTC) and the National Cancer Institute of Canada (NCIC) all have policies stating that the likely impact on quality of life should be assessed, or justification provided for not doing so.² Patient-based outcome measures have been used as the primary outcome measure in randomized controlled trials in many areas including cancer and heart disease. They are also useful in providing evidence of the overall value of a treatment in a way that allows comparison with other treatments in the same area or in other areas.

Patient-based outcome measures are particularly relevant in otolaryngology. Head and neck cancer forms a small proportion of our patients, though a much larger proportion of our clinical workload. The majority of our patients do not have a life-threatening condition and the morbidity is small. Most of our patients simply want us to make them feel better. In many cases we do not have reliable, objective clinical measures to assess the outcome of treatment. To justify our treatment we need patient-based outcome measures to demonstrate the efficacy of treatment – improvement in HRQoL. We also need patient-based outcome measures to demonstrate the effects of these non-life-threatening conditions on HRQoL.

Even when we have objective measures (e.g. closure of a tympanic membrane in myringoplasty), we often know

little about the effects on HRQoL. There are also occasions where there is disagreement between clinical measures of success and HRQoL outcomes (e.g. septal surgery for deviated nasal septums). It is likely that the results from one of the measures are unreliable or that they are measuring different things – the validity of both measures should be questioned.

ASSESSMENT OF PATIENT-BASED OUTCOME MEASURES

There are eight criteria that should be applied to patient-based outcome measures: appropriateness, validity, reliability, responsiveness, precision, interpretability, acceptability and feasibility (Table 42.1).³ There are few patient-based outcome measures for which there is sufficient evidence to allow judgement on all of these criteria.

Appropriateness

The first and most fundamental question when selecting a patient-based outcome measure is how to identify one that is appropriate to the aims of the particular trial. The aims of the trial, the patient group being studied, the type of treatment and the relevant quality of life questions should be carefully considered. The instrument should measure aspects of patients' lives that patients consider important, and should not omit aspects of HRQoL that are important to the patients in the trial.⁴ Clinicians often think that they know what aspects of HRQoL are important to patients. Many studies have demonstrated, however, that patients' views often differ from those of clinicians. The most effective way of establishing the importance to patients is asking patients their views. A list of aspects of HRQoL can be drawn up by clinicians and patients. A group of

TABLE 42.1 Assessment of patient-based outcome measures

Criterion	Meaning
Appropriateness	Does the content of the instrument match the intended purpose of the trial?
Validity	Does the instrument measure what it claims to measure?
Reliability	Does the instrument produce the same results when repeated in the same population?
Responsiveness	Does the measure detect clinically meaningful changes in the patient condition?
Precision	Can the instrument detect small differences between patient groups?
Interpretability	Can results from the measure be interpreted clinically and are they relevant?
Acceptability	Are the format of the instrument and the questions acceptable to the planned subjects?
Feasibility	Is it feasible to use this instrument in this setting with these subjects?

patients can then be asked which of these items are problems for them and how important these items are. This is the method commonly used in creating the patient-based outcome measures that are widely used, such as the SF-36 (see 'Generic instruments' below).

The purpose of the trial must be specified precisely in order to select an instrument that fits that purpose. In many studies, the rationale for selection of outcome measures is not clear. Careful consideration of content and relevance of a questionnaire to the purpose of the trial should be given. The instrument selected must be as relevant to the health problem and the proposed intervention as possible.

It is often recommended that one generic and one disease-specific instrument be used in a trial to increase the likelihood of appropriate assessment of outcomes.

Validity

The validity of a measure is an assessment of the extent to which it measures what it claims to measure. Validity is not a fixed property of a measure but is assessed in relation to a specific purpose and setting.⁵ It is, therefore, meaningless to refer to a validated outcome measure, as many reports do. Evidence of validity of an outcome measure in one situation does not mean that there will be adequate validity in another research setting.

This apparently simple property depends on a range of different types of evidence including how the content was chosen and its relationship to other variables. There are several different ways of assessing validity of a patient-based outcome measure. No single set of observations is likely to determine validity, so assessment of validity in relation to a specific trial is not straightforward.

CRITERION VALIDITY

Criterion validity is the correlation of a measure with an objective or 'gold standard' measure. As gold-standard measures rarely exist in assessment of quality of life, criterion validity is rarely relevant in patient-based outcome measures, and validity is judged by more indirect assessment of content and construct validity. It can be assessed when a shorter version of an instrument is used to predict the results of a full-length version.

FACE AND CONTENT VALIDITY

Face and content validity are among the most relevant issues for the use of patient-based outcome measures in clinical trials. They address whether items clearly address the intended subject matter and whether the range of aspects is adequately covered. They are explained by Guyatt et al.:⁶ 'Face validity examines whether an instrument appears to be measuring what it is intended to measure, and content validity examines the extent to which the domain of interest is comprehensively sampled by the items or questions in the instrument.' In other words, does the questionnaire look right and does it cover the right things? Face and content validity are mainly based on careful examination of

the content of the instrument and qualitative judgement rather than statistical criteria. Evidence of how the questionnaire was initially developed is useful. Questionnaires with good validity are constructed in phases with involvement of patients with experience of the particular health problem. The content of poor-validity questionnaires is chosen without consultation.

CONSTRUCT VALIDITY

Construct validity is also very relevant but is a quantitative assessment of the relationship of a construct to other variables. A construct is a theoretical idea about the domain to be measured. For example, patients with hearing disability should have poorer audiometric thresholds. Many patient-based outcome measures are multidimensional: they assess, for example, physical, psychological and social aspects of an illness. Those questions related to psychological aspects should correlate with each other much more than with questions assessing physical function. The internal structure of such instruments is established by construct validation, most commonly factor analysis. For a detailed discussion of assessment of construct validity, the reader is referred to Fitzpatrick et al.³

Reliability

Reliability is the reproducibility and internal consistency of an instrument. It assesses the extent to which the instrument is free from random error. It is essential to establish that any changes observed in a trial are due to the treatment and not to problems in the measuring instrument. As the random error increases, the size of the sample required to produce an accurate result increases.

REPRODUCIBILITY

Reproducibility is the degree to which an instrument gives the same results on repeated applications with the same subjects, and is also known as the test-retest reliability. An instrument should produce the same or very similar results on two or more administrations. This should be relatively straightforward to assess but care must be taken with the time interval between tests. Repeat measurements should be far enough apart in time for the subject to forget their earlier answers but not so far apart that their health status might have changed. This is commonly reported as a correlation coefficient. However, a correlation coefficient measures the strength of association between two measures and not the extent of agreement. Bland and Altman recommend plotting the scores from the two tests graphically, which is certainly a simpler method than a statistical comparison of repeated scores.⁷

INTERNAL CONSISTENCY

More than one question is usually used to measure one domain in a questionnaire because several related observations will produce a more reliable estimate than one. Individual questions in a domain should correlate highly

with each other and with the total score for questions in that domain. This is the internal consistency of a patient-based outcome measure. The correlation is often measured using Cronbach's alpha.^{8, 9} If all the questions in a domain are the same, Cronbach's alpha will be 1, while if there is no relationship Cronbach's alpha will be 0. If the correlation is too high, it is likely that the questions are addressing a very narrow aspect of an attribute and some items may be redundant, which then reduces the content validity. It is therefore suggested that Cronbach's alpha should be between 0.7 and 0.9.¹⁰

Responsiveness to change

Responsiveness is the ability of an instrument to detect clinically important change, even if that change is small.¹¹ This is sometimes called sensitivity to change but the term sensitivity has other, more general uses. It is particularly important in clinical trials when changes might correspond to therapeutic effects of treatment. An instrument can be both reliable and valid but not responsive to change.

There are several statistical methods of assessing responsiveness. The simplest method is to compare change scores for an instrument over time with changes in another variable or variables. The other variable preferably should be an objective indicator, such as a physiological measurement, or a clinician-based outcome measure.

An alternative method of assessing responsiveness is calculation of the effect size in a given clinical situation. This is the size of change in a measure between assessments, for example before and after treatment, compared with the variability of scores for that measure on one assessment. The effect size is defined as the mean change in a variable divided by the standard deviation of that variable.¹² The effect size can then be expressed in standardized units that allow comparisons with other outcome measures. It has been suggested that effect sizes can be used to assess the size of change in a study arm: an effect size of 0.2 is small, 0.5 is medium and 0.8 or greater is a large change.¹²

Other more complex statistical measures of responsiveness are described by Fitzpatrick et al.³

One of the main limitations on the responsiveness of an instrument is when the wording of questions does not allow reporting of very good or very poor health states: ceiling and floor effects. Subjects with initial high scores may not show any improvement following effective treatment and those with initial poor scores may not show any deterioration when their clinical situation deteriorates.

As with validity, evidence of responsiveness in one situation does not mean that there will be adequate responsiveness in another research setting.

Precision or sensitivity

The preferred term is precision as sensitivity has a number of other uses in research. Precision is the ability of the instrument to reflect true differences in health states. As clinical trials often aim to detect small differences between patient groups, precision is a desirable capability.

One of the main influences on the precision of an instrument is the format of the answers. The simplest answers are 'yes' or 'no' but they do not allow any assessment of difficulty or severity. The most commonly used graded response is a Likert scale, such as:

- very satisfied
- satisfied
- neither satisfied or dissatisfied
- dissatisfied
- very dissatisfied.

There is some evidence that using seven response categories rather than five increases precision, though this is rarely used.

The main alternative to a Likert scale is a visual analogue scale, where patients can mark any point on a line to represent their answer. Though this would appear to offer more precision, comparison studies of Likert scales and visual analogue scales have found no advantage of visual analogue scales. In addition, it appears that visual analogue scales are less acceptable to many patients, who find it difficult to translate their feelings into numbers. It is important to note that the questions should be worded as to potentially elicit all points along whichever scale is used (i.e. avoid wording that elicits only yes or no responses).

Patients' responses in patient-based outcome measures are generally converted into numerical values for statistical analysis. Most instruments use simple ordinal values, for example 1 to 5 (or 7) for a Likert scale, which are capable of less precision. However, the majority of published reports of health status measures use parametric statistical analysis that is appropriate for interval scales,¹³ though the interval between 1 and 2 (very satisfied and satisfied) may not be the same as between 4 and 5 (dissatisfied and very dissatisfied).

Some patient-based outcome measures use an explicitly derived weighting system for responses. The weights can be assigned by a panel of patients and health professionals, for example the Nottingham Health Profile,¹⁴ or be based on preference measurements obtained from a random sample of the general population, such as the Health Utilities Index.^{15, 16} The fact that weighted scoring systems appear to be much more exact with their scoring suggests that they might be more precise but this may well be deceptive. Several studies have compared weighted and ordinal scoring systems and have not shown any significant difference in precision between these two methods of scoring.

Ceiling and floor effects may influence scores of instruments. Some patient-based outcome measures do not include questions that would identify very poor levels of health, so all patients with poor health have similar scores and further deterioration will not be identified. Sometimes patients with minor health problems will be scored as having excellent health so treatment of their problem will not result in any improvement in score.

One other important factor in precision is bias. This can be reduced by general aspects of study design, such as making assessments blind to intervention. In many cases it is not possible to keep the patient blind to which treatment

arm of a trial he is in, so his judgement of outcomes may be influenced.

Patient-based outcome measures may therefore vary in how precisely their scores relate to underlying distributions of patients' health status. Researchers need to carefully consider factors that might influence precision. The degree of precision required of a patient-based outcome measure will depend on other aspects of trial design such as sample size and the expected differences between arms of the trial.

Interpretability

Can results from the measure be interpreted clinically and are they relevant? The interpretability of an instrument is concerned with how meaningful are the baseline scores or a change in scores. Clinically important changes in scores can be estimated by comparison with clinical or laboratory tests in the same patient group. Representative data are available from the general population for some widely used instruments such as the Health Utilities Index (see 'Utility measures' below) and the SF-36. The scores from the trial patients can be compared with the means and standard deviations for the general population. A significant change in the score in the trial could be set at one-and-a-half standard deviations from the population mean.¹⁰ Normative data can be key to interpreting both state and change questionnaires, as assumptions of no treatment resulting in no change in outcome can be erroneous. For example, in a study of hearing-aid interventions, those who were not given hearing aids exhibited participant acquiescence: a statistically significant increase in benefit without intervention.¹⁷

Acceptability

Clearly it is essential that the format of the instrument and the questions are acceptable to patients. An instrument should not cause distress to patients or be difficult to understand. In general, shorter instruments are more acceptable to patients. The instructions to patients should make it very clear that their answers will not influence their treatment. Acceptability is also important in order to obtain high response rates to questionnaires to make results of trials easier to interpret, more generalizable and less prone to bias due to non-response. When choosing an instrument, it is useful to know if the instrument has been used in similar settings before.

Ideally acceptability of an instrument should be directly tested at the design stage by seeking the views of patients. Subsequently, evidence of acceptability can be found in patient response rates.

Feasibility

The feasibility of an instrument is dependent on the time available for its completion and the staff available to help with its completion, either by interviewing patients or explaining the instrument to patients. The data collected have to be entered onto a computer and the time required

and ease of entering has to be considered. The measure must be short enough to be completed or administered in the intended setting and with the types of patients and families involved in the trial. This is one of the criteria of patient-based outcome measures that can usually be easily judged by investigators in the research setting. If in doubt, feasibility can be assessed by piloting the study methods.

TYPES OF PATIENT-BASED OUTCOME MEASURE

There are two basic types of patient-based outcome measure: generic and specific. Generic instruments access multidimensional health profiles, overall medical condition and personal function. Specific instruments focus on the problems found in individual diseases, disabilities and patient groups.¹¹ Within each of these categories there are different types of instruments (Table 42.2).

TABLE 42.2 Types of patient-based outcome measure

Category	Type	Example
Generic	Health profile	SF-36, Sickness Impact Profile, Nottingham Health Profile, Glasgow Benefit Inventory.
	Utility	Health Utilities Index (HUI), EQ-5D
Specific	Disease-specific	Dizziness Handicap Inventory (DHI)
	Site-specific	Sino-Nasal Outcome Test (SNOT-20)
	Dimension-specific	McGill Pain Questionnaire

GENERIC INSTRUMENTS

Generic instruments are designed to access a broad range of aspects of health status and the consequences of illness and therefore to be relevant to a wide range of patient groups and conditions. The advantage of generic instruments is that they can be used for a broad range of health problems and this enables comparisons across different groups of patients with diverse conditions. Because of their broad range of content and general applicability, such instruments have been used to assess the health of samples from the general population. Such data have been used to generate normative values across populations with which other groups of patients with specific health problems can be compared. Since generic instruments are used more often than specific instruments, there are usually more data available about their reliability and validity.

As generic questionnaires cover a broad range of aspects of health status, many items may be irrelevant to a particular condition. These items result in a wide range of scores that are not relevant to the condition being studied. As there are few questions relevant to a specific condition, the instrument may be insensitive to changes that might occur as a result of treatment for that condition.

Health profile

SF-36

The most commonly used health profile instrument is the Medical Outcome Study Short-Form 36-Item Health Survey (SF-36).^{18, 19} The SF-36 is a 36 item, self-completed questionnaire that measures health status in eight dimensions: physical functioning; role limitations due to physical problems; role limitations due to emotional problems; social functioning; mental health; energy and vitality; pain; and general perceptions of health. It can be completed by the patient in less than 10 minutes. Responses are summed to give a score for each dimension: physical component summary (PCS) and mental component summary (MCS).²⁰ It has been used in a wide variety of patient groups and conditions, including many otorhinolaryngological conditions (Table 42.3). Data from trial subjects can be compared with normative data for the population.²¹ Garratt et al.²² identified 408 papers that included aspects of development and evaluation of the SF-36 over a 10-year period (1990–99). It can also be used in a reduced 12-item version that is a subset of the original SF-36.²³ However, the larger instrument gives more reliable estimates of individual levels of health and is therefore the better choice of instrument in small studies.

Recently, Brazier et al.²⁴ derived from the SF-36 a preference-based single index measure, the SF-6D, to make the instrument more useful in evaluations of cost-effectiveness (see ‘Utility measures’ below). This weighted scoring model could potentially be applied to any SF-36 data set. However, initial validation studies demonstrated some inconsistencies and further assessment of the scoring model is required.²⁵

WORLD HEALTH ORGANIZATION DISABILITY ASSESSMENT SCHEDULE 2.0

The World Health Organization’s Disability Assessment Schedule 2.0 (WHO-DAS 2) was designed to measure domains coincident with the definitions of the WHO’s International Classification of Functioning (ICF), a replacement for the stigmatized labels of impairment, disability and handicap. It is very similar to the SF-36 except that its six domains – cognition, mobility, self-care, interaction, life activities (e.g. leisure and work limitations) and ‘social participation’ (e.g. emotional and social

burden) – fit the ICF framework. To date, it has only been applied in otorhinolaryngology with regard to hearing aids, where it was found to be sensitive to intervention, but the effect size was modest compared to hearing-specific questionnaires.¹⁷

SICKNESS IMPACT PROFILE

The Sickness Impact Profile (SIP) is a general health-status questionnaire comprising 136 questions answered as either ‘yes’ or ‘no’.³⁴ They are grouped into 12 categories: walking; body care and movement; mobility; social interaction; alertness behaviour; emotional behaviour; communication; sleep and rest; eating; home management; recreational activities; and work. Each item is weighted, and the scores of all answered questions are combined. There are 12 category scores, 2 summary scores (physical and psychosocial) and a total score. The scores are standardized and range from 0 to 100 points, with 100 indicating the poorest function. The test-retest reliability and internal consistency are high and it has good content and construct validity.³⁴ It is, however, a long questionnaire and is usually administered by interview. Its acceptability and feasibility in a trial must be carefully considered.

NOTTINGHAM HEALTH PROFILE

The Nottingham Health Profile is a generic, self-administered questionnaire designed to measure perceived physical, social and emotional health problems.^{14, 35} An initial pool of statements was collected from patients at interview, and from this pool 38 items were chosen relating to six dimensions: physical mobility, pain, social isolation, emotional reaction, energy and sleep. The scores can be compared with the average scores in a population matched for gender and age.

GLASGOW BENEFIT INVENTORY

As other generic instruments are often insensitive to the non-acute disorders generally seen in an ORL clinic, the Glasgow Benefit Inventory (GBI) was developed for use in patients with otolaryngological conditions.³⁶ The GBI is a post-intervention questionnaire that assesses the effects of interventions on the health status of patients, rather than the actual health status. The GBI has 18 items in three domains: psychological, social and physical well-being. Rather than attempt to assess the difference between before and after treatment measures, it asks directly about the change in health status resulting from treatment. It is likely, therefore, to be more sensitive to such change than two separate instruments before and after intervention. In addition, compliance will be significantly higher because patients are only required to complete one questionnaire. The response to each question is based on a five-point Likert scale, for example: ‘Since your *operation/intervention*, have you found it easier or harder to deal with company?’ The words in italics (*operation/intervention*) in each question are replaced by words appropriate to the intervention of interest. Responses are scored using

a weighted scale from a population sample to give a score between -100 and +100.

The GBI has been used to assess the benefit experienced by patients following various treatments (Table 42.4). Details of the questionnaire and its use can be found at www.ihr.gla.ac.uk. Hendry et al.³⁷ wrote a comprehensive review of the use of the GBI.

Utility measures

Multi-attribute utility measures access a broad range of aspects of health status, like other generic instruments, but have a particular form of numerical weighting or valuation of health states. Utility measures have been developed from economics and decision theory in order to provide an estimate of individual patients' overall preferences for different health states. They are scored as a single number between 1 (full health) and 0 (death). The weighted scoring method is based on preference measurements obtained from samples of a general population. They are asked to value different aspects of health as defined by the instrument using one of a number of valuation techniques, most commonly standard gamble, time trade-off and visual analogue scales (see Brazier et al.⁴⁶ for explanation).

Utility scores reflect the health status and value of that health status to the patient. As utility measures are scored as a single value, they do not define individual dimensions of health that contribute to the individual's overall sense of well-being. They are relatively insensitive to small but relevant changes in health and are therefore more suited to studies of large populations.

There are several health utility measures that have been widely used. Brazier et al.⁴⁶ carried out an extensive review of these and recommended the Health Utilities Index (HUI) and the EuroQol (EQ-5D) as the instruments of choice.

HEALTH UTILITIES INDEX

The Health Utilities Index (HUI-I) evolved from studies in neonatal intensive care.⁴⁷ A second version (HUI-II) was developed to assess outcomes in long-term survivors of childhood cancer but is suitable for use in a wider range of children.¹⁶ Though it is claimed to be a generic instrument,

its content is explicitly aimed at children with questions specifically aimed at developmental age.

The HUI-II was revised to make it more relevant to an adult population. The HUI-III assesses eight aspects of health status: vision, hearing, speech, ambulation, dexterity, emotion, cognition, self-care and pain.⁴⁸ It has 15 questions with 4 to 6 available responses for each and is easy for patients to complete. The HUI-III has been used in a wide variety of clinical studies and has been shown to be reliable and responsive.⁴⁹ It is one of the few generic patient-based outcome measures that specifically assesses hearing and speech and is therefore potentially useful in many areas of otolaryngology. Normative data have been collected from large populations and from these data weighted scoring scales have been devised.¹⁶ It has been used in a cost-utility study of cochlear implants⁵⁰ and in the UK cochlear implant study.⁵¹

EQ-5D

The EQ-5D is a self-completed questionnaire with five dimensions: mobility, self-care, usual activities, pain/discomfort and anxiety/depression.⁵² It is easy to complete and is very acceptable to patients. Responses can be scored using a weighted scale from a large general population sample.⁵³ It is very brief with only five questions and three levels of response for each.⁵⁴ It was compared with the Euroqol and the SF-36 in a survey of 1980 adults and the Euroqol was found to be less sensitive.⁵⁴ However, it was originally intended to complement other forms of health-related quality of life measures. It has been widely used and its test-retest reliability is good.⁵⁵

SPECIFIC INSTRUMENTS

Disease- or condition-specific instruments

The aim of these instruments is to provide the patient's perception of the problems related to a specific disease or condition. It should be remembered that disease may have a broad impact on the patient's life. To make these instruments comprehensive, a detailed survey of patients suffering from the condition should be conducted when developing the instrument. They may also not detect problems associated with a disease and its treatment that have not been anticipated by the developers if patients have not been involved in the planning. As all of the questions are developed specifically to assess a particular health problem, the content should be very relevant for use in studies of that condition: high validity. They are more likely to detect changes that occur in that particular condition as there should be few if any irrelevant questions: high responsiveness. They are also more acceptable to patients as the relevance of the questions to their condition is obvious so completion rates should be high.

The major disadvantage of disease-specific instruments is that they do not allow comparison to be made with other patient groups with other diseases or conditions.

Such comparisons require generic instruments designed for use with any health problem, and for this reason it is often useful to combine a specific instrument with a generic one.

VERTIGO

The Dizziness Handicap Inventory (DHI) is a 25-item questionnaire designed to measure the self-perceived disability and handicap caused by dizziness or imbalance.⁵⁶ They reported good internal consistency and test-retest repeatability. The questions were grouped in three domains of functional, emotional and physical aspects of dizziness with three possible answers to each question: yes, sometimes and no. The questions were selected from an initial bank of 37 questions chosen from the case histories of patients. They take a clinical perspective of disability and handicap in daily activities and therefore content validity should be carefully inspected before choosing this instrument for use in a trial. It is preferable to have more input from patients in the selection of items to include in a questionnaire (see 'Face and content validity' above). This instrument has been widely used in studies of imbalance in general. It has been shown to have a moderate correlation with balance performance measures.⁵⁷

The Vertigo Handicap Questionnaire (VHQ) was developed from patients' accounts of the problems that they experienced with vertigo.⁵⁸ It has 25 questions about restriction of physical and social activities and emotional distress, each scored on a 5-point Likert scale. It has good reliability and validity but has not been widely used.

HEARING

There are many instruments that have been developed for use in audiology. Assessing hearing disability has one major difference from assessing most other disabilities in otolaryngology – there is a gold standard, at least for audibility – pure-tone audiometry. One of the most widely used measures is the Hearing Handicap Inventory for the Elderly (HHIE).⁵⁹ This instrument has been shown to have good face and content validity.⁶⁰ Further, it has good sensitivity and specificity when used properly in tandem with an audioscope.⁶¹ A more in-depth instrument is the Speech, Spatial and Qualities of Hearing questionnaire (SSQ),⁶² which asks situation-specific questions on understanding speech, locating sound sources, and various qualities of sounds (e.g. detection, naturalness), resulting in an overall score and the three subscales of its title. It has shown good validity and reliability, and has been translated into many languages. Details of the SSQ and its use can be found at www.ihr.gla.ac.uk.

While there are reliable tools for measuring hearing, assessment of the efficacy of hearing aid provision and comparison of benefits from different prescription strategies are heavily reliant on patient-based outcome measures. The HHIE has been used for this purpose⁶³ but it has been shown to have poor precision when changes in the HHIE were compared with changes in the Speech Intelligibility Index when using a hearing aid.⁶⁴ This is probably because the HHIE assesses predominantly the emotional

and psychological response to hearing impairment. There are many self-report hearing-aid tools available, to such an extent that a good guide for how to choose one already exists.⁶⁵ Two of the more popular hearing-aid questionnaires that deserve additional mention are the Glasgow Hearing Aid Benefit Profile (GHABP)⁶⁶ and the Client-Oriented Scale of Improvement (COSI).⁶⁷ The GHABP was developed as a measure of hearing disability and the benefit obtained from use of a hearing aid.⁶⁶ It assesses unaided disability, handicap, benefit from a hearing aid, residual disability and patient satisfaction in eight listening situations – four specified and up to four chosen by the patient. It has been used as one of the primary outcome measures in the NHS programme of modernizing hearing-aid services in England. Details of the questionnaire and its use can be found at www.ihr.gla.ac.uk. The COSI asks the patient to provide (up to) five specific situations that are important to them. Communication ease is then rated before and after fitting (or change in fitting) for those specific situations, and benefit derived from the pre/post-fitting difference in ease. The 'open-set' approach of the COSI is notable in avoiding the assumption of experience with the hypothetical situations proposed by many questionnaires.

OTITIS MEDIA

The Otitis Media-6 (OM6) was developed for use in children with recurrent acute otitis media and otitis media with effusion.⁶⁸ Six domains (physical suffering, hearing loss, speech impairment, emotional distress, activity limitation, caregiver concerns) are each addressed by a single question. Test-retest repeatability was high, and responsiveness was demonstrated by significant change in scores after surgery for ventilation tube insertion.⁶⁹ The criterion validity has been questioned, however, in that it does not correlate well with other markers of disease severity, such as audiometry and severity of symptoms of recurrent acute otitis media.⁷⁰ Kubba also suggested that the instrument lacks precision as it does not differentiate between children with otitis media and others with sore throats.⁷⁰

CANCER

The European Organization for Research and Treatment of Cancer Quality of Life Study Group developed the EORTC QLQ-C30 as an instrument of 30 items for use in international trials in cancer.⁷¹ Further modules have been developed which can be added to the core instrument to provide assessment of specific cancers, for example head and neck cancer.⁷² This allows collection of data for comparison across cancer groups and additional data that are particularly relevant to specific cancers. The questionnaire has been translated into more than 60 languages and is widely used around Europe and the rest of the world.⁷³

Site-specific instruments

These instruments contain items that are particularly relevant to patients having treatment for a specific region of the body and should be sensitive to changes experienced

by patients following treatment in that region. They are particularly useful in otolaryngology and have the advantage that patient groups are not limited to a specific disease classification. They thus allow comparison of patients with similar symptoms but different pathology. Because they have a narrow focus, they are unlikely to detect any change in broader aspects of health or quality of life following intervention.

SINONASAL DISEASE

Many patient-based outcome measures have been designed for use in sinonasal disease. The 20-item Sino-Nasal Outcome Test (SNOT-20)⁷⁴ is a modification of the previously used 31-item Rhinosinusitis Outcome Measure (RSOM-31).²⁸ The 20 questions refer to specific sinonasal symptoms and some general health questions. It has good internal consistency (Cronbach's alpha 0.9), and showed good responsiveness to change. Face and content validity seemed good and the construct validity was high when compared with clinical assessment of disease. Test-retest scores were highly correlated ($r=0.9$) though this measures the association between tests rather than repeatability (see 'Reproducibility' above). Piccirillo et al.⁷⁴ report the SNOT-20 to be a valid outcome measure in their particular research setting. The questionnaire is easily completed by the patient and acceptability is high. It has since been modified with the addition of two further questions (the SNOT-22);⁷⁵ its validity and ease of use were confirmed in a study of more than 2000 patients.

VOICE

There is no generally accepted objective test to serve as a 'gold standard' for the assessment of voice disorders. Various questionnaires have been developed for evaluation of the consequences of dysphonia. The Voice Handicap Index (VHI) was designed to assess the self-perceived effect on quality of life of voice disorders.⁷⁶ It is a 30-item questionnaire divided into 3 subscales: functional handicap, emotional handicap and physical handicap. The questions use a 5-point Likert scale. It has been used to assess the impact of a number of voice disorders, including vocal cord polyps, cord palsy, spasmodic dysphonia and functional disorders. Its construct validity has been confirmed by comparing its subscales with appropriate subscales of the SF-36 in assessment of the health-related quality of life in patients after treatment for laryngeal cancer.³¹ A shortened version, the Voice Handicap Index-10, has been proposed as an equally effective alternative.⁷⁷ Carding et al.⁷⁸ wrote a review of measures of voice outcomes.

Dimension-specific instruments

These instruments assess one specific aspect of health status. The most commonly assessed dimension is psychological well-being. Another common dimension, more relevant to otolaryngology, is pain. The McGill Pain Questionnaire is one of the most widely used measures of pain severity for both clinical and research purposes.⁷⁹ It comprises 20 subclasses of pain descriptors that

provide pain severity scores across sensory–discriminative, motivational–affective and cognitive–evaluative dimensions. It has been found to have good short-term repeatability in chronic pain conditions, and it discriminates well between different types of pain syndromes. A short form of the McGill Pain Questionnaire has been developed.⁸⁰ It is highly correlated with the original longer version and has comparable sensitivity. It may be a useful instrument in situations in which the standard questionnaire takes too long to administer.

The advantage of dimension-specific instruments is that they provide a more detailed assessment in the area of concern than is possible in more general instruments. They are perhaps most useful in a study where they are used in combination with another instrument (e.g. van Agthoven).²⁶

HOW TO CHOOSE A PATIENT-BASED OUTCOME MEASURE

The choice of patient-based outcome measure depends on the purpose of the study. To assess the effects on health-related quality of life of a disease or condition, a generic instrument is required. Specific instruments are of little value as they do not allow comparison with other conditions. A specific instrument may provide additional information by assessing the severity of the disease if no objective measure is available, for example in tinnitus. Comparison of the scores from the specific instrument with the generic instrument may be valuable.

If the aim of the study is to assess the efficacy of treatment, it is usually recommended that two instruments be combined, a generic and a specific instrument. The two different measures are likely to produce complementary evidence. A disease-specific measure will be more responsive to the main effects of intervention, and therefore produce the evidence most relevant to the clinician. A generic measure may allow comparisons across interventions and disease groups, but is likely to be relatively insensitive to the effects of the intervention. It is possible, however, that the additional burden on the patient may reduce overall compliance, especially if there is overlap between questions in the two instruments.

WHICH GENERIC INSTRUMENT?

Acceptability to the patient and feasibility of completing the questionnaires are obviously important. The time required to complete the commonly used instruments varies. The Health Utilities Index (HUI) Mark II takes 3 minutes, the SF-36 10 minutes and the Sickness Impact Profile 20 minutes.⁸¹

Appropriateness depends on the study. Utility measures are, in general, only appropriate for studies with large numbers of subjects. Small studies would probably be better to choose a generic health status questionnaire. Some generic instruments have been shown to be better than others in assessing patients with particular problems. Edelman et al.⁸¹ reported that the HUI was better used for

evaluating relatively healthy populations because of some floor effects, while the SIP was better for more severely ill populations as their study patients were grouped at the healthy end of the scale. Other authors have similarly reported that the SIP has ceiling effects.^{82–84}

A careful evaluation of reports of the use of these instruments in similar patient groups and study settings should be carried out before making a final choice. In the absence of this, the SF-36 appears to be the safest choice. The HUI Mark III is suitable for large studies and has the advantage for otolaryngology research of including items about hearing and speech.

KEY POINTS

- Patient-reported outcome measures assess the patient's subjective experience of illness and of treatment.
- Generic instruments assess a broad range of aspects of health status, enabling comparisons across different patient groups with diverse conditions, but may not be sensitive to particular illnesses or treatments.
- Specific instruments are more sensitive to the effects of specific diseases or conditions, but do not allow comparison to be made with other patient groups with other diseases or conditions.
- The best assessment is usually achieved by using both a generic and a specific outcome measure.

THE FUTURE

Development of a valid and acceptable patient-based outcome measure takes a lot of time and effort. Large numbers of subjects are needed as development requires several stages. Patient involvement in the selection of items is essential. There have been many patient-based outcome measures that have been reported once and never used again. On the other hand, the currently available and widely used patient-based outcome measures are not ideal. We need better ones.

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: evidence-based medicine and EBM.

INTRODUCTION

Professor David Sackett’s definition of evidence-based medical (EBM) practice still holds true: ‘the conscientious, explicit and judicious use of current best evidence in making decisions about the care of individual patients’.¹ The principles are now considered to be ‘core’ in professional practice and praxis, across the four main phases of training, in the UK (Figure 43.1). Furthermore, endorsement by the World Federation of Medical Education and the World Health Organization secures it as an international characteristic of the medical profession, and therefore one that should be promoted globally.

EBM may be described as a patient-centred cycle with three linked phases: the clinical phase, the search phase and the evidence review phase (Figure 43.2). Taken together, this becomes a framework for teaching, learning and curriculum delivery in the continuum of professional training.

BEGIN WITH THE PATIENT

In addition to being at the heart of the ethos of care, the patient has a central role in medical education.

Figure 43.1 Evidence-based medicine is core to all four professional phases.

Figure 43.2 Patient-centred evidence-based cycle.

The patient may be actual, or described as a theoretical case, or the two may be used in combination. As actual cases for teaching and learning, real patients are frequently ‘opportunistic’, and therefore theoretical cases are normally constructed by clinicians as a vehicle for teaching and learning. The topics for the cases are chosen because they are common or frequent or, if rare, because they are important in understanding the fundamental principles or concepts of a particular condition. One such example is the autoimmune condition known as Wegener’s disease. A portfolio of cases in otolaryngology will include examples from the following areas:

- plastic surgery
- oral and maxillofacial surgery

- general upper GI surgery
- neurosurgery
- paediatric surgery
- cardiothoracic surgery
- ophthalmology
- accident and emergency medicine.

Well-structured cases may be prepared using a systematic framework (Figure 43.3), which is intended to encourage students and trainees to explore the bio-medical spectrum of relevance to that particular condition.

The cases themselves normally relate to the learning outcomes that are relevant and appropriate to the particular professional stage (Table 43.1). In the UK, these may be sourced from Tomorrow’s Doctors, The Foundation Programme,³ and the college documentation.⁴

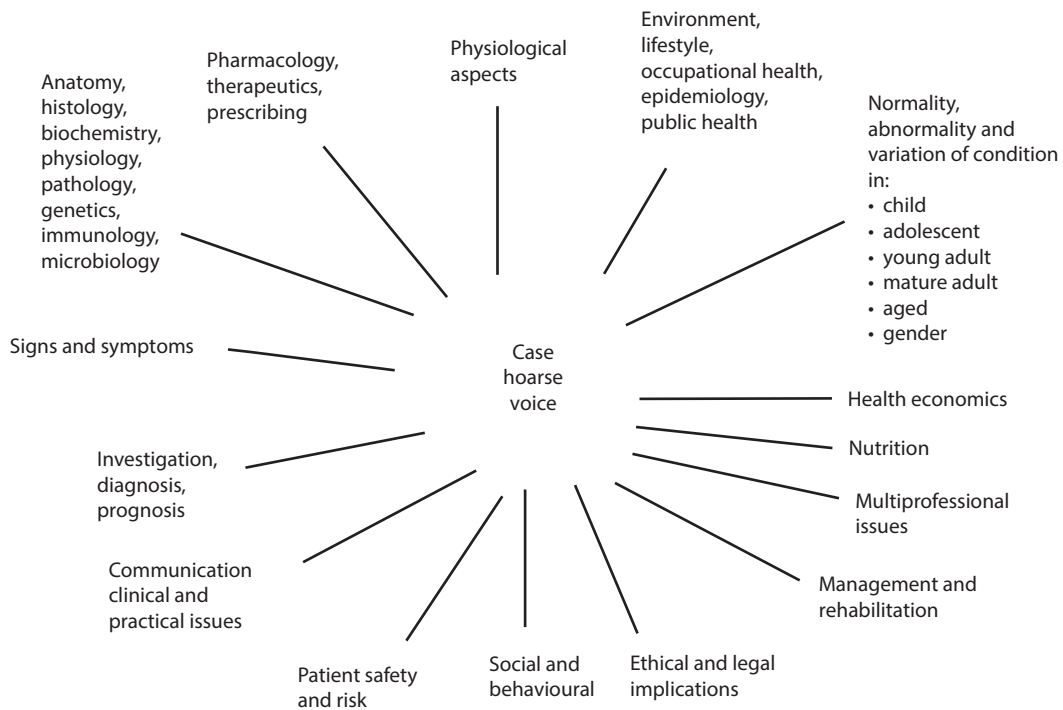

Figure 43.3 Factors to consider in writing and analyzing a case.

Core case from	Outcomes relevant to the stage of the student		
	Undergraduate	Foundation	Specialist training
Plastic surgery			
Oral and maxillofacial surgery			
General upper GI surgery			
Neurosurgery			
Paediatric surgery			
Cardiothoracic surgery			
Ophthalmology			
Accident and emergency medicine			

Outcomes are entered by the teacher in the relevant column.

Whilst it is suggested that EBM is used routinely for keeping up to date, clinical supervisors and other teachers should offer their students or trainees selected cases as part of the training process. The supervisor should give one case at the beginning of the week, with the expectation of it being presented as the basis for discussion with the supervisor towards the end of the week, together with a report summarizing the key points and a reasoned evidence-based appraisal of the critical points of the case. This might be included in the student's reflective portfolio. There may be an advantage for the student or trainee to work with a partner (peer-assisted learning) or in a small group (case-based learning). The case itself is part of the normal spectrum of activities in the student's or trainee's normal experience of workplace learning and assessment, and may be linked to a DOPS, MiniCex or video-based discussion. The cases should be central to the curriculum, should form a structured framework for the student's or trainee's self-directed learning, and should be part of the normal provision of teaching and learning activities (blended learning). The case presentation at the end of the week confirms and tests the professional judgement of the student or trainee, and provides an opportunity for extending their understanding.

The student or trainee will undertake the following steps to prepare and present the case thoroughly:

1. Appraise the patient and the condition
2. Identify and ask the questions, in an appropriate way
3. Establish the evidence
4. Critique the evidence
5. Present the conclusions and discuss the case.

ASK THE RIGHT QUESTIONS

At all stages, the trainee should think ahead, and form a judgement as to how best to proceed, and this normally requires asking two categories of questions:

1. What do I need to know to understand the case?
2. What do I need to know to form a clinical judgement?

The nature and quality of the questions posed will vary according to the age and stage of the student or trainee. Clearly an undergraduate student will be expected to read more widely about the basic and clinical science related to the case. In addition, they will also require more guidance about appropriate communication skills, performing the clinical and practical skills, and interpretation of tests. Trainees with more experience will consolidate their knowledge and extend their understanding of diagnosis and management of the condition.

Questions related to the 'best' clinical judgement require greater thought and refinement, and a higher level of skill with respect to searching the literature and interpreting the available evidence. A suitable search

strategy should take into consideration the following aspects:

- an overall structure for the search
- anticipation of the nature of papers found in the search
- forethought about conducting the search itself
- a strategy for reading the literature.

STRUCTURING THE SEARCH

PICO is the acronym commonly used as a strategy when searching the bibliographic databases:

- P = Patient/Population:** Who was the subject of the investigation?
- I = Intervention:** What was done?
- C = Comparison:** What are the alternatives and appropriate options?
- O = Outcome:** What are you trying to accomplish or achieve with this case?

The search structure should seek the best evidence for diagnosis, therapy, prognosis, and harm or aetiology, and at this stage it is also useful to anticipate the nature of the papers present in the literature. The most common categories are:

- **Cases.** Reports of individual patients, groups of patients or cohort studies, which may be retrospective or prospective, are highly valid and authentic, but have low reliability.
- **Randomized controlled clinical trial.** An RCT is a carefully structured prospective study, in which bias and influence have been carefully controlled. These are highly specific.
- **Systematic reviews and synopses.** The author has undertaken an extensive literature search and review of a particular clinical topic, and has prepared our systematic analysis of the quality of the evidence. Such papers are beneficial as they save the individual a great deal of time, but the assumption is that the review is up to date. Therefore it is wise to search for the most recent evidence.
- **Meta-analysis.** This combines the results of valid studies in that field, and uses statistical analysis to combine the results in a way that expresses the conclusions as if the collected reports were a single study.
- **Qualitative or humanistic enquiries.** These explore questions and issues related to psycho-social and attitudinal aspects that cannot be measured in a prospective randomized controlled trial.

CONDUCTING THE SEARCH

The search should be organized and planned⁵ by focusing on the purpose of the search, and identifying the characteristics that are sought ([Table 43.2](#)).

TABLE 43.2 The purpose of the search

Focus	Outcomes sought
Goal	Establish the recommendations
Perspective	Establish the clinical evidence
Coverage	Selective and relevant
Organization	That the scientific style is robust
Audience	What type of clinician?

TABLE 43.3 Establishing alternative terms

Question component	Subject or MeSH term	Synonyms
Patient	Patient Inpatient Outpatient	Person Case
Cause		Reasons
Sudden hearing loss (SHL)	Hearing loss, sudden	Deafness

A search of the literature is essentially a text-matching exercise between the search question and the text in the databases. The first step is to clarify one key question,⁶ for example, ‘What is the cause of sudden hearing loss?’.

Due to the complexity and ambiguity of the English language, it is necessary to establish alternative words (refer to a thesaurus), keywords or medical subject headings (MeSH terms) used by other authors. These are identified and written down at the start of the search, and may be augmented with experience from the search (Table 43.3).

The search terms will be used, with truncations (if appropriate) and use ‘variant spelling’ if possible, singly and then in combination, using the Boolean operational commands, AND, OR, NOT and AND & OR.

SETTING THE SCOPE

It is desirable to establish the scope of the search by establishing the inclusion and exclusion criteria of the paper. Examples of inclusion criteria are:

- meta-analyses
- systematic reviews of randomized trials
- physiological studies
- English language only
- time-frame (last 5 years).

Examples of exclusion criteria are:

- studies that do not cover clinical evidence
- studies published prior to the 5-year cut-off, except key papers or definitive studies.

GATHERING THE EVIDENCE

Searching the literature in otolaryngology may be relatively straightforward. The options are to conduct an

electronic search of NICE, the Cochrane Collaboration (Embase) and databases such as Medline (PubMed), and to complete a ‘hand-search’ of specific journals. Google Scholar may be an unattractive alternative because it can throw up an enormous number of results, though there may be benefits if it highlights ‘grey literature’, such as book reviews and web pages. Reference manager software, such as Mendeley or Zotero, is an aid in managing the papers found in the literature.

A pathway for completing the exercise is given in Figure 43.4.⁷

CRITICAL EVALUATION

A critical evaluation of the significant papers is necessary at this stage. The first step is to review the type of paper. Categories are as follows:

- randomized controlled trial (RCT)
- systematic review of RCTs
- methods that are not RCTs
- systematic review of papers that are not RCTs
- basic science paper (physiology, microbiology, genetics)
- other (clinical observation or case study, synopsis, guideline).

A critique of each paper entails a systematic evaluation of the following points:

- The title: is it relevant?
- The method: is it valid?
- The results: what are they?
- The conclusions: in what way are they useful?

The summary in Table 43.4 is an example of a useful, but not definitive, framework for the process.

Evidence for each phase of the case report should be set out and considered using questions that are appropriate for the information available. The framework in Table 43.5 might be used as an example.

The papers may also be categorized using the PICO approach. Dividing the papers into these categories allows a systematic analysis of the evidence about diagnosis, therapy, prognosis and risk of harm. It is necessary to establish that the validity and significance of the evidence has been demonstrated in the paper. If it has not, then the necessary data may be extracted and analyzed by an appropriate statistical instrument to establish the level of confidence.

PREPARING THE EVIDENCE

The final case discussion should provide an overview of each stage in the process, setting out the evidence used in determining the conclusions. The correct answer is not arriving at the diagnosis, but understanding the basis on which the clinical judgement is made, and declaring the evidence (Table 43.6).

Management options				
Care and compliance				

CONCLUSION

The exponential increase in scientific papers, and expansion of 'what is known' makes it almost impossible not to make clinical judgements without some reference to the evidence in the literature. It may be argued that the expansion of the literature has surpassed our capacity to maintain a comprehensive review of all the information available. However, as the flexibility of modern information technology allows convenient access to a wide range of resource materials, this is less problematic now than in times past. Indeed, web-based information is a commonly used platform for learning and keeping up to date. Therefore, acquiring a rational and systematic competence in finding and using valid, reliable and appropriate

information is a fundamental part of clinical praxis. However, this is not to dismiss the values of professional judgement based on experience and often 'gut reaction'. Indeed, it has been acknowledged that the capability of forming a professional judgement is a greater order of magnitude than mere technical competence.⁹ Yet it is certainly the case that, in this digital age, evidence in the literature does provide a significant input into informing the *best* clinical judgement.

KEY POINTS

- EBM is fundamental to clinical practice, globally.
- It has a series of skills that require mastery
- It contributes to an informed clinical judgement.

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: critical appraisal, evidence-based care, evidence-based healthcare, systematic reviews. As this chapter is essentially a 'How I do it,' there was no formal strategy used.

WHY DO WE NEED CRITICAL APPRAISAL?

Evidence-based practice (EBP) begins and ends with patients. We can harm patients by giving inaccurate information about prognosis, make assumptions about diagnostic test results that are false, give therapy that is ineffective or harmful, or fail to give effective therapy. The only way to prevent this happening is to ensure that we have the most up-to-date knowledge available so that we can share that information with patients.

There were 26 randomized control trials regarding otitis media alone published in the last two years. Therefore, even with maintaining a diligent approach to reading journals during continuing professional development (CPD) time and attending postgraduate seminars, it is becoming increasingly difficult for clinicians to keep up to date with everything that is important affecting their patients. EBP starts with the clinician accepting that there is uncertainty about what we do and that sometimes (when that uncertainty occurs frequently or when it is important) we should search for the latest knowledge. Pragmatically, what we do at present is ask colleagues. The inherent flaw here is the inability to assess the quality of the evidence presented to you by your colleague. Does this matter? If the question is important or frequent then yes, it does matter.

Research evidence can be approached from two angles. The first is the clinician who wants to undertake research

and the second is the clinician who wants an answer to a clinical question. The latter wants to know what to believe. Is it the randomized trial, or the case series or case-control trial? What papers should they look for to answer their question?

Levels of evidence have been proposed to help clinicians identify trials most likely to yield the 'truth' and associated with these are grades of recommendation. For questions about the efficacy of a therapy, these state that a systematic review of homogenous trials is likely to be the most believable evidence.

The process of EBP therefore requires that one searches for the best evidence. For therapeutic decisions, this is usually going to be a systematic review, where data from relevant randomized control trials on the topic of interest have been identified and screened according to pre-defined inclusion criteria. Data may potentially be combined together in the form of a meta-analysis. Systematic reviews should include the data from all up-to-date trials with this completeness being one of the significant advantages of this method of review. Yet, it is not an approach to be underestimated. A search for papers to be included in the review might often generate a list of more than a thousand papers, with all the titles and abstracts being read to select relevant articles. The full text of these relevant articles must then be obtained (in itself a time-consuming and expensive task) and read to ensure they meet the selection criteria. The data then have to be independently abstracted from the selected articles. Undertaking a valid,

well carried out systematic review is no easy task, but is essential for clinicians to determine the latest evidence.

Once a trial or trials have been found that seems to answer your question, you have to check three things. Is the study valid? What are the results? Can these be applied to my patients?

The need to check for validity seems, on the surface, to be bizarre. Surely this is what journals should be doing. That assumption is correct but in reality the job of a journal is primarily to make a profit. Therefore you will find articles with flawed trials in even the most highly cited journals.¹

Journals started as the diaries of researchers. These were then passed around colleagues so that the information could be shared. The development of trials and the assessment of bias are subsequent to that descriptive era. What we are now faced with are seemingly complex long papers with obscure statistical analyses. The scenario is no different to a medical student facing their first anatomy class. By reading around the subject and by practice, will be able to quickly identify key anatomical structures. The same is true of reading scientific articles. You can learn certain aspects of trial design very quickly to be able to assess whether an appropriate design was used for a certain research question. The journal *Evidence-Based Medicine* critically appraises the literature from over 100 journals. However, it only includes a few that are likely to change the way you think about a problem or change the way you practise. Sadly for the other articles, we must appraise them ourselves.

The need to assess the methodology of individual trials is extremely important. In large systematic reviews of the same clinical outcome with the same therapy, researchers have compared the results of those trials that were randomized and those that were not randomized. There are some large differences in certain studies that are more than one would expect by chance. One cannot always say that randomized trials show less effect than non-randomized trials.²

However, it is not enough to accept that a trial is believable at face value. There is now overwhelming evidence that trial methodology has a major influence on the results of therapeutic trials.^{2, 3} Concealment of randomization, masking and randomization itself are three main components of randomized trial design. The numbers of patients involved in the study and their follow-up are the other key features.

Inadequate concealment of randomization may exaggerate the efficacy of a treatment compared to trials where adequate concealment has occurred. The size of this effect may be considerable, over 40% in some studies although it should be noted that it is not possible to quantify the size or direction of such bias on effect size from study to study.^{4, 5} Surprisingly, perhaps of lesser importance is blinding (masking) – the doctor looking after the patient, or the patient themselves, knowing whether they are giving (being given) the experimental or placebo treatment. If there is no blinding, the results may exaggerate the effectiveness of the treatment by 15%. If less than 80% of patients are followed up, one cannot tell what is happening and the results become meaningless.

To assess a study there are checklists some of which have now been incorporated into computer programmes such as that found at the Centre for Evidence-Based Medicine website (www.cebm.net) that enable health professionals to appraise the quality of the evidence for themselves.

Systematic reviews therefore need to assess the individual validity of the trials that are included. If they do not assess whether there was concealed randomization, for example, then you, the reader, may be given incorrect information. The assessment of methodological quality – now better termed risk of bias – of a randomized controlled trial may be carried out using a variety of available systems. The Cochrane Collaboration has recently updated their tool for assessing risk of bias in randomized trials.⁶ Furthermore, systematic reviews should be conducted using the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines, an evidence-based minimum set of items for reporting in systematic reviews and meta-analyses.⁷ The PRISMA guidelines have replaced the previously used Quorum statement.⁸

For systematic reviews, effective transparent searches and defined inclusion and exclusion criteria are important. The homogeneity (similarity) of the studies is also critical in determining whether a meta-analysis of the data is appropriate. The meta-analysis (combination of the results of the individual trials) is usually only appropriate when there is clinical and methodological homogeneity (that is, the methods and clinical outcomes and starting points are similar). In addition, the results must be put into context of present formats of care.

The need to understand how trials may come to the ‘wrong’ conclusion is as important as understating the treatment itself. Clearly, all this may be daunting to a busy clinician so there are sensible short cuts. Always start by looking at evidence that has already been appraised such as that in *Evidence-Based Medicine* and *Clinical Evidence*. The essential part of effective clinical practice is to continue to ask questions.

We need to make sure that what we do is based on the soundest evidence possible. If the only evidence is experiential and anecdotal then that is perfectly satisfactory. However, if there is a systematic review of randomized control trials that all point to an alternative treatment being more effective then that should only be ignored at your patients’ peril.

TIPS FOR PRACTISING EVIDENCE-BASED HEALTHCARE

Tip 1: Ask questions

Try making one question per clinic. Select one question because:

- There is likely to be an answer.
- The question has arisen more than once or is important:
 - record briefly the problem, for example, ‘Sudden onset hearing loss’

- write down the question, for example, ‘are steroids an effective treatment (efficacy and morbidity)?’
- put time aside each week to research the answer to the question.

Tip 2: Searching

- Search one question regularly: every two weeks, every month or every quarter!
- Conduct your search in a logical order:
 - clinical evidence
 - journal EBM
 - Cochrane
 - PubMed.

Keeping up to date with literature searches can be facilitated by developing highly specific search strategies (for example using PubMed). These searches are set up to deliver regular alerts directly via email. Any new articles relevant to the topic of interest will then be sent through on a regular basis without the need to specifically perform a search each time.

Often you will find too few articles, or that the articles you do find are not in your library or will take a long time to obtain. Sometimes you will find too many articles and a systematic review is needed. Unless you have time and the question is desperately important, pass and move on to the next question – let someone else answer this one!

Appraise only the article(s) that answer your question, have the highest level of evidence and are readily available.

Tip 3: Appraisal

- Look for letters about the article in subsequent issues of the journal.
- Appraise with others until confident.
- Appraise using worksheets or using software, for example CATmaker.
- Mark (highlight) on the printed article where you found the important data.
- Get someone else to check it for you.
- Appraise the article as part of a departmental journal club.

Tip 4: Share your knowledge

- Try sharing uncertainty with your colleagues.
- Discuss your questions with colleagues (maybe they have already answered them).
- Find fault with the article(s) rather than your colleagues.

BASICS OF CRITICAL APPRAISAL

Read the abstract

Assuming you have three or four articles to appraise, how should you start? First read the abstract. Read it briefly trying to gain an overview firstly of the methods used and secondly the results. For example, a parent brings

in a child referred by their GP for recurrent epistaxis but is worried about surgery (describing cautery in dramatic terms) and wonders whether a cream used by a friend’s child might help (Naseptin). You make a note of this and later formulate the question ‘In children with recurrent epistaxis, is Naseptin effective, compared with placebo, at reducing attacks of epistaxis?’ and find this paper.⁹ The abstract is available online. It takes a minute or two to read through the abstract:

Epistaxis is common in children. Trials show anti-septic cream is as effective as cautery, but it is not known whether either is better than no treatment. We wished to know the efficacy of cream in children with recurrent epistaxis. The design was a single-blind, prospective, randomized controlled trial set in the otolaryngology clinic in a children’s hospital.

The participants were 103 children referred by their general practitioner for recurrent epistaxis. Excluded were those with suspected tumours, bleeding disorders or allergies to constituents of the cream. Referral letters were randomized to treatment and no treatment groups.

Treatment was antiseptic cream to the nose twice daily for four weeks, which was prescribed by the general practitioner before clinic attendance. All children were given an appointment for eight weeks after randomization.

The main outcome measures were the proportion of children in each group with no epistaxis in the four weeks preceding clinic review. Complete data were available for 88 (85%) of the children. Of the treatment group, 26/47 (55%) had no epistaxis in the four weeks before the clinic appointment. Of the controls, 12/41 (29%) had no epistaxis over the four weeks. This is a relative risk reduction of 47% for persistent bleeding (95% CI 9–69%) and an absolute risk reduction of 26% (95% CI 12–40%), giving a number needed to treat of 3.8 (95% CI 2.5–8.5).

We conclude that antiseptic cream is an effective treatment for recurrent epistaxis in children.

The format of any abstract should be similar to this. If there is a complex description of the trial that is confusing, ask yourself why. Is it because the authors are hiding an overall negative result or is it really a necessary peculiar design?

So, in this study there were 103 patients with epistaxis in a single blind randomized controlled trial with various outcomes described and a promising result overall.

Does the paper answer the question you are asking?

This is a qualitative judgement that you must make on reading the abstract. Unless the paper is the highest level of evidence (systematic review) and deals specifically with the question you have posed it will be necessary to next look for individual randomized controlled trials that address the specific outcomes relevant to your patient.

Find answers to the validity questions using a checklist for the relevant study

It is very much easier to read an article when you know what you are looking for. The same occurs when an experienced doctor finds it easier to filter the enormous number of questions and signs they can ask or examine for, and homes in on specific areas they think are relevant. This ability to put the patient's symptoms quickly into context is the key to skilful practice. In exactly the same way, learning what to look for in a research article is key. When teaching medical students, we give them exactly the same list of questions that are shown below. This gives them focus and they will work through an article in 10 minutes answering all the validity questions.

The first place to check for validity questions about the methods employed is, not surprisingly, in the methods section of the paper. However, you will frequently find that certain elements of the methodology may be mentioned in the introduction, results or even the discussion. So if you cannot find out, for example, the rate of follow-up in the methods, then scan the rest of the text for the answer.

What sort of research design is the trial?

You may have to resort to checking the methods section of the paper to obtain this. The trial under discussion was a randomized control trial with single blinding.⁹

Assess the level of bias

At this stage, you have all the methodology neatly summarized. For example, in the paper under discussion there were some problems with follow-up. They had data available on 88 of the 103 patients randomized, but 15 of these were assessed by telephone. This introduces an element of bias that may reduce the validity. If this was less than 80% then really the trial is so severely compromised that you cannot make any interpretation of the result. If there is not concealed randomization (see 'Concealed randomization' below) then the results *may* overestimate the effectiveness of the treatment. So, assessing bias is the art of appraisal. In the end you have to decide whether the effect of the treatment demonstrated is likely, taking into consideration the level of bias, to translate into benefit in your patient.

Translate the results into something clinically meaningful

If the article describes analysis data with quoted figures for risk reduction, how does that apply to an individual patient? A frequent term used now is numbers needed to treat. This puts the effect into the context of the patient and lets them decide whether the benefit is worth the trouble or potential side effect(s).

How can I implement this?

Does this help my practice, either by reinforcing what I know and making me more confident, or does it change my practice? If it is the latter, how am I going to go about implementing that change?

The numbers

The most frequent fear expressed is that of the statistics. How can I tell whether these were the correct statistics to be used? This can initially be tackled obliquely. First, ask what is likely to represent a clinically beneficial outcome for your patients. Is a reduction in mortality of 1% enough for an invasive procedure, or should it be 5%? This is by far the most important feature of the results. If the trial was designed to establish a benefit that you regard as clinically insignificant then no further examination of the study is necessary.

Following this example a little further, assume a 5% reduction in mortality is considered a clinically meaningful difference, and the results of the trial demonstrate that this was achieved. The statistical test is there to show you that this difference was very unlikely to have occurred by chance in two ways. First, that the difference observed in this trial was unlikely to have happened by chance (p value) and, second, if this trial were repeated 100 times, 95% of the trials would have shown a similar result (confidence interval). How they determine the p value (i.e. with a student t test or a chi-square) is beyond the scope of this article but a quick tip is to check the letters written in response to the article because, if the article is in a major journal, statisticians will be quick to point out the incorrect use of statistics. In our experience, there is much less use of incorrect statistical tests than there is of poor trial methodology.

To summarize, check that the difference is clinically significant and did not occur by chance.

Summary

Critical appraisal is a logical way of assessing the likely truth of a piece of research, evaluating the results in terms of individual patient care, and then assessing the whole and determining whether it is useful for your practice. It combines some knowledge of trial design, a small amount of basic arithmetic and some qualitative judgements.

FORMING ANSWERABLE QUESTIONS

The reason we do not usually ask questions is they are so difficult to answer. This was clearly illustrated in the *Hitchhiker's Guide to the Galaxy* when the super computer gave the answer '42' to the Ultimate Question of Life, the Universe, and Everything.¹⁰ The people asking the question were horrified and angry. The computer calmly suggested that, instead of panicking, they should go back and consider the question and that he would of course help them do this. Clearly, this is an extreme example of where

the question has been so badly formed that the answer is meaningless.

Imagine a patient with diabetes. Their control has been haphazard and they have had repeated haemoglobin A1C (HbA1C) tests performed over the last year. Their control seems better now but the HbA1c test is expensive to perform. How effective is blood glucose at monitoring diabetes? A search for ‘blood glucose’ and ‘diabetes mellitus’ identifies 25 000 articles.

Two mistakes were made here. The search was unstructured, the terms so vague that a manageable list of relevant items unable to be generated. This arose partly because of the unfocused nature of the question. The goal was to discover how ‘effective’ the test is. What is meant by that? If it is negative does that rule out poor control – or if it is positive (high) does that mean they have poor control? In this case it is the former that really is of interest.

You could start with a textbook and read thoroughly about diabetes. For a broad overview of the topic area textbooks may be ideal; however, they are often many years out of date. For understanding more about therapy in general, a resource such as *Clinical Evidence*¹¹ is extremely valuable (*Clinical Evidence* cites all the evidence from which therapeutic recommendations are made). This form of enquiry is termed a ‘background question’ or one that helps the person understand the problem in general. This in contrast to what is being discussed here, which are termed ‘foreground questions’ or decision-making questions. As a student, you ask mainly background questions but as your experience with a condition increases and the clinical need for decision-making increases, the proportion of background questions fall as the foreground questions rise (Figure 44.1).

Incorporating this, the question now becomes: In diabetics, is fasting blood glucose (compared with HbA1c) effective at excluding poor diabetic control?¹² (A fasting blood glucose < 7.8 rules out poor glycaemic control.)

The query is becoming better but the first part is still vague. Including something about non-insulin-dependent

diabetics would further refine the question. By structuring a question, the answer may be found more efficiently.¹³ It is therefore important to try to break the question down into several parts, the most common approach being to use the PICO format:

- patient and problem
- intervention (or diagnostic test)
- comparison intervention (optional)
- outcomes.

Patient and problem

The first part is to identify the problem or the patient. Some healthcare problems are not always about patients! For example, an administrator may want to know whether having acute medical beds in a temporary holding ward next to the accident and emergency department is any better than having conventional acute medical wards in the hospital. Make sure at this stage in the question you are describing the problem or patients that you see. However, if you are too specific at this stage you may miss some important evidence and there is a balance to be struck between obtaining evidence about exactly your group of patients and obtaining all the evidence about all groups of patients.

Intervention

The intervention is equally important. It may in fact be a postponement of an action, such as an operation. In patients with abdominal pain lasting less than 12 hours, does an additional 24-hour delay before referral to hospital alter outcome? Most interventions are more straightforward, such as types of dressings, drug therapies or counselling. Alternatively, they can be about the provision of differing environmental factors, such as the décor of waiting rooms or dealing with the way in which information is given to patients, i.e. positively or negatively.¹⁴

The intervention can be a diagnostic test. However, specify whether you are trying to detect or exclude a disease.

Comparison intervention

Sometimes, there is a comparison of the intervention. For example, you might seek papers comparing the use of an active compound compared with either a placebo or another active drug. Considering whether you are looking for comparative studies will help when searching for that evidence. You may be comparing one diagnostic test against another.

Outcomes

Outcome measures are particularly important when considering the question. It is worth spending some time working out exactly what it is you want. In serious diseases it is often easy to concentrate on the mortality and miss the important aspects of morbidity. For example, the use of toxic chemotherapies for cancer may affect both aspects.

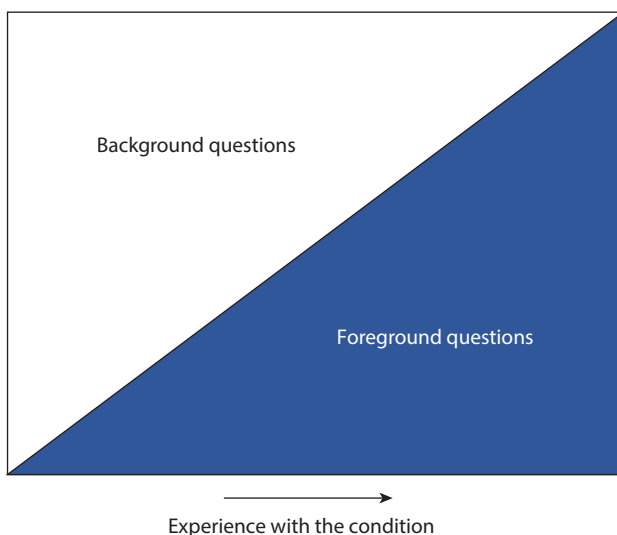

Figure 44.1 Foreground and background questions.

This is also the time when it is important to know what outcome is relevant to the patient. In Menière's, deafness and tinnitus may occur but the patient may only really be interested in controlling one problem as a priority. The search should primarily focus on that outcome. The Core Outcome Measures in Effectiveness Trials (COMET) initiative aims to develop and encourage application of agreed standardized sets of outcomes, known as 'core outcome sets'. These can be applied to both controlled and non-controlled trials. The intention is not to limit the range of outcomes measured but to ensure a minimum core set is included in all studies of a particular condition such that pooling or comparison of trial data can be more meaningful.¹⁵

Type of question

Once we have created a question, it is helpful to think about what type of question you are asking, as this will affect where you look for the answer and what type of research you can expect to provide the answer. For example, although randomized controlled trials (RCTs) are a very valid type of study, it would be unethical to perform an RCT on harm. (Would you volunteer for the exposure arm of such a study?) Questions about harm should look for different types of research, such as case-control studies or cohort studies.

APPRAISING DIAGNOSTIC ARTICLES

Diagnoses are usually made through interpreting and combining information from a combination of the clinical history, examination findings and the results of investigations, such as blood tests and X-rays. An important component of evidence-based healthcare is working out how useful these different pieces of information are in making a diagnosis. For example, if you test a patient's urine and find protein in it, how likely is it that this represents kidney disease? A test result needs to be interpreted in the light of how accurate you think the test is, and what you already know about the patient.

In making a diagnosis you are consciously (or subconsciously) weighing up probabilities. Each question you ask or each observation changes those probabilities. For example, if a patient limps in then there is a probability of arthritis being the cause of the limp. If the patient is 70 years of age, the probability is higher than if the patient is 30. The age of the patient is a diagnostic test, either increasing or decreasing the probability. It is essential, when contemplating a test, that the person requesting the test has some idea of the probability of the diagnosis. They will also need to decide whether the test is helping them exclude or include the diagnosis. Finally, they need to know what is the likely probability of the diagnosis after a positive or a negative result.

What is meant by test accuracy? Accuracy is a description of how well the test diagnoses and excludes the disease when the result is positive or negative (see 'What are the results?' below).

Sensitivity reflects the ability of a test to identify people who have disease and specificity reflects the ability of the test to identify 'normality', or people who do not have disease. So this means that tests with very high sensitivities and specificities can be extremely useful at either excluding or including a diagnosis. It is not uncommon to spend time seeing the worried well. These are patients who present with symptoms caused by a mild or self-limiting disease but are naturally worried that it may be something more serious. In these cases what is required are tests that mainly exclude disease. In hospital, where patients are potentially significantly unwell, what is required is to be able to make a diagnosis (including disease).

To see an example of how high sensitivity and specificity values of a test can be used in clinical practice, let us consider how general practitioners deal with patients with a sore throat. This is a common presenting complaint in general practice and it would be useful to know whether a new 'rapid test' could be useful in helping diagnose bacterial sore throats.¹⁶ This particular paper is selected for illustrative purposes rather than it being the 'best' level of evidence.

In the paper four patient features were determined:

- fever $\geq 38^{\circ}\text{C}$
- lack of cough
- tonsillar exudates
- anterior cervical lymphadenopathy.

Five hundred and fifty-eight patients older than 11 years presenting with sore throat were swabbed and examined for these features. They all also had a rapid streptococcal antigen detection test for detecting group-A B-haemolytic streptococcus (GABHS).

The next step was to go through the paper checking for validity.

Is the study valid?

- **Did the authors answer the question?** The question is often found at the end of the introduction section of the paper. Some authors leave you guessing as to what the original question might have been. If the paper does not have a clear question, it cannot give any clear answer, so you can save yourself time by moving on to the next paper. You should also consider whether the research question is relevant to your clinical question.
- **What were the characteristics of the groups?** This would contain some description about the numbers of patients, their race and gender, age and any other features that are pertinent to the study. This would also include any characteristics that are known or likely confounders (i.e. factors that might introduce bias if highly represented in one group compared to the other).
- **Is it clear how the test was carried out?** To be able to apply the results of the study to your own clinical practice, you need to be confident that the test is performed in the same way in your setting, as it was in the study.

What was the test undertaken? How was it done and by whom? Was it a multi-level test (i.e. a serum level) with different thresholds?

- **Is the test result reproducible?** This is essentially asking whether you obtain the same result if different people carry out the test, or if the test is carried out at different times on the same person. One thing to consider here of course is the distinction between reproducibility and validity. It is perfectly possible for a study to generate a series of results that are reproducibly wrong.
- **Was the reference standard (gold standard) appropriate?** To start with, we need to find out how the study found out what the ‘truth’ really was about patients. That is to say, how did the investigators know whether or not someone really had a disease? To do this, they will have needed some reference standard test (or series of tests) which they know ‘always’ tells the truth.
- **Were the reference standard and the diagnostic test interpreted blind and independently of each other?** If the study investigators know the result of the reference standard test, this might influence their interpretation of the diagnostic test and vice versa. The potential effect of non-blinding of investigators has already discussed.
- **Was the reference standard applied to all patients?** Ideally, both the test being evaluated and the reference standard should be carried out on all patients in the study. There may be a temptation, for example, if the test under investigation proves positive, not to bother administering the reference standard test. In many cases, the reference standard test may be invasive and may expose the patient to some risk and/or discomfort. While it would usually be ethical to use such a test on a patient in whom you had grounds to suspect that it might be positive, it would not be ethical if you thought that the test would be negative (i.e. if the diagnostic test being evaluated had been negative). Therefore, when reading the paper, you need to find out whether the reference standard was applied to all patients, and if it was not look at what steps the investigators took to find out what the ‘truth’ was in patients who did not have the reference test.
- **Was the test evaluated on an appropriate spectrum of patients?** Another complication is that a test may perform differently depending upon the sort of patients on whom it is carried out. For example, the more severe a disease is, the easier it tends to be to detect. Thus, you might find that testing for bacterial sore throats might be ‘better’ at detecting infection when evaluated in patients who attend an ENT clinic, than in those attending family practice. This may be because people with chronic disease who attend an ENT clinic will be more symptomatic and have more bacteria in general, making it easier to detect. This problem is referred to as spectrum bias. A test is going to perform better in terms of detecting people with disease if it is used to identify it in people in whom the disease is more severe, or advanced. Similarly, the test will produce more false-positive results if it is carried out on patients with other diseases that might mimic the disease that is being tested for.

The issue to consider when appraising a paper is whether the test was evaluated on the typical sort of patients in whom the test would be carried out in real life.

The optimal study method for the assessment of a diagnostic test is a cohort study evaluating the test in a group of patients thought to be at risk of having the disease. A less valid alternative method that has been used is a case-control study. The latter method studies patients known to have the disease and control patients without the disease. The performance of the test in the two groups is compared. This sort of study has been shown to overestimate the effectiveness of the diagnostic tests.¹⁷

What are the results?

In an ideal world, a positive test would mean that someone has disease, and a negative test would mean they do not have disease. Unfortunately, this is rarely the case. When a test is carried out, there are four possible outcomes:

1. The test can correctly detect disease that is present (a true positive result).
2. The test can detect disease when it is really absent (a false-positive result).
3. The test can correctly identify that a disease is not present (a true negative result).
4. The test identifies someone as free of a disease when it is really present (a false-negative result).

These possible outcomes are illustrated in [Table 44.1](#).

Given that a test may potentially mislead us if we obtain a false-positive or a false-negative result, we need to have some way of characterizing how accurate the test really is ([Table 44.2](#)). What does this mean? The high specificity means that there is a high true negative rate (359 out of 375). Or put another way, only a few (16) falsely positive test results were found out of the 375 people who did not have GABHS. So that means (using some reverse logic) that if the rapid test was positive (going across the row), by inference they almost certainly have the disease.

We can simplify this to say that in tests with high specificities, where the result is positive, it rules the diagnosis in. The mnemonic for this is **SpPin**.

TABLE 44.1 Possible outcomes of a diagnostic test

Test result	‘True condition status’		
	Condition present	Condition absent	Totals
Positive	a True positive	b False positive	a + b
	c False negative	d True negative	c + d
Totals	a + c	b + d	a + b + c + d

Sensitivity = $a / (a + c)$ Positive predictive value = $a / (a + b)$.
 Specificity = $d / (b + d)$ Negative predictive value = $d / (c + d)$.
 Prevalence = $(a + c) / (a + b + c + d)$.
 Accuracy = $a + d / a + b + c + d$.

TABLE 44.2 Results of rapid test screening for group-A β -haemolytic streptococcus (GABHS) in patients with a sore throat

Test result	'True condition status'		
	GABHS+ve	GABHS-ve	Totals
Positive	119	16	135
Negative	64	359	423
Totals	211	375	558

Sensitivity = $119/211 = 65\%$.Specificity = $359/375 = 96\%$.Positive predictive value = $119/135 = 88\%$.Negative predictive value = $359/423 = 85\%$.Prevalence = $211/558 = 33\%$.Accuracy = $478/558 = 85\%$.

In tests with high sensitivities and the test is **negative** then it rules **out** the disease. So the mnemonic for this is **SnNOut**. Clearly it is not 100% accurate at excluding (that would only happen if the sensitivity was 100%). How you take that finding and put it into practice depends on the severity of the disease as well as the other symptoms and signs that indicate the pretest probability of the disease.

In reality, patients who are well where you are trying to exclude disease need tests with high sensitivities (primary care). Patients who are ill need tests with high specificities to determine the cause of the illness. This is an oversimplification of the process of diagnosis but is helpful in terms of remembering what tests do.

Often, of course, we are faced with tests whose sensitivity and specificity are not so high that we can use the test to rule in or rule out a disorder. For such cases, we need a measure of a particular test result's ability to predict the presence or absence of disease.

We might think that this is provided by the positive and negative predictive values (for positive and negative results, respectively). However, in practice we find that these values can change depending on the prevalence of the target disorder amongst the test population: if the disorder is more common, the positive predictive value will be higher and the negative predictive value lower.

For example, if the results show a much lower prevalence (**Table 44.3**), the sensitivity remains similar and the specificity is the same but the positive predictive value

TABLE 44.3 Potential results of a rapid test screening for GABHS in patients with sore throat in an imaginary low prevalence setting

Test result	'Truth'		
	GABHS+ve	GABHS-ve	Totals
Positive	12	16	28
Negative	6	359	365
Totals	18	375	393

Sensitivity = 67%.

Specificity = 96%.

Positive predictive value = 43%.

Negative predictive value = 98%.

Prevalence = 4.5%.

drops considerably. Now the test only has a 50:50 chance of detecting someone with disease. You can see how the prevalence will sometimes significantly alter the effectiveness of a test. It is important always to consider the setting before recommending tests that perform well in an alternative healthcare setting.

However, since sensitivity and specificity are not affected by disease prevalence, we can combine them to create a combined measure of the efficacy of a particular test result. This can be thought of as, for a given test result, the likelihood that a patient with the disorder would yield that test result compared to the likelihood that a patient without the disorder would yield that same test result. This is the likelihood ratio (LR). As a rule of thumb, for positive test results, an LR of 10 or above shows that the test result is good at ruling in disease; for negative test results, an LR of 0.1 or less shows that the test result is good at ruling out disease.

Two additional benefits of the LR are that they can be used to generate specific post-test probabilities for your patient and that, where we have multiple independent tests, the LRs can be multiplied together to yield a much more powerful test.

The prevalence of GABHS was 33%. If the test is positive it is very likely they have GABHS, but what about if it is negative?

What you can do is work out the likelihood ratios: **Figure 44.2** shows the nomogram for likelihood ratios. To use the nomogram a line is drawn from the pre-test probability of 33% through 16 (on the likelihood ratio line) to obtain a post-test probability of approximately 90% if the result is positive and through 0.36 (roughly) to obtain a post-test probability of approximately 12% if the result is negative.

But what if our patient has a lower pre-test probability? For example, this might be a patient with only a 20% pre-test probability. Using a ruler, see what their post-test probability would be. The nomogram lets you quickly see the implications of a positive or negative result in terms of post-test probability.

Will the results help my patient?

ARE THE RESULTS RELEVANT TO YOUR PATIENT?

So far, we have considered how to interpret results of tests for your patients. However, it may be that you feel that the results of studies carried out to assess the accuracy of the test are not generalizable (or relevant) to your setting, or you may consider that it would not be helpful to your patient to perform the test.

GENERALIZABILITY TO YOUR SETTING

One aspect to consider is whether the assessment(s) of test validity that have been carried out are applicable to your setting. We have already seen how predictive value is dependent upon prevalence, so the predictive value of a test in one setting is usually not the same in another setting.

Figure 44.2 Nomogram for likelihood ratios.

Sensitivity and specificity (and likelihood ratios) are not dependent on prevalence, but they can vary according to the type of patients on which the test is carried out. The sensitivity of a test will depend upon the severity of disease in the population being tested. The more advanced or severe the disease, the more likely the test is to identify it.

The specificity of a test will depend upon the prevalence of other diseases in the population that might lead to false-positive results. The more that other diseases are present, the more likely a false-positive result.

A second aspect to consider is whether the test is carried out the same way in your setting as it was in the study. Some diagnostic tests depend upon the skill of the person carrying out the test, and the skill of the people interpreting the test result. Tests may be carried out in different ways, and it is important to know that it is carried out the same way in your local hospital or laboratory as it was in the study which evaluated the test.

WILL IT HELP YOUR PATIENT?

One way to think about whether or not to perform the test is whether it will influence the management of the patient or groups of patients you are likely to see. If you think that a disease is unlikely in a particular patient, it may be that if you carried out the test and it was positive, you would still think that the disease was unlikely, so it would not influence your management. Conversely, if you think that a disease is likely in a given patient, it may be that a negative test result would not stop you treating the patient, since you would still think that the disease is likely whatever the test result. Putting this in terms of pre- and post-test probabilities, in the first instance the pre-test probability of disease is so low, that even with a positive test result, the post-test probability will be less than 50%. In the second instance, the pre-test probability of disease is so high that even with a negative test result, the post-test probability will be more than 50%.

In practice, knowledge about the accuracy of diagnostic tests will perhaps be most useful when planning protocols or guidelines to manage particular groups of patients.

Summary

An evidence-based approach to deciding whether a test is effective for your patient involves the following steps:

- Frame the clinical question.
- Search for evidence concerning the accuracy of the test.
- Assess the methods used to determine the accuracy of the test.
- Find out the likelihood ratios for the test.
- Estimate the pre-test probability of disease in your patient.
- Apply the likelihood ratios to this pre-test probability using the nomogram to determine what the post-test probability would be for different possible test results.
- Decide whether or not to perform the test on the basis of your assessment of whether it will influence the care of the patient, and the patient’s attitude to different possible outcomes.

APPRAISING THERAPY ARTICLES

When we are required to answer a question about therapy, the identification of information from an article is not straightforward. The layout is frequently different depending on the journal you are reading. One is often relying on the editorial board of the journal, as well as the people who reviewed the article, to have ensured the quality of the article. There may be confusing statistics that make interpretation of the data seem difficult. These problems seem to be very daunting when one is trying to identify information that may affect the care of a patient. These following questions will help you identify the real validity of the therapy article.

- **Is the study valid?** Did the authors answer the question? For this example I shall be using the Kubba paper⁹ on Naseptin and epistaxis. The abstract of this article is shown under ‘Read the abstract’ above. Kubba et al.⁹ have answered their question about the effectiveness of Naseptin in epistaxis. They state clearly how they did this and what they used to determine ‘effective’.
- **What were the characteristics of the groups?** This would contain some description about the numbers of patients, their race and gender, age and any other features that are pertinent to the study. This is usually found in Table 1 in most papers but in this case is described in the protocol part of the subjects and methods section.
- **Are the comparison groups similar?** To determine whether bias has occurred in the selection procedure, certain potentially relevant characteristics of the two populations should be displayed in tabular form. Usually these include age, sex, duration of illness and other demographic and functional characteristics. This is covered in the first paragraph of the results section of the paper being considered here. There were more boys than girls, but the age and duration of history were the same in both groups. Is it likely that girls and boys would differ in response? The aim is not to find whether there are statistical differences between the two groups but to find whether there are clinically significant differences. You as a clinician reader should judge whether you think the differences are clinically significant.
- **What was the treatment?** In this case it was either Naseptin or nothing. The authors describe clearly the reasons for not using a placebo.

Equal treatment

The groups in the trial were treated equally throughout apart from the experimental intervention. It should be clear from the article that, for example, there were no co-interventions that were applied to one group but not the other, or more frequent or detailed assessments on one group compared to the other.

Placebo control

Patients do better if they think they are receiving a treatment than if they do not, even if the treatment is an

inactive substance: the placebo effect is a widely accepted potential bias in trials. A placebo is an inactive treatment that is given so that the patient does not know whether he or she has been given the active treatment; the control group in a trial will often receive a placebo treatment so that this effect is equal in both groups. Patients in both groups of the trial should not know whether or not they are receiving the active therapy. However there is a twist in the tail – one can have a placebo-controlled trial where the patients are having active treatments in both arms of the study in addition to the new treatment or the placebo. So the term ‘placebo-controlled trial’ does not exclude the use of active treatments (as long as both groups get the same).

Follow-up

There are three major aspects to assessing the follow-up of trials:

- Did so many patients drop out of the trial that its results are in doubt?
- Was the study long enough to allow outcomes to become manifest?
- Were patients analyzed in the groups to which they were originally assigned (intention-to-treat)?

Drop-out rates

A good clinical trial requires the complete follow-up of patients in both the control and experimental groups. If less than 80% of patients are adequately followed up then the results may be invalid. In this study they had problems and had to phone subjects as they did not attend the outpatient clinic. This weakness of the study was evaluated in the discussion.

Length of study

The length of the study is critical in determining the clinical significance of the results. For a disease of short duration, such as an acute infectious disease, the period of the study need only be long enough to cover the course of that infection. Where the disease is more progressive and lengthy then the duration of the study needs to reflect that. The question that the research is trying to answer will also be helpful in deciding the appropriate length of the study.

Intention-to-treat

Because anything that happens after randomization can affect the chances that a patient in a trial has an event, it is important that all patients are analyzed in the groups to which they were randomized. This is an essential prerequisite for valid evidence about therapy. For example, it has been repeatedly shown that patients who do and do not take their study medicine have very different outcomes, even when the study medicine they have been prescribed is a placebo. The correct form of analysis, in which patients

are analyzed in the groups to which they were assigned, is called 'intention-to-treat' analysis.

Were the groups randomized?

The major reason for randomization is to prevent bias. The largest potential cause of bias in research about effectiveness of an intervention is if the patients allocated to the treatment group are different from those allocated to the control group in a way that might influence outcome. To reduce this bias as much as possible, the decision as to which treatment a patient receives should be determined by random allocation. Why is this important?

There could be any number of confounding variables that affect a given situation, some of which we know about, but also others that our knowledge of human physiology has not yet uncovered. Randomization is important because it spreads all confounding variables evenly amongst the study groups, even the ones we do not know about. Occasionally, simple randomization may not ensure that there is an equal balance between treatment groups of known confounding variables. Where there are important confounders known and a need to be sure these are balanced between two groups, a process of stratified randomization can be employed.

CONCEALED RANDOMIZATION

As a supplementary point, clinicians who are recruiting patients into a trial may consciously or unconsciously distort the balance between groups if they know the treatments that will be given to patients. For this reason, it is preferable that the randomization list be concealed from the clinicians. The amount of impact the lack of concealment may have is larger than if the trial was not blinded. If there is inadequate concealment, the size of the effect may be overemphasized by as much as 30%.

BLINDING

It is also important that, if possible, both clinician and patient be 'blind' to whether or not they are receiving treatment. Lack of blinding may lead to exaggeration of the effectiveness of the therapy by as much as 20%.³

Outcome measures

To determine the impact of an intervention on patient health, one needs to define clearly the outcome that needs to be measured. This sounds straightforward enough but it can take up a larger amount of the preparation time of the research. An outcome measure is any feature that is recorded to determine the progression of the disease or problem being studied. In this paper a comprehensive questionnaire was used to determine outcomes.

What are the results?

- How large is the treatment effect?
- How precise is the estimate of the treatment effect?

In any clinical therapeutic study there are three explanations for the observed effect:

- the effect of the treatment
- chance variation between the two groups
- bias.

Good research will explicitly endeavour to reduce the effects of chance and bias by using special designs, as we have seen.

NUMBERS NEEDED TO TREAT

The most common approach is to describe the effect of a drug in terms of the risk reduction. The risk is usually of continuing to have, for example, pain or an event. When evaluating a paper on a therapeutic manoeuvre, it is possible to establish its clinical effectiveness by determining the proportion of patients receiving treatment who gain benefit.

Table 44.4 shows the results drawn from the paper.

From the paper the following results are drawn:

The simple statement above obscures the fact that identifying the correct table in the paper and then obtaining the correct figures from it is often not as easy as it sounds. This is one of the parts of appraisal that it is often useful to share with others to ensure you have the correct data.

From Table 44.4 it can be seen that 47 patients were assigned to the active treatment (or experimental) group and 41 to the watchful waiting (or control) group. There were a total of 50 children with epistaxis; 21 occurred in the experimental group and 29 in the control group.

EVENT RATES

It is important to set some standard methods of describing these data. In therapy, we start by converting the numbers of patients into event rates. In the control group, 29 out of 41 patients had epistaxis. This may be presented as an event rate of $(29/41)=0.71$. So the control event rate (CER) is 0.71 (this number is also the risk of epistaxis in the control group, and corresponds to a percentage risk of 71%).

In the experimental treatment group there were 21 children with epistaxis out of 47 children. The experimental

TABLE 44.4 Results of a trial of Naseptin against watchful waiting in stopping epistaxis in children

	Epistaxis	No epistaxis for four weeks	Total
Active treatment (Naseptin)	21	26	47
Watchful waiting	29	12	41
Total	50	38	88

event rate (EER) was therefore 0.44 (44%). Now that we have these numbers we can start working with them.

RELATIVE RISK

One way of combining the event rates is to use relative risk (RR). Here, we make a ratio of the two risks to show which group has a higher or lower risk. The relative risk is calculated by dividing the risk of having epistaxis in the treatment group by the risk of the control group = $0.44/0.71 = 0.62$. This means that the risk of epistaxis continuing with Naseptin was 0.62 (or 62%) of the risk without Naseptin.

Relative risk reduction

It is also possible to show the extent of the benefit compared to the original risk by calculating the relative risk reduction (RRR). This is similar to relative risk, except that we take the difference in risk between the two groups and divide that by the control group's risk: RRRs are often presented as percentages.

The RRR means that the treatment reduced the risk of continued nosebleeds by 38% relative to that occurring in this control population (the RRR given by the authors is for persistent bleeding whereas I have calculated for cessation of bleeding). This is a large risk reduction in a population that are all bleeding. But what if it was an RRR for primary stroke reduction where the events are far fewer? So the RRR has to be judged against the prevalence of the outcome we want to prevent.

Absolute risk reduction

The absolute risk is that 71% of individuals in the placebo group had nosebleeds and that 44% of the treatment group had nosebleeds. The difference (absolute risk reduction (ARR)) between these gives us another view of the effectiveness of the treatment. The ARR of this therapy is 0.27 (CER – EER = $0.71 - 0.44$).

ARR = CER – EER

Consider 100 people given this treatment. We would expect 27 fewer children to have epistaxis if this group were given Naseptin than if they were not. We can convert this into how many people we would need to treat to prevent one child continuing to have epistaxis. This number is the reciprocal of the ARR. In this example $1/0.27 = 3.7$. Therefore, to prevent a child continuing to have epistaxis we need to treat four people. This is the number needed to treat (NNT). It is more useful than relative measures because, as well as measuring the benefit of a therapy, it also represents the baseline risk and the absolute benefit you can expect from the therapy.

NNT = 1/ARR

Sometimes, papers will present their results in the form of NNTs, as in this one, which is very helpful, but often they do not, and prefer to present risk ratios (perhaps not surprisingly, since these tend to make beneficial results look

more spectacular) or similar measures. You will often be required to calculate NNTs from the data in the study. Fortunately, the arithmetic is fairly straightforward. Some other examples of NNTs are included in Bandolier (<http://www.bandolier.org.uk/band59/NNCalc.html>).

This is a small study and like the relative risk there is a confidence interval around the NNT. To calculate this¹⁸ it is easier to use software (www.ebm.net). Also, there is the 'believability' issue of a relatively small trial. This is where the clinical judgement comes in – would you use this treatment based on 100 patients?

Will the results help my patient?

- Can the results be applied to my patient?
- Were all clinically relevant outcomes considered?
- Are the benefits worth the harms and costs?

Given that your patient was not in the trial and may not even have been eligible for it (due to age, sex, comorbidity, disease severity or for a host of other sociodemographic, biologic or clinical reasons), how can you extrapolate from the external evidence to your individual patient? (We use the term 'extrapolate' here, although this might more accurately be described as 'particularizing' the results of a trial (which looks at a generic population) to your particular patient.) This requires that you apply some of your knowledge of human biology and clinical experience to answer the question: 'Is my patient so different from those in the trial that its results cannot help me make my treatment decision?'

When analyzing the results of a trial it is important therefore to identify whether the trial has been designed to be explanatory or pragmatic in its approach. The former is often used to test whether the intervention works under ideal conditions – often in a highly selected cohort. This design may also be able to quantify the magnitude of any effect. A pragmatic design on the other hand often has much less strict inclusion criteria and consequently much more closely represents a 'real world' scenario. The results of a pragmatic trial may be more easily translated into a likely benefit for your particular patient.

HOW MUCH BENEFIT CAN YOU EXPECT FOR YOUR PATIENT?

Given that you have decided that your patient is sufficiently similar to those in the study for the effect to be applicable, the next questions is how much? Here is one way of going about this.

f method

First estimate, as a decimal fraction, your patient's risk compared to the control group from the study. Thus, if your patient is twice as susceptible as those in the trial, $f = 2$; if half as susceptible, $f = 0.5$. As long as the treatment produces a constant RRR across a range of susceptibilities, the NNT for your patient is simply the trial's reported NNT divided by f . (This is a big assumption and we are

only beginning to learn when assuming a constant RRR is appropriate (for numerous medical treatments such as antihypertensive drugs) and inappropriate (for some operations such as carotid endarterectomy, where the RRR rises with increasing susceptibility). So, in the above example, we might assign an f of 0.7 (70% chance of having epistaxis to the control group of subjects), which would yield an NNT of $(3.7/0.7)=5$.

INCORPORATING YOUR PATIENT'S VALUES AND PREFERENCES

What does your patient think? Have you talked to them about their personal preferences, concerns and expectations? Here, we must try to determine whether the outcome of the therapy actually serves the values and preferences of the patient. Many factors can come into play, not least the difficulty of representing them. Sometimes, the situation may be very clear-cut or demand immediate action. For example, in a patient having a heart attack, the value of survival and the preference for a simple, low-risk intervention such as aspirin, given the efficacy of this regimen, usually makes this decision quickly agreed and acted upon. In other cases, the answer may take weeks and several visits to sort out, such as in choosing between radiation and adjuvant chemotherapy for stage II carcinoma of the breast.

These questions are perhaps the most important, yet have the least written about them in this chapter. That is because they are also the most complex and depend to a great extent on the clinical situation.

Summary

An evidence-based approach to deciding whether a therapy is effective for your patient involves the following steps:

- Frame the clinical question.
- Search for evidence concerning the accuracy of the test.
- Assess the methods used to carry out the trial of the therapy.
- Determine the NNT of the therapy.
- Decide whether the NNT can apply to your patient, and estimate a particularized NNT.
- Incorporate your patient's values and preferences in to deciding on a course of action.

APPRAISING SYSTEMATIC REVIEWS

What happens when there is more than one randomized control trial on the same treatment or diagnostic test? In this case you want to look for a paper that has combined these trials together.

What you need here is a systematic review, a publication that collects all of the evidence in a particular area and summarizes it. More formally, a systematic review is 'a review of a clearly formulated question that uses systematic and explicit methods to identify, select and critically appraise relevant research, and to collect and analyze data

from studies that are included in the review. Statistical methods may or may not be used to analyze and summarize the results of the included studies.'

This section will look at how you appraise studies that search for all research on a specific question and in some way combine it.

You may be familiar with the narrative reviews traditionally found in many journals. Normally someone, usually an expert, looks at the evidence in a certain area. Mulrow¹⁹ argues that traditional reviews do not routinely use systematic methods to identify, assess and synthesize information. Thus, normally there is no methods section for the actual conduct of the review. The reader then has no way of knowing whether the review is based on a systematic review of the evidence, or on a collection of papers that the author has found in a less systematic way and thus the evidence presented may not be complete. There is a need for systematic reviews of the evidence. This needs to be undertaken in just as rigorous a way as any primary piece of research, with a clear question and explicit methods for all stages of the process, such that another person could replicate the review. Three key features of such a review are:

- a strenuous effort to locate all original reports on the topic of interest
- critical evaluation of the reports
- conclusions drawn based on a synthesis of studies that meet preset quality criteria.

When synthesizing results, a meta-analysis may be undertaken. This is 'the use of statistical techniques in a systematic review to integrate the results of the included studies', which means that the authors have attempted to synthesize the different results into one overall statistic.

Where can you find systematic reviews?

Systematic reviews have been published in a variety of journals, and in addition the Cochrane Collaboration provides an important resource in this area. The Cochrane Collaboration is an international collaboration that is committed to 'preparing, maintaining and disseminating systematic reviews of the effects of health care'. It promotes and publishes the Cochrane Library (www.cochrane.org). This contains the Cochrane Database of Systematic Reviews. These reviews have a prespecified protocol, where every stage of the process of undertaking the review is made explicit.

Sections covered in a protocol include background, objectives, criteria for considering studies for the review (including types of participants, types of interventions, types of outcome measure, types of study), search strategy for identification of studies, study selection, methodological quality assessment, data extraction, meta-analysis, the comparisons to be made, subgroup analysis and sensitivity analysis to be undertaken. The point to note here is that all these aspects of the protocol are set out before the review is undertaken. The PRISMA guidelines are freely available online (www.prisma-statement.org) and contain a checklist to assist when performing a systematic review.

Many journals now require adherence to these guidelines and will ask for the article to be peer reviewed against them.

Many of the systematic reviews so far completed are based on evidence of effectiveness of an intervention from RCTs.

Is the review valid?

In this section we will focus on systematic reviews of therapy. Of course, systematic reviews exist for other types of research.²⁰

- **What databases and other sources did the authors of this review search?** The paper should give a comprehensive account of the sources consulted in the search for relevant papers, and the search strategy used to find them. Since standard databases fail to correctly index up to half of published trials, and negative trials are less likely to be published in the first place, the search strategy should include hand searching of journals and searching for unpublished literature. Other questions to ask yourself about the search strategy are: Have any obvious databases been missed? Did the authors check the reference lists of articles and of textbooks? Did they contact experts (to obtain their list of references checked for completeness and to attempt to find out about ongoing or unpublished research)? Search terms used are also important – has an obvious medical subject heading (MeSH) (a standard thesaurus for medical indexing) term been missed or is there another term they have not used? For example, when searching for papers looking at care of the elderly, use of the term ‘senior’ in the North American literature may be overlooked. Searching should include languages other than English. Unpublished data are useful to include because studies with significant results are more likely to be published than studies without significant results, known as publication bias. For example, research that is carried out by non-English language teams is more likely to be published in English if it shows a strong result in favour of an intervention than if it shows a negative or indifferent result.
- **How were the studies selected – eligibility criteria?** You should look for a statement of how the trial’s validity was assessed, using criteria such as those in the therapy guides. It is particularly reassuring when two or more investigators applied these criteria independently and achieved good agreement in their results. You need to know what criteria were used to select the research. This should include who the study participants were, what was done and what outcomes were assessed. A point to consider is that the narrower the inclusion criteria, the less generalizable are the results. However, this needs to be balanced with using very broad inclusion criteria, when heterogeneity becomes an issue. Such studies may cover a wide range of patients and/or interventions and/or outcomes and the justification for then combining these differing groups comes into question. The importance of a clear statement of inclusion criteria is that studies should be selected on the basis of these criteria

(that is, any study that matches these criteria is included) rather than selecting the study on the basis of the results.

- **How were the data abstracted?** Data are usually obtained by two individuals working separately (independently) and then compared later. Where consensus between reviewers cannot be reached it is customary for a third reviewer to act as arbiter. Often the data are not available within the paper and there may be a statement about obtaining the raw data from the authors.
- **Is there a description of the quality of each trial?** A table of the studies meeting the inclusion criteria should include some data on the validity checks itemized in the section on randomized control trials.⁴
- **Were the results consistent from study to study?** Although we might expect some variation from study to study, we would be concerned if some trials confidently concluded a beneficial effect of the therapy, while others confidently concluded harmful or no effects. Unless this heterogeneity can be explained to your satisfaction (such as by differences in patients, dosage or duration of treatment), this should lead you to be very cautious about believing any overall conclusion about efficacy from the review.

Statistical heterogeneity exists when there is greater variation between the results than is likely due to chance. The chi-square statistic on which they are based has on average a value equal to its degrees of freedom. Values much larger than the degrees of freedom suggest a smaller p value and thus significant statistical heterogeneity. This means greater variation exists between the studies than is likely by chance alone. One might then conclude that the studies are so different that it makes no sense to combine them. Since this test of heterogeneity is described as having a low power, a non-significant test cannot be interpreted as evidence of homogeneity. The aim of the authors should be to clearly describe the influences of specific clinical differences between the studies, rather than purely relying on an overall statistical test of heterogeneity.

Clinical and statistical heterogeneity need to be distinguished. Clinical heterogeneity refers to differences between settings, patients, techniques and outcomes, which might lead you to suggest it does not make sense to combine the data.

What are the results?

Terms that you will probably come across when looking at systematic reviews include odds ratios, relative risks, weighted mean differences and fixed and random effects, amongst others.

BINARY OR CONTINUOUS DATA

The type of data will dictate what you see when you look at a meta-analysis:

- binary data (for example, an event rate: something that happens or it does not, such as myocardial infarction, stroke, improved/not improved) is usually combined using odds ratios

- continuous data (for example, numbers of days, peak expiratory flow rate) are combined using differences in mean values for treatment and control groups (weighted mean differences (WMDs)) when units of measurement are the same (for example, all using the same anxiety scale), or standardized mean differences when units of measurement differ (for example, using a variety of anxiety scales, where one numerical value could mean very different things, depending on the scale used). Here, the difference in means is divided by the pooled standard deviation.

Thus when you look at a meta-analysis, you will see odds ratios or relative risks and/or weighted mean differences or standardized mean differences, depending on the outcomes measures that have been used in the included studies.

ODDS RATIO

Odds are another way of describing risk. The odds of an event are the probability of it occurring compared to the probability of it not occurring. We cannot do a randomized control trial to assess whether gastroesophageal reflux disease (GERD) may be associated with laryngeal neoplasm. However, we can do a case-control study looking at people with and without cancer.²¹

We do not know the incidence of laryngeal cancer in the population from this study as they took cases with cancer and compared them to controls, but we can work out the odds (Table 44.5). For GERD, the odds of having cancer is $731/1315=0.555$. This clearly is not the risk in the general population! The odds of having laryngeal cancer in non-GERD patients was 0.237. The odds ratio was $0.555/0.237=2.3$. So patients with GERD in this study had 2.3 times the odds of having laryngeal carcinoma. This was unadjusted for the other major risk factor of smoking. In large studies, odds ratios approximate risk ratio.

Clearly, as in randomized controlled trials with risk reduction, unless we know the baseline risk it is impossible to put odds ratios into context. A number needed to treat can be derived from an odds ratio but remember that many assumptions have been made in that process and treat them with some caution.

Many systematic reviews use odds ratios to represent differences between treatment and control groups. Relative risk and absolute risk reduction may also be used to express these sorts of differences, as we have already seen.

TABLE 44.5 Prevalence of gastroesophageal reflux disease (GERD) in a case control study of patients with and without laryngeal cancer

	GERD	No GERD
Laryngeal cancer	731	7497
No laryngeal cancer	1315	31,597
Total	2046	39,094

WHAT DO ODDS RATIOS USED IN A META-ANALYSIS LOOK LIKE?

The square box on the Forrest Plot (Figure 44.3) is the individual study effect (technically referred to as the point estimate), with its associated confidence interval as lines either side of that box (technically known as the interval estimate). Sometimes the size of the box may vary to reflect the weight that particular study is given, with larger boxes representing higher weighting. Lower weighted studies are usually those with smaller samples and large confidence intervals. The overall or summary effect (from combining or pooling the studies) is usually depicted as a diamond. Since patients may respond differently to treatment, this pooling may need to be supplanted by summarizing evidence along multiple covariates of interest. Thus, although one overall number is appealing in its simplicity, it may oversimplify a more complex situation.

An odds ratio of 1 on a linear scale means there is no difference between the experimental and control group. This value of 1 is the line down the middle of the figure (sometimes with the wording ‘favours treatment’ on one side and ‘favours control’ on the other). If the confidence interval does *not* cross the line, it means that there is a 95% chance that there is a true difference between the groups. That is, that there is a significant difference on that particular outcome between the intervention and control groups. If the confidence interval does cross this vertical line labelled ‘1’ it means that any difference in that outcome between the treatments could have occurred by chance (that is, there are no statistically significant differences). It may be that a very wide confidence interval is due to a very small sample size, and it would reduce with more people in the study. A 95% confidence interval covers likely results from a set of similar studies. It therefore provides a more realistic view of what will happen in practice than a point estimate, because it takes potential variability into account.

It is worth noting that a lack of evidence for an intervention is not the same as evidence of a lack of effect.

HOW PRECISE ARE THE RESULTS?

This is asking whether there are any confidence intervals used, so the reader can see the range of values around the effect size, where one has 95% confidence that the ‘true’ effect would lie. The *Cochrane Handbook* (2011)²² defines precision as ‘a measure of the likelihood of random errors. It is reflected in the confidence interval around the estimate of effect from each study ... more precise results are given more weight’. Thus the more precise the results, the narrower (smaller) the confidence interval. NNTs can be calculated from the odds ratios. However, these should be treated with caution as they can oversimplify.

WILL THE RESULTS HELP ME IN CARING FOR MY PATIENTS?

- Can the results be applied to my patient care? How similar are the patients you care for to those included in the review? The wider the type of patients included

Review: Antibiotics for acute maxillary sinusitis
 Comparison: 06 Macrolide/cephalosporin versus Amoxicillin-clavulanate
 Outcome: 01 Clinical cure

Figure 44.3 A Forrest plot. Redrawn from Ref. 23, with permission.

in the review, the more likely you are to feel the results may apply across a range of different patients. However, it is sometimes a difficult decision to know whether, for example, something that works on men will be equally effective on women, or something that works in younger people will work in the same way in older people. Subgroup analysis may be one way of addressing this, although there are concerns with this approach.

- **Were all clinically important outcomes considered?** What is clinically important can depend on your perspective. Sometimes, whilst factors such as bone density may be included in a review to assess the effectiveness of certain orthopaedic procedures, it may be some other outcome, such as ability to get to the shops, that needs to be considered as this sort of outcome may be crucial from the patient's perspective.
- **Are the benefits worth the harms and costs?** This may cover a range of factors, such as benefit of early treatment following a positive cervical smear versus the harms of high anxiety. Or it may be the benefits of a chemotherapeutic agent versus its unpleasant side effects. An economic evaluation may be included.

What is sometimes difficult using a set of criteria like this, is that you end up with a variety of 'no's' or 'can't tell's' in answer to the questions you pose. It is sometimes difficult to decide when a review is 'too bad' to give you any confidence in the findings. Perhaps one pragmatic approach would be that when you have several 'no's' or 'can't tell's' you are more wary about the validity and robustness of the review's findings. What this does illustrate is that,

like undertaking a systematic review, critically appraising these reviews is not an exact science, but there are many subjective decisions along the way. Just like undertaking a systematic review, making explicit your decisions in the critical appraisal is therefore very important.

Although a systematic review can provide you with high quality evidence, clinical experience and patient preferences are an important part of evidence-based medicine. It may be that even high quality evidence does not apply to a particular patient. Similarly, Cochrane reviews do not include recommendations, as reviewers cannot know the local situation or the patient, and this is the province of the health professional caring for the patient.

Levels of evidence

Table 44.6 provides a breakdown of the types of research that answers questions on therapy, prognosis, diagnosis, differential diagnosis or prevalence and economic studies. For each type of research a level of evidence is shown. This helps the reader identify the likely validity of the research. It does not mean that all systematic reviews are 'better' than randomized controlled trials. It should be used more as a pointer for searching and then a guide to the likely level of evidence. If one has a therapeutic question then looking for a systematic review first is logical. If there is no review then one next looks for a randomized controlled trial, etc.

If there is no trial evidence then consensus statements becomes the highest level of evidence answering that question. This just makes the grade of recommendation D rather than A if there was a systematic review. The grades

TABLE 44.6 Levels of evidence

Level	Therapy/prevention, aetiology/harm	Prognosis	Diagnosis	Differential diagnosis/symptom prevalence study	Economic and decision analyses
1a	SR (with homogeneity) ^a of RCTs	SR (with homogeneity) ^a of inception cohort studies; CDR ^b validated in different populations	SR (with homogeneity) ^a of Level 1 diagnostic studies; CDR ^b with 1b studies from different clinical centres	SR (with homogeneity) ^a of prospective cohort studies	SR (with homogeneity) ^a of level 1 economic studies
1b	Individual RCT (with narrow Confidence interval) ^c	Individual inception cohort study with >80% follow-up; CDR ^b validated in a single population	Validating ^d cohort study with good ^h reference standards; or CDR ^b tested within one clinical centre	Prospective cohort study with good follow-up ^c	Analysis based on clinically sensible costs or alternatives; systematic review(s) of the evidence; and including multi-way sensitivity analyses
1c	All or none ^d	All or none case-series	Absolute SpPins and SnNouts ^g	All or none case-series	Absolute better-value or worse-value analyses ⁱ
2a	SR (with homogeneity) ^a of cohort studies	SR (with homogeneity) ^a of either retrospective cohort studies or untreated control groups in RCTs	SR (with homogeneity) ^a of Level >2 diagnostic studies	SR (with homogeneity) ^a of 2b and better studies	SR (with homogeneity) ^a of level >2 economic studies
2b	Individual cohort study (including low quality RCT; e.g., <80% follow-up)	Retrospective cohort study or follow-up of untreated control patients in an RCT; Derivation of CDR ^b or validated on split-sample ^f only	Exploratory ^k cohort study with good ^h reference standards; CDR ^b after derivation, or validated only on split-sample ^f or databases	Retrospective cohort study, or poor follow-up	Analysis based on clinically sensible costs or alternatives; limited review(s) of the evidence, or single studies; and including multi-way sensitivity analyses
2c	'Outcomes' research; Ecological studies	'Outcomes' research		Ecological studies	Audit or outcomes research
3a	SR (with homogeneity) ^a of case-control studies	SR (with homogeneity) ^a of 3b and better studies	SR (with homogeneity) ^a of 3b and better studies	SR (with homogeneity) ^a of 3b and better studies	SR (with homogeneity) ^a of 3b and better studies
3b	Individual case-control study	Non-consecutive study; or without consistently applied reference standards	Non-consecutive study; or without consistently applied reference standards	Non-consecutive cohort study, or very limited population	Analysis based on limited alternatives or costs, poor quality estimates of data, but including sensitivity analyses incorporating clinically sensible variations
4	Case-series (and poor quality cohort and case-control studies) ^e	Case-series (and poor quality prognostic cohort studies)	Case-control study, poor or non-independent reference standard	Case-series or superseded reference standards	Analysis with no sensitivity analysis
5	Expert opinion without explicit critical appraisal, or based on physiology, bench research or 'first principles'	Expert opinion without explicit critical appraisal, or based on physiology, bench research or 'first principles'	Expert opinion without explicit critical appraisal, or based on physiology, bench research or 'first principles'	Expert opinion without explicit critical appraisal, or based on physiology, bench research or 'first principles'	Expert opinion without explicit critical appraisal, or based on economic theory or 'first principles'

The levels of evidence used throughout this book are as stated in the prelims on the How to use this book page. These are very similar to the five levels given in this table, except that Levels 3 and 4 of the system described in this table are equivalent to Level 3, and Level 5 (expert opinion) is equivalent to Level 4 in the system used in this book.

Produced by Bob Phillips, Chris Ball, Dave Sackett, Doug Badenoch, Sharon Straus, Brian Haynes and Martin Dawes since November 1998.

Users can add a minus sign '-' to denote the level of that fails to provide a conclusive answer because of:

- EITHER a single result with a wide confidence interval (such that, for example, an ARR in an RCT is not statistically significant but whose confidence intervals fail to exclude clinically important benefit or harm).
- OR a systematic review with troublesome (and statistically significant) heterogeneity.
- Such evidence is inconclusive, and therefore can only generate Grade D recommendations.

- a By homogeneity we mean a systematic review that is free of worrisome variations (heterogeneity) in the directions and degrees of results between individual studies. Not all systematic reviews with statistically significant heterogeneity need be worrisome, and not all worrisome heterogeneity need be statistically significant. As noted above, studies displaying worrisome heterogeneity should be tagged with a “-” at the end of their designated level.
- b Clinical decision rule. (These are algorithms or scoring systems which lead to a prognostic estimation or a diagnostic category.)
- c Good follow-up in a differential diagnosis study is >80%, with adequate time for alternative diagnoses to emerge (e.g. 1 to 6 months acute, 1 to 5 years chronic).
- d Met when *all* patients died before the Rx became available, but some now survive on it; or when some patients died before the Rx became available, but *none* now die on it.
- e By poor quality *cohort* study we mean one that failed to clearly define comparison groups and/or failed to measure exposures and outcomes in the same (preferably blinded), objective way in both exposed and non-exposed individuals and/or failed to identify or appropriately control known confounders and/or failed to carry out a sufficiently long and complete follow-up of patients. By poor quality *case-control* study we mean one that failed to clearly define comparison groups and/or failed to measure exposures and outcomes in the same (preferably blinded), objective way in both cases and controls and/or failed to identify or appropriately control known confounders.
- f Split-sample validation is achieved by collecting all the information in a single tranche, then artificially dividing this into ‘derivation’ and ‘validation’ samples.
- g An ‘Absolute SpPin’ is a diagnostic finding whose Specificity is so high that a Positive result rules-*in* the diagnosis. An ‘Absolute SnNout’ is a diagnostic finding whose Sensitivity is so high that a Negative result rules out the diagnosis.
- h Good, better, bad and worse refer to the comparisons between treatments in terms of their clinical risks and benefits.
- i Good reference standards are independent of the test, and applied blindly or objectively to all patients. Poor reference standards are haphazardly applied, but still independent of the test. Use of a non-independent reference standard (where the ‘test’ is included in the ‘reference’, or where the ‘testing’ affects the ‘reference’) implies a level 4 study.
- j Better-value treatments are clearly as good but cheaper, or better at the same or reduced cost. Worse-value treatments are as good and more expensive, or worse and the equally or more expensive.
- k Validating studies test the quality of a specific diagnostic test, based on prior evidence. An exploratory study collects information and trawls the data (e.g. using a regression analysis) to find which factors are ‘significant’.
- l By poor quality prognostic cohort study we mean one in which sampling was biased in favour of patients who already had the target outcome, or the measurement of outcomes was accomplished in < 80% of study patients, or outcomes were determined in an unblinded, non-objective way, or there was no correction for confounding factors.

TABLE 44.7 Grades of recommendation

A	Consistent level 1 studies
B	Consistent level 2 or 3 studies or extrapolations from level 1 studies
C	Level 4 studies or extrapolations from level 2 or 3 studies
D	Level 5 evidence or troublingly inconsistent or inconclusive studies of any level

'Extrapolations' are where data are used in a situation that has potentially clinically important differences than the original study situation.

of recommendations vary from country to country and organization to organization and should only be considered as a guide (Table 44.7).

KEY POINTS

Appraising diagnostic articles

- Criteria for validity of diagnosis trials: was there a reference standard, was it appropriate and was it applied blind, independently and to all patients?
- Appropriate spectrum of patients; clear and reproducible description of test, follow-up, intention-to-treat.
- Outcome measures.
- Measures of the accuracy of diagnostic tests: sensitivity, specificity, positive predictive value negative predictive value, likelihood ratios.
- Applying the results to your patient: pre- and post-test probability, SpPin and SnNOut.

WORKSHEETS

The worksheets shown in Figures 44.4, 44.5 and 44.6 can be used to appraise a randomized controlled trial, a diagnostic study or a systematic review. They are aide memoirs about the items to look for in a paper when appraising the validity, identifying the results and assessing the applicability.

They can be used in journal clubs or in other settings when an important new paper is being discussed. The data from these checklists can be entered into software to make your own electronic database of critical appraisals and saved as web pages or text documents.

Appraising therapy articles

- Criteria for validity of therapy trials: randomization, blinding, placebo control, equal treatment, follow up, intention-to-treat, outcome measures.
- Measures of the importance of the results of therapy trials: risk, event rates, NNTs.

Appraising systematic reviews

- Criteria for validity of systematic reviews: search for relevant trials, assessment of included trials' quality, heterogeneity.
- Measures of the importance of the results: risk, event rates, NNTs, odd ratios.

The answer:

Are the results of this single preventive or therapeutic trial valid?

PICO QUESTION	
Search terms used	
Databases searched to find this article	
Citation of article	
Why did you select this article(s)?	
Did the authors answer the question?	
1. What were the characteristics of the patients?	
2. Were the groups similar at the start of the trial?	
3. Aside from the experimental treatment, were the groups treated equally?	
4. What was the treatment and what was it compared against (placebo)?	
5a. Was the assignment of patients to treatments randomized? 5b. and was the randomization list concealed?	
6a. Were all patients who entered the trial followed up at its conclusion? 6b. and were they analyzed in the groups to which they were randomized (Intention to treat)?	
7. Were patients and clinicians kept 'blind' to which treatment was being received?	
8. Was the length of study appropriate?	

Are the valid results of this randomized trial important?

YOUR CALCULATIONS:

		Absolute risk reduction (ARR)	Number needed to treat (NNT)	Relative risk reduction (RRR)
Control group rate (CER)	Experimental Group Rate (EER)	CER-EER	1/ARR	ARR/CER

95% Confidence Interval (CI) on an NNT = 1/(limits on the CI of its ARR) =

$$\pm 1.96 \sqrt{\frac{CER \times (1-CER)}{\text{No. of control pts.}} + \frac{EER \times (1-EER)}{\text{No. of exp. pts.}}} =$$

Can you apply this valid, important evidence about a treatment in caring for your patient?

Do these results apply to your patient?	
Is your patient so different from those in the trial that its results cannot help you?	
How great would the potential benefit of therapy actually be for your individual patient?	
Method I: f	Risk of the outcome in your patient, relative to patients in the trial. expressed as a decimal: _____ NNT/F = ____/____ = _____ (NNT for patients like yours)

Are your patient's values and preferences satisfied by the regimen and its consequences?

Do your patient and you have a clear assessment of their values and preferences?	
Are they met by this regimen and its consequences?	

Figure 44.4 Randomized control trial worksheet.

The Answer:

Are the results of this diagnostic study valid?

PICO QUESTION	
Search terms used	
Databases searched to find this article	
Citation of article	
Why did you select this article(s)	
Did the authors answer the question?	
1. What were the characteristics of the patients?	
2a. New diagnostic test description. Is it clear how the test was carried out?	
2b. Is the test reproducible in your setting?	
3a. Gold standard description.	
3b. Was there an independent, blind comparison with a reference ('gold') standard of diagnosis?	
4. Was the reference standard applied regardless of the diagnostic test result?	
6. Was the diagnostic test evaluated in an appropriate spectrum of patients (like those in whom it would be used in practice)?	

YOUR CALCULATIONS:

		Target disorder		Totals
		Present	Absent	
Diagnostic test result	Positive	a	b	a + b
	Negative	c	d	c + d
Totals		a + c	b + d1770	a + b + c + d

- Sensitivity = $a / (a + c) =$
- Specificity = $d / (b + d) =$
- Likelihood ratio for a positive test result = $LR+ = sens / (1 - spec) =$
- Likelihood ratio for a negative test result = $LR- = (1 - sens) / spec =$
- Positive predictive value = $a / (a + b) =$
- Negative predictive value = $d / (c + d) =$
- Pre-test probability (prevalence) = $(a + c) / (a + b + c + d) =$
- Pre-test-odds = $prevalence / (1 - prevalence) =$
- Post-test odds = $Pre-test odds \times likelihood\ ratio =$
- Post-test probability = $post-test\ odds / (post-test\ odds + 1) =$

Can you apply this valid, important evidence about a diagnostic test in caring for your patient?

Is the diagnostic test available, affordable, accurate and precise in your setting?	
Can you generate a clinically sensible estimate of your patient's pre-test probability (from practice data, from personal experience, from the report itself or from clinical speculation)	
Will the resulting post-test probabilities affect your management and help your patient? (Could it move you across a test-treatment threshold? Would your patient be a willing partner in carrying it out?)	
Would the consequences of the test help your patient?	

Additional notes:

The Answer:

Are the results of this systematic review of therapy valid?

PICO QUESTION	
Search terms used	
Databases searched to find this article	
Citation of article	
Why did you select this article(s)?	
Did the authors answer the question?	
1. What databases and other sources did the authors of this review search?	
2. What were their eligibility criteria (inclusion and exclusion) for papers in this study? Do these seem appropriate?	
3. Was their independent data extraction of the results by the reviewers (then compared later)?	
4. Is there a description of the quality of each trial included?	
5. Were the results consistent from study to study (Homogeneous)?	

Are the valid results of this systematic review important?

What was the odds ratio?	
What was the control group rate (PEER)	

Can you apply this valid, important evidence from a systematic review in caring for your patient?

Do these results apply to your patient?	
Is your patient so different from those in the overview that its results cannot help you? How great would the potential benefit of therapy actually be for your individual patient?	
To calculate the NNT for any OR and PEER $\text{NNT} = \frac{1 - (\text{PEER} * (1 - \text{OR}))}{(1 - \text{PEER}) * \text{PEER} * (1 - \text{OR})}$ Or use calculator from www.cebm.net	

Are your patient's values and preferences satisfied by the regimen and its consequences?

Do your patient and you have a clear assessment of their values and preferences?
Are they met by this regimen and its consequences?
Should you believe apparent qualitative differences in the efficacy of therapy in some subgroups of patients? Only if you can say 'yes' to all of the following:
Do they really make biologic and clinical sense?
Is the qualitative difference both clinically (beneficial for some but useless or harmful for others) and statistically significant?
Was this difference hypothesized before the study began (rather than the product of dredging the data), and has it been confirmed in other, independent studies?
Was this one of just a few subgroup analyses carried out in this study?

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: intra-operative monitoring, facial nerve, cranial nerve and auditory evoked potentials.

DEVELOPMENT OF FACIAL NERVE MONITORING

The first description of intra-operative cranial nerve stimulation was by Fedor Krause in 1898.¹ During cochlear nerve section for tinnitus, he noted 'unipolar faradic stimulation of the (facial) nerve-trunk with the weakest possible current of the induction apparatus resulted in contractions of the right facial region, especially of the orbicularis oculi, as well as the branches supplying the nose and mouth'. Over the next three-quarters of a century, a series of articles refined the technique, all relying on observing movement of the face in order to confirm the functional integrity of the facial nerve.²⁻⁷ The evoked facial twitch was observed by either the anaesthetist or ancillary staff under the drapes using a flashlight or mirror. These techniques lacked both quantitative control of the stimulus and objective recording of the evoked responses.

In 1979, Delgado and colleagues first described the use of evoked compound muscle action potentials (CMAP) to monitor facial nerve function in response to stimulating the intra-cranial portion of the facial nerve.⁸ The introduction of facial electromyography (EMG) enabled not only facial nerve identification either by electrical stimulation or inadvertent manipulation, but also the possibility of mapping its course through the temporal bone and assessing changes in function during surgical resection of tumour from the nerve's surface.⁹ Facial nerve monitoring

has proved an invaluable aid during vestibular schwannoma surgery.¹⁰⁻¹² The introduction of an auditory signal enabled instantaneous real-time auditory feedback to the surgeon during tumour dissection without information passing through an intermediary.^{13, 14}

Three trials tested the hypothesis that facial nerve outcome improved when using intra-operative facial nerve monitoring. Harner and colleagues¹² demonstrated the usefulness of facial nerve monitoring in 91 consecutive cases of vestibular schwannoma resection via the suboccipital route. At 1 year, 78% of those patients who were monitored demonstrated facial function, compared with 65% in an unmonitored group, these data were not studied statistically. Niparko and colleagues¹⁵ described the results of 29 patients who underwent translabyrinthine removal of vestibular schwannoma and compared them with a similar group of 75 unmonitored patients. They demonstrated that monitoring was associated with a significant improvement of facial function at 1 year for tumours over 2cm intra-cranial diameter. Kwartler and colleagues¹⁶ demonstrated that monitored patients with tumours over 2.5cm had a significant improvement of facial function when compared with a matched unmonitored group.

The benefit of facial nerve monitoring during surgery for chronic middle ear disease is less certain. Facial nerve injury after otological surgery is rare in experienced hands and there are no randomized controlled trials examining its efficacy. Silverstein and others recommend that

the facial nerve should be monitored during all general anaesthetic cases where the facial nerve is at risk.^{17, 18} This view is in contrast to most American otolaryngologists, although those who trained in the 1990s, those in an academic setting and those who perform more otology than other types of surgery are more likely to use monitoring techniques.^{19, 20} Hu et al. reported a survey that showed an increase in the number of surgeons who felt that facial nerve monitoring should be used as a standard of care from 32% in a similar study performed 10 years previously, to 49% in their more recent survey group.²¹ This proportion is thought to be higher in the UK and Australia, however.²²

Increasing usage of nerve monitors has implications for litigation cases. In general such cases question whether a reasonable body of practitioners would employ a nerve monitor during surgery (Bolam test). If any such body is likely to recommend use of monitoring, then failure to use a monitor would likely become indefensible, as breach of duty could be established. The principle remains, however, that if any adverse outcome would have occurred regardless of the lack of nerve monitoring, then the claim would fail. The claimant must therefore establish causation. At the time of writing, a freedom of information request from the NHS litigation authority had identified 15 claims for facial nerve injury during otological surgery from 2003 to 2013, 9 of which had been successful with total damages claimed of £488,571.

Facial nerve injury often occurs when there is an unexpected change to normal middle ear anatomy, precisely the time when monitoring is so valuable. The senior surgeon must take responsibility to ensure that the equipment is functioning normally. A simple technique for confirming equipment function is described under 'Technique for continuous facial nerve monitoring' below. Intra-operative facial nerve monitoring is no substitute for experience in the otological setting and should not replace good surgical practice, but if the operating team adopt the approach that all patients are monitored, the set-up technique becomes routine and more reliable. With developments in robotic surgery, investigators have evaluated facial nerve monitoring systems that have been integrated into the drill system, to determine whether such systems could reliably warn of impending facial nerve contact during robot-assisted direct cochlear access procedures. At present, however, such systems lack sensitivity and repeatability.²³

TECHNIQUE FOR CONTINUOUS FACIAL NERVE MONITORING

The operating theatre is filled with electrical interference generated by the equipment surrounding the anaesthetized patient. Monitoring techniques have developed to minimize this interference and amplify only relevant information. Two sets of subdermal platinum or stainless steel needle recording electrodes are inserted into the upper and lower face. The electromyographic electrical response is biphasic (as electrical potential moves past one electrode it becomes negatively charged compared to its

paired neighbour, until it reaches that electrode and the situation reverses). The amplifiers amplify the difference between the potentials recorded at each electrode. This arrangement has the advantage of common mode rejection; electrical interference from other sources is recorded by both electrodes equally and therefore does not create a potential difference between the two closely aligned electrodes. A number of commercial EMG cranial nerve monitoring systems are now available including the NIM-2 (Xomed Treace, Jacksonville, FL, USA) and the Neurosign (Magstim, Whitland, UK). They rely on recording facial muscle activity and delivering the information as a visual and audible representation of the CMAP response. The audible response is presented as either raw EMG activity or a characteristic sound when EMG activity reaches a set threshold.

All systems are isolated and self-contained electrical nerve stimulator and monitoring units. The electrodes are connected to a preamplifier pod, which is attached to the operating table. The recorded electrical signal is filtered through high- and low-pass filters and either rectified and displayed on a logarithmic bar chart or presented as a CMAP waveform. Different systems use different methods of presenting the same information to the surgeon. The logarithmic bar chart has a delayed response decay to enable calculation of rectified CMAP amplitude. Systems that present a CMAP waveform present it as visual and audible real-time information or utilize image capture strategies that also give waveform amplitude information. This allows the surgeon time to examine the waveform and size of the CMAP. So-called 'repetitive responses' occur as a result of repetitive depolarizations after surgical manipulation has ended. They can be used as a measure of nerve irritability as a result of early damage (e.g. from thermal injury). Compare this with non-repetitive responses that are indicative of direct mechanical stimulation of the nerve.

Familiarity with the set up and function of a chosen monitoring system is essential. The senior surgeon must take responsibility and should check that the equipment is functioning normally. Tapping the skin overlying the two sets of subdermal electrodes will generate a recorded response on the monitor. This confirms that electrodes are connected to the preamplifier pod and in turn the preamplifier pod is connected to the monitor, which is switched on. The volume should be checked so that a response is audible over background theatre noise.

Facial nerve stimulation is delivered as a short (0.1 ms) electrical pulse. This is the default setting for most monitors. The stimulating electrode is either monopolar or bipolar. The monopolar electrode is favoured because it is simple to use, but has the disadvantage of stimulating a larger area. The bipolar electrode requires careful positioning of both electrode tips on to the tissue surface; this can prove difficult in the tight confines of the temporal bone. The use of constant voltage stimuli has an advantage over constant current stimuli because it delivers a relatively reliable current to the nerve whatever the medium that surrounds the nerve. In 2013 the American Society of Neurophysiological Monitoring established a position statement on intra-operative motor evoked potential

monitoring, based upon best available evidence,²⁴ which included guidelines on proper usage, interpretation and general anaesthesia use in a variety of clinical settings including facial nerve monitoring. Regarding general anaesthesia, Choe et al. also concluded that induction of total intravenous anaesthesia with propofol and remifentanyl provided reliable conditions for facial nerve monitoring during complex ear surgery.²⁵

PREDICTING POST-OPERATIVE FACIAL FUNCTION

A number of studies have described an objective technique that correlates parameters of the evoked CMAP to eventual facial outcome.^{15, 26-29} The test gives non-dichotomous results and therefore a retrospective cut-off point is used to predict those patients who have a good prognosis. Results indicate that a low stimulation threshold, across the site of tumour dissection, is a valuable prognostic indicator of good long-term facial function. The technique, which is simple to perform, assesses the minimum current required to evoke a muscle response after tumour resection. The drawback to the described technique is that the majority of patients have some degree of facial function immediately after surgery. This group will almost certainly have good long-term outcome.³⁰ It is the small group of patients with poor facial function immediately after surgery that will benefit most from a sensitive and specific predictive test. Axon and Ramsden compared post-dissection minimal stimulation thresholds with immediate post-operative facial function for predicting long-term facial function in 184 patients undergoing vestibular schwannoma surgery.³⁰ Post-dissection stimulation thresholds demonstrated only a moderate relation to eventual outcome, which was of limited clinical value. The test criteria were then applied to patients with poor immediate post-operative facial function for predicting long-term outcome; the predictive accuracy fell, further reducing test validity.

Some studies compared the supramaximal CMAP to either facial nerve stimulation proximal and distal to tumour dissection or before and after tumour dissection. These techniques have been advocated as more accurate methods of analysing data, because they remove absolute amplitude comparisons and rely on comparison of ratios.^{31, 32}

DIFFICULTIES OF MONITORING FACIAL FUNCTION

All otological procedures rely on a facial muscle response, warning the surgeon that the facial nerve is near. A simple audible noise is all that is required. Recent monitoring systems have increased the amount of information available to the surgeon, stimulating the desire to expand monitoring techniques and so improve patient outcome. This information is superfluous to most procedures and of benefit to only a few. Facial CMAPs represent a complicated

interplay between groups of muscle fibres depolarizing in response to facial nerve stimulation. The muscles of the face are very different to those found in the limbs. The facial motor units are small, often having only 25 muscle fibres supplied by each motor neuron compared with many thousands in more peripheral muscles. As a consequence, each muscle has a wide, ill defined motor end-plate zone. The muscles are also arranged in an almost haphazard arrangement, overlying each other and aligned in different directions. This makes meaningful electrophysiological recording difficult. Intra-subject variability (test-retest variability) is high and intersubject comparison almost impossible. The CMAP waveform is usually multiphasic instead of the well-recognized biphasic responses recorded from peripheral muscles, a consequence of phase cancellation. Calculation of maximum amplitude or area under the waveform bears little relation to the number of motor neurons innervating the muscle fibres that create the response.

MONITORING FACIAL FUNCTION FOR NON-OTOLOGICAL PROCEDURES

The facial nerve is at risk of iatrogenic injury in the cerebellopontine angle and parotid. Intra-operative facial nerve monitoring has been advocated during microvascular decompression and superficial parotidectomy.^{33, 34} Arguments for adopting its use for all surgical procedures are the same as those for otological surgery.

MONITORING AUDITORY FUNCTION

The aim of monitoring the status of the auditory pathway during cerebellopontine angle (CPA) surgery is the prevention of avoidable post-operative hearing deficit. The achievement of this laudable aim is fraught with difficulty and hearing preservation rates in comparison with facial nerve outcomes remain poor.³⁵ The cochlear nerve is sensitive to mechanical manipulation and easily damaged, as the intra-cranial section of the nerve is sheathed in central myelin and has no perineurium.³⁶ Additionally, the cochlear nerve is intimately involved with pathologies, such as vestibular schwannoma, and hence at very considerable risk during the surgical removal of such lesions, even when every care is taken to preserve the nerve anatomically. The basic principle of intra-operative monitoring is that changes in recordable neuroelectric potentials occur whilst the injury is still reversible and before permanent deficits result.³⁷ Recent research³⁸ has demonstrated that this principle holds for changes in auditory brainstem responses (ABR) wave V amplitude (and to a lesser extent latency) in rat auditory nerves manipulated in a fashion analogous to that undergone in humans during vestibular schwannoma removal. It is therefore theoretically feasible that monitoring auditory function may inform the surgeon of reversible injury to the cochlear nerve.

One prerequisite of monitoring auditory function during surgery is that sufficient pre-operative hearing must remain such that meaningful recordings may be made in the operating theatre and change observed if and when it occurs. If ABR or electrocochleography (ECoChG) are the monitoring techniques of choice, a further prerequisite is for pre-operative recordings with that technique. Monitoring with ABR is not possible if waveforms are absent or of grossly abnormal morphology.

Whilst the techniques and equipment utilized for auditory monitoring may seem familiar from the outpatient clinic, their use in monitoring is significantly different. Rather than comparing an individual's data with group data, in monitoring, one is comparing a sequence of waveforms over time and evaluating for change. The time allowed for eliciting each recording is limited and this will influence the choice of recording parameters. The decision whether to inform the surgeon of a change in recorded activity is both urgent and crucial. As such, the person undertaking monitoring should be familiar with the operating theatre environment and team, and be able to interpret and communicate observed and measured change to the surgeon confidently and concisely.³⁹ Such skills are rare and this may prove to be a hindrance to the widespread adoption of these techniques.

Lloyd et al.⁴⁰ have shown that patients benefit from cochlear implantation after a translabyrinthine approach for acoustic neuroma excision with cochlear nerve preservation. Such findings highlight the clinical relevance of being able to monitor the eighth nerve intra-operatively in order to reliably predict who might benefit from such strategies.

TECHNIQUES

Otoacoustic emissions

Cane et al.⁴¹ undertook a feasibility study of the use of otoacoustic emissions (OAE) as a technique for monitoring the auditory pathway during surgical removal of a vestibular schwannoma. The experience was that OAE recordings were feasible despite the noise within the surgical environment, but the study did not indicate that OAE would be a useful indicator of early, reversible injury. Theoretically, OAE recording may furnish evidence of cochlear function, but as the site of surgery is the internal auditory canal (IAC), one would not be measuring activity deriving from the point of possible injury. OAE monitoring might therefore give information about ischaemic or noise injury to the cochlea, but it has not yet been demonstrated that this would be at a point where the injury was reversible. At the present time, however, the use of OAE in monitoring auditory function during surgery is rare.

Electrocochleography

Similarly, electrocochleography records activity associated with cochlear function and the distal portion of the

cochlear nerve, rather than the intra-cranial portion of the cochlear nerve, which is acutely at risk during surgery. As such, even strong advocates of ECoChG in monitoring have seen it as adjunct to ABR, and not providing the surgeon with the required information when used alone. There is research evidence that responses to auditory stimulation recorded by ECoChG persist after complete transection of the eighth nerve in the rat,⁴² and so this technique has the potential to mislead if used in isolation.

One potential advantage of the use of ECoChG is the large amplitude of the activity recorded.⁴³ This allows interpretation of the elicited waveform after fewer averages, so that decision-making may be more rapid.⁴⁴ As with ECoChG in the outpatient context, there is debate about the optimal site of the recording electrode, with advocates for extratympanic intra-meatal placement³⁶ and transtympanic placement.⁴⁵ A further advantage is that ECoChG recordings are less compromised by acoustic noise or by electrical artefact as may occur during cautery, and may serve some purpose whilst these are present.⁴⁶

Auditory brainstem responses

Auditory brainstem responses have a theoretical advantage over other techniques in that certain peaks within the waveform derive from anatomical structures at risk of injury during surgery. The generator of wave I is considered to be the distal portion of the cochlear nerve, the site also held to be the generator of the N1 component of the compound action potential recorded by ECoChG.³⁶ Wave II is associated with the proximal section of the cochlear nerve,³⁷ wave III with the lower pons (specifically the superior olivary complex)⁴⁷ and wave V with the inferior colliculus.⁴⁷ The generators of waves III and V are, therefore, unlikely to be directly challenged by surgical manipulation during hearing preservation surgery for space occupying lesions of the CPA, but the latencies of these easily identifiable waves are used during monitoring as change reflects latency change of waves I and II.

Specific methodologies and parameters utilized in intra-operative ABR have been described in detail. The reader who intends to perform this procedure is directed to the comprehensive reviews by Moller³⁷ and Martin and Mishler.³⁶ Several points should be noted. There is considerable variability in the methods advocated and clinical trial evidence is not apparent. Second, this variability may account in part for the lack of a strong evidence base for the benefits of auditory monitoring. Further, the reviews cited underline the difference between utilizing ABR in the outpatient clinic and the operating theatre, the need for the technique not to inconvenience surgical techniques and the utility of clear and timely interpretation and communication of change in recordings to the surgeon. In more recent work the importance of obtaining pre-operative ABR has been highlighted.⁴⁸ The authors concluded that knowledge of the ABR before surgery helps to solve problems such as choosing to monitor the interaural latency difference of wave V, cochlear nerve action potential or alternative sound-evoked ABR.

Direct recordings from the cochlear nerve

The need for rapid acquisition of responses may be met by recording directly from the cochlear nerve, the large amplitude of the elicited activity obviating the need for lengthy averaging.⁴⁹ This technique was first developed to monitor cochlear nerve function during microvascular decompression surgery, but has been adapted for use during surgical removal of space occupying lesions of the CPA.⁴⁴ The site of recording is usually the root entry zone, and both monopolar and bipolar electrodes have their advocates.⁵⁰ Click stimuli similar to those used in ABR are used to elicit the response, which comprises a compound action potential. Changes in latency, amplitude and morphology should all be reported to the surgical team.³⁷ Ehrmann-Müller et al.⁵¹ compared direct cochlear recordings using a ball electrode, to ABR results, to evaluate its effectiveness in predicting hearing outcomes after acoustic neuroma excision. They found that such direct recordings gave a sensitivity of 100% and specificity of 70%, and it was possible even in cases where they were unable to obtain reliable ABR results.

Combining techniques

Given that each of the techniques described above has technical challenges and shortcomings, many teams choose to utilize more than one, the most common combination being direct cochlear nerve recording and ABR.⁵²

EVIDENCE OF THE EFFICACY OF MONITORING AUDITORY FUNCTION

Authors have reported hearing preservation rates following vestibular schwannoma excision, but the heterogeneity of pathological status, surgical technique, surgical experience and criteria for reporting of hearing preservation combine to frustrate analysis of the clinical utility of auditory monitoring. Observational evidence in this area abounds.^{53–55} The need for well-designed, hypothesis-driven clinical trials in this field is paramount.

A similar dearth of evidence is found when determining the relative efficacy of techniques or combinations

of techniques. Several studies have reported that direct cochlear nerve recordings are more effective in the maintenance of hearing function than ABR, to an extent that is statistically significant.^{56, 57} This effect is said to be due to the immediacy of direct recordings.⁵⁸

Despite the lack of evidence, a consensus is building that monitoring auditory function during CPA surgery is best practice,⁵⁰ and that a combination of ABR and direct cochlear nerve recording is optimal,⁴³ with the adjunctive use of ECoChG if desired.⁴⁵

BEST CLINICAL PRACTICE

- ✓ Regarding monitoring of facial nerve function, there is evidence that these techniques offer benefit in improving facial nerve outcomes in surgery that may challenge the facial nerve. As such it is strongly indicated.
- ✓ The evidence base for monitoring auditory nerve function is less robust, but it should be regarded as best clinical practice.

FUTURE RESEARCH

- Further work is required to develop an intra-operative technique that enables accurate assessment of clinical facial nerve function at any point during skull base procedures. Only accurate estimation of motor neuron function will give the surgeon a true representation of immediate facial function and hopefully then enable development of a valid predictive technique.
- The specialty as a whole requires a good evidence base to support the use of intra-operative facial nerve monitoring as the standard for all otological procedures that place the facial nerve at risk.

KEY POINTS

- Monitoring facial nerve function is straightforward and neither hampers nor impedes surgery.
- There is good evidence that monitoring facial nerve function improves outcomes of facial function.
- A consensus has not yet been reached on techniques for monitoring auditory function, but it looks likely that a combination of techniques will be optimal.

SEARCH STRATEGY

Data in this chapter may be updated by PubMed, Embase and the Cochrane Library performed by an information specialist librarian. Searches used the following keywords: optical coherence tomography, needle biopsy, surgical guidance, nasal, vocal cord and/or otology. Levels of evidence are not really applicable to the scientific principles of this area, but the human studies that underlie the discussion of optical coherence tomography as applied to otorhinolaryngology are observational, or at best non-randomized.

INTRODUCTION

Medical imaging technology has advanced rapidly over the past 25 years, providing physicians with essential information on the macroscopic anatomy of patients. Techniques capable of imaging subepithelial structure *in situ*, such as conventional X-ray radiography, magnetic resonance imaging (MRI), computed tomography (CT) and ultrasonography have allowed the non-invasive investigation of relatively large-scale structures in the human body, with resolutions ranging from 100 μm to 1 mm. Resolution on this scale, however, is insufficient to detect the subtle changes in tissue microstructure characteristic of many ear, nose and throat (ENT) pathologies.

In the field of laryngology, light endoscopy currently forms the cornerstone of clinical imaging and biopsy guidance, yet conventional light endoscopic techniques are unable to reveal information concerning subepithelial tissue. Since many laryngeal pathologies originate near the boundary between the epithelium and the underlying mucosa, or within the mucosa itself, the inability to image subepithelial tissue represents a serious limitation of conventional light endoscopy. Even as a method for guiding biopsy, conventional light endoscopy gives only a relatively coarse indication of prospective biopsy locations. Frequently, a large number of biopsies are required to achieve high diagnostic accuracy, a situation that is often

undesirable or unfeasible given the fragility of adjacent structures. This is particularly true for the vocal folds, which have a specialized and delicate microstructure that is highly intolerant of trauma. These limitations restrict the effectiveness of light endoscopy for the diagnosis, monitoring and treatment of many laryngeal pathologies. Clinical laryngology would thus greatly benefit from a non-invasive imaging technology capable of resolving subepithelial tissue microstructure in the range of conventional biopsy.

Optical coherence tomography (OCT) is a relatively new optical imaging modality that allows high-resolution, cross-sectional imaging of tissue microstructure. OCT can image with an axial resolution of 1–15 μm and has an imaging depth of 2–3 mm in non-transparent tissue. OCT was first applied in 1991 to imaging optically transparent structures, such as the anterior eye and retina.^{1, 2} Subsequent technological advances have enabled high-resolution imaging of non-transparent tissue in the cardiovascular system³ and the gastrointestinal,⁴ urinary⁵ and female reproductive tracts.⁶ In addition, the application of OCT to surgical guidance⁷ and carcinoma detection^{6, 8} has been explored.

The aforementioned imaging studies have demonstrated that OCT is particularly informative in tissues in which non-keratinized epithelium is separated from the underlying stroma by a smooth basement membrane zone, suggesting that OCT may have a strong clinical relevance

in laryngology. This indication is further strengthened by several features of the OCT system itself:

- OCT imaging can be performed *in situ* and non-destructively, enabling the imaging of tissue for which biopsy should be avoided or is impossible.
- OCT gives images of high resolution, 10–100 times that of conventional MRI or ultrasound.
- Imaging can be performed in real time, without the need to process a specimen, as in conventional biopsy, and without the need for a transducing medium, as in ultrasound imaging.
- OCT is fibre-optically based and can thus be interfaced to a wide range of instruments including catheters, endoscopes, laparoscopes and surgical probes.
- OCT systems can be engineered to be compact, portable and low cost, depending on the desired system specifications.

Although now entering human trials in a variety of areas within otolaryngology, early research focused on the potential applications of OCT to laryngeal tissue, imaging of the middle ear⁹ and of rat cochlea¹⁰ *ex vivo* and nasal tissues¹¹ with promising results. Before presenting and discussing OCT images of larynges *ex vivo*, it is useful to briefly describe the basis by which OCT systems form subepithelial images.

OCT: SYSTEM OPERATION

Optical coherence tomography performs high-resolution tomographic imaging by measuring light backscattered, or backreflected, from internal tissue structures. OCT imaging is analogous to ultrasound B-mode imaging, but is based on the detection of infrared light waves, instead of sound. Like acoustic waves, light is characterized by its propagation direction. Light is distinct, however, in that it has an additional vector characteristic known as polarization. The polarization direction is orthogonal to the propagation direction and can be influenced by the medium in which the light propagates. This is known as ‘birefringence’. Polarization measurements can be used to provide additional insights into the microscopic structure and integrity of tissues. An adjunct to conventional OCT, polarization-sensitive OCT (PS-OCT), exploits birefringence as an additional contrast mechanism for imaging tissue. PS-OCT will be discussed in further detail under ‘Polarization-sensitive OCT’ below.

The analogy with ultrasound is a useful starting point for understanding the basics of OCT. In ultrasound, a high frequency acoustic pulse travels into the tissue and is reflected, or backscattered, from internal structures having different acoustic properties. The magnitude and the delay time of the echoes are electronically detected, and the structural properties of the internal tissues are determined from the measured signals. In OCT, imaging is performed by measuring the echo delay time and

magnitude of light backreflected, or backscattered, from internal structures with distinct optical properties. Unlike in ultrasound, though, the speed of light is very high, rendering electronic measurement of the echo delay time of the reflected light impossible. OCT systems circumvent this limitation by using low coherence interferometry, also known as white light interferometry, to characterize optical echoes.

The most common OCT echo detection scheme is based on a Michelson interferometer set up with a scanning reference delay arm, shown in **Figure 46.1**. Within the interferometer, the beam leaving the optical light source is split into two parts, termed the reference and sample beams, at the beam splitter. The reference beam then travels to a mirror, located at a known distance from the detector and subsequently returns to the beam splitter. The sample beam travels to the tissue sample and is reflected back towards the detector by scattering sites within the tissue. Light reflecting from deeper tissue layers has traversed a greater optical pathlength (optical distance) and therefore arrives at the detector at a later time. In addition, the various backreflected parts of the sample beam will have different amplitudes based on the differing strengths of the scattering sites. The reflected portions of the sample beam then return to the beam splitter where they interact with the reflected reference beam and are directed towards the detector.

When two waves from the same source recombine in this manner, an interference pattern will result if the optical path length travelled by the two waves is identical. The output detector measures the intensity of this interference pattern and thus only measures information contained in the portion of the sample beam that has travelled the same optical distance as the light in the reference arm. Information about the remaining tissue layers can be extracted by moving the mirror in the reference arm, which changes the optical path length travelled by the reference beam. Two- or three-dimensional images are produced by scanning the beam across the sample and

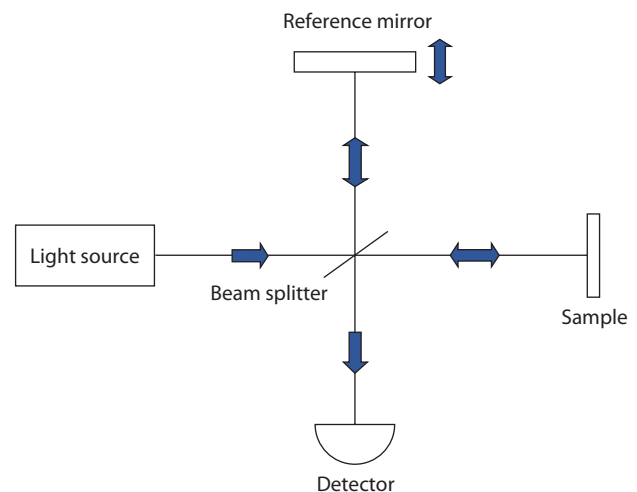

Figure 46.1 Schematic of an optical coherence tomography system using a Michelson interferometer with scanning reference delay arm.

recording the optical backscattering versus depth at different transverse positions. The resulting data is a two- or three-dimensional representation of the optical backscattering of the sample on a micron scale.

OCT IMAGING OF THE LARYNX

To assess the potential value of OCT imaging technology in improving visualization and pathology, as well as the diagnosis and treatment of a given organ system, it is essential to first image normal tissue from that particular organ and then reference the resulting OCT images to parallel histology.

Initial studies of the laryngeal imaging using OCT^{12, 13} have focused on the following structures due to clinical relevance:

- the laryngeal surface of the epiglottis
- the false folds
- the inferior surface of the true folds.

The images presented are based on a similar focus. It should be noted, however, that since OCT can be readily adapted to fibre optic-based probes, other areas of traditionally poor visibility in light endoscopy, such as the anterior commissure, the subglottis and the laryngeal ventricle, could also be readily imaged using this technology.

In **Figure 46.2**, an OCT image of the laryngeal surface of an ovine (sheep) epiglottis and the associated histological section are shown. Several different layers of the epiglottic tissue are visible, with epithelium, lamina propria

Figure 46.2 (a) OCT image of an ovine epiglottis; (b) corresponding haematoxylin and eosin histology section. Scale bars represent 150 μm .

and cartilage being clearly demarcated. Glandular structures and vessels are also frequently visible.

Figure 46.3 presents an OCT image taken along the inferior portion of a porcine true fold, as evidenced by the transition from free-edge non-glandular mucosa to subglottal glandular mucosa observed in the OCT image and corresponding histological section. This image illustrates the ability of OCT to allow visualization of the epithelium, basement membrane and lamina propria of the true fold, as well as of certain structural features, such as glands and vessels. Note in particular that local epithelial thickness and transparency of the true fold can be readily deduced from these images, implying that OCT may prove useful for the diagnosis of hyperplasia, early-stage keratosis and papillomas, and other pathologies resulting in epithelial abnormalities not normally visible by conventional light endoscopy until an advanced stage. Since many laryngeal pathologies originate at the border between the mucosa and the epithelium, the ability to observe the integrity

Figure 46.3 (a) OCT image of the inferior surface of a porcine true fold; (b) corresponding haematoxylin and eosin histology section; (c) phase-contrast viewing of the stained histology section. Scale bars represent 150 μm .

of the basement membrane via OCT imaging may have important implications for the use of this technology in aiding the diagnosis and monitoring of such laryngeal disorders, possibly including early stage carcinoma.

POLARIZATION-SENSITIVE OCT

A monochromatic light wave carries three potential sources of information contained in the amplitude, phase and polarization state of its electrical field vector. Conventional OCT, by detecting only the intensity of the interference pattern resulting from interaction of the sample and reference optical beams, fails to quantify the effects of tissue on the polarization state of the sample light beam. An adjunct to conventional OCT, known as polarization-sensitive OCT, therefore has focused on exploiting the information contained in the polarization state of the light backreflected, or backscattered, from the sample relative to that of the reference beam to obtain information about the tissue microstructure.

In order to appreciate the power of PS-OCT and its potential applications, it is helpful to describe briefly the main mechanisms by which tissue alters the polarization state of light. Two mechanisms dominate the changes in the polarization state of light propagating through biological tissue: scattering and birefringence. Scattering changes the polarization of light mainly in a random manner, so it is generally not useful in mapping tissue structure. Organized linear structures, on the other hand, such as collagen fibre bundles with a clear orientation, can exhibit birefringence, resulting in a predictable change in polarization state. Many biological tissues exhibit birefringence, such as tendons, muscle, nerve, bone, cartilage and teeth.¹⁴ Since changes in birefringence may, for instance, indicate changes in functionality, structure or viability of tissues, PS-OCT images may contain information that can be used to evaluate tissue microstructure and health beyond the level possible with the use of OCT alone.¹⁵

The potential implications for clinical laryngology of the sensitivity of PS-OCT to organized linear structures, such as oriented collagen fibre bundles, are numerous. To illustrate, the human vocal fold lamina propria is generally subdivided into the superficial, intermediate and deep layers, with each layer having a characteristic composition and functionality. The relative thickness and integrity of these various layers appear to have a profound impact on voice. This idea is supported by the fact that the average adult will experience marked thinning of the superficial lamina propria relative to the intermediate and deep layers with increasing age,¹⁶ with a concomitant reduction in voice quality.

Histological studies of normal adult human vocal fold tissue have repeatedly noted increased density and longitudinal orientation of collagen fibres as one progresses from more superficial to deeper lamina propria layers.¹⁶ PS-OCT, due to its sensitivity to oriented collagen fibre bundles, may thus allow indirect detection of these lamina propria layers *in situ* and hence monitoring and possibly

improving treatment of voice ageing. In the case of vocal fold scarring, the biomechanical integrity of the lamina propria is disrupted, resulting in reduced vocal fold pliability and thus decreased vocal range and quality. Scar tissue has collagen fibre orientation and density that is generally distinct from that of normal tissue and therefore PS-OCT may also prove useful in visualizing, localizing and treating vocal fold scars within the lamina propria. These capabilities could have a profound impact in the area of voice management.

Figure 46.4 compares a PS-OCT image of the inferior surface of a human true fold with the corresponding OCT image and histological section. Note the banding pattern apparent in the PS-OCT image of the vocal fold. A transition from white to black banding indicates a change in the polarization state of light. In particular, observe the marked increase in the thickness of the initial subepithelial white band in the leftmost portion of the PS-OCT image (corresponding to the true fold free edge) relative to that in the more subglottic tissue. The spatial location of this thickened initial band corresponds closely with the increased prominence of the superficial lamina propria in this region. Since collagen in normal superficial lamina propria is sparse and relatively randomly oriented, a net change in the polarization state of light will be slow to occur in this region. Hence, the thickness of the superficial lamina propria can potentially be inferred from the thickness of the initial subepithelial PS-OCT band. The true fold superficial lamina propria features critically in vocal health and disease. Although the presented results are not definitive, the potential of PS-OCT to detect changes in the superficial lamina propria thickness and collagen alignment is an exciting area for future study.

Again, it must be stressed that further studies must be carried out to determine what the observed vocal fold polarization patterns truly indicate. In the case that these studies show that the relative thickness and/or health of the lamina propria layers can indeed be indirectly assessed by this imaging adjunct, PS-OCT could prove very useful to the study of lamina propria health and in the development of targeted scar treatment strategies.

CLINICAL STUDIES UTILIZING OCT

A number of studies have explored OCT use *in vivo*. Whilst these studies are predominantly non-randomized pilot or proof of concept studies they illustrate potential clinical applications for widespread clinical practice.

The most studied area of interest in otolaryngology has been for imaging of the larynx. A number of studies have utilized OCT in conjunction with microlaryngoscopy, with or without histology for a range of benign and malignancy pathologies.^{17, 18} Initial experience is promising, with good correlation between OCT and histological diagnosis. However, the exact role of OCT remains unclear and we currently lack large-scale studies to justify replacement of histological confirmation.

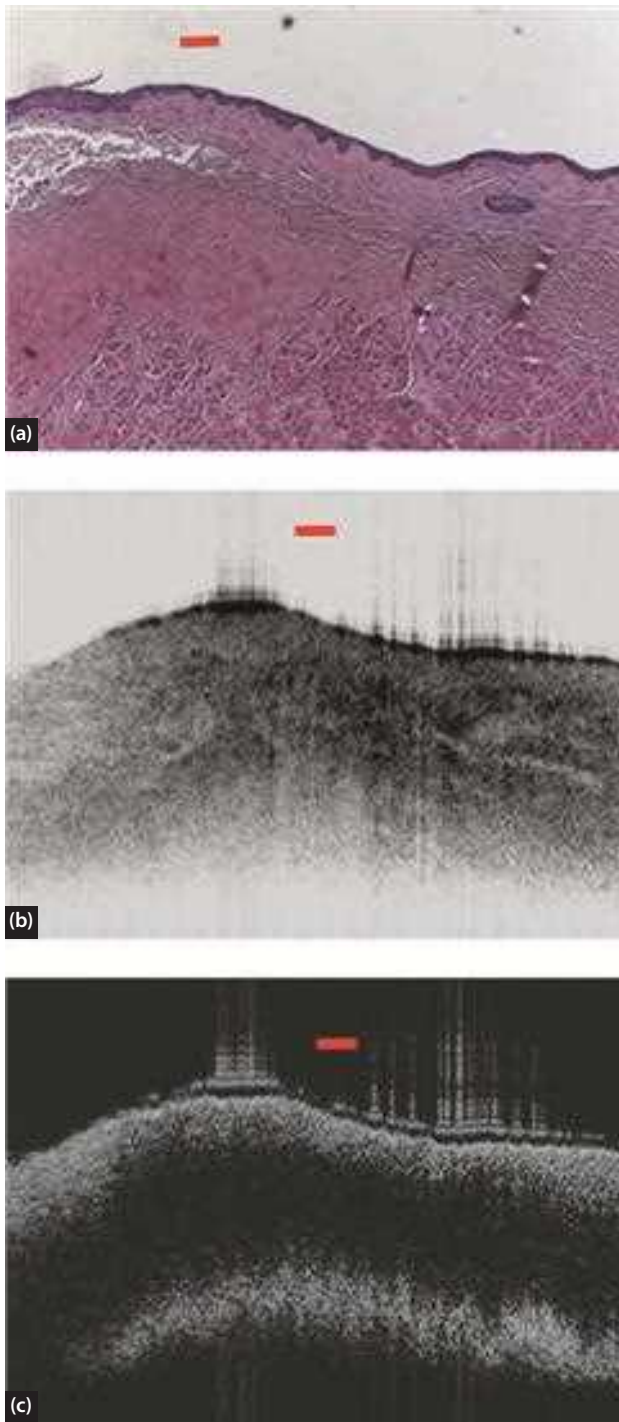

Figure 46.4 (a) Haematoxylin and eosin histology section of the inferior surface of a human true fold; (b) corresponding OCT image; (c) corresponding PS-OCT image. Scale bars represent 150 μm .

In paediatric otolaryngology studies have explored the use of fourier domain optical coherence tomography (FD-OCT) and long-range optical coherence tomography (LR-OCT) for the development of computerized airway models for predicting neonatal subglottic stenosis following intubation¹⁹ and localizing the site of upper airway obstruction in children with sleep disordered breathing.²⁰

Furthermore, OCT may be helpful to evaluate cartilage in the lower trachea or bronchi. Congenital absence of cartilaginous tracheal rings associated with esophageal atresia and trifurcated carina: a novel anomaly?²¹ Again whilst these avenues show promise there remains some distance from definitive trials likely to change routine practice.

In head and neck surgery, one study has demonstrated the feasibility of using two newer generation OCT systems – optical frequency domain imaging (OFDI) and micro-optical coherence tomography (μOCT) imaging – to identify parathyroid tissue with histology-like levels of certainty, without the need for frozen section.²² It is not too much of a leap to imagine a handheld probe used in a similar manner to a nerve stimulator for intra-operative localization, though this is not currently available. Another study reported two cases where OCT was combined with endobronchial ultrasound (EBUS) for the potential identification of residual hypertrophic and persistent inflammatory tissue (known contributors to stricture recurrence) following laryngotracheal dilation of post-intubation laryngotracheal stenosis, with some promising results, although the sample size was small.²³

Within Otology OCT imaging has been demonstrated in combination with robotic surgery for localization and electrode placement for cochlear implantation has been demonstrated on dry-fixed human temporal bones.²⁴ Further small case series advocate the use of OCT to identify the stapes footplate in revision stapes surgery²⁵ and as an adjunct to otomicroscopy for the identification of myringitis and potential biofilm formation.²⁶

SUMMARY

OCT and OCT adjuncts have enormous potential for improving the diagnosis, monitoring and both surgical and non-surgical management of diseased ENT tissues. Conventional OCT provides objective information concerning the structure of tissue elements with distinct optical backscattering and backreflection properties. With regard to the larynx, conventional OCT studies of healthy laryngeal tissues *ex vivo* have demonstrated that OCT can detect spatial changes in the thickness and transparency of the epithelium, the content of the connective tissues in terms of glands and vessels, as well as pronounced transitions in connective tissue type and the architecture of the basement membrane.²⁷ PS-OCT holds promise for permitting indirect visualization of the layers of the true fold lamina propria, as well as of vocal fold scar beds. In addition, a number of other OCT adjuncts, such as spectroscopic OCT²⁸ and phase dispersion tomography²⁹ exist, or are currently in development, each with distinct imaging advantages and capabilities over conventional OCT imaging. Whilst not yet in widespread use in clinical practice, OCT has the potential to significantly alter the diagnostic and treatment pathway across the range of otolaryngology. The next few years provide the opportunity for future research and discovery in this fascinating field.

FUTURE RESEARCH

Although OCT and OCT adjuncts hold substantial promise for improved visualization of ENT-related tissues, OCT/OCT-adjunct feasibility studies for most of these tissues are either extremely limited or entirely lacking. For those ENT tissues that have been imaged with OCT, the primary focus of the imaging studies has been the necessary, but insufficient, first step of assessing the degree to which normal tissue microstructure can be accurately identified from OCT images. Before the OCT imaging modality can be regarded as a diagnostic tool in ENT, rigorous correlation of OCT/OCT-adjunct images of diseased tissue with parallel histology must be carried out to demonstrate that a given disease state can be accurately and reliably identified from OCT image structures. In the case of the larynx, although conventional OCT images of pathological laryngeal structures *in vivo* have been recorded,¹² the corresponding histology necessary to guide OCT image interpretation has most often been lacking. Thus, whether OCT/OCT-adjuncts can reproducibly and accurately identify laryngeal pathology or other ENT pathologies remains to be determined and constitutes an exciting and vital area of future work.

In addition to pathology identification, OCT or certain OCT adjuncts may prove useful in guiding laser and non-laser-based

microsurgery of ENT tissues. In laser microsurgery, PS-OCT may be particularly applicable, since laser damage of collagenous tissue has been shown to alter the tissue's effect on the polarization state of incoming light.³⁰ This is yet another exciting avenue for future research.

In brief, the following are a few of the many vital areas for current and future investigation:

- ▶ correlation of histology with OCT images of pathologic laryngeal specimens
- ▶ further investigation of the potential use of OCT in laryngology and correlation of PS-OCT images to laryngeal microstructure
- ▶ investigation of other OCT adjuncts, such as spectroscopic OCT, to laryngeal imaging
- ▶ further exploration of the possible applications of OCT/OCT adjuncts to ear-related imaging and a feasibility study of OCT applied to nasal tissue
- ▶ exploration of the use of OCT in conjunction with image guidance and/or robotic systems.

KEY POINTS

- The diagnosis and treatment of many ENT pathologies would benefit from the ability to image subepithelially and with high resolution *in situ*.
- Optical coherence tomography enables subepithelial imaging of tissue with a resolution ranging from 1 to 15 μm and is fibre-optically based, allowing OCT systems to be interfaced with a wide range of instruments, including catheters and endoscopes.
- Conventional OCT appears to be able to detect spatial changes in the thickness and transparency of laryngeal epithelium; the content of the connective tissue, including the presence of glands and vessels; and the integrity of the basement membrane.
- Polarization-sensitive OCT, with its sensitivity to organized linear structures, such as oriented collagen fibre bundles, may prove useful for vocal fold visualization and health assessment.
- OCT and OCT adjuncts hold substantial promise for improved diagnosis and treatment of many ENT disorders, a potential that remains largely untapped and constitutes an exciting avenue for future research, development and discovery.

SEARCH STRATEGY

This chapter is based on literature obtained by electronic searches of four biomedical databases (Medline, Embase, Cochrane Library, PubMed) using combinations of keywords including PET, PET-CT, FDG, positron emission tomography, tomography emission computed, FDG, head and neck, cancer, neoplasm, squamous cell cancer, thyroid cancer, neck, staging, nodal metastases, occult primary, recurrence, surveillance, MR. Studies were also sought from hand searches of H&N surgery and other relevant journals, and scanning the reference lists of relevant articles. No beginning date limit was used and the search was updated on November 2, 2016.

PET-CT has replaced PET. Notwithstanding, there is good justification for continuing to take into account the FDG PET evidence when considering FDG PET-CT as both assess the same aspects of tissue metabolism. Also, the whole body is routinely scanned in both techniques. Furthermore, there is evidence that PET-CT is more accurate as a diagnostic test compared with PET because PET-CT can more sensitively detect radiotracer emitted from the body and more accurate anatomical localization of the radiotracer emitted.¹ In other words, PET studies set a baseline for performance which is likely to be improved by PET-CT.²

POSITRON EMISSION TOMOGRAPHY (PET) – COMPUTED TOMOGRAPHY (CT)

The main role of PET-CT in head and neck surgery is in the assessment of people with head and neck (H&N) cancer using the radiotracer 2-[¹⁸F] fluoro-2-deoxy-D-glucose (FDG). So the focus of the chapter, after consideration of the principles of PET-CT, is on FDG PET-CT in people with H&N squamous cell cancer (SqCC). Separate short commentaries are provided on the role of FDG PET-CT for other tumours and on the evolving role of radio-tracers beyond FDG. In addition, brief observations are made on the current status of PET-MR.

Computed tomography (CT), magnetic resonance (MR) and ultrasound predominantly produce anatomical images, whereas positron emission tomography (PET) identifies pathology based on altered tissue metabolism. Modern whole-body PET scanners are physically integrated with

standard CT scanners enabling the creation of accurately computed combined [registered] fused PET-CT scans.

CT component of PET-CT

The CT component of PET-CT has two important functions. Firstly, it contributes directly to more accurate diagnosis. It does this by facilitating precise anatomical location of radiotracer activity which leads to more exact anatomical localization of pathology and more accurate distinction between pathology and normal appearances. Secondly, the CT component corrects for the reduction in PET signal [attenuation] as it travels through the patient's body; the deeper the site the signal arises in the body the greater the attenuation. The correction results in more accurate measurement of radiotracer uptake.

CT is usually performed with a lower radiation dose than conventional diagnostic CT. Also, unlike conventional diagnostic CT, PET-CT is commonly performed without intravenous contrast. This is because there is

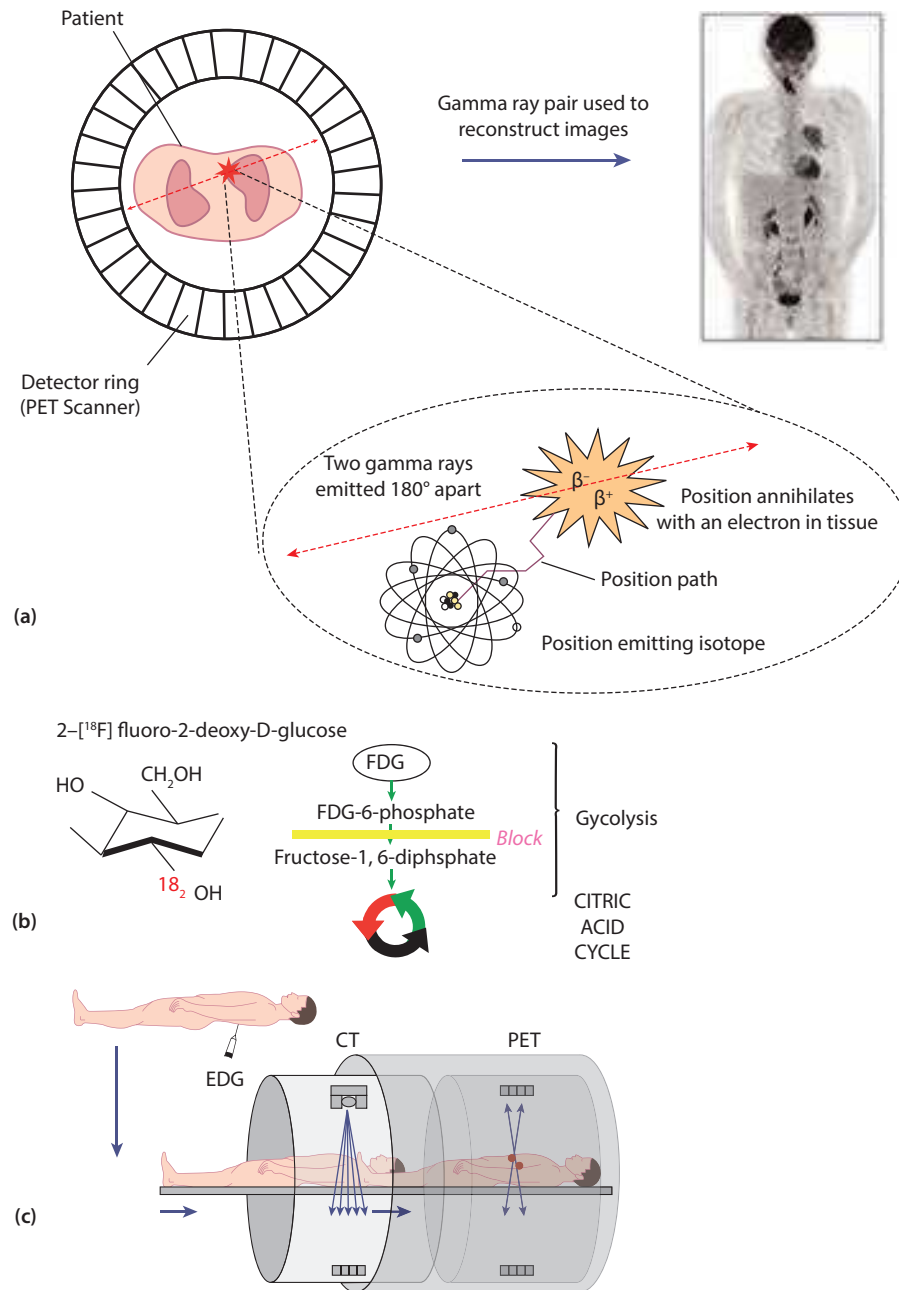

FIGURE 47.1 (a) Projection FDG-PET shows a patient with a primary bronchogenic carcinoma with extensive bony and cutaneous deposits. (b) Schematic representation of FDG metabolism. (c) Schematic representation of scanning with integrated PET/CT. The radiation burden is equivalent to two whole body diagnostic CTs. The CT is usually obtained using a low-voltage technique with no intravenous contrast given, but it provides diagnostic information.

some evidence to suggest that intravenous contrast results in PET artefacts. That said, the actual impact intravenous contrast makes to interpretation of clinical PET-CT scans is debatable. This has prompted some centres to carry out PET-CT scanning with intravenous contrast in an effort to reduce the number of investigations for patients. More typically, however, if a contrast-enhanced CT is required it is performed following low dose attenuation CT.

Recently, similar to CT, manufacturers have introduced continuous bed motion PET acquisition systems with potential for less artefacts and increased sensitivity.

This is in contrast to conventional whole-body PET-CT scans which comprises a series of overlapping static 'step and shoot' bed acquisitions taking approximately 30 mins in total to perform.³

PET component of PET-CT

PET is a functional imaging technique which relies on a radioactive molecule (radiotracer) that decays with positron emission. The radiotracer is given intravenously to the patient and is taken into cells. The cell recognizes it as

being 'foreign' and as a consequence it is trapped early in its metabolic pathway. Malignant cells trap more radiotracer compared with non-malignant cells. The local radiotracer concentration can be measured *in vivo* since these unstable radiotracers decay by positron emission. Positrons travel a short distance in tissue before colliding with electrons. When they collide, the annihilation reaction results in two photons also known as gamma rays of 511 kilo electron volts (keV) each emitted at approximately 180° to each other. The photons are detected by opposing detectors. A computer reassembles these signals into images that represent radiotracer uptake in the part of the body scanned.

One of the main strengths of PET is the ability to perform quantitative studies. Absolute quantification is not often carried out in clinical practice as it is complicated to obtain and can demand direct arterial blood sampling. The standardized uptake value (SUV), which provides a semi-quantitative index of radiotracer uptake is widely used in clinical PET:

$$\text{Tracer uptake (MBq/mL)} \\ \text{Administered activity (MBq)} / (\text{patient weight (kg)} \times 1000)$$

Depending on the radiotracer used, different aspects of tissue metabolism can be studied, such as distribution of blood flow, oxygen utilization and protein synthesis. The overwhelming majority of clinical studies are in conjunction with an analogue of glucose, 2-[¹⁸F] fluoro-2-deoxy-D-glucose (FDG), which reflects glucose metabolism. Cancer cells have a greater avidity for glucose than normal cells. Otto Warburg and colleagues made this observation in the 1920s.⁴ FDG can be used to exploit the differences in glucose metabolism between cancer cells and normal cells.

FDG-PET has been used effectively for imaging of a variety of malignancies including breast, lung, colorectal, oesophageal cancer, brain tumours, malignant melanoma and lymphoma.⁴⁵ Seifert and others demonstrated that H&N cancers take up FDG, an observation which was subsequently confirmed by other studies.⁶

Occult primary tumours

The cornerstone for investigating people with malignant nodes and no primary site on usual assessment is biopsy of suspicious sites and sites likely to harbour the primary site at examination under anaesthesia (EUA). There is universal agreement that FDG PET-CT should be included prior to EUA.⁷ Applied in this context, FDG PET-CT influences the management plan in three main ways. Firstly, and primarily, FDG PET-CT detects an unexpected primary site, and with FDG PET-CT superior to FDG PET. A National Institute of Care and Health Excellence (NICE) review, based on the combined results of 5 FDG PET-CT studies and 198 patients, provided an estimated sensitivity of 0.89 and specificity 0.73.⁸ In addition, one meta-analysis of eight studies which included 430 people, FDG PET-CT detected 31.4% more primary sites not diagnosed at usual assessment.⁹ This compares favourably with FDG PET where in a meta-analysis of 16 studies with 302 patients FDG PET detected 24.5% more primary sites not apparent after conventional work-up.¹⁰ However, the exact likelihood of detecting an unexpected primary site will depend on the investigations prior to FDG PET-CT, and the more investigations the less likely the value of FDG PET-CT.

Secondly, FDG PET-CT improves diagnosis by contributing directly to detecting unexpected nodal and unexpected distant metastases, albeit infrequently.

Figure 47.2 A 55-year-old man presented with a left neck lump due to an enlarged neck node infiltrated with SqCC. No primary site on clinical assessment and usual assessment including indirect laryngoscopy and MRI. FDG PET-CT (a) shows the left neck node (hollow arrows), and (b) the subtle base of tongue primary site (hollow arrow), confirmed at subsequent EUA and biopsy.

In a retrospective cohort study of 78 people, one of the largest studies in this area, FDG PET-CT detected primary tumours in 30 people not identified on usual assessment which included flexible fibre-optic nasoendoscopy and CT/MR or both; unexpected contralateral neck nodal disease in two, mediastinal nodal disease in one, and liver metastases in one.¹¹ Finally, occasionally, but importantly, FDG PET-CT detects occult synchronous cancers, most often silent lung and colorectal cancers.^{9, 10} The former because of the linked causes between H&N and lung cancer and the later because colorectal cancer is a common cancer and is often initially asymptomatic.

Currently, many centres offer FDG PET-CT only after clinical assessment and CT/MR shows no primary site, and prior to EUA and biopsy. Increasing confidence in the use of FDG PET-CT and the wider availability of PET-CT scanners is leading to a growing view that FDG PET-CT should be considered as the initial investigation, reserving CT/MR only if necessary for treatment planning.¹² This approach is justified on the grounds that it will improve patient experience by reducing the number of investigations prior to EUA and without overall compromise to detection of occult primary sites.

That said, the diagnostic pathway requires critical consideration. Firstly, it does not take into account the complementary potential of emerging MR techniques, and specifically diffusion MR.^{13, 14} In addition, one study showed FDG PET-CT was cost effective in N1 and N2 occult H&N primaries but questioned the cost effectiveness of FDG PET-CT for N3 occult H&N primaries.¹⁵ Finally, given that in HPV-positive people the occult primary site is almost invariably in the tongue base and palatine tonsil the question arises whether a different approach should be taken in HPV-positive people from those who are HPV negative; specifically, as to whether

FDG PET-CT should be only for the HPV-negative group. While for those who are HPV-positive, advancing those patients directly to surgical diagnostic assessment, including consideration of emerging techniques such as narrow-band imaging and tongue-base mucosectomy, if no primary site is identified on CT/MR.¹⁶

SQUAMOUS CELL CARCINOMA

Primary disease

STAGING

FDG PET-CT has a limited use in the staging of the primary site and for assessment of nodal disease in the neck. FDG PET-CT can detect the majority of clinically visible primary tumours. This capability is of limited clinical value in the main, but can occasionally be utilized to more precisely delineate the primary tumour where submucosal extension of disease is a feature, such as in post-cricoid carcinoma and tracheal carcinoma.

With regard to the neck, FDG PET-CT is also of limited clinical value. It is clear from the literature that FDG-PET cannot consistently detect subclinical disease and that reactive nodes can be FDG avid.^{14–20} So FDG PET-CT cannot obviate elective neck treatment. However, it can have a role in those with equivocal nodal disease following conventional assessment. In those with a moderate to high risk of neck metastases, a positive FDG PET-CT scan will be highly indicative of neck nodal disease and this can be particularly useful for highlighting possible contralateral or bilateral nodal disease. Conversely, in those with a low risk of nodal metastases, a negative FDG PET-CT is highly indicative of no nodal disease. In other words, FDG PET-CT can highlight possible additional

Figure 47.3 A 49-year-old man with nasopharyngeal cancer (NPC). Staging FDG PET-CT (a) shows the primary NPC (red hollow arrow), bilateral neck nodes (red arrowhead), and (b) two bone metastases, one in a vertebral body (arrow), corresponding to a lucent lesion on CT component (arrow) and one in the RT femur (hollow arrowhead).

unexpected nodal disease which may have a direct and immediate impact. In some it will justify further neck assessment; this is most often initially ultrasound with fine-needle aspiration cytology. In others, treatment may be modified to include the suspicious node or nodes. Determining which nodes are potentially significant is largely influenced by the probability of nodal disease at the location and this will influence the interpretation of nodes that are potentially significant. If the node lies in the nodal drainage area for the primary site and there is a moderate to high probability for nodal disease at this site then the node, notwithstanding its relatively small size and mild FDG uptake, requires consideration. On the other hand, if a node lies outside the drainage area and there is low probability for disease at this site then it is unlikely that the node contains tumour. For example, a right level II node, 8 mm, mildly FDG avid, SUVmax 3.0, in a person with nasopharyngeal cancer must be viewed with much more suspicion than that of a node in a person with a left maxillary antral cancer.

The main role of FDG PET-CT in the assessment of people with primary disease is in the detection of distant metastases. In a significant number, FDG PET-CT detects metastases not diagnosed on usual assessment.²¹⁻²³ In a meta-analysis, including 1147 patients from eight studies, FDG PET-CT had a pooled sensitivity and specificity for detecting distant metastases of 0.83 and 0.96 respectively, compared with usual assessment, 0.44 and 0.96, respectively. In addition, the superiority of FDG PET-CT applied to both nasopharyngeal cancer and non-nasopharyngeal head and neck cancers.²⁴ Specifically with regard to bone metastases, in a meta-analysis which included 1184 patients from five comparative studies, which compared FDG PET CT to bone scanning, FDG PET-CT was

more sensitive, with a pooled sensitivity of 0.85 compared with 0.55.²⁵

There is divergence in guidance as to whom should be offered FDG PET-CT. Taking cost-effectiveness considerations into account, recent NICE guidelines recommend offering FDG PET-CT only to people with T4 nasopharyngeal and hypopharyngeal cancer and to people with advanced neck disease (N3).⁸ Other guidelines recommend FDG PET-CT more extensively.⁷ This divergence highlights the many factors that come into play with complex decision-making processes, beyond guideline development process and methodology, and they include the value beliefs and value systems of the individual on the panel making the decisions.⁷

Post-treatment assessment

FDG PET-CT has a high negative predictive value, greater than 90%, 8 weeks or more after chemo-radiotherapy (CRT).^{26, 27} Stratification for neck dissection with FDG PET-CT after chemo-radiotherapy results in fewer neck dissections and a reduced incidence of complications.²⁸ In a prospective study of 564 people with H&N SqCC and advanced neck nodal disease following CRT, 282 were recruited into the neck dissection arm, 282 had FDG PET-CT 8–12 weeks following CRT and neck dissection only if FDG PET-CT showed residual disease. Fifty-four neck dissections were performed in the surveillance arm with 22 surgical complications; 221 neck dissections in the neck arm with 85 complications. FDG PET-CT surveillance was cost-effective compared to planned neck dissection with a £1,415 per person saving and an additional gain of 0.07 quality added life years (QALY).²⁸

Figure 47.4 FDG PET-CT (bottom row) shows intense FDG avidity of the right glosso-tonsillar fossa SqCC and right neck nodal disease. FDG PET-CT 12 weeks post chemo-radiotherapy (top row) there is resolution of FDG uptake at the primary site and no FDG uptake in the residual right neck node on CT.

Of current interest is the influence of HPV status on FDG PET-CT in the assessment of residual nodal disease following CRT.²⁹ HPV-positive nodal disease can take longer to involute.³⁰ So enlarged nodes with no residual disease occur at the 12-week assessment following CRT. Several studies have shown that FDG PET-CT is more accurate than CT for distinguishing nodes with residual disease from those with no disease.^{31, 32} In one study, FDG PET and PET-CT at a mean of 12 weeks following treatment, with a range of between 8 and 16 weeks, was significantly more accurate at predicting complete response compared to contrasted CT assessment, 90% compared with 46%, and especially for the HPV-positive group, 93% compared with 50%.³¹ In one of the largest studies to date which specifically considered FDG PET-CT response in HPV-positive oropharyngeal cancer, FDG PET-CT at 12 weeks post-CRT demonstrated high-negative predictive value for loco-regional failure though the positive predictive value and sensitivity was disappointing.³² However, Pryor et al. demonstrated that surveillance strategies including FDG PET-CT was more cost effective than CT-guided surveillance alone, regardless of HPV status. Furthermore, that study showed that combined strategies using CT followed by FDG PET-CT in non-responders were only marginally more cost effective than FDG PET-CT alone, and were highly sensitive to changes in circumstances.³³ Therefore, some advocate that HPV-positive people with enlarged nodes but with no FDG avidity after 12 weeks post-CRT may be considered for close surveillance with serial scanning, with limiting neck dissection for those with FDG avid enlarged nodes, especially if HPV-negative or at high risk and HPV-positive.

This approach however is challenged. In one prospective study, FDG PET-CT had no advantage over CT in low-risk non-smokers with HPV-positive oropharyngeal primaries. In addition, in that study, FDG PET-CT was only better than CT in high-risk patients who have HPV-negative disease, non-oropharyngeal primaries or who have a smoking or alcohol history.³⁴ The authors acknowledge that the study is limited for several reasons. Firstly, it was performed in a high-throughput cancer institution where the proportion of high-risk patients and radiotherapy non-responders may be greater than in other treatment settings. Secondly, FDG PET-CT nodal response was assessed at a mean of 8 weeks, with a range of between 5

to 12 weeks following treatment, which may not be the optimal timing for FDG PET-CT after radiotherapy.^{30, 31} Finally, histopathology of post-CRT neck dissection was used as evidence of persistent disease, which is known to overestimate persistence.^{27, 33}

As yet, independent validation of CT scan-driven response systems or comparison with PET-CT-driven systems in multicentre, randomized settings have not been published. As a final comment, even if further studies establish that FDG PET-CT is of limited value in HPV-positive patients, in many countries, HPV-positive patients constitute only a minority, and FDG PET-CT would still have an important role in the majority of patients.

RECURRENT DISEASE

FDG PET-CT is accurate at detecting recurrent disease. A survey of the literature identified 23 studies which

Figure 47.5 A 73-year-old man with clinical suspicion of floor of mouth SqCC recurrence. FDG PET-CT shows the left floor of mouth recurrence (arrow) and a metastatic ipsilateral level IB node (arrowhead).

Figure 47.6 FDG PET-CT shows the right poster-lateral oropharyngeal wall recurrence (arrow). It also shows metastases in the lungs (narrow arrow) and within subcutaneous tissue around the left shoulder (arrowhead). It also shows incidental linear FDG in the chest due to oesophagitis (broad arrow).

considered the accuracy of FDG PET-CT done at least 4 months after therapy for detecting active disease at the primary site, within neck nodes and distant metastases.³⁵ Drawing on the pooled data of 2247 patients from 12 FDG PET and 11 FDG PET-CT studies, the pooled sensitivity and specificity for detection of disease were 0.92 and 0.87, respectively. The pooled sensitivity and specificity performed 4 to 12 months after treatment were 0.95 and 0.78, respectively, and for scans performed at or more than 12 months after treatment, 0.92 and 0.91 respectively. These results concur with a meta-analysis which reported a sensitivity and specificity for the primary site of 0.92 and 0.87, respectively, and for neck nodes 0.90 and 0.94, respectively.³⁶ Another meta-analysis which included 10 studies reported a sensitivity of 0.92 and specificity of 0.95 for detecting distant metastases in people with suspected head and neck cancer.³⁶ Individual studies show varying results and this is a reflection not only on the small number of patients in each study, but also on the various clinical situations where FDG PET was used.³⁵⁻³⁷

Compared with other imaging, prospective studies provide evidence that FDG PET is effective and superior to CT and MR for distinguishing active disease from treatment sequelae in people who develop symptoms during follow-up.³⁸⁻⁴⁵ In a study of 38 people, FDG PET differentiated between post-irradiation laryngeal recurrent cancer from laryngeal oedema with an accuracy of 79% and was superior to CT (61%) and clinical assessment (43%).⁴⁴

In addition, a recent study evaluated the accuracy of FDG PET-CT with intravenous contrast for suspected recurrent H&N SqCC in 170 people who underwent FDG PET-CT, which consisted of non-contrast-enhanced and contrast-enhanced CT, to investigate suspected recurrence. Diagnostic performance of FDG PET-CT / contrast enhanced CT (FDG PET-CT/ceCT), FDG PET-CT / non-contrast-enhanced CT (FDG PET-CT/ncCT) and contrast-enhanced CT (ceCT) for local or regional recurrence, distant metastasis, overall recurrence and second primary cancer was evaluated. FDG PET-CT was a more accurate restaging tool than ceCT. The added value of ceCT to FDG PET-CT is minimal.⁴⁶ The study supports the conclusion from a previous retrospective study which compared FDG PET-CT to that of contrast-enhanced CT and to standard-of-care follow-up, physical examination and endoscopy, in detecting locally recurrent H&N cancer. FDG PET-CT had higher accuracy than contrast-enhanced CT alone and increases the sensitivity and negative predictive value of physical examination and endoscopy.⁴⁷

The value of FDG-PET as a surveillance tool for patients with high risk of relapse remains unclear. A survey of the literature extending to March 2012 found a lack of evidence to support FDG PET-CT surveillance of people with H&N cancer.² There have subsequently been several further published studies. These studies show FDG PET-CT can detect disease before it is clinically evident. One retrospective review included 512 patients who underwent surveillance FDG PET-CT. FDG PET-CT was performed at

3-month intervals, starting 2 months after the conclusion of therapy with scans routinely obtained at 2, 5, 8 and 14 months after therapy. Patients were assessed clinically and radiographically for at least 12 months from their last FDG PET-CT (mean, 26 months; median, 28 months; range, 12–89 months) to determine recurrence rates. All suspected recurrences underwent biopsy for confirmation. A single FDG PET-CT with negative findings carried a NPV of 91%, which is not adequate to defer further radiological surveillance. Two consecutive FDG PET-CT examinations with negative findings within a 6-month period, however, resulted in a NPV of 98%, which could obviate further radiological imaging in the absence of clinical signs of recurrence.⁴⁸

One single institution prospective study performed FDG PET-CT at 6 months after the end of treatment in all 116 patients treated for histologically proven H&N cancer from April 2009 to May 2012 who did not show any findings suggestive of recurrence at 6 months of their usual follow-up. FDG PET-CT findings were correlated with histopathology or imaging follow-up. Results from the study included 116 patients. Of the 82 FDG PET-CT considered as negative, only one had a recurrence. Among the 34 positive FDG PET-CT, 22 relapsed whereas 12 did not show evidence of recurrence. The sensitivity and specificity of FDG PET-CT were 96% (22/23) and 87% (81/93), respectively. The positive predictive value was 65% (22/34). The negative predictive value was 99% (81/82). The overall accuracy was 89% (103/116). Of the 116 patients, FDG PET-CT highlighted 22 (19%) sub-clinical recurrences. These results confirmed that FDG PET-CT is more accurate than conventional follow-up physical examination alone in the assessment of recurrence after previous curative treatment for H&N SqCC.⁴⁹ One retrospective review was performed on a series of H&N patients at a single institution who had undergone FDG PET-CT as an integral part of follow-up after definitive treatment. Of the 123 patients, 24 (20%) had asymptomatic lesions (either recurrent or new primaries) on FDG PET-CT (8% of surveillance scans) at an average interval of 35.7 weeks post treatment. Asymptomatic lesions were detected most frequently at distant sites, with 50% being thoracic, but also included were primary (9%), regional (9%), and other distant (32%) sites. At last follow-up of the 24 patients in whom an asymptomatic lesion was detected, 14 have died of disease; 10 remain alive, 4 with disease; and 1 patient had a subsequent recurrence treated and is currently disease-free. The authors concluded that FDG PET-CT is an effective tool for detecting asymptomatic disease in people previously treated for H&N cancer. Disappointingly, they found that even with early detection of recurrent disease, the mortality rate remains high.⁵⁰ In a 10-year retrospective analysis of H&N cancer patients with long-term serial imaging, those with negative 3-month imaging appear to derive limited benefit from subsequent FDG PET-CT surveillance. Furthermore, no survival differences were observed between PET/CT-detected and clinically detected recurrence.⁵¹ So even if results substantiate the ability to predict recurrence

earlier than conventional assessment, there remains the question of whether earlier detection afforded by FDG PET-CT results in an improved clinical outcome.

Other comments

CHARACTERIZATION OF INDETERMINATE LESIONS

In common with other cancers, FDG PET-CT is a key investigation for the assessment of lesions indeterminate on usual assessment when improved characterization can change the treatment plan. These indeterminate lesions are usually in the lung, liver and adrenal glands, with the lung being the most common site. FDG PET has been shown to be an accurate non-invasive test for the diagnosis of pulmonary lesions. In a meta-analysis limited to pulmonary nodules including 13 studies with a total of 450 nodules, FDG PET had a sensitivity of 93.9% and specificity of 85.8% respectively.⁵² Another meta-analytic comparison of the cross-sectional imaging modalities for the diagnosis of malignancy in SPNs (up to 3 cm diameter) from a pooled analysis of 1008 nodules from 22 eligible studies reported a similar sensitivity and specificity of FDG PET, 95% and 82%, respectively.⁵³ Abscesses and granulomas including those due to sarcoid, tuberculosis (TB), anthracite and fungus (asperilloma, blastomycosis, coccidiomycosis, cryptococcosis, histoplasmosis) can mimic malignant lesions.^{54,55} False-negative FDG PET-CT results are unusual, although mucinous carcinomas such as those arising from the stomach, highly-differentiated neuroendocrine carcinoma and adenocarcinoma, especially within a scar, can cause confusion.^{54,55} Lesions smaller than 1 cm across can be detected by FDG PET-CT, as detection is influenced not only on size but also FDG avidity of the lesion. That said, with lesions less than 1 cm false-negative results occur and so a negative FDG PET-CT must be interpreted with caution and cannot reliably exclude malignancy.⁵⁵ Recent British Thoracic Society Guidelines recommend FDG PET-CT as the preferred investigation in the further evaluation of pulmonary nodules, partly because it is widely available and partly because no alternative investigation shows superiority.⁵⁶

In detection of synchronous and metachronous malignancies (Figures 47.7 and 47.8) FDG PET-CT will detect synchronous other H&N cancers and lung cancers, linked by their common aetiologies. In addition, FDG PET-CT will also diagnose unexpected other cancers. The cumulative incidence of a second malignancy following H&N cancer is up to 18%.⁵⁷ Fewer than half will have a detectable synchronous primary malignancy and almost half will be detected by a thorough clinical assessment and a further number by chest CT. So the expected pick-up rate of FDG PET-CT at the time of primary diagnosis is likely to be in the order of 2–3%. This is substantiated by one South Korean study of 349 patients. FDG PET-CT detected second primary H&N cancer over 2 years in 14 people, 10 (2.8%) at initial staging and 4 (1.2%) during the follow-up, with a mean duration of 15 months; H&N cancer arising from the

Figure 47.7 A 45-year-old man with nasopharyngeal cancer. FDG PET-CT shows incidental focal intense FDG uptake in the pelvis (arrowhead). Excision biopsy confirms a small rectal cancer. The maximum intense projection (MIP) image shows the nasopharyngeal cancer (red arrow) and bilateral neck nodal disease (hollow arrow). It also shows FDG avid nodes in the chest due to a sarcoid like reaction (blue arrow).

Figure 47.8 FDG PET-CT shows the primary laryngeal cancer. It also shows a silent synchronous stomach cancer. FDG uptake in the stomach is usually due to *Helicobacter Difficile* infection, which can be focal or diffuse and FDG PET-CT cannot reliably distinguish between the two conditions.

nasal cavity: one, lung cancers: seven, colorectal cancer: two, thyroid: two, upper GI tract: two.⁵⁷ The low rate of synchronous malignancy perhaps does not justify routine screening. However, when FDG PET-CT is indicated for other reasons, detection of an unexpected second cancer

may influence the plan of treatment. The main dilemma is that both malignant and benign incidental lesions are FDG avid and often only biopsy or excision of the lesion can distinguish between the two. This may lead, in some people, to unnecessary investigations and in some the additional unnecessary tests may contribute to delayed initiation of treatment.

FDG uptake and outcomes

There is increasingly strong evidence that pre-treatment FDG PET-CT uptake at the primary site and within involved nodes is an independent predictor of subsequent prognosis. Two meta-analyses concluded that there was a correlation between SUVmax and outcome in people with H&N cancer.^{58, 59} Most studies included in the meta-analyses, however, report either univariate or relatedly small multivariate analyses. More recently, one single-centre study which included 287 people confirmed FDG uptake retains statistical significance in multivariate analysis and has a clinically relevant prognostic impact.⁶⁰ The contribution of FDG uptake to personalized treatment of H&N cancer has yet to be formally assessed.

EMERGING APPLICATIONS

Response assessment

The role of FDG PET/CT in this area is evolving. With revived enthusiasm in chemotherapy for H&N SqCC, there is interest in non-invasive imaging which can distinguish responders from non-responders early during treatment. FDG PET-CT has been shown to predict early-on response to neo-adjuvant chemotherapy in a variety of solid tumours including oesophageal carcinoma. There is currently one published study for H&N SqCC. In 15 patients, an FDG response after two cycles of chemotherapy predicted event-free survival.⁶¹

Radiotherapy (RT) planning

FDG PET-CT is increasingly used for radiotherapy target volume delineation.⁶² Benefits include inter-observer variability in gross tumour volume (GTV) delineation reduction, GTV size reduction and identification of tumour that would not otherwise have been treated but for PET-CT, reducing geographical misses. However, two major challenges prevail. Firstly, inflammation leads to tumour margin over-estimation. Secondly, there is presently no reliable, universally accepted, standardized method of identifying tumour margins. Notwithstanding, two small retrospective studies show significantly better overall survival and event-free survival applying FDG PET-CT-based intensity modulated radiotherapy (IMRT), compared with the control group.^{63, 64} More studies are needed to clarify the benefits of FDG PET-CT in this area.

NON-SQUAMOUS CELL CARCINOMA

Thyroid cancer

FDG PET-CT is of limited value for the pre-operative assessment of thyroid nodules as both malignant and benign thyroid lesions can be equally avid for FDG.⁶⁵ However, it has an important role in the assessment of differentiated thyroid cancer, which includes papillary and follicular histological types, following treatment.⁶⁶ In this group, metastases have an alternating pattern of uptake with ¹³¹I-iodine and FDG where either some ¹³¹I-iodine uptake combined with low FDG trapping or no ¹³¹I-iodine uptake combined with high FDG trapping.⁶⁷ The hypothesis was that persistent iodine metabolism is consistent with better cell differentiation, while the loss of this ability together with increased glucose metabolism is consistent with dedifferentiation.⁶⁷ A meta-analysis of 958 patients from 20 studies which

Figure 47.9 A 48-year-old woman following treated for follicular thyroid cancer with elevated and raising serum thyroglobulin levels. (a) No unaccountable uptake on ¹³¹I-iodine scan (b) FDG PET-CT shows a left prevertebral node in keeping with active disease at this site. It also shows no other suspicious areas. (c) The node corresponded to an indeterminate node on MRI. Subsequent surgery confirmed the FDG PET-CT; subsequent fall in serum thyroglobulin level following surgery.

included 11 studies that used FDG PET only, 7 FDG PET-CT only and 2 studies which used both FDG PET and FDG PET-CT, confirmed the value of FDG PET-CT in treated papillary and follicular thyroid cancer patients who have suspected recurrent disease and negative ¹³¹I-iodine scan, with a pooled sensitivity of 95%, and specificity 81%, respectively, and compared favourably with FDG PET, sensitivity and specificity 84%.⁶⁶

With regard to other histological types of thyroid cancer, FDG PET-CT can detect Hurthle cell carcinoma and anaplastic carcinoma.^{68, 69} However, the clinical role of FDG PET-CT in these tumours is currently unclear. Concerning medullary thyroid cancer, preliminary results suggest FDG PET to be an accurate technique for detecting metastases and recurrent disease. The largest study in the literature, a German multicentre retrospective survey, reviewed 100 FDG PET studies performed on 85 patients.⁷⁰ The results of the FDG PET were compared with 46 indium-111 pentetreotide (SMS) studies, 33 Pentavalent technetium dimercaptosuccinate acid (DMSA) scans, 8 hexakis (2 Methoxyisobutyl isonitrile) technetium-99m (MIBI) scans, 64 CT and 37 MR. One hundred and eighty-one lesions were identified by at least one technique; FDG PET detected the majority of lesions with a lesion detection probability of 68% compared with 25% for SMS, 29% for DMSA, 6% for MIBI, 53% for CT and 58% for MR. In the 55 lesions confirmed histologically, FDG PET had the highest overall accuracy with a sensitivity of 78% and specificity of 79%; MR had a slightly higher sensitivity of 82%, but a specificity of 67% and MIBI had a specificity of 100%, but a sensitivity of only 25%.

OTHER MALIGNANT TUMOURS

There is limited evidenced guidance for the use of FDG PET-CT here, beyond anecdotal reports, as these tumours are extremely rare. Notwithstanding, FDG PET/CT is often done prior to treatment and for several reasons. Firstly, to demonstrate that the tumour is FDG avid. And if so, FDG PET-CT is considered for pre-treatment staging, and subsequently to detect residual/ recurrent disease.

In one published report of post-operative parathyroid carcinoma, FDG PET provided more accurate information compared with other imaging.⁷¹ FDG PET-CT cannot reliably distinguish between malignant and benign major salivary gland tumours as both can be equally FDG avid.⁷² It can, however, be useful for distinguishing active disease from sequelae of treatment.⁷³ Caveat, muco-epidermoid and adenoid cystic cancers may not be FDG and particularly following treatment.⁷⁴ FDG PET-CT is effective for detecting lymphoma except low-grade non-Hodgkin's lymphoma and extra-nodal marginal zone B-cell lymphoma, which are not consistently FDG avid.^{75, 76} H&N malignant melanomas, sarcomas and paraganglionomas have been shown to be FDG avid.^{77, 78}

Normal variants and artefacts

Brown adipose-tissue FDG uptake can be difficult to distinguish from adjacent small FDG avid nodes, especially when there is slight mis-registration of PET to CT.

Skeletal muscle FDG uptake is usually linear and symmetrical and does not pose a diagnostic quandary. Occasionally, pre-vertebral muscle FDG uptake and

Figure 47.10 A 36-year-old woman with non-Hodgkin's lymphoma. FDG PET-CT shows (bottom row) intense FDG uptake in enlarged nodes in the neck on both sides and within Waldeyer's ring lymphoid tissue in the tongue base, (top row) following completion of chemotherapy, there is resolution of FDG activity in the tongue base and neck nodes; all that remains are indeterminate non FDG avid nodes in the neck.

Figure 47.11 A 25-year-old woman who presented with a neck node due to malignant melanoma. FDG PET-CT shows (top row) intense FDG uptake in the involved right neck node. It also shows (bottom row) an intensely FDG avid nodule within the right parotid gland. Malignant and benign parotid lesions are FDG avid and so fine-needle aspiration cytology was required to confirm the diagnosis. Both lesions were resected and provided histological confirmation of the FDG PET-CT diagnosis. Importantly, FDG PET-CT demonstrated that there was no disease beyond the head and neck.

especially when asymmetrical, needs separating from pre-vertebral nodal FDG uptake, and this may not be possible without resorting to correlation with MR or post-intravenous contrast CT.

Waldeyer's ring normal lymphoid tissue FDG uptake in the nasopharynx, tongue base (lingual tonsil) and palatine tonsils needs careful distinction from FDG uptake from an occult primary tumour arising at these sites, these being common sites for an occult primary tumour. That said, the role of FDG PET-CT is not to make the diagnosis but to increase the number of malignancies diagnosed at EUA and biopsy. In this setting, a low threshold for diagnosing abnormality should be adopted and any asymmetrical FDG uptake at these sites reported. SUV measurement is of limited use because of the overlap of values between tumour and normal lymphoid tissue.⁷⁹

Dental amalgam causes FDG uptake in the anterior two thirds of the mouth. In practice, this rarely poses a clinical dilemma. If there is doubt as to the cause, direct inspection and palpation will almost invariably provide reassurance.

LIMITATIONS/PITFALLS

As on CT/MR, branchial cysts can be challenging to distinguish from necrotic nodes. No FDG uptake in the wall of the lesion favours the diagnosis of a branchial cyst. On the other hand, presence of FDG uptake in the lesion wall does not assist, as both pathologies can show this appearance, the necrotic node due to tumour and inflammation and the branchial cyst due to inflammation.

Granulomatous disease mimicking metastases deserve comment. Firstly, sarcoid and sarcoid-like reaction. With FDG uptake in chest nodes careful distinction needs to be made between those due to sarcoid-like reaction and cancerous nodes. Sarcoid-like reaction is not rare in H&N cancer. There is also an increased likelihood in recurrent disease. The pattern of FDG uptake assists. FDG uptake in normal-sized nodes which include those in paratrachea, both hila and subcarina would favour sarcoidosis, especially if there are no FDG avid neck nodes, but even when there is neck nodal disease.⁸⁰ In addition, sarcoid can mimic disease beyond chest nodes including in the lung, liver and bone.⁸¹ Secondly, TB needs distinction from malignancy, and especially from lung metastases and synchronous lung malignancy.

Figure 47.12 Branchial cyst. FDG PET-CT shows a left level IIA cystic lesion with no FDG uptake (hollow arrow).

Lung metastases and synchronous lung cancers can pose a challenge to diagnosis. Adeno-carcinoma may not be FDG avid. Also small sub-centimetre lung metastases may not be FDG avid.

Post-treatment, before making the diagnosis of residual or recurrent disease FDG uptake due to treatment sequelae needs careful consideration (**Table 47.1**). In clinical practice, taking a pragmatic approach, and drawing from experience, a definitely positive FDG PET-CT should be taken as highly suspicious of disease as long as there is no infection. A negative scan is highly likely to represent absence of active disease, but still demands careful surveillance as microscopic foci of active disease cannot be excluded. An equivocal scan requires biopsy of areas of FDG activity or an early repeat FDG PET-CT. False-positive and false-negative results occur and so FDG PET-CT findings must be interpreted, not in isolation but in the context of the overall assessment.^{35–37, 38–45} This is especially pertinent as determination of definitely positive, definitely negative and equivocal FDG uptake is still relatively subjective as, notwithstanding efforts, there is

Figure 47.13 A 61-year old-man with SqCC recurrence in the left post-treatment neck FDG PET-CT shows the neck recurrence (arrow) and a left upper lobe lung adenocarcinoma, which shows no FDG uptake (centre of red cross-hairs).

currently no universal consensus agreement on the meaning of these terms.⁸²

There is a commonly held view that recent biopsies cause focal FDG uptake in the H&N. This concern is probably overestimated as biopsies are usually tiny and limited to the mucosa.

RADIOTRACERS OTHER THAN FDG

Thymidine 3-Deoxy-3-¹⁸F-fluorothymidine [FLT]

Currently, its only potential role is for more accurately distinguishing lung metastases and from benign lesions, compared with FDG.⁸³⁻⁸⁵ However, if confirmed that FLT is only taken up by malignant cells, then this may be of value on the rare occasion when more information on the extent of disease at the primary site is required following usual assessment for treatment planning. Also, FLT may be effective for detecting residual disease following RT and chemotherapy and to predict the outcome to RT and chemo-RT.⁸⁶⁻⁸⁸

TABLE 47.1 Sequelae of interventions that mimic active disease following surgery

Residual tongue mimicking recurrent disease
Asymmetrical FDG uptake in the oral cavity and oro-pharynx following partial resection of the tongue and hypertrophy of the normal residual tongue. Such an appearance also occurs following radiotherapy to the tongue.

FDG PET-CT shows intense FDG uptake in the left oral cavity and oro-pharynx following radiotherapy which included the right side of the oral cavity and oropharynx [hollow arrow].

Post-tonsillectomy
The normal palatine tonsil mimics a palatine tonsil lesion, particularly relevant when looking for an occult primary site or assessing for recurrent disease.

The normal left palatine tonsil mimics a palatine tonsil lesion. [hollow arrow], following a previous right tonsillectomy,

(Continued)

TABLE 47.1 (Continued) Sequelae of interventions that mimic active disease following surgery

Osteonecrosis following surgery

This can also occur following radiotherapy. FDG PET-CT cannot reliably distinguish osteonecrosis from infection and recurrence.

FDG PET-CT shows intense FDG uptake due to osteonecrosis following surgery to the left mandible (arrow).

Following recent neck dissection

FDG uptake occurs directly related to inflammation post-surgery. Cylous collections also cause FDG uptake.

FDG PET-CT shows intense FDG uptake in the right neck 6 weeks following neck dissection (arrow). Right gleno-humeral joint synovitis due to osteoarthritis causing incidental FDG uptake (arrowhead).

FDG PET-CT shows intense FDG uptake related to a clyous collection complicating neck dissection.

(Continued)

TABLE 47.1 (Continued) Sequelae of interventions that mimic active disease following surgery**Granulomas**

Specifically, vocal cord injection with Teflon and collagen needs distinction from a primary vocal cord cancer. Stitch granuloma following neck dissection also very rarely causes increased FDG uptake and needs distinction from a neck node containing disease.

(a) FDG PET CT shows intense FDG uptake related to a granuloma post vocal cord injection (hollow black arrow). (b) FDG PET-CT also shows the cause of the left vocal cord palsy, namely a left upper lobe non-small cell cancer invading the mediastinum and causing left recurrent laryngeal nerve paralysis (arrowhead). There is also FDG uptake in normal prevertebral (hollow red arrow) and steno-mastoid muscles (hollow black arrow).

Following other interventions**Radiation myelitis**

A very rare complication with modern radiotherapy techniques.

Around stoma sites

FDG uptake due to inflammation needs consideration as an alternative to recurrence around the tracheostomy stoma site and tract. FDG uptake is also present around gastrostomy stoma sites.

Increased FDG uptake around the tracheostomy stoma site and tract (arrow). There is also FDG uptake related post cricoid SqCC (arrowhead).

Gastrostomy stoma site**Post-chemo-radiotherapy neck**

Especially in HPV-positive people mild FDG uptake can persist in post-treatment neck nodes beyond 8 weeks.

Radiotracers for detecting hypoxia

There has been considerable interest in PET tracers which can detect hypoxia in H&N SqCC, because inadequate treatment of hypoxic cells is one of the main causes of failure to effectively treat the primary site. Hypoxic cells require three times more radiation to kill compared with non-hypoxic cells; often it is not possible to deliver the required dose because of the damage it will cause to surrounding normal tissue. Imaging of hypoxia would provide the opportunity to apply RT to the subvolume of hypoxic cells only.^{89, 90}

Fluorinated nitromidazole compounds, including 1-[2-nitro-1-imidazolyl-3-[¹⁸F]fluoro-2-propanol [[¹⁸F]FMISO], have been used for imaging hypoxia in H&N SqCC*. Copper isotopes of varying half-life, including ⁶⁰Cu, ⁶¹Cu, ⁶²Cu and ⁶²Cu labelled to copper-diacetyl-bis(N⁴-methylthiosemicabazone) [Cu-ATSM] and copper-pyruvaldehyde-bis(N⁴-methylthiosemicarbazone) [Cu-PTSM] have also

* Other fluorinated nitromidazole compounds that have been studied include 1-(5-[¹⁸F]fluoro-5-deoxy- α -D-arabinofuranosyl)-2-nitro-imidazole [[¹⁸F]FAZA], ¹⁸F-2-(2-Nitro-imidazol-1-yl)-N-(3,3,3-trifluoropropyl)-Acetamide [¹⁸F-EF3] and ¹⁸F-Fluoroerythronitromidazole [¹⁸F-FETNIM]

been studied. There is as yet no one clear front runner. [¹⁸F]FMISO is the most commonly used and best validated tracer and most studies have shown correlation between hypoxia and [¹⁸F]FMISO uptake.⁹¹ But it is only slowly cleared from the blood compartment and the radiotracer passively diffuses into the cell which takes a relatively long time. This means that for imaging to be effective it has to be done between 2 to 3 hours post-injection.⁹² There are as yet inadequate data to recommend the other tracers as superior.

11C-choline PET/CT

In a pilot study¹¹C-choline improved the delineation of orbital and skull involvement compared with FDG PET/CT in people with nasopharyngeal cancer.⁹³ This is because physiological ¹¹C-choline uptake in the brain and extra-ocular eye muscles is minimal compared with FDG. The advantage of ¹¹C-choline beyond this specific scenario has been questioned.⁹⁴

PET-MRI [magnetic resonance imaging]

Integrated PET-MRI is an emerging technology, a development of registering PET with MRI obtained from different scanners.⁹⁵ Combining PET with MRI for assessment

of H&N cancer is an area of considerable interest because MRI is often performed as a complement to PET-CT in the assessment of H&N cancer. The added value of PET-MRI compared with separate PET-CT and MRI scanning has yet to be fully evaluated. Beyond a significantly lower dose of ionizing radiation, the advantage of PET-MRI as an alternative to PET-CT is unclear. A pilot study of 25 patients designed to evaluate the accuracy of FDG PET-MR for loco-regional tumour evaluation compared to FDG PET-CT and MRI in initial tumour and recurrence diagnosis in histo-pathologically confirmed H&N SqCC found no significant differences were observed in T and N staging among the three modalities. In 13 patients undergoing hybrid imaging for cancer recurrence diagnosis, diagnostic accuracy was 57% with MRI and 72% with FDG PET-CT and FDG PET-MRI, respectively.⁹⁶ In a study designed to evaluate and compare the diagnostic potential of FDG PET-MRI to FDG PET-CT for people with cancer of unknown primary a total of 20 patients underwent a dedicated head and neck and whole-body FDG PET-CT and subsequent simultaneous FDG PET-MRI. Both hybrid imaging techniques provide a comparable diagnostic ability for detection of primary cancer and metastases, with comparably high-lesion conspicuity and diagnostic confidence, offering superior assessment of cervical lesions in PET-MRI and potentially of pulmonary lesions in PET-CT.⁹⁷

BEST CLINICAL PRACTICE

FDG PET-CT is not necessary for all people with Head and Neck cancer. For many, clinical assessment complemented by conventional imaging will give all the necessary information for providing the person with H&N cancer with enough information to make an informed choice of treatment and for the planning treatment. However, with the current evidence:

In SqCC:

- ✓ Offer FDG PET-CT in T3, T4 nasopharyngeal and hypopharyngeal cancer and N3 nodal disease; consider FDG PET-CT in others with a moderate and high risk of disseminated disease.
- ✓ Consider FDG PET CT where staging is difficult clinically; for example, where there is uncertainty on other imaging or equivocal findings that would preclude radical treatment.
- ✓ Offer FDG PET-CT following completion of chemoradiotherapy in advanced neck nodal disease to inform the need for neck dissection.

- ✓ Consider FDG PET CT when there is suspicion of recurrent disease and equivocal on radiological assessment.

Consider FDG PET-CT in occult primary tumours prior to EUA.

Offer FDG PET-CT in papillary and follicular thyroid cancer post-treatment with suspected recurrence.

Consider FDG PET-CT in treated medullary thyroid carcinoma associated with elevated calcitonin levels with equivocal or normal cross-sectional imaging, bone and octreotide scintigraphy.

Consider FDG PET-CT pre-treatment in rare cancers to confirm that the tumour is FDG avid, and especially if there is a reasonable chance that subsequently FDG PET-CT may be considered for detection of residual / recurrent disease.

Consider FDG PET-CT in indeterminate lesions which are not accessible to biopsy or where a biopsy would be particularly hazardous.

FUTURE RESEARCH

- Large prospective studies evaluating FDG PET-CT as an early predictor of response to neo-adjuvant treatment in Head and Neck SqCC.
- Large prospective studies evaluating the value of FDG PET-CT as a surveillance tool in Head and Neck SqCC with high risk of recurrence.
- PET-CT studies with hypoxic and cell proliferation markers for evaluating the biology of malignant Head and Neck tumours.

KEY POINTS

- The use of FDG PET-CT in Head and Neck cancer is supported mainly by data from observational and non-randomized studies. There are limited randomized controlled trials available.
- The body of evidence shows that FDG PET-CT appropriately used can contribute to more accurate assessment of Head and Neck cancer, including more accurate staging, earlier and more accurate detection of residual and recurrent disease, improved detection of the occult primary and earlier detection of occult disease in treated differentiated thyroid cancer.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: image-guided surgery, endoscopic sinus surgery and skull base surgery.

INTRODUCTION

The use of X-ray images to guide a surgeon dates back to the middle of the 20th century. Pioneering attempts to use Cartesian coordinates to determine locations of target points in the brain in three-dimensional space predated the development of computers. The limitations of radiographic images did not stop scientists from developing over 40 stereotactic apparatus by the 1950s.¹

The development of both computers and digital imaging opened up the field of computer-aided surgery to include their use in diagnosis, pre-operative planning, surgical simulation, intra-operative image guidance, robotics, telemedicine and, no doubt, numerous other applications yet to come.

The term computer-aided surgery is used to describe computer-aided surgical planning, surgical simulation, intra-operative image guidance, robotics and prosthetics design and manufacture. Computer-aided surgery has become an integral part of modern surgical practice and training in all surgical specialties including neurosurgery, otorhinolaryngology, maxillo-facial, general and orthopaedic surgery.

BACKGROUND AND OVERVIEW

A CT or MRI scan produces a stack of digital images to create a 3D volume.² The data within this volume can be extracted and used as an accurate representation of the patient anatomy. Anatomical structures can be displayed in a variety of ways to show skin, bone, muscles, tumour

and other structures, including vessels, nerves and so on.³ The data can then be made to be transparent/semi-transparent, opaque and even colour coded. Multiple data sets can be superimposed to show different tissues and structures. An MRI could be fused to a CT 3D volume and displayed simultaneously to show accurately bone and soft tissues.

A CT scan contains an extremely accurate coordinate system of the patient data. This can be used to generate 3D models of every structure including a whole head (using skin coordinates), bones, blood vessels, lesions and bone defects. These 3D models can then be used (on screen) to make measurements, and drive numerically controlled milling machines and 3D printers to create physical models representing the patients anatomy. In maxillo-facial surgery, this is extensively used to produce prostheses for reconstruction of defects in the skull.⁴

Digital image processing algorithms have been developed to segment (extract), enhance and suppress the display of any structure contained within the 3D volume.

The 3D volume of data as well as virtual surgical tools can be aligned (registered) with the patient's real world coordinates such that the surgeon would be able to navigate surgical tools and these be displayed on a computer screen to indicate their position in relationship to patient anatomy.

The display of the data to the surgeon may be presented as three orthogonal 2D images or as a 3D volume. Augmented reality displays present the real-world patient with 3D structures or even vectors superimposed to guide the surgeon. These images may be displayed through the operating microscope as overlays on the surgical field.⁵

Alternatively, part of the 3D data set can be superimposed on the patient's anatomy, thus providing the surgeon with an extraordinary 'X-ray' type vision⁶ (Figure 48.1).

As the normal anatomy is often distorted by disease, trauma or previous surgery, and as minimally invasive surgical techniques have been developed, intra-operative image guidance has become an invaluable tool.⁷

These 3D virtual models can be used to simulate surgery. Using appropriate devices, the surgeon is able to practice surgical techniques using a virtual model and virtual tools. These virtual tools may be used to simulate different actions including cutting, suturing, manipulation and drilling. Exercises can be designed to improve hand-eye coordination and to monitor and measure a trainee's progress and development. Some of these surgical simulators include a haptic feedback mechanism that produces a realistic 'feel' to the tool that is being used. Haptic feedback allows mistakes to be made that are essential to understanding limitations as the exercises can be repeated over and over until the trainee develops the confidence needed to perform surgery on real patients.

Figure 48.1 Vestibular schwannoma. (a) MR scan; (b) intra-operative view through the microscope with the segmented image data overlain on the operative scene.

Trainers are able to monitor progress by reviewing technical data produced by the simulator to enable them to decide whether to progress the trainee on to the next step in their surgical training.

Today's doctors are relaxed and comfortable with using computers in all aspects of their lives and this extends to their surgical practice. The use of 3D models and reconstructions as well as image processing algorithms to enhance images extends to diagnosis and pre-operative surgical planning. It is difficult to imagine a surgeon performing endoscopic sinus surgery without first reviewing a CT scan (with a bone window) of the patient's individual anatomy. The surgeon still has to reconstruct a 3D model, in his or her mind, using these 2D images and their learned and prior knowledge of anatomy. 3D reconstruction removes the guesswork and utilizes all the information to make surgery safer and to provide better training of future surgeons.

Robots have, for some time now, been used by orthopaedic surgeons to perform accurate drilling of the femur and tibia during hip and knee replacement surgery. Urologists now routinely use robots to perform prostatectomy surgery and indeed general surgeons have started to use these robots when performing minimally invasive laparoscopic surgery. ENT as a specialty has now started to use robots in transoral resection of tumours as well as thyroid surgery. The size of the robotic arms prohibits them from being used as an aid in endoscopic sinus surgery, yet it is only a matter of time before these arms are made smaller to facilitate their use as an aid to endoscopic sinus and skull base surgery.

Robots offer several advantages that enable accurate, safer and ultimately better surgery for the patient. They are extremely accurate and, when operated by a surgeon, eliminate tremor. They provide a higher degree of freedom, which enables the surgeons to perform manoeuvres that are not normally possible. The surgeon's hand movement can be magnified or miniaturized to enable extremely small and delicate movements in a small or confined space.^{8,9}

The geometric accuracy of these robots and of the image guidance devices depends, not only on the precision of these instruments, but also the accuracy of the 3D data that are input to represent the patient coordinates. It is also dependent on the accuracy of registration of the data to real-world coordinates, image reconstruction and segmentation, tracking devices and the displays. In the next section we will discuss these components to enable a better understanding of the principles of computer-aided surgery, image navigation and guidance.

IMAGE RECONSTRUCTION

CT and MRI data are acquired on a 2D plane. Sequential 2D images are then stacked to create a 3D volume. The geometric accuracy of the 2D slices is extremely high and in the case of CT is even higher to a resolution as high as 0.2 mm per pixel on a 512 × 512 matrix. The 2D slices can be as thin as 0.5 mm and this, along with slice separation,

will affect the resolution in the Z (longitudinal) direction and therefore affect the resolution of the coronal and axial reconstructions. This is also applicable to multislice spiral CT scanners that acquire images in a contiguous manner. These scanners are faster, have a better resolution and expose the patient to less radiation.

Pixels and voxels

Two-dimensional slice sections are composed of pixels, which are the smallest picture elements. The more pixels, the better the resolution. Currently, the highest resolution available for both CT and MRI is 512×512 pixels per image. In a field that is 30×30 cm, this gives a high definition picture, whereas in a larger field this gives a low resolution. By convention, the image resolution is stated by the number of pixels in the x and y axis.

Each pixel has a value ranging, in the case of the CT scan, from -1000 to 3096 . This is referred to as Hounsfield units (HU). CT scans are calibrated such that the value of 0 equates to the density of water. By convention, high pixel values are displayed as white. The lower the value, the lower the density of the tissue (X-ray absorption) and the darker the pixel would appear. Pixels are two-dimensional, but it is possible to convert these picture elements into a 3D block. This 3D block is referred to as a voxel or a volumetric picture element. Voxels can be a cube or cuboid depending on the inter-slice distance.

Volume averaging

If a structure falls partially within a pixel, the true value of that structure will then be assigned a value less than the normal value of the structure. In the case of bone, which has a value of say 1000HU, the value of a pixel that includes a part of that part of the bone will be much less, perhaps 500HU. This is referred to as partial volume averaging and is a major problem in delineating where the edge of a structure should lie within a given image. Higher resolution images would overcome that problem to some extent. This is not always possible as higher X-ray dosages would be required and an order of magnitude increase in the complexity of the hardware. Algorithms have been developed to overcome this problem and define the edge of a structure with a greater degree of confidence. Each one has its own unique problems and for clinical use in the area of neurosurgery and otorhinolaryngology the accuracy difference is submillimetric and can be ignored.

VISUALIZATION OF IMAGE DATA

Many factors have to be considered when deciding which visualization technique to use. The clinical purpose for which the data are to be used is the most significant and the image data are rendered for that purpose. *Rendering* is the process of generating computer images that represent the three-dimensional anatomy with varying degrees of tissue transparency.¹⁰

Surface rendering

Optical surface scanners produce structured 3D coordinate point sets that relate to an anatomical surface.⁹ Triplets of data points are generally grouped as the vertices of adjacent triangles that interconnect to make up the entire surface. These triangular surface patches are known as facets or polygons.

The rendering of surfaces from volume data requires pre-processing. The properties of voxels containing anatomical surfaces must first be decided and voxels with these properties can then be processed. Usually voxels are considered to lie on a surface if they are connected and all have the same associated property within a given range of values. The derived surfaces are called isosurfaces and are selected to correspond to the surfaces of anatomical structures or to surfaces of equal functional activity.

Geometric primitives are also derived from volumetric data by processes such as contour tracing, surface extraction or boundary following. Alternatively, voxels belonging to anatomical parts may be isolated from the full data set by applying thresholds to the data values associated with them. This extraction of tissue topology has become known as 'segmentation'. The derived geometric primitives (such as polygon meshes or contours) are rendered for display using conventional computer graphics techniques.

Figure 48.2b shows the rendering of a facial surface that is made up of a large set of triangular facets that are also shown in **Figure 48.2a**. This type of image can be produced using data from an optical scan of the face.

Volume rendering can be undertaken for notional surfaces between distinct tissue types. The surface normals are derived directly from the voxel values neighbouring the boundary. These derived surface normals are used for calculating the final image using algorithms. A technique of this sort was used to produce the image depicted in **Figure 48.2c**.

Volume rendering

Volume rendering has become the most commonly used method with which to visualize 3D medical image data. The basic idea is that 3D volumes are composed of voxels and that these are analogues of their 2D counterparts, the pixels. Fine details throughout a volume of interest are displayed, enabling a more direct understanding of visualized data with fewer artefacts.

This visualization technique works by projecting each voxel on to a viewing plane with a value related to the physical property represented in the voxel array. For example, a voxel containing bone with a high X-ray absorption coefficient might be projected with a high value. The most advanced systems allow the operator to construct a look-up table that relates the physical value associated with the voxel to the value it contributes to the image at the chosen viewing plane. A pixel in the viewing plane usually receives contributions from many voxels and the operator may control the manner in which these contributions are composed. For example, the operator may choose to

Figure 48.2 (a) Wire mesh; (b) polygon-rendered; and (c) volume surface.

display only the maximum contribution from any voxel along a ray. This produces an image known as the maximum intensity projection (MIP). On the other hand, any individual voxel-associated value may be assigned a maximum opacity value to produce the same images as would be produced by surface rendering.

Figure 48.3 shows two volume-rendered images with different look-up tables. These demonstrate how different anatomical structures may be made visible through others that are being rendered transparent. Major blood vessels, for example, may be effectively rendered visible within the anatomical data set.

Generally, a volume-rendered image appears different from that of a surface-rendered image in that anatomical structures are presented as having some degree of transparency. For some clinical procedures, such as image-guided biopsy or transcutaneous thermal ablation,

transparency may greatly enhance depth perception and thus increase the accuracy of the procedure. It is apparent that surfaces are not explicitly rendered, but human perception reconstructs images that are perceived to be in the correct spatial relationship. The transparency that volume rendering offers also enables the placement of surgical instruments within 3D structures with great accuracy.¹⁰

Registration

Once the patient is secured on the operating table, registration of the Cartesian coordinates of the CT scan to that patient in the theatre is achieved by one of two methods. The first is by locating anatomical landmarks visible both on the patient and image data using a probe that is visible to the tracking device. For example, using navigation

Figure 48.3 Volume-rendered data with different look-up tables.

software, the surgeon would point to pre-specified landmarks, such as the tragus, outer canthus and nasion. This is usually sufficient to achieve a registration accuracy or error of 3–4 mm. This can then be improved by entering a random sample of points from around the operative region (typically 40–100 points) using the probe. The position of the tip of the probe is identified by the tracking device and the coordinates are fed back to the navigation software. In this way, accuracy/errors of 2–3 mm can be achieved.

Other methods of registration use masks¹¹ and laser scanning tools (Figure 48.4)¹² that speed up the acquisition of surface points. With all these methods, calculations made in real time indicate the point accuracy. It is then up to the surgeon to reject or accept that point in order to improve the overall registration accuracy. Some types of image guided systems make use of fiducial markers that

Figure 48.4 (a) A laser registration being undertaken before endoscopic sinus surgery; (b) the laser beam is shone on to the skin around the operative site; (c) a band onto which fiducial balls have been mounted is attached to the patient's head.

are applied to the patient before scanning on the day of surgery. These markers are clearly visible in both MR and CT data sets and, of course, on the patient when in theatre. They help to improve the accuracy of registration.

No matter whether skin fiducials or anatomical landmarks are used for registration, these reference points

should describe or be immediately adjacent to the surgical field. Failure to pay attention to this results in navigational inaccuracies. It is important to realize that the registration error is only a measure of the accuracy of correlation between selected points in the virtual data set and the fiducial markers or anatomical landmarks identified on the patient. It is not synonymous with target error, which is the error that could be expected if a probe was placed on a random point of interest within the surgical field. The target error is influenced by the registration error and is unlikely to be much worse if the target is within the volume described by the fiducial markers. However, if the point is outside that volume, the target error will be proportionately greater.

Tracking

Sensors that provide dynamic positional information are known as 'tracking devices'. They are employed in a multitude of everyday situations that range from virtual reality games, GPS systems, to missile guidance and electronic tagging of prisoners.¹³ Although these measurement acquisition systems may be similar, each has different tracking properties that are optimal for a particular application. Without some form of tracking device, it would not be possible to move the patient once they had been registered. In surgical practice, tracking systems must be very precise, consistently accurate, fast enough to provide more than 25 readings per second, and be insensitive to changes in air temperature, unaffected by metal objects and able to track at least two objects simultaneously.

Several tracking systems have been employed over the years. Some of the earliest devices were mechanical arms fitted with potentiometers at every joint. These were fast and accurate but were cumbersome, had a restricted range of movement and hindered the movement of the tracked object to which they had to be attached. Systems based on magnetic field distribution are effective and relatively cheap. However, their disadvantage is that tracking accuracy can be both easily and significantly affected by the presence of metal objects. The quality and accuracy of these types of tracking devices is constantly improving and because there are no line-of-site issues, these are ideal for ENT applications. The latest types of electro-magnetic tracking devices are flexible, again making them ideal for areas that are difficult to reach such as the frontal sinus.

Infrared light sensors are the most commonly used image-guided surgical systems. They are referred to as either active or passive devices. Active devices sense infrared light from light-emitting diodes (LED) attached to the patient or location probe. Passive tracking devices detect infrared light reflected from metallic balls attached to the patient or probe. In the latter case, the infrared light source is situated on the sensing device itself (Figures 48.5 and 48.6). In order to detect changes in the patient's head position, haloes or arches with light-emitting diodes or reflective spheres can be fitted to a Mayfield clamp or the patient's head. Systems based on light-emitting diodes are reliable if the light path is not impeded.¹⁴ Within the operating

theatre an accuracy of 2–5 mm can usually be achieved.⁴ In general, optical tracking systems are expensive. Cheaper variations do exist, but they lack high degrees of accuracy.

Inertial trackers have also been developed that are small and accurate enough for virtual reality applications. These devices generally provide one rate of change of rotational measurement only; hence, a number would be required. They are also not accurate for slow position changes. Systems based on standard ultrasound signals have the potential to achieve much greater accuracy, but are susceptible to changes in temperature and air currents. Other drawbacks include long lag times and interference from echoes and other noises in the environment.

Figure 48.5 A patient with their head held in a Mayfield clamp being prepared for image-guided surgery. An arc with metallic ball fiducials has been attached to the clamp. The arc describes the operative volume. A laser light is being centred on the field to find the optimal position for the tracking device.

Figure 48.6 An infrared optical tracking system. In the centre of the gantry is a laser light that is used to position the arm during the set-up procedure.

Clinical applications

Image-guided surgery (IGS) offers most promise in the areas of skull base and endoscopic sinus surgery. Skull base surgeons have found this technology particularly useful for pre-operative surgical planning, design of bone flaps, identification of important structures and for finding small tumours in obscure parts. This takes on additional importance when normal anatomy is distorted by disease or anatomical variations.

In rhinology, IGS systems are already in use in difficult revision endoscopic sinus surgery where there are no recognizable anatomical landmarks (Figure 48.7).¹⁵ In particular, surgeons have found the guidance systems useful to localize the frontal recess during Draf type 2 and 3 procedures, where the floor of the frontal sinus is to be opened.¹⁶ With the help of these systems, the need to perform open, external procedures will become less. Extended applications of endoscopic sinus surgery include trans-sphenoidal, trans-nasal endoscopic hypophysectomy where conventionally X-ray image intensifiers have been used to localize the sella.¹⁷⁻¹⁹

In the field of otology, IGS has been used to aid the surgeon in locating the facial nerve, identifying and localizing lesions of the petrous apex²⁰ and tumours, particularly in the internal auditory meatus. These include meningiomas and vestibular schwannomas.^{21, 22} It is possible that when these systems gain in acceptance, are more accurate and involve shorter set-up times, they may become mainstream intra-operative equipment in all types of mastoid surgery. Their role then would be to aid the surgeon in localizing important anatomical structures such as the facial nerve, dura, brain and jugular bulb, as well as diseases such as cholesteatoma and acoustic schwannoma.

Surgical planning

Surgical planning is usually carried out in the surgeon's mind, drawing on past experience, knowledge of anatomy and anatomical variation. Some individuals are able to do this very well, others are not. In endoscopic sinus surgery, the surgeon must have the ability to think in 3D, having studied the information available from 2D CT slices.

Figure 48.7 Functional endoscopic surgery being undertaken using image guidance.

Surgeons may or may not be able to communicate their impressions to other surgeons. Furthermore, their mental image cannot be reviewed, audited or measured by other surgeons or indeed by the surgeon themselves when assessing patients at a later date. Planning using reconstructed 3D data enables the surgeon to assess the patient's anatomy objectively, to communicate this with other surgeons and to review these films at a later date. The data can be segmented and manipulated to familiarize the surgeon with specific features pertinent to that patient and the procedure to be performed.

Surgical simulation

The major driving force behind the development of surgical simulators was the morbidity that accompanied the introduction of new techniques such as endoscopic 'keyhole' surgery. These techniques were conceptually different from traditional surgery. Surgeons had to operate using a 2D image on a television monitor and had to develop new hand-eye coordination skills not previously required for open surgery. Training surgeons in these new skills and the assessment of their competence was entirely different from the 'apprentice-master' approach that had been the mainstay of traditional surgical teaching. Three-dimensional reconstructions of image data can be used for surgical simulation. Simulators that create a virtual surgical environment or a set of tasks that enhance hand-eye coordination skills seem to be the answer.^{23, 24}

Surgical simulators are now being developed and employed in other surgical specialties, for example skull base surgery. They are being used by trainees and experienced surgeons who might find it useful to practise a specific difficult surgical technique before performing the actual operation. Surgeons are able to 'virtually' manipulate, move and drill the mastoid process, to perform laparoscopic or endoscopic sinus procedures. The sensations and resistance encountered during real surgery may be simulated using positive feedback mechanisms in the form of a passive robotic arm.

IMAGE-GUIDED SURGERY

A thorough knowledge of anatomy is essential for all types of surgery, particularly those using microscopes and endoscopes. Pre-operative imaging alerts the surgeon to variations of anatomy that are either inherent in the patient or caused by a disease process or previous surgery. As stated before, image guidance offers the surgeon the ability to use the patient's image data intra-operatively to determine position, distance to vital organs and other anatomical features that might be hidden from direct vision. Structures in the vicinity of the skull base are either embedded or closely adherent to bone, making this region ideal for image guidance as CT has great spatial accuracy.

Two fundamental processes are required for intra-operative image guidance, registration and tracking. Registration is the process that relates the patient in the operating theatre to pre-operatively acquired

image data sets. Tracking is the mechanism of following the position of the patient or an instrument within the operative field. Both processes are potentially subject to

significant mathematical error and it is vital that how this might happen is fully appreciated.

FUTURE RESEARCH

- ▶ Image-guided and augmented reality surgery relies heavily on technology research in the areas of computer hardware (processors, graphics and tracking) and software for segmentation and registration. Developments in these fields are driven by a variety of customer-driven demands. It is vital that clinicians make these demands and provide ideas for the computer scientists.
- ▶ The most important requirements are for accurate, robust, fail-safe systems that will give clinicians greater confidence. These systems must be user-friendly and ergonomically efficient. Computer user interface remains the biggest deterrent to regular use of these systems. These need to be simplified and easy to operate. Surgeons will eventually develop trust in the accuracy of these systems.
- ▶ In the future, we are likely to see more developments in the areas of surgical simulation and planning. Surgical training should benefit from simulators that will enable the trainee to develop their hand-eye coordination skills prior to applying them in clinical practice.
- ▶ At present, augmented reality still has to prove its position in surgical practice. Several research groups are producing encouraging results and future reliance on these types of systems is likely to replace traditional IGS systems.
- ▶ Robots are already being used for drilling in the field of orthopaedics and to manoeuvre and control cameras in laparoscopic surgery. These are far more accurate than humans and are likely to enter other fields of surgery where there is a reliance on power instrumentation, including drills and debriders.
- ▶ In the future, we are likely to use IGS systems to audit surgical procedures as they already have the inherent capacity to store all information relating to intra-operative navigation. This will be an invaluable and auditable operative record.

KEY POINTS

- IGS aids the surgeon in diagnosing the extent of disease, planning surgery and providing intra-operative positional information.
- Image-guided surgical techniques may reduce complications in endoscopic sinus surgery.
- IGS techniques offer greater accuracy and confidence in structure and disease localization.
- Major applications are skull base and revision nasal surgery where there is complex or distorted anatomy.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: interventional neuroradiology, endovascular therapy, embolization, meningioma, paraganglioma, epistaxis, tumour embolization.

INTRODUCTION

This chapter reviews the role of interventional neuroradiology (INR) in the management of patients with pathologies of the head and neck and describes common techniques. Endovascular embolization originated in surgery when Brooks¹ closed a cavernous-carotid fistula with a muscle embolus introduced by arteriotomy in 1930. The need for vascular imaging to monitor embolization was obvious, but the capacity developed slowly after the first description of cerebral angiography by Egas Moniz in 1927.² As a result, embolization for head and neck pathologies is generally performed in Neuroradiology departments.

Endovascular embolization is the most common technique. It is used to treat arterio-venous shunts, devascularize tumours and close large arteries prior to surgical resections. But also included in the INR repertoire are percutaneous techniques for embolization of vascular malformations and tumours, image guided biopsy and focused endovascular delivery of chemotherapy agents. The technologically driven evolution of the discipline will almost certainly produce new methods and applications to replace more invasive surgery in the future.

INDICATIONS

MR or CT scanning is usually adequate for diagnosis and pre-operative assessment of head and neck lesions so digital subtraction angiography (DSA) is rarely needed unless

there is a possible role for INR. Combining embolization using DSA means that the indications for INR techniques should be considered early in treatment planning. This process involves considering a lesion's blood supply as well as its extent and relationship to normal structures. Pre-operative embolization may be indicated and information about adjacent major vessels may be vital, either because of tumour proximity or because their sacrifice may be a necessary component of the surgical approach or resection.

Embolization of vascular tumours is indicated prior to surgical resection to reduce intra-operative blood loss, operation times and facilitate complete resection. It can be considered as the definitive intervention in patients with minimal symptoms in whom surgery is contraindicated. It may also be indicated as palliative treatment to relieve pain for patients when surgery, radiotherapy or chemotherapy are unsuitable or to manage haemorrhage or increasing neurological symptoms. It is most effective in tumours with high blood flows. In most instances this can be inferred from the degree of contrast enhancement evident on CT or MR scanning but it should be remembered that the uptake of radiographic contrast within a tissue reflects the degree of extravascular leakage of these agents and not necessarily the blood supply. So occasionally tumours showing pronounced enhancement are not suitable for embolization.

Embolization is targeted to occlude the smaller arteries of the tumour vascular bed since the proximal occlusion of arteries is a relatively ineffective method of causing tumour necrosis and/or regression.

Large artery occlusions are sometimes indicated as pre-operative manoeuvres and rarely for tumour palliation. Emergency embolization may be required to manage tumour haemorrhage.

Functional testing by temporary vessel occlusion is indicated prior to endovascular ligations and may be useful when surgical resections are likely to require the ligation of a large artery or vein. Blood flow in the target vessel is occluded by inflating a balloon with the patient awake so that neurological examination can be performed and collateral blood flows can be assessed by DSA. Permanent occlusion by endovascular ligation is performed after a satisfactory test. The potential of INR to access lesions under imaging control, either using highly flexible endovascular microcatheters or by direct puncture, can also be exploited for the selective delivery of drugs for sclerotherapy, chemotherapy or functional tests of nerve function using sedative agents, such as barbituates (in brain) or lignocaine (in spine).

The decision to perform an INR procedure depends on clinical and anatomical factors. These should be reviewed in multidisciplinary consultations between the treating otolaryngologist (or other specialist) and interventional neuroradiologist. For pre-operative embolization, the guiding principle is that an additional INR procedure should not add to the management's overall risk. This risk/benefit analysis may require information that can only be obtained at the time of DSA. Therefore close cooperation and a team approach is needed, to ensure that the risks of complications caused by embolization or pre-operative invasive functional tests are acceptable and are justified because they are likely to improve the outcome of subsequent surgery. These issues, as they apply to specific tumour types, and the use of embolization in the management of epistaxis, will be discussed below. The purpose and potential benefits of INR techniques are summarized in [Table 49.1](#).

TOOLS AND TECHNIQUES

Endovascular catheters

The catheters used for transarterial or transvenous catheterization are available in a range of sizes and shapes. They are used to select and inject radiographic contrast media in cranial vessels for angiography or as guiding catheters for smaller catheters used for the selection

of small vessels (i.e. microcatheters). Microcatheters are generally 0.02 inches (0.5 mm) or smaller in diameter and are used to inject embolization materials. They are constructed with flexible distal ends for navigation through tortuous vessels and stiffer proximal sections to allow the operator to advance them by pushing.

Two basic types of microcatheter are used: flow directed and over-the-wire catheters. The former have extremely light and supple distal ends so that they are carried by antegrade blood flow to the target position. The latter are pushed over a guide wire to the objective. Flow directed catheters work best when blood flow is increased and are therefore used to treat arteriovenous shunts. Their size limits their use to the injection of liquids or very small particles. Over-the-wire catheters are used when blood flow is slower. The combination of guide wire and a stiffer catheter makes navigation easier and their larger lumen allows the delivery of liquids and both particles or coils. They are usually used in the treatment of head and neck tumours.

Materials used for embolization

PARTICLES

Embolic agents can be categorized on various criteria. Traditionally, they are divided according to whether the resulting devascularization is permanent or temporary. Examples of temporary agents are autologous blood clot, gelfoam powder and microfibrillar collagen, which are biodegradable, whilst particles manufactured from non-degradable materials are considered permanent agents ([Table 49.2](#)). However, the effectiveness of embolization using non-degradable particles is liable to be temporary because small vessel occlusions may be circumvented by the development of new collateral vessels.^{3, 4} In practice, the development of a new blood supply is likely given time but is less likely if particles can be deposited in small vessels within the tumour bed rather than in proximal arteries. To ensure the deep penetration of injected particles, they are engineered to mix well with radiographic contrast so that they can be injected as an even suspension. Non-degradable particles in current use are made of polyvinyl alcohol (PVA),⁵ trisacryl gelatin⁶ or cellulose porous beads,⁷ which are coated or mixed with radiographic contrast material to make them radioopaque and visible on X-ray fluoroscopy. They are available in sizes varying between 40–800 microns in diameter. The choice

TABLE 49.1 Interventional neuroradiology techniques and their uses

Procedure	Technique	Purpose/benefit
Biopsy	Percutaneous needle	Histology and treatment selection
Functional testing	Temporary balloon occlusion	Assessment of collateral blood supply prior to surgical or endovascular ligations
Embolization of small vessels	Particle, liquid embolics, sclerosants	Devascularization of tumour to reduce operative blood loss, palliation or cure
Embolization of large vessels	Balloon, coils, plug devices, liquid embolics, sclerosants	To aid surgical exposure/dissection, palliation or cure
Chemotherapy	Endovascular or intra-lesion injection	To maximize drug delivery to the lesion

TABLE 49.2 Embolic agents

Agent	Embolization	Target vessels
Autologous blood clot	Temporary	Afferent arteries
Gelfoam	Temporary	Afferent arteries
Polyvinyl alcohol particles	Permanent	Tumour vessels
Trisacryl gelatin particles	Permanent	Tumour vessels
Coils	Permanent	Large arteries/veins
Balloons	Permanent	Large arteries
Alcohol (ethanol)	Permanent	Malformations or tumour vessels
Sodium tetradecyl sulphate	Permanent	Malformations or tumour vessels
Cyanoacrylate adhesives (NBCA)	Permanent	Malformations or tumour vessels
Ethylene vinyl alcohol copolymer (Onyx)	Permanent	Malformations or tumour vessels

of particle size is important because, though smaller particles will penetrate to smaller vessels, they are more likely to pass through arteriovenous shunts and reach the lungs. They are also more likely to cause ischaemic damage to normal tissues. On the other hand larger particles occlude proximal arteries and achieve less reliable tumour devascularization.⁸

The effect of PVA or gelatin particles on tissues is to cause an initial acute inflammatory response, which is followed by a chronic foreign body reaction within weeks.^{4, 9} Devascularization causes ischaemia and necrosis within hours, which in turn causes tumours to swell (exacerbating symptoms and causing pain) or haemorrhage. For this reason pre-operative embolization is often performed immediately prior to operation.

COILS AND BALLOONS

Embolization coils are made from steel, tungsten or platinum. Because of problems of corrosion, tungsten is generally no longer used and platinum, though expensive, is preferred because it is inert and not liable to magnetization effects during MRI. A new development is to enhance their effect by adding a thrombogenic coating. The materials used include collagen, bioabsorbable polymers and dacron fibres.¹⁰ Originally coils were simply pushed through a delivery catheter and could not be retrieved or repositioned. Retrievable coils with controlled delivery are now standard. There are various methods for controlling their detachment from a delivery wire. These include couplings released by mechanical or hydrostatic pressure, electrolysis or thermal heating.¹¹

Balloons are made of latex or silicone.¹² They are either fixed to a catheter tip for temporary test occlusions or can be detached for vessel occlusion. They are inflated by injecting fluid; usually radiographic contrast media. Detachable balloons are released mechanically from a delivery microcatheter but their detachment is less reliable than the newer methods developed for coils. In many centres they have been superseded by coils.

Coils or balloons are used for large artery occlusion (i.e. endovascular ligations), usually after a satisfactory temporary balloon occlusion test. High blood flow fistulas are occluded with coils or balloons positioned at the point of transition between artery and vein. The delivery of coils is easier to control than balloons and they can be positioned more accurately. They are used to embolize large veins or dural sinuses in order to close dural arteriovenous fistulas (DAVF) and less often for tumour embolizations.

LIQUID EMBOLIC AGENTS

Various liquids are used for embolization including sclerosants, adhesives and soluble plastics. They have the advantage over coils and particles of being injectable via smaller lumen catheters or needles. Most commonly used are quick-setting adhesives and polymers. Examples of liquid agents are the tissue adhesive N-butyl-2-cyanoacrylate (NBCA) and ethylene-vinyl alcohol copolymer (EVAL). There are various commercial formulations available (e.g. NBCA marketed as Histoacryl and Glubran, and EVAL marketed as Onyx).^{13, 14} NBCA thickens and sets on exposure to blood and copolymers set after injection as the solvent (e.g. dimethyl sulfoxide) in which they are dissolved disperses. Both agents are liable to embed the delivery catheter within vessels and require considerable expertise to deliver safely, but they are generally regarded as producing the most permanent form of embolization. They are therefore preferentially used for definitive or palliative treatments as well as for pre-operative embolization. Sclerosants such as ethanol or sodium tetradecyl sulphate are used to treat facial vascular malformations, bleomycin is effective in certain types of low flow vascular malformations¹⁵ and mannitol has been used to embolize meningiomas.¹⁶

APPLICATION OF EMBOLIZATION TECHNIQUES

Tumour embolization

TRANSARTERIAL

Embolization of tumours of the head and neck is most often performed to reduce blood loss and facilitate surgical resection or for palliation. It is rarely curative. Pre-operative embolization is performed for vascular tumours such as meningioma,^{9, 11, 17} haemangioblastoma, juvenile nasopharyngeal angiofibroma,¹⁸ schwannoma and paraganglioma¹⁹ (Table 49.3). Pre-operative functional evaluations by temporary balloon occlusion of at-risk major arteries can also be performed. Pre-operative embolization is largely reserved for extra-axial intra-cranial tumours and only rarely are highly vascular intra-axial CNS tumours, such as haemangioblastoma, treated.

Pre-operative transarterial embolization is usually performed with PVA particles (sized to occlude the pathological circulation) or liquid agents (e.g. NBCA or Onyx).²⁰

TABLE 49.3 Head, neck and skull base tumours treated by embolization

Commonly treated tumours	Less frequently treated tumours
Meningioma	Schwannoma
Paraganglioma	Carcinoid
Juvenile angiofibroma	Alveolar sarcoma
Haemangiopericytoma	Thyroid carcinoma
	Granular cell myoblastoma
	Capillary haemangioma
	Esthesioneuroblastoma
	Neurinoma

Liquid agents can also be injected directly into tumours (see below). Serious procedural complications occur in about 4% of patients and these include cranial nerve palsies (including blindness), stroke due to unrecognized spread of emboli and induced bleeding due to vessel perforation or secondary to tissue necrosis.²¹ Complicating cranial nerve palsies are more common when very small particles or NBCA are used.²² Though technically relatively straightforward, safe embolization of skull base lesions should only be undertaken after adequate training. Safe embolization demands a sound knowledge of vascular anatomy and the potential sites of spontaneous external to internal carotid artery or vertebral artery anastomoses, if cerebral or spinal migration of emboli is to be avoided.²³

PERCUTANEOUS EMBOLIZATION

This technique involves the injection of a liquid embolic or sclerosant directly into tumour vessels. The objective is to devascularize tumours before surgical resection or for palliation of symptoms by causing tumour involution. Pre-operative embolization is usually performed following percutaneous puncture but perioperative needling can be performed. The technique was first used to devascularize hypervascular juvenile angiofibromas²⁴ but has also been used to treat haemangiopericytoma and paraganglioma.^{25,26} The technique is particularly attractive for the management of recurrent lesions and has been reported to achieve total or near-total tumour devascularization.²⁷

Delivery of chemotherapy agents

Selective catheterization allows endovascular delivery of chemotherapy drugs directly into tumours to maximize the local dose. Direct puncture of tumour vessels under X-ray or ultrasound imaging is an alternative. The objective is to deliver higher doses in the target tumour whilst avoiding systemic toxic symptoms. The amount of drug delivered to a tumour is proportional to its rate of plasma clearance within the tissue and inversely related to tumour plasma flow.²⁸ Selective catheterization allows the delivery rate to be fine-tuned to the prevailing rate of blood flow. This benefit has been used in studies of local chemotherapy for cancers of the head and neck, specifically advanced

squamous cell carcinomas.²⁹ Combination therapies with radiotherapy, for example RADPLAT, have been effective at inducing remission and Kumar and Robbins³⁰ recently reviewed their use. The systemic toxic effects of Cisplatin can be mitigated by the simultaneous intravenous administration of its competitive antagonist thiosulphate. Despite logistical problems associated with catheterization and long infusion times, preliminary trials have shown the technique to be effective at causing tumour shrinkage.³¹

Temporary and permanent large artery occlusions

Temporary endovascular occlusion of large arteries prior to head and neck surgery allows neurological testing of the awake patient and angiographic assessment of the consequences of vessel sacrifice.

There are many described protocols for temporary artery occlusion and dynamic testing. Only two elements are common to all: that the procedure is performed under local anaesthesia so that the patient is accessible for neurological examination; and that anticoagulants are given. Test occlusion involves inflating a balloon in the target artery for 20–30 minutes and assessing the effect on cerebral blood flow. The adequacy of collateral blood flow to the territory of the occluded vessel can be demonstrated by angiography, Doppler ultrasound, xenon CT, single photon emission computed tomography (SPECT) and positron emission tomography (PET) scanning. Additional provocative testing can be performed by simultaneously lowering the systemic blood pressure or administering a vasodilator drug such as acetazolamide.³² All these techniques are designed to improve the reliability of the test but the lack of a consensus protocol testifies to the fact that there remains a risk of the collateral blood flow being inadequate, despite normal test data.

It is generally accepted that preliminary testing reduces the risk of delayed stroke, but its value depends on risk posed by the test. Reported rates of morbidity come largely from audits of its use in aneurysm patients.^{33,34} Amongst patients undergoing ligation for skull base tumours, rates for complications range between 5% and 20%.³⁵ The additional risks faced by cancer patients was documented in a single institution report, which found the complication rate to be 10% whilst that of aneurysm patients was only 3%.³⁶ Following a satisfactory period of temporary occlusion, the artery is permanently occluded by detaching the balloon or replacing it with embolization coils. Some practitioners prefer the latter because the detachment systems for coils are more reliable. It is obviously important that permanent occlusion is performed at the same arterial level (i.e. at the same place) as the test occlusion.

EMBOLIZATION FOR SPECIFIC TUMOURS

The commonly treated tumour types will be described in detail to illustrate the goals of INR in the management of patients with tumours of the skull base and neck.

Meningioma

These typically benign tumours originate from arachnoid cap cells found in arachnoid granulations. They therefore arise in continuity with dura. Though generally intracranial they are found at extra-cranial sites by extension from a dural origin or rarely occur entirely extra-cranially (presumably from ectopic dural rests). Thus tumours may involve the skull base, orbit and cervical spine or the upper neck. They occur in middle age, affect women twice as commonly as men and are linked to a genetic deficit on chromosome 22. Multiple lesions occur in patients with neurofibromatosis II and meningiomatosis.^{37,38} Associations have been reported with exposure to ionizing radiation³⁹ and hormonal influences due to the presence of androgen and other hormone receptors.³⁸ They may be locally invasive and the WHO classification of histological findings recognizes three grades (grade 1 – benign, grade 2 – atypical and grade 3 – anaplastic), which are independent of the traditional histopathological descriptions of meningothelial, fibrous, transitional, syncytial and psammomatous subtypes. They are usually highly vascular tumours with the transitional subtype being most vascular and the psammomatous subtype least vascular.

Clinical presentation varies according to location and imaging by CT scan or MRI is usually adequate for diagnosis and pre-operative assessment. Tumour calcification and skull hyperostosis is easier to recognize on CT than MRI and suggests a less vascular subtype. Enlarged vessels within or adjacent to more vascular tumour are easier to see on MRI. Tumour enhancement after intravenous contrast media administration is typical and is more avid in vascular tumours, but such enhancement does not imply that a particular lesion is suitable for embolization.

Treatment is by resection, and radiotherapy is reserved for more aggressive histological types. Pre-operative embolization is indicated for vascular tumours and for the palliation of inoperable newly diagnosed or recurrent tumours. Intra-arterial angiography is required to assess the extent of tumour vascularity and therefore the potential of embolization. In a minority of tumours, dense calcification on CT or lack of enhancement after contrast media administration, imply a less vascular tumour and that embolization will not contribute to management but the majority warrant angiography to select tumours likely to benefit from embolization.

The vascular supply to meningioma seen on DSA is typically arranged in a radial pattern of dilated feeding arteries of decreasing size with a delayed venous phase of contrast passage (often termed a 'blush') through the tumour bed. Arterial supply may be from external carotid artery branches or from dural or trans-pial branches of the internal carotid artery or a mixture of the two (Figure 49.1). The endovascular therapist therefore needs a detailed pre-embolization DSA to evaluate the feasibility (and risks) associated with superselective catheterization and embolization. In practice treatment and diagnostic DSA are usually combined in the same session and scheduled as part of the patient's overall treatment plan.

A universal need for pre-resection embolization is controversial and patients are usually selected on a case-by-case basis after multidisciplinary review. The goal is to reduce operative blood loss and facilitate complete resection. It may be performed using particles (e.g. PVA), or liquid embolic agents (e.g. NBCA or Onyx). Since the typical blood supply is by arteries and arterioles of gradually reducing size, small particles (for example, 150 microns) are used first to obstruct intra-tumour vessels and larger particles injected subsequently to obstruct larger afferent arteries (Figure 49.1). Effective embolization will cause acute tumour infarction and swelling. The optimum timing of subsequent operation is debatable; the argument for early operation is that symptoms due to swelling or haemorrhage are avoided whilst for delayed surgery that operative blood loss is lessened and surgery facilitated.⁴⁰ If operation is delayed then steps must be taken to ensure that worsening neurological symptoms or signs are quickly detected and treated. Rarely, tumour necrosis causes bleeding and life threatening expansion of tumours. Prolonged delay risks revascularization, due to growth of vessels and new blood supply to the meningioma, which can occur within as short a period as 3–4 weeks after particulate embolization.

Another indication for meningioma embolization is to arrest or impede tumour growth when lesions are inoperable and radiotherapy inappropriate.⁴¹ In theory, particles delivered into the tumour bed only, will cause tissue ischaemia/necrosis without stimulating growth of collateral blood vessels. In this situation, very small particles (50 microns) are injected slowly and no attempt is made to obstruct larger feeding arteries. Tumour devascularization and shrinkage is monitored by MRI enhanced by intravenous gadolinium administration. Areas of non-enhancement imply devascularization (Figure 49.3f).

The efficacy of pre-operative embolization is difficult to objectively evaluate. Criteria used in reported studies include comparisons of blood transfusion volumes between tumour resection operations performed with or without pre-operative embolization, surgery times, lengths of hospital stay, extent of tumour necrosis and clinical outcomes. A reduced need for blood transfusion was reported by Teasdale et al.⁴² and Oka et al.,⁴³ shorter lengths of hospital admission by Dean et al.⁴⁴ and Oka et al.,⁴³ and improved clinical results by Oka et al.⁴³ when adjuvant embolization was performed. A reduction in neurological complications after surgery was reported by Oka et al.⁴³ but this benefit was only evident for patients with large tumours (greater than 6 cm in diameter). Delaying surgery until 7 days or more after embolization is associated with lower blood transfusion volumes⁴⁵ and greater induced tumour necrosis.⁴⁶ The conduct and evaluation of such studies is difficult because of the variations in size and site of the tumours studied.

Several specific complications have been reported after meningioma embolization due to inadvertent occlusion of vessels supplying normal tissues, the effects of tumour swelling and haemorrhage. Intra-tumoural haemorrhage resulting from devascularization may occur 24–36 hours after embolization. In the author's practice, this complication has occurred once in 40 treatments over the

Figure 49.1 Parasellar meningioma. This tumour is supplied by meningeal branches arising from both internal and external carotid arteries. Figures (a) and (b) are lateral views from internal and external carotid injections respectively. Pre-operative embolization of the external carotid supply only was performed after selective catheterization of the accessory meningeal artery (c). The effect of embolization is seen in (d); compare this DSA with (b). Figures (e) (f) are axial T1W gadolinium enhanced MRI of the tumour before and after embolization of the external carotid blood supply. Note that enhancement occurs in only the medial portion of the tumour on (f).

last 5 years. Selective catheterization risks causing vessel damage, perforation and rupture. The last is more likely to occur at sharp bends in vessels. Such bends occur in the course of the middle meningeal artery (a common route for meningioma embolization) and rupture of this artery has been reported to cause bleeding or delayed arteriovenous shunting.^{32,33} The incidence of complications related to pre-operative embolization ranges from 3% to 6% with about half due to haemorrhage.^{20, 21} Gruber et al.⁴⁷ reported morbidity of 6.4% and mortality of 6.2% in a small series of patients treated with combined surgery and embolization.

Paraganglioma

These benign but locally invasive tumours arise from paraganglionic chemoreceptor cells of neural crest origin. About 50% occur in the temporal bone, arising from either the cochlear promontory (i.e. tympanicum) or the jugular blub (i.e. jugulare), 35% in the carotid body, 12% in the region of the high cervical vagus and the rest at various other sites in the head and neck.⁴⁸

Though relatively rare tumours they are usually targets for embolization because of their highly vascular nature. Most occur sporadically though familial cases occur with autosomal dominant inheritance. In approximately 10% of patients tumours are multifocal and up to 5% of tumours secrete catecholamines. Symptoms are related to tumour location and typically are due to compression of adjacent structures, tinnitus (tympanicum) cranial nerve palsy (jugulare, vagale) and pain. The role of imaging by planar scanning is to support the clinical diagnosis and usually includes both CT and MRI. The former (performed with high resolution parameters) will best demonstrate bony involvement and MRI will best demonstrate the soft tissue character of tumours.

Tumour vascularity and extent can be assessed from scans performed after intravenous contrast administration and evidence of involvement of the carotid artery or intracranial invasion should be sought. Intra-arterial angiography is usually undertaken as part of a pre-embolization evaluation rather than diagnosis.⁴⁹ Though the typical angioarchitecture of this tumour type makes angiography a very specific diagnostic test and it should be considered prior to biopsy.

On intra-arterial angiography feeding arteries are found to be enlarged and there is an early and intense blush in the tumour bed. The intra-tumour angioarchitecture comprises centripetally orientated arterioles estimated to be 90 microns in diameter at the periphery and 300–600 microns in the centre of the tumour with arteriovenous shunts (Figure 49.2).⁵⁰ To further complicate embolization, the majority of tumours show a multi-compartment pattern of blood supply with arterial and venous supply confined to haemodynamic unit so that separate injections of embolic agent have to be made into each feeding artery. The technique for embolization has evolved with the development of embolization particles small enough to penetrate the smaller peripheral arteries (Figure 49.3). The presence of intra-tumour shunts may justify the use of the percutaneous (or intra-operative) direct puncture technique with injections of a liquid embolic agent²⁶ since spread of emboli to the lungs is less likely; however, AV shunting is rarer in paraganglioma than within the vascular bed of some other tumour types (e.g. nasopharyngeal angiofibroma, see below).⁵¹

Embolization is usually performed as an adjuvant to surgical resection. When surgery and/or radiotherapy are considered inappropriate, embolization may alone provide symptomatic relief by stabilizing tumour growth.⁵² The benefits of pre-operative embolization have been demonstrated in several single institution reports.^{53, 54}

Figure 49.2 Temporal paraganglioma. Lateral subtracted (a) (c) and unsubtracting (b) (d) angiograms following selective injections into the ascending pharyngeal artery before (a) (b) and after (c) (d) embolization with particles.

Figure 49.3 Histological section showing embolization particles (trisacryl gelatin microspheres) within tumour vessels.

Murphy and Brackmann assessed the effects of pre-operative embolization in a cohort of 35 glomus jugulare tumour patients, and found pre-operative embolization reduced the volume of operative blood loss and the duration of procedures but not the length of bed stay.⁵⁵ Tikkakoski et al. reported that pre-operative embolization improved operating conditions with subjective benefits to surgical results if performed by superselective catheterization with effective devascularization of the tumour vascular bed.⁵⁶

Juvenile nasopharyngeal angiofibroma

These benign locally invasive tumours of the nasopharynx are also commonly embolized prior to surgical resection. The histological features include the presence of vascular cavities with an endothelial layer but no muscle layer which are mixed with a more conventional arterio-capillary tree with muscle layers. There are similarities between the appearance of cells of the nasal mucosa, genital erectile tissue and vascular spaces of this tumour type. The target cells of the nasal mucosa are assumed to develop into muscularized vascular channels secondary to testosterone stimulation and oestrogen hypersensitivity at puberty.

Patients present with epistaxis and symptoms due to nasal obstruction. Epistaxis may lead to anaemia and require embolization for control though embolization is usually performed as part of planned resection procedures.

CT and MRI performed with contrast enhancement should define the extent of the tumour and be able to differentiate tumour extension into adjacent paranasal sinuses from sinusitis due to retained secretions. Diffuse or patchy enhancement with bone expansion suggests tumour invasion, and dural enhancement may suggest intra-cranial extension. The blood supply arises from branches of the external carotid artery and the internal carotid artery if local spread has occurred. DSA typically shows enlarged intra-tumoural vessels mixed with more regular arterioles (Figure 49.4). In the venous phase there

is an intense inhomogenous blush which shows the full extent of tumour.

Complete surgical removal is the optimum treatment. Pre-operative embolization is a well established surgical adjunct to induce tumour shrinkage, improve surgical access and reduce blood loss.⁵¹ Originally embolization was performed transarterially with particles (i.e. PVA) or liquids (i.e. NBCA) and since most tumours are supplied by branches of the external carotid artery it is relatively straightforward with a low risk of complications.⁵⁷ Intra-cranial tumour spread and supply by branches of the internal carotid arteries increase the risk of embolization causing neurological deficit and limits the potential for complete devascularization.⁵⁸ For this reason a direct tumour puncture technique with injections of liquid embolic agents (i.e. NBCA or Onyx) was introduced.⁵⁹ The goal is to facilitate surgery and reduce operative blood loss since pre-resection embolization does not appear to improve long-term outcomes.⁶⁰

The introduction of the direct puncture technique with Onyx injection has been shown to improve the extent of devascularization after embolization⁶¹ but the transarterial method still has its advocates.⁶² Similarly the introduction and success of endoscopic surgical resection has changed some surgeons' opinion on the need for pre-operative embolization for smaller tumours (i.e. without spread) with some now considering pre-operative embolization unnecessary.⁶³

Pre-operative embolization commonly causes a facial dull ache. Other reported effects are generally mild. These include transient facial numbness and hemiparesis.^{59, 64} But there have been case reports describing blindness and permanent disability.⁶⁵

EMBOLIZATION FOR EPISTAXIS

Transarterial embolization using particles, coils or balloons has been used to control intractable idiopathic epistaxis. For effective embolization, superselective catheterization of the sphenopalatine artery is performed after locating the bleeding site. This goal is hampered if prior surgical ligation of the internal maxillary artery has been performed or if the site of bleeding cannot be established. In these situations, particles may need to be injected via both internal maxillary and facial arteries.

There is no consensus on the most effective timing of embolization after the onset of spontaneous epistaxis and different definitions of intractable epistaxis make it difficult to compare published reports. The vast majority of patients admitted to hospital with epistaxis respond to packing, balloon tamponade or local cauterization and only a small minority will need embolization.⁶⁶ Whether embolization is substantially safer or more effective than internal maxillary artery (IMA) ligation is also debated. In a recent review of the literature comparing embolization with IMA ligation, Cullen and Tami⁶⁷ found that embolization was generally reported to be more reliable, but this was not the case in their institution, where outcomes were similar but the procedural complication rate was

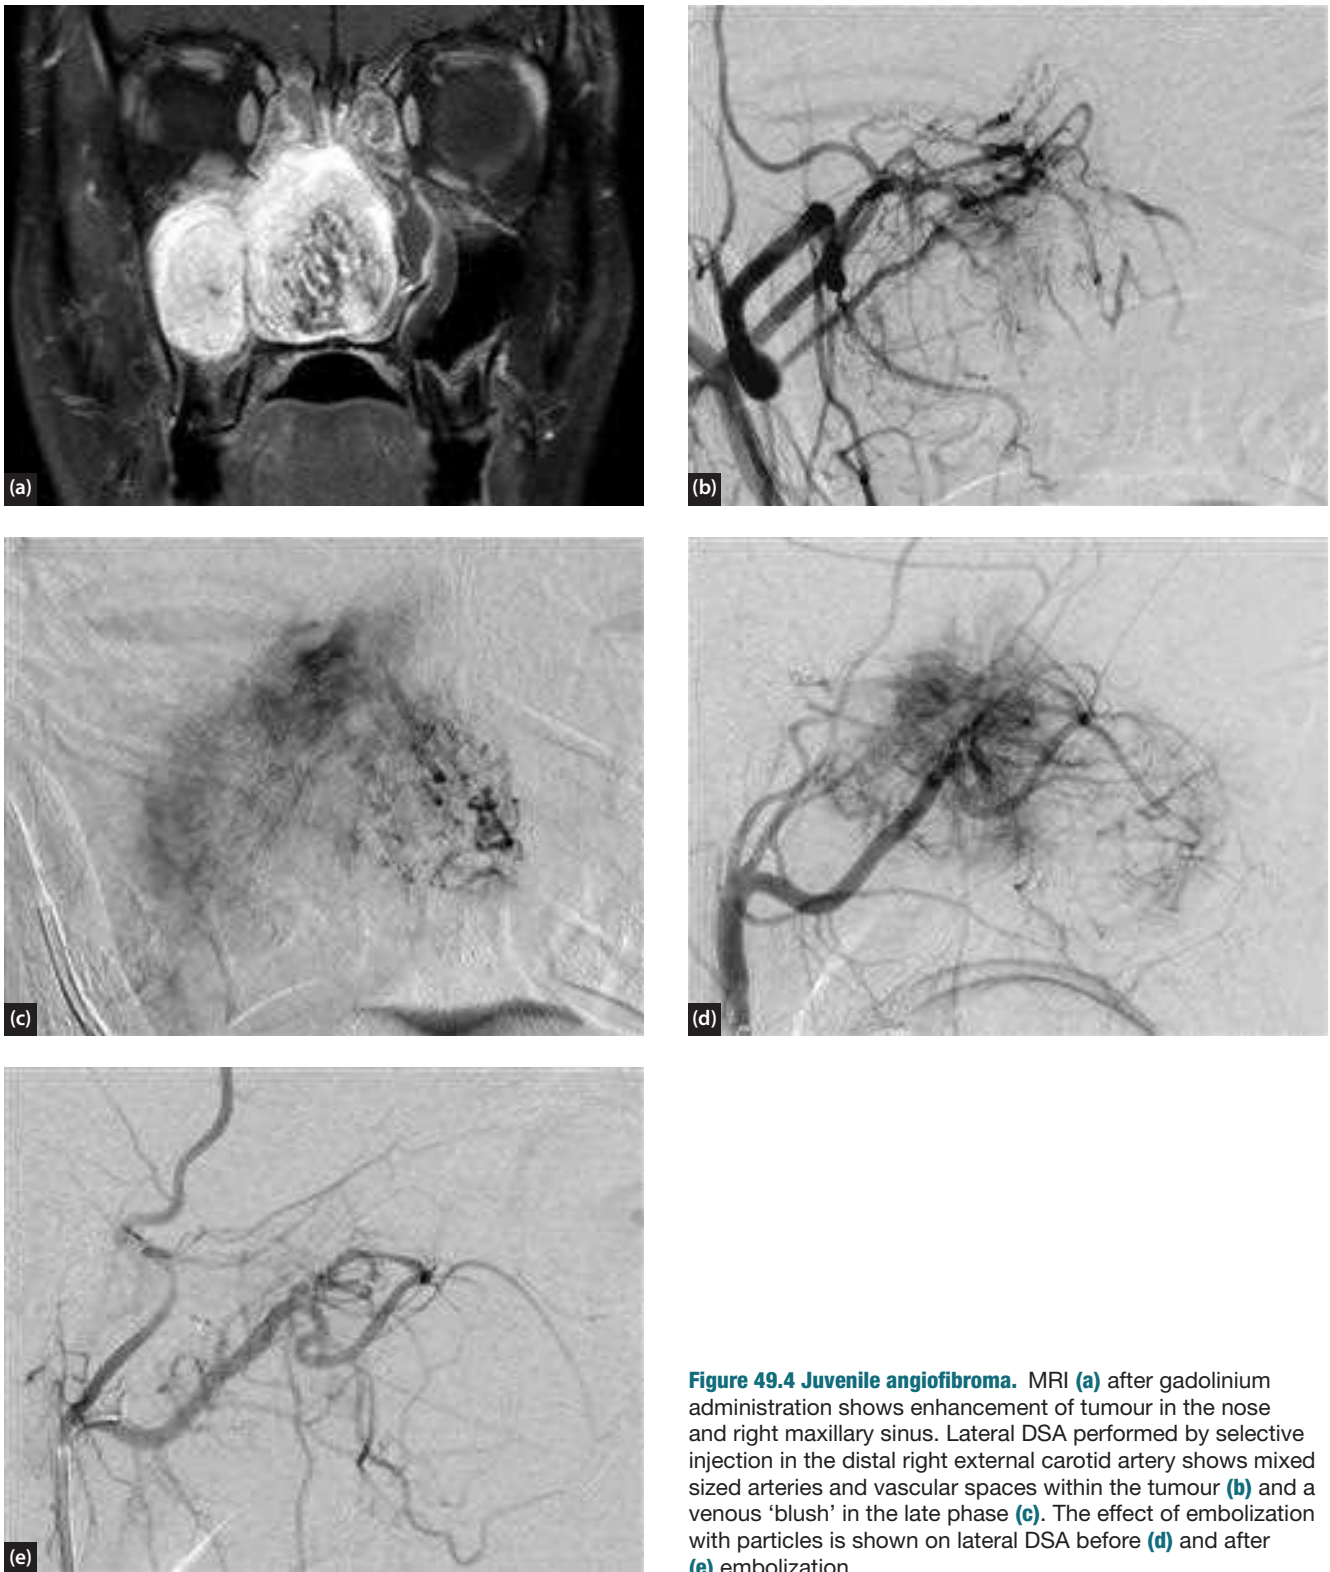

Figure 49.4 Juvenile angiofibroma. MRI (a) after gadolinium administration shows enhancement of tumour in the nose and right maxillary sinus. Lateral DSA performed by selective injection in the distal right external carotid artery shows mixed sized arteries and vascular spaces within the tumour (b) and a venous 'blush' in the late phase (c). The effect of embolization with particles is shown on lateral DSA before (d) and after (e) embolization.

higher after IMA ligation. Even if the risks are no greater, it is logical to perform embolization before IMA ligation because ligation limits the effectiveness of subsequent embolization.

For patients with epistaxis secondary to a vascular malformation or nasal tumour, particulate embolization

is indicated to stop acute haemorrhage. In patients with Osler-Weber-Rendu disease, multiple sessions may be required to induce remission and embolization is rarely curative.¹⁰ In patients with epistaxis due to the rare internal carotid aneurysm or pseudoaneurysm that erodes the sphenoid bone and bleeds intra-nasally, emergency

embolization can be life saving. Embolization also has a small but important role in the management of patients' bleeding as a result of head and neck cancers. Haemorrhage may occur from large or small vessels and

may be associated with radiation induced tissue necrosis. A variety of embolization techniques using particles, coils, stents and balloons may be needed to control such bleeding.⁶⁸

FUTURE RESEARCH

The evidence-base for most INR treatments is lacking. Research has largely involved reports of single institute case audits. Large-scale trials are difficult because relatively small patient numbers are treated at each hospital and multicentre cooperation is needed. This problem is being addressed by various specialist interest groups who organize case registries and multicentre trials to study the efficacy of embolization in different situations.

Areas for future research include:

► Technical:

- Development of non-X-ray imaging. Fluoroscopy using magnetic resonance imaging is now feasible. This avoids the potential hazards of ionizing radiation but requires the development of new catheters and embolic agents. Attempts to develop liquid agents that remain stable in high strength magnetic fields are proving difficult. A great deal of investment is being made to develop

ways of monitoring minimally invasive surgical techniques without X-ray fluoroscopy.

- Current liquid embolic agents are to a greater or lesser extent adhesive and non-adhesive materials that remain coherent during delivery and permanent need to be developed.
- Improvements in reliability of data from functional tests are needed. A great deal of research has been directed at the problem of falsely reassuring temporary vessel occlusion tests. A completely reliable protocol is still needed.

► Biological:

- The evolution of embolized tissue has been studied but we do not know much about the mechanisms that cause secondary haemorrhage in some tumours.
- The potential benefits of local delivery for gene therapy and future chemotherapy agents will probably open new areas of research. The *in vivo* response of lesions will need further study.

KEY POINTS

- Pre-operative embolization should be considered for all vascular tumours.
- Tumour vascularity can only be inferred from CT and MR scans. Intra-arterial angiography is still required to identify tumours suitable for embolization.
- Functional testing of vessels 'at risk' during surgery is performed under local anaesthesia by temporary inflation of an endovascular balloon.
- Most embolizations are performed transarterially but direct percutaneous injections of tumour or vascular malformation vessels, or transvenous injections are also possible.
- Occasionally embolization alone is used for palliation and management of inoperable tumours.
- Embolization should be considered early rather than late in the management of intractable epistaxis

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: head and neck cancer and photodynamic therapy.

INTRODUCTION

Laser is the acronym for light amplification by stimulated emission of radiation. Surgical lasers are devices that amplify light and create coherent light beams ranging from the infrared to the ultraviolet parts of the spectrum.

HISTORY

In 1917, Albert Einstein described the theory of stimulated emission that is the underlying process for laser action. The American physicists, Arthur Schawlow and Charles Townes, described the working principles of lasers in 1958.¹ In 1960 Theodore Maiman demonstrated the first laser action in solid ruby² and a year later Ali Javan built the first helium-neon gas laser.³ C Kumar N Patel introduced the carbon dioxide (CO₂) gas laser in 1962. In 1972, in Boston, USA, Jako and Strong were the first to pioneer the use of the CO₂ laser in otolaryngology, head and neck surgery.⁴⁻⁶

PRINCIPLES OF LASER ACTION

A laser empowers atoms to store and emit light in a coherent form. The electrons in the atoms of a laser medium are first pumped or energized to an excited state by an external energy source. These electrons are then stimulated by external photons to emit their stored energy in the form of photons. This process is 'stimulated emission'.

The photons emitted have a frequency characteristic to their atoms and travel in step with the stimulating photons. These photons now strike other excited atoms to release even more photons. These photons move back and forth between two parallel mirrors triggering further stimulated emission. This part of the process is known as 'light amplification'. One mirror in the laser tube is partially silvered and it allows the exit or leak of the intense, collimated, monochromatic and coherent laser light.

Nature of laser light

A beam of laser light is:

- **coherent:** the photons or waves travel in step, or in phase with one another
- **collimated:** the laser light travels in one direction
- **monochromatic:** one wavelength or colour (if the energy is in the visible spectrum).

Types of lasers

Depending on the type of laser medium used, lasers can be classified as solid state, gas, semiconductor, liquid or free electron.

A pioneering example of a solid-state laser is the ruby laser. The neodymium yttrium aluminium garnate (YAG) laser and the related (frequency doubled) potassium titanyl phosphate (KTP) are examples of solid-state lasers in surgical practice.

The carbon dioxide laser (CO₂) is a very efficient gas laser that delivers laser light as an invisible continuous wave beam. The carbon dioxide surgical laser has been the most widely applied laser in oral and laryngological practice. The helium-neon laser is a gas laser with high frequency stability, good colour stability (red) and minimal beam spread. The helium-neon gas laser is often superimposed on an invisible laser beam, such as the CO₂, to facilitate surgical targeting. Activation of chemicals in photodynamic therapy can be achieved with the helium-neon laser.

The gallium arsenide laser is the most commonly used semiconductor laser. This laser is used in CD players and laser printers and has some surgical applications.

The most common medium for a liquid laser is an inorganic dye contained in a glass vessel. This laser is pumped or energized by intense flash lamps or by a gas laser in a continuous wave mode. The frequency of a tuneable dye laser can be altered with the aid of a prism inside the laser cavity. Tuneable dye lasers can be well suited for treating pigmented cutaneous lesions.

Lasers that utilize beams of electrons unattached to atoms and spiralling around magnetic field lines were initially developed in 1977 and are important research instruments. Free-electron lasers are tuneable and, in theory, could cover the electromagnetic spectrum from infrared to X-rays. Free-electron lasers could be capable of producing very high power radiation and may have medical applications in the future.

Patterns of laser output

The configuration of the resonator cavity and the method in which an energy source is applied to the 'active laser medium' will determine the pattern of a laser output. The output may be continuous wave or pulsed. A continuous wave laser operates with a constant intensity. A laser that operates with a continuous output for longer than 0.1 seconds is considered a continuous wave laser. A pulsed laser produces a single or train of pulses with each individual pulse less than 0.1 seconds. A Q-switch is an electro-optical component that facilitates the production of a very short (less than 1 microsecond) but high intensity pulse of laser energy.

Basic laser tissue interaction

The reaction of laser energy with living tissue can be photoablative, photochemical, photomechanical or photothermal. Most lasers react with a combination of all these mechanisms although for a specific wavelength and delivery system one form of tissue reaction may predominate:

- **Photoablative** reactions occur when molecular bonds are divided. The ruby laser, for example, can split the molecular bonds of tattoo ink with minimal local thermal damage. Macrophages remove the tattoo ink after the molecular bonds are broken.
- **Photochemical** reactions occur when infrared, visible or ultraviolet laser light interacts with photosensitizers

to produce chemical and physical reactions. This forms the basis for photodynamic therapy that is discussed later in this chapter.

- A **photomechanical** effect occurs when the laser energy is pulsed to disrupt tissue or stones by the mechanism of shock waves. An example of this mechanism would be the use of the Holmium YAG laser to shatter ureteric and renal calculi.
- The conversion of absorbed laser light into heat is a **photothermal** reaction. The tissue effect can be cutting, coagulation or vaporization depending on the laser wavelength and the laser delivery device. The photothermal mechanism is predominant in laser use in otolaryngology and examples include CO₂ microlaryngoscopy and the argon laser for stapledotomy.

LASER LIGHT DELIVERY DEVICES

Many delivery devices are available to deliver laser energy to tissue in a safe and efficient manner. Most delivery devices are suited specifically for the wavelength that they transmit. Examples of delivery systems would be an articulated arm, a mirror lens system, micromanipulator, fibre optic fibre, shaped tip fibre optic fibres and robotized scanners.

An articulated arm uses a system of hollow tubes and mirrors to direct the laser beam to the target area. Most articulated arms have a lens system to focus the emerging beam on the target tissue. The carbon dioxide laser wavelength is absorbed in fibre optic material and hence this laser energy is delivered with an articulated arm system.

Micromanipulators and other focusing devices can be connected to microscopes. Micromanipulators and focusing devices will create an accurate and reproducible spot on target tissue. This facilitates very accurate and multiple laser strikes, which suits surgical techniques in otology and laryngology.

Laser energy exits from a micromanipulator or focusing device in a similar style to the 'laser beam weapon' of science fiction. This means that inadvertent strikes beyond the target tissue or misdirection from a reflective surface are a significant operative risk. This also means that a mirror can deliberately redirect a 'laser beam'. An example of this would be to use a mirror to redirect CO₂ laser energy on to adenoid tissue or on to lymphoid tissue on the base of the tongue.

The bare fibre optic fibre is the most common technique for delivering laser energy to tissue. The flexibility and diameter of fibre optic fibre facilitates their use with both rigid and flexible endoscopes. This means that laser energy can be delivered to almost any tissue that can be seen with an endoscope.

Laser light exits the tip of the fibre optic fibre in what is called the 'angle of divergence'. The light exiting from the tip of the fibre projects in a similar manner to water projecting from the nozzle of a hosepipe. The smallest light spot and, consequently, the highest concentration

of energy is found very close to the fibre tip and as the distance from the fibre to tissue increases, the projected area of light decreases and the energy intensity reduces. Consequently, the tissue response to laser energy exiting from the tip of a fibre can be controlled by altering the distance of the fibre from the tissue. Changing the distance between the fibre and the tissue can produce all the tissue photothermal effects of coagulation, incision and vaporization. A fibre 'in contact' with tissue will create an incision. The cut is similar to a saw rather than a knife. This means that some tissue is removed like the kerf of a saw as compared to being split with a scalpel. There is a degree of tactile control with a laser fibre 'in contact' mode. As the fibre is retracted and hovers above the tissue (2–4 mm), it is in the 'near contact' position and vaporizes tissue. As the laser fibre is retracted even further from tissue into the 'non-contact' mode, then the tissue effect is coagulation.

A fibre optic laser cable can be inserted through the biopsy channel of a fibre optic endoscope. The end of the laser fibre must protrude beyond the end of the endoscope or heat damage to the endoscope can occur when the laser is fired. To simplify this problem one can perform a preliminary check of the length of fibre required to achieve a satisfactory distal position and then mark the laser fibre with a 'steristrip' at the entry port.

A fibre optic laser fibre can be inserted through a narrow metal tube to help direct the laser energy. In otology, for example, the laser fibre can be presented through a hollowed out needle. An aspiration channel can be added to the hollow metal fibre carrier to remove smoke from the surgical site. **Figure 50.1** shows a modified ear suction tube and fibre holder that is used for endoscopic intra-nasal surgery. In the design of these instruments, the curves of the fibre carrier should create sufficient resistance that when combined with the torque of the laser fibre it results in a fibre that is 'held' in position without any additional mechanism. In **Figure 50.2**, the 0.6-micron laser fibre can be set at the position of choice for the surgeon and will not move unless the surgeon applies additional pressure. The indent of the finger shows the pressure to overcome the self-retaining torque.

A shaped tip laser is a laser fibre with a tip constructed of another material, such as metal or synthetic sapphire. The laser energy heats the tip and it is the conduction of heat from the tip that produces the tissue interaction. Different materials and shapes of tip will create different tissue reactions. Some tips become so hot that a secondary cooling mechanism is required. An example of this type of device in head and neck practice would be a sapphire tipped neodymium YAG fibre used to ablate tracheobronchial tumours.

Robotized scanners can facilitate laser treatment by reproduction of previous instrument settings or by being able to control precisely the distance a laser is placed or 'hovered above' the target tissue. A robotized scanner can 'trace' an area of treatment before delivery of laser energy to ensure accuracy or can apply a pattern to the area of laser treatment. At present, the greatest use for

Figure 50.1 A 0.6-micron laser fibre inserted through a modified aural suction tube to create a laser delivery device. The natural torque of the fibre holds the laser fibre in place.

Figure 50.2 The pressure required to move or regress the laser fibre tip into the delivery device.

robotized scanners is in the cutaneous treatment of pigmented lesions and for skin resurfacing or recontouring.

LASER-TISSUE INTERACTION

When laser light strikes tissue, it scatters until all the laser energy is either absorbed or reflected. The absorption of laser energy heats tissue. The volume of tissue affected is larger than the area shown by the laser spot size. The depth of penetration by a given wavelength of laser light is determined by the absorption and scattering of the type of tissue and the wavelength of the laser.

The strength of the tissue effect is altered by changing the fluence. Fluence is defined as the laser power in watts, multiplied by the length of exposure in seconds, divided by the area (mm^2) of the target tissue. This implies that when the distance between a fibre optic tip and the tissue varies, the spot sizes become bigger or smaller and the fluence will accordingly increase or decrease.

The heat in the tissue produces a series of changes in the tissue as the temperature rises. The changes are denaturation, coagulation, vaporization, carbonization and incandescence. Cutting with a laser is narrow controlled

vaporization! The heat produced by the absorption of laser light is partly dissipated into air but also produces a secondary thermal effect in surrounding tissue. This lateral thermal effect produces haemostasis by coagulation. The lateral haemostasis effect varies with wavelength of laser, the rate at which the energy is applied, fluence and the nature of the tissue.

LASER APPLICATIONS IN OTOLARYNGOLOGY

The specific clinical applications of lasers are not described in this chapter, but the following list identifies particular lasers for disease-specific regions:

- stapedectomy and tympanomastoid surgery: CO₂ laser, KTP laser, argon laser
- endonasal dacryocystorhinostomy: Holmium YAG laser, KTP laser, 810 nm laser
- nasal and sinus surgery, including tumour surgery, telangectasia destruction, antrostomy creation and turbinate reduction: Holmium YAG laser, KTP laser, Nd YAG laser, argon laser, 810 nm
- nasal polyp reduction: CO₂ laser 'swiftlase' (oscillating device)
- microlaryngeal surgery: CO₂ laser
- laryngopharyngeal tumour resection/ablation: CO₂ laser.

LASER SAFETY

Throughout the world each country applies different safety regulations. Usually the Medical Devices Agency of a country or state will produce guidance for clinicians and hospitals. In the UK, the local Medical Physics Department will produce local laser rules (based on national guidance) and ensure training of all staff involved in the use of the laser. Training for medical and nursing staff should be mandatory. A laser company will typically provide a safety manual on their particular wavelength of laser. Staff should read the laser safety manual and in many countries produce signed documentation that the manual has been read.

The principles of safety are as follows:

- A laser beam may hit or damage objects outside the target area and cause a fire, tissue damage or eye/visual damage.
- The patient should be shielded by wet gauze or fire-proof material from accidental strikes.
- The anaesthetic tube and airway should be protected from accidental strikes that could produce a fire.
- All personnel in the operating room should wear correct eye protection appropriate to the wavelength of the laser.
- A warning sign plus locked doors should prevent unprotected and unprepared individuals from walking into the operating room when the laser is in use.

- The key to switch on the laser should be held by a senior member of the operating team to ensure only properly qualified individuals use the laser.
- The operating room and windows should be laser protected.
- Endoscopic equipment should be blackened to reduce accidental reflective strikes of the laser.

PHOTODYNAMIC THERAPY IN OTORHINOLARYNGOLOGY

Principles of photodynamic therapy

Phototherapy is the use of light in the treatment of disease. An example would be the treatment of neonatal hyperbilirubinaemia with visible light.

Photochemotherapy is a subset of phototherapy where a treatment requires the administration of a drug in addition to the application of light. An example would be treatment of a skin condition such as psoriasis with the combination of a furocoumarin sensitizer drug and UV-A (320–400 nm) light.

Photodynamic therapy (PDT) is a subset of photochemotherapy where, in addition to an administered drug and the application of light, oxygen is required to complete the process. The administered drug is known as a 'photosensitizer'. This type of drug accumulates within a cell and reacts with light and oxygen to form 'singlet' oxygen. The 'singlet' oxygen damages the cell membranes and produces cell death.

One of the attractions of PDT for oncology is that the photosensitizer drug is, typically, retained in tumour tissue for a longer period than in normal tissue. This improves the therapeutic effect while reducing toxicity to normal tissue. The use of PDT is not affected by prior radiotherapy, chemotherapy or surgery. To date, the principle shortcomings of PDT have been the limited depth of tissue penetration and extensive skin phototoxicity. This skin phototoxicity requires that the patient is not exposed to daylight during treatment or they develop extensive and painful skin reactions.

In photodynamic therapy for head and neck cancer the photosensitizer is usually administered by intravenous infusion. The perfect photosensitizer drug would be absorbed selectively only by tumour tissue in the drug uptake period (also called the drug–light interval). The drug uptake period may last between 3 and 96 hours. The tumour is then irradiated with a measured light dose. Singlet oxygen is released to kill only tumour cells and thus destroy the target tumour.

The tumour targeting arises firstly from the structure of the photosensitizer that leads to the selective uptake by a tumour and secondarily by the accurate application of an appropriate light wave.

There are many potential applications for PDT but few, currently, in routine practice. The diseases in which trials of photodynamic therapy have taken place include malignant tumours, such as squamous carcinoma of the oral cavity, squamous carcinoma of the nasopharynx,

oesophageal carcinoma and metastatic squamous carcinoma of the neck. Non-malignant disease such as inverted papilloma of the sinonasal cavity has also been targeted.

Photodynamic clinical reports in otorhinolaryngology

Both palliative and curative therapy has been reported for oesophageal cancer. The patients receive a photosensitizer followed by light delivered via optical fibres through a flexible endoscope. A phase II trial⁷ randomized 218 patients to receive palliative oesophageal PDT (porfimer sodium sensitizer) versus Nd:YAG laser ablative therapy. Each arm gave an equivalent improvement in dysphagia but with fewer perforations in the PDT group (1 versus 7%, $p < 0.05$).

Overholt and Panjehpour⁸ reported the results of 55 patients with dysplasia or early carcinoma in Barrett's mucosa of the lower end of the oesophagus treated with PDT. The patients received porfimer sensitizer followed at 48 hours with red light therapy. There was a good response at the 6-month follow-up. Forty-three patients with high-grade dysplasia/adenocarcinoma had endoscopic-proved ablation of their problem. Eleven of the 12 patients with low-grade dysplasia had no dysplasia on endoscopic review. Oesophageal stricture, however, developed in 53% of the patients.

There has been hope for PDT in the treatment of head and neck tumours. The endoscopic access to squamous tumours of the upper aerodigestive tract combined with the tendency to develop 'field cancerization' make these tumours good candidates for PDT. Gluckman⁹ treated a mixture of carcinoma *in situ*, early and advanced squamous cell carcinoma of the head and neck. Dihaematoporphyrin ether and light at 630nm were used to treat these patients. The best results were obtained in the oral cavity and oropharynx where 11 out of 13 patients had a complete response and 2 out of 13 a partial response. Four of these tumours had recurrence within 1 year of treatment. Eight patients with advanced tumours were treated palliatively, but the results were no better than with standard regimes of the time.

Karakullukcu et al.¹⁰ analyzed the outcomes of photodynamic therapy in 170 patients with early stage oral cavity and oropharynx neoplasms giving results of a 90% response rate and a 70% complete response (cure) rate.

Biel¹¹ treated 25 patients with early squamous cell tumours of the larynx, obtaining a complete response in patients despite the fact that radiation therapy had previously been unsuccessful in 17 of them.

Biel¹² also reported a summary of the results of a collection of studies on the treatment of early squamous cell carcinoma of the head and neck with PDT. There were a total of 217 patients. One hundred and ninety-four (89%) showed a complete response to treatment, 23 (10.6%) showed a partial response and no patient failed to show any response to the therapy.

Dilkes et al.¹³ had considerable experience with the use of PDT using the sensitizers m-TPHC, photofrin II and ALA for squamous carcinoma at multiple sites in the head and neck during the mid-1990s. The patients they treated included palliative, primary and adjunctive forms of treatment and, in nearly all cases, the authors identified a visible response to the effects of PDT. Their complications included local pain at the photosensitizer injection site and, in some patients where appropriate precautions had not occurred, post-treatment skin photosensitivity.

Lofgren et al.¹⁴ used PDT in 5 patients with circumscribed nasopharyngeal carcinoma. The drug was activated with laser light under topical anaesthesia and after 4 years, 3 of the patients has no evidence of disease.

FUTURE RESEARCH

All of the papers on photodynamic therapy for head and neck cancer suggest that photodynamic therapy has a significant place in the future management of this disease. The problem is in determining the exact type of photodynamic therapy associated with which photosensitizer and whether primary therapy, adjunctive therapy or palliation is the optimum course.

KEY POINTS

- Laser light amplification by stimulated emission of radiation.
- Laser light – collimated, coherent and monochromatic.
- Laser tissue action – photoablative, photochemical and photomechanical.
- Laser 'star wars' beam of micromanipulator – hosepipe type jet of fibre optic laser delivery.
- Read and follow the safety regulations for your laser and operating room.
- PDT requires administered drug, light and oxygen.
- Skin phototoxicity and limited tissue penetration are the current PDT shortcomings.
- PDT has a future place in head and neck cancer management.

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: contact endoscopy, mucosal vascular network, narrow band imaging and Methylene blue.

INTRODUCTION

The investigation of blood vessels and their microcirculation has been an area of interest to surgeons for many years. In 1970, surgeons¹ started research on the arterial vascularization of the larynx. Over the years, anatomical and clinical research on the pathways of extension of laryngeal tumours has been published.²⁻⁵ The systematic evaluation of operated specimens allowed for a better understanding of the progression and invasion of the laryngeal tumours.

In order to enhance the evaluation of the operative specimens, nasal endoscopes and endoscopes of other territories and specialities were used. It soon became obvious that the endoscopes offered a superior view compared the operative microscope alone.⁶ With the microscope the assessment is limited by a straight line of vision.

A group of endoscopes were produced by Karl Storz (1995)⁷ that were specifically designed for the intraoperative evaluation of the larynx. This technique is called contact endoscopy and typically involves examination of the superficial epithelium of the larynx. Rigid endoscopy associated with microlaryngoscopy⁸⁻⁹ allowed the direct observation of the vascular networks

and alterations. This led to the the next phase in which contact endoscopy was used to visualize the microvascular networks.¹⁰

The first description of contact endoscopy is attributed to Desormaux in 1865,¹¹ who observed the vascular network of the bladder mucosa. The development of this technique was only possible due to technological progress. In 1955, Jaupitre¹² promoted contact cystoscopy associated to photography and cinematography and in 1983, Hamou¹³ developed the microcolpohysteroscopy used in gynaecology. This technique allowed for the better comprehension of the pathology of the uterine cervix, but due to its complexity and difficulty, its use remained only within a limited number of centres.

The contact microlaryngoscope was developed in 1995¹⁴ and the study of the larynx using contact endoscopy was initiated.

Contact endoscopy, using amplifications of 60x and 150x, allows for the *in vivo* and *in situ* observation of the mucosal vessels. By staining the mucosa with methylene blue, it is possible to visualize the cells of the superficial layer of the mucosa of the larynx, which allows diagnosis, the evaluation of the extension of the lesions and,

when tumour is present, defining the safety margins. The advantages of this technique led to it being used daily in clinical practice.¹⁵⁻²²

Contact endoscopy was further developed and systematized for the other areas of the aerodigestive tract. Confronted with the richness of the microcirculatory and cellular images obtained with contact endoscopy, new endoscopes were designed and produced by Karl Storz, for use in the nasal fossa, in the nasopharynx, mouth, oropharynx, hypopharynx and trachea.²³⁻²⁶

In 2007, observation of the mucosal vascular network was enhanced by combining contact endoscopy with an Olympus system of illumination called 'narrow band imaging'.²⁷ This produces a specific wavelength, which is selectively captured by haemoglobin and allows a better contrast of the vessels relative to the neighbouring tissues. This enhances the visualization of the deeper vessels.

With contact endoscopy, anatomical-pathological concepts of mucosal illnesses are evaluated clinically in multiple sites and stages, at times associated with aetio-pathological factors. With this technique vascular and cellular alterations of the mucosa can be observed both in the outpatient clinic and in the operating theatre.

With contact endoscopy, the notion of illness has surpassed the classic concept of the macroscopic lesion that was biopsied.

With these techniques, the non-invasive pathological evaluation can be made during an endoscopic examination. This allows, in many cases, for the diagnosis to be made at the time of observation, having a direct implication on the planning and method of treatment that is chosen. Contact endoscopy may deliver further information on the subclinical staging and improve understanding of the physiopathology of the diagnosed condition.

The objective of contact endoscopy is not to visualize at the surface what is expected to be observed from histological sections and it should not be considered a substitute for biopsy. Instead it is a clinical method that adds to the information available during an endoscopic examination. It is an anatomical-pathological examination that supports the cytology.

The development of contact endoscopy of the upper aerodigestive tract has led to establishing parallels with other areas such as gynaecology, gastroenterology, pulmonology and ophthalmology, as we further converge at the pathological and cytological level.

Contact endoscopy is now used in centres with benefits for patients around the world. The same principles are being used in other specialties, as can be seen through work published in the medical literature.²⁸⁻⁴⁹ Technological evolution and collaboration between centres will contribute to the further development of this technique.

TECHNIQUE

The contact microlaryngoscope (Karl Storz 8715 AA) is an endoscope with a diameter of 5.8mm, and 24cm in length. Another contact endoscope with an angulation

of 30° (Karl Storz 8715 BA) was manufactured in order to improve the access to certain locations of the larynx. Later, shorter contact endoscopes (18cm) with a smaller diameter (4mm) for the observation of the nasal cavity, the oral cavity, the oro- and the nasopharynx (Karl Storz 7215 AA e 7215 BA) have also been designed.

At the level of the larynx and hypopharynx contact endoscopy is performed under general anaesthesia with endotracheal intubation. The nasal mucosa, nasopharynx, mouth and oropharynx can be observed, in many cases, without the need for any anaesthetic.

For the observation of the vessels the contact endoscope is applied directly on the mucosa without any staining. The microcirculation is visible with illumination from a regular endoscopy light source. However when the illumination is changed for the Olympus 'narrow band imaging', the emitted light is absorbed by the haemoglobin of the erythrocytes, improving substantially the visibility of the vascular network allowing the identification of deeper vessels.

To observe the cells of the epithelium the mucosa is stained with methylene blue. The contact endoscope is gently applied to the mucosal surface. The colouration lasts for 4 to 5 minutes.

The contact endoscope has a round control near the proximal ocular end that allows a change of magnification (60× to 150×) and controls focus. Sliding the contact endoscope over the mucosa, it is possible to visualize the cells and their alterations at the level of the lesion and of the neighbouring areas. Furthermore, it allows mapping of the disease or the various diseases that can occur in distinct sites and stages.

Contact endoscopy must always be performed with video recording and if possible in high definition. The image is immediately shared and the recording can be reviewed and analyzed later by the otolaryngologist and pathologist or cytologist.

CELLULAR AND MICROVASCULAR STRUCTURE OF THE MUCOSA OF THE UPPER AERODIGESTIVE TRACT

The mucosa that covers the upper aerodigestive tract is constituted by ciliated epithelium and by squamous stratified epithelium in accordance with the function of the different regions. Acting as an interface with the external environment, this mucosa is subjected to frequent stimuli and insults that may cause clinical and sub-clinical alterations at different tissue levels. Alterations of one part of the aerodigestive tract may cause consequences of other anatomical territories within the aerodigestive tract.

Contact endoscopy in otolaryngology reinforces clinical evaluation through the concept of the anatomical and functional units, as it allows a non-invasive method to identify alterations at various anatomical territories that would not be perceived in other ways.

NORMAL AND PATHOLOGICAL PATTERNS

The systematic observation of the various organs and territories of the upper aerodigestive tract with contact endoscopy allows a better understanding of how the mucosa reacts to the conditions and insults to which it is subjected. In each of the territories the pathology acquires specific characteristics; however, the overall behaviour of the mucosa, in general, is very similar.

Normal pattern

When observed by contact endoscopy the cells of normal squamous epithelium have a polyhedric shape, being in continuity with each other. The nuclei are round and dark. The cytoplasm has a light blue colouration. The nucleus:cytoplasm ratio is regular and the general morphological pattern is homogeneous (Figure 51.1).

The ciliated epithelium observed with contact endoscopy has a distinct appearance. The nuclei are round and dark but the cytoplasm limits are difficult to define. The nuclei are very close to each other creating a higher density of nuclei per optic field (Figure 51.2). The filamentous structures displaced by the endoscope are due to bundles of cillia. These bundles of cillia may have variable size, being very exuberant at the level of the nasal and nasopharyngeal mucosa.

The transition of squamous to ciliated epithelium is easily observed with contact endoscopy. In some cases there is a very sharp line of separation (Figure 51.3). In other cases the transition is less well defined. Occasionally islands of squamous epithelium are found in the middle of the ciliated epithelium.

Glandular orifices are observed scattered through the mucosa of the upper aerodigestive tract.

The mucosa undergoes a process of metaplasia with age and particularly when submitted to damaging factors. For example, the ciliated epithelium of the larynx changes into

Figure 51.1 Normal squamous epithelium of the vocal cord. The nuclei are regular and homogeneous, 60X.

Figure 51.2 Normal ciliated epithelium of the vocal cord, 60X.

Figure 51.3 Transition of the ciliated epithelium to squamous epithelium of the vocal cord, 60X.

squamous epithelium in chronic smokers. The same happens with the trauma of reflux at the posterior commissure of the larynx. The same phenomena occur at the nasal and nasopharyngeal sites when exposed to traumatic factors.

Contact endoscopy allows a detailed observation of the mucosal vessels. The most superficial microvascular network is situated immediately below the basal membrane. The morphology of the vascular network is conditioned by the topography and function of the mucosa. In most of the mucosa of the upper aerodigestive tract the vessels have a course parallel to the surface and are connected by many anastomoses constituting a plexus. In specific sites, vessels with a perendicular course to the surface are identified in gums, hard palate, cheek mucosa, superior surface of the tongue and in the papillae of the nasal mucosa. At the level of the vocal cords the blood vessels are parallel to each other (Figure 51.4) and are connected by transverse anastomotic vessels. This arrangement favours the vibratory movements of the vocal mucosa.

Figure 51.4 Normal vessels of the vocal cord. The vessels are thin and parallel, 60X.

The more superficial microvascular network drains to venules that go to collecting vessels of larger calibre at the deeper planes. The angioarchitecture of this deeper plane depends on the thickness of the mucosa and the neighbouring structures. Contact endoscopy offers a fascinating image of the blood flow. The red cells circulate to the rhythm of the heartbeat and travel in several directions, and sometimes change direction with the pressure of the contact endoscope on the mucosa.

Chronic inflammation

When chronic inflamed mucosa is observed through contact endoscopy, the general aspect of the squamous epithelium is homogeneous, but the size of the nuclei is larger with an increased nucleus/cytoplasm ratio (Figure 51.5). As the cellular turnover is accelerated due to the inflammation, more immature cells become visible at the surface, similar to those that are observed at the intermediate layers of the normal epithelium.

The mucosa of chronic inflammation has a higher vascular density due to the increased number of vessels and vessel enlargement. However, the pattern of distribution remains organized.

FUNGAL INFECTION

In some cases of chronic inflammation, in addition to the typical pattern of increased diameter of the nuclei, it is possible to identify with contact endoscopy small dark dots that seem to spoil the image. These correspond to fungal spores (Figure 51.6). Hyphae and micelium can also be observed as well as filamentous structures.

Contact endoscopy has identified that fungal infections are in many cases associated with chronic inflammatory changes, and dysplastic or neoplastic lesions in different anatomical sites. In general the fungal infection does not disturb the microcirculation more than inflammation due to other aetiologies. However, in more

Figure 51.5 Chronic laryngitis. The nuclei are of increased size with a homogeneous pattern, 60X.

Figure 51.6 Laryngeal fungal infection and dysplasia, 60X.

aggressive forms of disease there are profound vascular changes, including aberrant shaped vessels causing thrombosis and tissue necrosis.

KERATOSIS

In the same patient, and even within the same lesion, different degrees of keratinization can be observed by contact endoscopy. Initially isolated cells without nuclei are identified. Unfortunately, it is not possible to identify individual cells in areas of amorphous or laminar structure (Figure 51.7). Keratosis is present in different clinical entities. In some cases keratinization is very discrete while in others it is pronounced. Occasionally keratosis is not suspected and its finding with contact endoscopy is a surprise.

With leukoplakias, in addition to keratosis, other types and degrees of cellular alterations can be observed by contact endoscopy, including heterogeneity of the cellular population. The variety of the cellular images can be accounted for as different pathological alterations such as

Figure 51.7 Keratosis of the vocal cord, 60X.

hyperkeratosis and dysplasia can occur simultaneously. In other clinical entities such as chronic inflammation, papillomas and tumours, keratosis can also exist in different degrees.

While in some cases the vessels pass below the area containing keratosis they may sometimes surround the leukoplasic lesion.

DYSPLASIA

In the majority of the cases of dysplasia, there are alterations at the superficial layers, making it accessible to contact endoscopy. Most tissue alterations that are necessary for the diagnosis of dysplasia by a pathologist are also identifiable by contact endoscopy, specifically alterations in size, shape and colouration of nuclei, altered nucleus:cytoplasm ratio (dyskaryosis and anisokaryosis) and keratosis (Figure 51.8). The more pronounced the changes observed by contact endoscopy the more severe is the dysplasia.

The microvascular alterations that accompany the dysplastic lesion are fundamental to the understanding of the pathology hence its treatment. The normal microvasculature is substituted by vessels with different degrees of alteration.

When the vascular network becomes disorganized and the vessels are irregular it can be interpreted that the pathology of the epithelium has passed the boundary of the basal membrane, which may be damaged, thus allowing the vessels to penetrate the epithelium. The mobility of the contact endoscope allows assessment of the regions neighbouring the lesion. This information benefits an understanding of the main lesion.

TUMOUR

In carcinoma, contact endoscopy identifies the marked cellular irregularity and heterogeneity. The nuclei have different sizes, shapes and colouration. The nucleus:cytoplasm ratio is very irregular (Figure 51.9). Sometimes nuclear inclusions, prominent nucleoli and mitosis are identified.

Figure 51.8 Dysplasia, 60X.

Figure 51.9 Tumour of the larynx observed by contact endoscopy. Nuclei are irregular in size, shape and colouration.

The angioarchitecture is also very disturbed. The blood vessels are atypical with differences in size and shape, but also ectasias, haemorrhages and reduced blood flow, which results in thrombosis (Figure 51.10).

Depending on the anatomical region of the tumour, distinct images can be observed. In places where the tumour growth infiltrates the deep planes but does not reach the surface, vascular alterations can be identified with normal superficial epithelial cells.

The direct demonstration *in vivo* and *in situ* of a tumoural pattern in the operating room and in the outpatient clinic is a reality. Contact endoscopy also allows the assessment of transition areas, the identification of early stages of disease, guidance of biopsies, guidance of sample collections for cytology, establishment of safe margins and demonstration of different diseases.

PAPILLOMA

Contact endoscopy contributes to the assessment of the papilloma, allowing the identification of its extent, offering

Figure 51.10 Tumoural vessels.

Figure 51.11 Papilloma of the larynx. Vascular axis of the papillas, 60X.

Figure 51.12 Papilloma of the larynx. Vascular axis of the papillas observed with NBI, 60X.

better conditions for removal and potentially reducing the risks of residual disease.

The direct application of the contact endoscope allows the identification of the typical vascular loops (Figures 51.11, 51.12). The degree of visualization of the

vascular structure depends on the density of the keratosis that is associated with the disease in some cases.

With the vital stain, in some cases it is possible to identify the typical koilocytes (ballooned cells) (Figure 51.13) and inflammatory infiltrates. Koilocytes are typical of human papillomavirus infected cells.

Figure 51.13 Papilloma of the larynx. Koilocytes are identified, 150X.

Beyond the characterization of the lesions, contact endoscopy allows the assessment of neighbouring areas, and sometimes it is possible to identify subclinical stages of the disease.

CONCLUSION

Contact endoscopy is a non-invasive clinical technique and is currently the only technique that allows an *in vivo* and *in situ* assessment based on the observation of the microvascular networks and of the cells of the superficial layers of the epithelium.

In some cases, the cellular alterations precede or are more evident than the vascular alterations. In other cases the modifications of the vascular networks and the course of the vessels that are present occur before the identification of cellular changes.

Contact endoscopy allows not only the observation of vessels and cells of the lesion or of a suspected area identified macroscopically, but also of all the anatomical territory. The application of the contact endoscope to several anatomical sites allows an assessment of the extent of pathology and importantly the transition of a normal to pathological tissue.

The information that is obtained (vascular and cellular alterations of a pathological entity) is obtained in real time.

These alterations are not limited to the macroscopic lesion and become integrated in a much wider concept – the concept of disease. This occurs in the subclinical stages that become associated with the main lesion.

The visualization of vascular network alterations simultaneously with the observation of the cells of the superficial layers of the mucosa opens an enormous window for the understanding of the physiopathology allowing a more correct and precise diagnosis, with repercussions in the therapeutic planning, in the follow-up and prognosis.

Contact endoscopy of the upper aerodigestive tract, with the exception of the larynx and trachea, can be performed in the outpatient setting. Beyond being minimally invasive, it does not cause pain to the patient, typically does not even require local anaesthesia and the image recording of the image allows a single endoscopy. The high definition video technology allows a more detailed analysis.

The association of contact endoscopy with the ‘narrow band imaging’ is currently the most detailed way (in clinical practice) of studying the microvasculature of the mucosa of a patient with upper aerodigestive pathology.

Combining the conventional endoscopic techniques with contact endoscopy and analyzing the patterns with the cellular and vascular changes, it is possible to aid diagnose in a more precise way for chronic inflammation, fungal infections, some viral infections, mechanical trauma, metaplasia, keratosis, dysplasia and tumours, hence improving the mapping of alterations of the disease.

Having access to all this information can modify the therapeutic approach, medical as well as surgical, and in some cases changing both simultaneously.

Whatever the developments of new therapies, there is little doubt that a more detailed and profound knowledge of a disease with the *in vivo* and *in situ* observation of the vascular networks combined with the alterations at the cellular level will create a new way of thinking.

Contact endoscopy represents a new phase of the development of endoscopy. With experience from different centers and technological progress, new ideas, concepts and instruments will occur. If all this progress facilitates a more thorough examination it will also require a more detailed knowledge and understanding of each organ and anatomical territory of the upper aerodigestive tract.

Images obtained by contact endoscopy promote intense and fruitful interdisciplinary work. This will continue to be fundamental to the development of the technique.

KEY POINTS

- Contact endoscopy allows non-invasive evaluation of microvasculature and cells.
- Contact endoscopy allows appreciation of cellular differences at transition zones.
- Most upper aerodigestive mucosa has vessels which run parallel to the surface mucosa.
- Contact endoscopy may assist the identification of safe margins during surgery.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: thyroid, goitre, history, endocrine, surgery. Key historical texts were consulted in print where possible, or via online access if not. Reference lists were examined for further sources of evidence.

THYROID SURGERY

The dark ages: Shoe laces, seaweed and the King's touch

Thyroid surgery has its roots over one millennium ago, with goitre being recognized well before that. Pliny the Elder (AD 23–73) in his work *Naturalis Historia* mentions hernia gutteris, as does Aëtius of Amida (c.5th–6th century) in his compilation the *Tetrabiblion*. In this time, the thyroid gland was not recognized as a normal structure and these enlargements were considered new formations. In time, the thyroid was seen as a normal organ, although its function was still unknown. In 1511, during the Italian Renaissance, Leonardo Da Vinci was the first person to draw the anatomical shape of the thyroid gland correctly, but he misinterpreted its function as only filling up empty space in neck. In the 16th century, Andreas Vesalius described the thyroid structure, considering it a laryngeal gland, while Bartholomeus Eustachius correctly noticed that this gland had two lobes conjoined by isthmus; Aelius Galemus reported its role was lubrication of the larynx. In 1656 Thomas Wharton named it the 'glandulae thyroidea' or 'thyroid' because of the juxtaposition to the thyroid cartilage, which is shield-shaped.^{1,2}

Treatment of thyroid goitre was first described in 2700 BC in Chinese literary works; this involved administering seaweed and burnt sea sponge (we now know this is due to their high iodine content). The earliest recorded operation on the thyroid was performed by Albucasis (Abu al-Qasim al-Zahrawi, AD 936–1013), a Moorish

physician, using simple ligatures and hot cautery irons; however, his works seemed to be forgotten. Indeed, Ruggiero Frugadi (pre AD 1140–1195) of the Salerno School of Surgery is often credited as performing the first goitre surgery in 1170, using bootlaces as setons to ligate and transfix a pedunculated goitre, allowing it then to slough off.³ King Henry IV of France (1553–1610) practised the 'King's touch', akin to the laying on of hands, in the 16th century. This technique was famous in Europe between 1100 and 1600 with many thousands of people reportedly 'cured' of different ailments.

The true beginnings: Foolhardy performances and horrid butchery

Despite these early attempts, thyroid surgery did not progress for several centuries. Early attempts by Benjamin Gooch (1708–1776) resulted in fatal haemorrhage and the thyroid's adherence to the trachea meant that for many years it was considered impossible to safely separate the two structures. During the French Revolution, Pierre-Joseph Desault (1744–1795) performed a successful thyroidectomy on a 20-year-old woman.⁴ He demonstrated that careful dissection coupled with ligation of the key vessels would allow the surgeon to remove the thyroid gland and for the patient to survive through the post-operative period. For many years, Desault's technique was the accepted standard, but mortality in 1850 was still in the region of 41%.⁵ Most patients suffered with both primary or secondary haemorrhage and an almost inevitable sepsis.

The unacceptably high mortality and morbidity rates, both short- and long-term, led to the French Academy of Medicine banning thyroid surgery. It was described as ‘breath-taking heroics fraught with danger to the patient and almost certain bereavement for the family’.⁶ Johann Dieffenbach (1792–1847), a German surgeon who reportedly tried every method known to treat vesicovaginal fistula, thought of thyroid operations as ‘foolhardy performances’ and ‘one of the most thankless, most perilous undertakings which, if not altogether prohibited, should at least be restricted’.⁷ Even the great American surgeon Samuel Gross (1805–1884) wrote that ‘every step he takes will be environed with difficulty, every stroke of his knife will be followed by a torrent of blood, and lucky will it be for him if his victim lives long enough to enable him to finish his horrid butchery’ and ‘also no honest and sensible surgeon will ever engage in it’.⁸ However, as the 19th century progressed, the practice of thyroid surgery was revolutionized by three advances that took it from the realms of a last-ditch approach for the rapidly succumbing patient to a recognized, valid treatment for goitre.

The new dawn: Three great advances and the fathers of thyroid surgery

During the mid 1800s, three important discoveries changed the evolution of thyroid surgery.⁵ In 1842 Crawford Williamson Long (1815–1878), an American surgeon, was the first doctor to administer inhaled ether as an anaesthetic agent, although at the time the credit was given to the dentist Horace Wells (1815–1848) and the surgeon John C. Warren (1778–1856) for an operation in 1846. The first thyroidectomy under ether anaesthesia took place in St Petersburg under Nikolay Pirogoff (1810–1881) in 1849.⁹ Secondly, and a few years later in 1867, Joseph Lister’s (1827–1912) theories of antiseptic using carbolic acid, followed shortly after by asepsis, dramatically reduced the infection and sepsis rates after surgery and did a great deal to reduce mortality.⁴ The last development was of haemostatic forceps, used in central Europe in 1870 by Thomas Spencer Wells (1818–1897)¹⁰ and redesigned as the operative haemostat in 1874 by Jules-Emile Péan (1830–1898).⁶ These led to improved haemorrhage control over the traditional methods such as the artery hook, mass ligation, crushing forceps and crude cautery.

These three developments prepared the way for Christian Albert Theodor Billroth (1829–1894) (Figure 52.1a), arguably the most famous surgeon of his day. Billroth trained at the University of Berlin before becoming the chair of surgery at the University of Zurich at the age of 31. In his first year at Zurich, he performed 20 thyroidectomies, but his mortality rate was around 40%, mostly from sepsis. Despite becoming disheartened and abandoning thyroid surgery for almost 10 years, he returned to it when he moved to the chair of surgery at the University of Vienna. He embraced anaesthesia and initiated the use of antiseptic and haemostats. He was also the first surgeon to wear gloves, albeit cotton, when operating, and his mortality rate fell from nearly 40% to 8%, making him the most

well-known thyroid surgeon at that time. Despite this, he was still troubled by post-operative tetany and damage to the recurrent laryngeal nerve.

Billroth’s most valuable contribution to thyroid surgery is arguably the students he taught, many of whom went on to become outstanding surgeons in their own right. Anton Wölfler (1850–1917), Anton von Eiselsberg (1860–1939), Jan von Mikulicz-Radecki (1850–1905) and Hans von Haberer (1875–1958) all contributed not only to thyroid surgery but to surgery in general. However, Billroth’s greatest student, and the surgeon who can be truly considered the ‘Father of thyroid surgery’, was Emil Theodor Kocher (1841–1917) (Figure 52.1b).

Having trained with Lucke, Billroth and Langenbeck, Kocher studied and acted on the successes and failures of those around him, constantly updating his technique to give better results. His knowledge of anatomy and circulation aided his meticulous dissection technique, and he adopted the now standard collar incision that bears his name in 1890.

Kocher was also one of the first surgeons to audit his own results. In a review of his 101 cases in the mid 1880s, he found that most of his unilateral excision patients were well, but all of the total resections were suffering with symptoms we would now recognize as hypothyroidism. This had also been described by Jacques-Louis Reverdin, with patients who underwent total thyroidectomy experiencing

Figure 52.1 The fathers of thyroid surgery. (a) Theodor Billroth, (b) Theodor Kocher, (c) William Halsted, (d) Thomas Dunhill.

personality change and distressed physical features named ‘myxoed me operatoire’.¹¹ Kocher realized that this adverse condition was caused by deprivation of thyroid hormone, and then called it ‘cachexia thyreopriva’, acknowledging that the thyroid gland had a function. Subsequently, Kocher prohibited total thyroidectomy except in the treatment of thyroid cancer, to avoid this condition. His method of preventing damage to the recurrent laryngeal nerve was to switch from extracapsular to intracapsular dissection, leaving thyroid tissue behind posteriorly. He was also an early proponent of iodinating drinking water to prevent goitrogenesis. Kocher kept detailed outcome records and it is a testament to his ability as a surgeon and innovator that, when he presented his surgical experience to the Swiss Surgical Congress in 1917, his mortality was 0.2% for ordinary goitre and 2% for what we now consider hyperthyroid goitre, all in an era before antithyroid drugs and radioactive iodine.¹² His work in physiology, pathology and surgery on thyroid gland led to the award of the Nobel Prize in Medicine in 1909.¹³

Kocher went on to train William Halsted (1794–1878, **Figure 52.1c**), an American surgeon who studied in Vienna. On his return to America, Halsted popularized the use of haemostatic forceps and his work on parathyroid preservation and post-operative calcium/parathyroid extract supplementation to prevent hypocalcaemia did much to improve thyroid surgery. Halsted also swapped Billroth’s cotton gloves for ones made from rubber. He later concluded that: ‘The extirpation of the thyroid gland for goiter typifies perhaps better than any other operations the supreme triumph of the surgeon’s art’.⁹

Another difficulty that thyroid surgeons were encountering was that of the patient with exophthalmic goitre. First described by Caleb Hillier Parry (1755–1822) in a posthumous publication in 1825,¹ the condition we now know as Graves’ disease linked thyrocardiac symptoms, such as palpitations and tachycardia, with exophthalmos, extreme nervousness, and goitre. Surgery in these patients was reserved for those in extremis as the operation was fraught with difficulty, and mortality was very high. Nevertheless, in 1884 Ludwig Rehn (1849–1930) reported the full recovery of patients from thyrotoxic symptoms following thyroid surgery due to compressive goitres. In 1887, Theodor Kocher demonstrated increased vascularization of the thyroid gland in a patient diagnosed with Graves’ disease and recommended that the thyrotoxic symptoms originated by an increase in thyroid hormone level. Thereafter, he practised staged thyroidectomy, first ligating the main feeding vessels to the gland and then removing one lobe at a second operation.

Over the following decade, the mortality rate for surgery for Graves’ disease improved to around 6%; however, 25% patients developed recurrent disease requiring a second operation.¹⁴ In 1905 Frank Hartley advocated that the cure rate of thyroidectomy for Graves’ disease relied on removing a sufficient amount of the thyroid gland, and he recommended resecting one thyroid lobe and some portions of the opposite lobe for treatment of hyperthyroid patients.¹⁵ Thomas Dunhill (1876–1957) (**Figure 52.1d**)

followed Hartley’s theory and in 1912 published the outcomes of 380 thyrotoxic patients who underwent surgery, with a mortality of around 1% and a minimal recurrence rate.¹⁶ Over the next two decades, Dunhill gradually moved to carrying out bilateral subtotal thyroidectomy, as Jan Mikulicz-Radecki (1850–1905) did for the treatment of simple goitre.¹⁷

The pre-operative preparation of hyperthyroid patients became more widely recognized as key to reducing complications. Charles Mayo (1865–1939) and George Crile (1864–1943) worked closely with the endocrinologist Henry Plummer (1874–1936), pioneering this cross-specialty collaboration in the United States.

Plummer began treating hyperthyroid patients with iodine before passing them on to Mayo for surgery; this approach decreased the incidence of thyroid storm and also mortality rate.¹⁸ Consequently, the staged thyroid operation could be abandoned and the whole gland removed in one sitting. The improved survival and cure rate moved thyroidectomy for Graves’ disease from an operation reserved for moribund patients to a curative procedure for those with much milder disease. The introduction of radioiodine in Boston and Berkley for the treatment of thyroid cancer and Graves’ disease in 1942^{19, 20} did much to improve outcomes further, as did the use of the antithyroid drugs thiourea and thiouracil created and advocated by Edwin Bennett Astwood (1909–1976) in Boston.²¹

The modern age

The history of thyroid surgery belongs to general surgery, but over the past three decades we have seen a shift towards otolaryngologists and head and neck surgeons working together with endocrine surgeons. Endocrine surgery has now come of age and, from a thyroid and parathyroid point of view, multidisciplinary and collaborative specialist work began when Dick Welbourn founded the British Association of Endocrine Surgeons (BAES) in 1983 (later to become the British Association of Endocrine and Thyroid Surgeons (BAETS)). This organization focused on specialist endocrine multidisciplinary working to include education and research and welcomed the ear, nose and throat (ENT) surgeon into its fold. It was much more recently that the American Association of Endocrine Surgeons (AAES) included otolaryngology in their membership.

Modern-day greats of endocrine/head and neck surgery reflect the shared responsibility between general surgery and otolaryngology. In the United States, general surgeons Jatin Shah, Ashok Shaha, Keith Heller and Joseph Attie (New York) and Orlo Clark from San Francisco as well as Samuel Wells from Duke have led the way in both surgical techniques and education. Significant contributions from otolaryngology in the USA have come from David Terris (Augusta), Greg Randolph (Massachusetts), and David Eisele and Ralph Tufano (both Baltimore). In Australia, Leigh Delbridge and Tom Reeve (Sydney) did much to advance endocrine surgery, in particular the creation and maintenance of prospective surgical databases.

In Europe, Charles Proye from Lille and Jean Françoise Henri from Marseilles (both general surgeons) led the way; in the United Kingdom, much is owed to Professor Malcolm Wheeler (general and endocrine surgery) from Cardiff and Omar Shaheen (otolaryngology) from Guy's Hospital; the link between general surgery and otolaryngology in the UK and the USA was cemented when John Watkinson (Birmingham) was the first ENT surgeon to be elected President of the BAETS (2011–13) and recently Greg Randolph has become the first otolaryngologist member of the AAES.

With the advent of thyroid specialists, the operative technique has undergone significant refinement and subsequent changes in the extent of surgery performed. While initially total thyroidectomy/lobectomy were the procedures of choice, concerns over preservation of the parathyroid glands and recurrent laryngeal nerves, as well as maintaining some functioning thyroid tissue, led to a move towards sub-total thyroidectomy. This has been largely abandoned now, however, and the current recommendations are for either total lobectomy or total thyroidectomy as the only valid operations, with near-total acceptable to preserve a nerve at risk. These changes have resulted from the era of evidence-based medicine and subsequent focus on outcomes. The prognostic factors and risk group analyses in thyroid cancer were very well defined by Hay from the Mayo Clinic²² and Cady from the Lahey Clinic,²³ as well as Shaha from Memorial Sloane Kettering.²⁴ The American Thyroid Association (ATA) has now incorporated these risk groups into the third edition of their thyroid cancer guidelines, published in 2015, which is a landmark document for the management of thyroid cancer.²⁵ For medullary thyroid cancer, Sam Wells defined the implications of RET mutation and the role of prophylactic thyroidectomy in these patients,²⁶ and recent guidelines have further detailed the timing of surgery.²⁷

While other chapters will cover the latest technological advances that relate to thyroid surgery, a review of their development is appropriate here. The first major change has been the approach to the gland itself. While Kocher's classic 8–10 cm transverse incision was the standard for almost a century, the move towards minimally invasive approaches has resulted in scars commonly of 3–6 cm in length being usual for both thyroid and parathyroid surgery.²⁸ As well as smaller scars for access, the use of the endoscope has found its way into the thyroid surgeon's armamentarium. First described in 1997 by Paulo Mucozi,²⁹ this has evolved into minimally invasive video-assisted thyroidectomy (MIVAT) with access from the neck,³⁰ the axilla³¹ or lateral approaches.^{32, 33} Thus far, complication rates are comparable to open surgery³⁴ and although operation time is longer, cosmesis and recovery appear improved over open. An almost inevitable extension from endoscopic thyroid surgery has been robot-assisted operations as pioneered by Chung at Yonsei University, South Korea. Designed to address the limitations of two-dimensional visualization and basic endoscopic instruments, a number of centres are now performing robotic thyroidectomy more often. The advantage of absent neck scar is currently countered by the extra dissection needed

to reach the thyroid bed, longer operation time, learning curve and significant cost associated with the procedure. Whether this technique represents the future of thyroid surgery remains unclear.

The tools available to the surgeon have also advanced greatly, although their uptake has been variable. The intra-operative nerve monitor epitomizes this, with surgeons divided across the world as to its benefits versus disadvantages. As litigious medicine becomes more universal, the requirement for both real-time monitoring and assessment following surgery will surely increase. Dissection tools such as the harmonic scalpel and Ligasure™ are most widespread, and proponents herald the associated reduced operating time and improved haemostasis. Again, cost is a factor that rules these out for many units.

Surgical outcomes are now routinely measured in some manner by all hospitals, whether this be a personal or national audit. With the increased demand for transparency from the public, the requirement to participate in a national audit will become mandatory, as will the need for multidisciplinary meetings for suspected cancer cases.

The medical treatment of thyroid disease has also seen great leaps over the past half-century. In the post-war period, radioiodine treatment, antithyroid drugs and the technology surrounding thyroid surgery have advanced significantly. For thyrotoxic patients, medical treatment now carries high remission rates and reduces the number of patients requiring surgical treatment. Those who do progress or choose to have an operation are usually rendered euthyroid pre-operatively to decrease peri- and post-operative morbidity and mortality.

What is without doubt is that, in the modern era, the thyroid surgeon must act as a 'thyroidologist', capable of understanding the complexities of medical care as well as the nuances of surgery, and be willing to adapt their techniques and methods as modern technologies continue to gain ground.

PARATHYROID SURGERY

What we now know as the parathyroid glands were first identified by Sir Richard Owen, Hunterian Professor and Conservator of the Museum at the Royal College of Surgeons of England, in 1862 when he was asked to perform an autopsy on a Great Indian Rhinoceros. Owen described 'a small compact yellow glandular body attached to the thyroid at the point where the vein emerged',³⁵ resulting in the occasional use of the name 'Owen's glands'. However, the naming and description of the parathyroid glands is credited in 1880 to the Swedish medical student Ivan Viktor Sandstrom (1852–1889). Sandstrom's finding was unrecognized for more than 10 years until in 1891 Eugene Gley (1857–1930) repeated his discovery and also found that removal of these glands in animals resulted in tetany.³⁶ William George MacCallum (1874–1944) and Carl Voegtlin (1879–1960) subsequently discovered that the tetany produced by parathyroidectomy could be treated with a calcium infusion.³⁷ In parallel to these findings, Friedrich von Recklinghausen (1833–1910),

a pathologist in Strasbourg, described the characteristics of a specific bone disease which correlated with parathyroid lesion in 1891,³⁸ followed by the report in 1904 by Max Askanazy (1865–1940) of a female patient with a severe bone condition and a tumour lateral to her thyroid gland. Askanazy incorrectly interpreted that the parathyroid lesion was secondary to the bone disease rather than being the primary lesion itself.³⁹ In 1915, Friedrich Schlagenhauer (1866–1930) suggested that parathyroid tumours themselves are the primary lesions affecting severe skeletal changes.⁴⁰ Nearly a decade later, Felix Mandl (1892–1957) treated a patient suffering from osteitis fibrosa cystica of the femur who had failed treatment with thyroid and parathyroid extract. Mandl planned to perform a parathyroid transplantation, but on exploring the neck he discovered a parathyroid tumour, which he proceeded to excise. The patient's post-operative serum calcium levels returned to normal and their bone disease recovered, supporting Schagenhauer's hypothesis.

In 1926, Edward Delos Churchill (1895–1972) set out to explore the neck in a patient with primary hyperparathyroidism but failed to find a parathyroid tumour.¹ Just 3 years later, however, David Barr and Harold Bulger carried out the first successful parathyroidectomy for a patient with parathyroid disease, and they originated the term 'hyperparathyroidism'.⁴¹ More surgeons began to perform the procedure, although there were still patients in whom no tumour was found.

One such patient was Captain Martell, treated by Oliver Cope (1902–1994). Cope, a student of Churchill who went on to become a leader in parathyroid surgery in his own right, performed numerous unsuccessful neck explorations before asking Churchill's opinion. Churchill proceeded to find the adenoma in the anterior mediastinum via a partial sternotomy, becoming the first surgeon to describe this.⁴² As well as the anatomical variants of the parathyroid glands, advances in the understanding of the physiology of parathyroid hormone (PTH) continued throughout the early to middle 20th century. PTH was first isolated in 1923 by Adolph Hanson (1888–1959) and successfully extracted by James Collip (1892–1965).⁴³

It was Gerald Aurbach (1927–1991), however, who first purified the hormone in 1959.⁴⁴ In 1963, Solomon Aaron Berson (1918–1972) and Rosalyn Yalow (1921–2011) developed a radioimmunoassay to quantify PTH levels in the bloodstream, which greatly aided the diagnostic process.⁴⁵ After that period, determination of parathyroid disease and parathyroid surgery were greatly advancing.

From then to the present day, as for thyroid surgery, the management of parathyroid disease has been improved through previously described multidisciplinary working and advances in imaging, medical therapies and surgical techniques. Key among these advances is the use of localization studies (ultrasound, sestamibi and computed tomography (CT), specifically SPECT-CT scans and 4D CT with venous sampling) to identify the site of a diseased gland, thus greatly reducing the need for multi-gland exploration, and the risks inherent to operating in the central compartment on both sides of the neck – all of this facilitates minimally invasive techniques and targeted approaches. Intra-operative PTH measurement has allowed the surgeon to check for a fall in the PTH minutes after removing a suspect adenoma, again to determine whether further exploration is needed.

However, despite all the advances, the key to parathyroid surgery remains as it was when Edward Churchill described it: 'the success of parathyroid surgery must lie in the ability of the surgeon to know a parathyroid gland when he saw it, to know the distribution of glands, where they hide, and also be delicate enough in technique to be able to use this knowledge'.⁴²

SUMMARY

The history of thyroid and parathyroid surgery is rich in the names of famous surgeons who advanced the practice from butchery to art form. With technological advances being made regularly, we can expect to see further changes over the coming years, although it will be some time before the original operation, described by Kocher over a century ago, ceases to be the gold standard.

KEY POINTS

- Thyroid surgery has a rich history stretching back a thousand years, and it is replete with the names of the most famous surgeons of the day.
- While technology has leapt forward over the past 50 years, thyroidectomy is still based on Kocher's original description.
- More recent advances have led to both thyroid and parathyroid surgery becoming increasingly specialized.

DEVELOPMENTAL ANATOMY OF THE THYROID AND PARATHYROID GLANDS

Julian A. McGlashan

Introduction	603	Parathyroid glands.....	607
The thyroid gland.....	603	References	609

SEARCH STRATEGY AND EVIDENCE BASE

Much of the evidence for this topic is well documented in standard tomes on this subject such as *Werner and Ingbar's The thyroid*¹ and Bilezikian's *The parathyroids – Basic and clinical concepts*.² Medline, Embase and Google Scholar searches were performed for the years 1993–2013 to review new evidence pertinent to the topic using the keywords: thyroid gland, parathyroid gland, developmental anatomy, embryology, histopathology, and microstructure.

INTRODUCTION

Study of the developmental anatomy of the thyroid and parathyroid glands helps in the understanding of the normal and abnormal variations in anatomy seen at surgery and the related pathology of these organs. Although the main steps in the developmental anatomy have been known for over half a century, it is only in the last decade that the morphogenesis, control of cell growth and cellular differentiation of these organs have begun to be unravelled.³ This has followed significant advances in our understanding of the molecular biology^{4, 5} and genetic^{3, 6–8} basis of thyroid and parathyroid function in health and disease in the last 20 years. There is now increasing knowledge of the role of the cellular aspects of thyroid stem cell biology⁹ and pathogenesis of many thyroid and parathyroid diseases.^{6, 10} Much of the information has been obtained from limited human studies and more extensive investigations in rodents and sheep. The events of thyroid development are roughly comparable to humans except for the timing.¹¹ Detailed discussion is beyond the scope of this chapter, which will focus on summarizing the key anatomical features and stages in the development of the thyroid and parathyroid glands relevant to surgical practice. There is also an emphasis on the link between developmental abnormalities and some of the more common clinical presentations. Further information on the physiology of the thyroid and parathyroid glands can be found in [Chapter 55](#). For details of cellular development and their abnormalities, see [Chapter 9](#), Genetics of endocrine tumours.

THE THYROID GLAND

Macroscopic anatomy

The thyroid gland is situated in the lower anterior neck straddling the upper trachea. It is the largest endocrine organ in the body. It weighs 15–20 g in adulthood.^{12, 13} It is a highly vascular, reddish-brown, bi-lobed structure with each lobe joined together by a narrow isthmus ([Figure 53.1](#)). Each lobe is pear-shaped, measuring approximately 5 cm in length, 3 cm in width and 1.5 cm in depth. The apex of each lobe is narrow and extends beneath the sternothyroid muscle up to its insertion on the oblique line of the thyroid cartilage. The more rounded lower pole extends down to the level of the fourth or fifth tracheal ring. It lies lateral to the trachea and oesophagus and medial to the carotid sheath. The isthmus overlies the second to fourth tracheal rings.

The thyroid gland, together with the oesophagus and trachea, is invested in a visceral layer of deep fascia known as the pretracheal fascia.¹ It is attached superiorly to the hyoid bone and extends inferiorly into the mediastinum, fusing with the fascia surrounding the aorta, pericardium and parietal pleura at the level of the carina. Laterally the fascia blends with the carotid sheath. Anteriorly the fascia forms a distinct layer separating the thyroid from the strap muscles and posteriorly it merges with the prevertebral fascia. On the posterior aspect of the isthmus the fascia is sometimes known as the anterior tracheal ligament and is perforated by small

Figure 53.1 Relationship between thyroid gland, larynx and trachea. A pyramidal lobe +/- a fibrous or fibromuscular band is a common finding, particularly on the left side. It may arise from the isthmus or upper poles of the thyroid and extend a variable distance up to the body of the hyoid.

tracheal vessels, but at the upper part on each side it is much thicker and binds the gland firmly to the sides of the cricoid cartilage and first tracheal ring. This condensation is known as the lateral ligament of the thyroid or the ‘suspensory ligament of Berry’. Its fixation to the trachea causes the thyroid gland to move up and down on swallowing. During thyroid surgery it must be divided with care and by sharp dissection as the recurrent laryngeal nerve may lie lateral, medial or within the ligament just before it enters the larynx.

Microscopic anatomy

The thyroid gland is made up of multiple lobules supplied by a lobular artery.¹⁴ A thyroid lobule consists of 20 to 40 follicles which are spherical in shape and 0.02–0.9 mm in diameter.¹⁵ Each follicle is an aggregate of follicular cells which are one cell thick surrounding a central pool of viscous colloid (Figure 53.2). When the gland is relatively inactive, the cells are flattened and the colloid is abundant, dense and homogenous in appearance. On prolonged and excessive thyroid-stimulating hormone (TSH) stimulation the follicular cells become hypertrophied and hyperplastic and they adopt a more columnar shape.

The follicular cells have the characteristic cytoplasmic features of an endocrine gland in that they have long segments of rough endoplasmic reticulum and a large Golgi apparatus for synthesizing and packaging protein and prominent electron-dense lysosomal bodies. The plasma membranes of the apical and basal layers have separate functions and are kept separate by tight junctions which bind adjacent cells together. This allows the cell to control the storage of the thyroid hormones in the colloid and their release into the circulation. When stimulated

Figure 53.2 Angiofollicular unit and relationship between thyroid follicles and parafollicular cells.

by TSH, the intracellular organelles become more prominent and microvilli develop on their apical surfaces.¹⁶ The microvilli enable the colloid to be absorbed by endocytosis. This is associated with the development of ‘reabsorption lacunae’ and a reduction in the size of the follicular lumen. The process is also associated with an overall increase in vascularity of the gland. The thyroid hormones released into the circulation ensure that the metabolic demands of the tissues of the body are met by stimulating oxygen consumption and regulating carbohydrate and lipid metabolism. They are also essential for embryonic development, normal growth and especially for brain maturation.

Each follicle is invested and interlaced with loose connective tissue (stroma) containing a close-meshed plexus of fenestrated capillaries forming morphological and functional angiofollicular units (AFUs).^{17, 18} The inter-follicle connective tissue spaces are relatively large and contain a collagenous matrix, fibroblasts, unmyelinated nerve fibres with Schwann cells, and fat cells, plasma cells, macrophages, expanded lymphatics and lymphocytes.^{14, 16, 19} The fibroblasts form a highly organized ‘neuro-reticular network’ by linking their long, thin, branching cytoplasmic processes. These processes are surrounded by autonomic nerve endings in a similar manner to that found in bone marrow and in the submandibular gland. The presence of CD34-positive antigen on the fibroblasts may mean they play an important role in immune surveillance.¹⁹

Scattered in the stroma are some embryologically distinct cells known as parafollicular cells or C cells (Figure 53.2). They are found either singly or in small clumps and are characterized by their polygonal or spindle shape, their relatively large size and their ‘light’ cytoplasm.^{14, 20} They secrete calcitonin in response to elevated serum levels of calcium or gastrin. A total thyroidectomy does not always abolish calcitonin secretion as it can be produced by other organs such as the brain, gastrointestinal tract, urinary bladder, thymus and lungs.²¹ Calcitonin lowers serum calcium and phosphate levels by inhibiting the osteoclastic resorption of bone and enhancing the excretion of calcium by the kidneys. Its physiological importance is debatable as parathyroid hormone and vitamin D are thought to be more important in calcium haemostasis.²²

Developmental anatomy

The thyroid gland is the earliest endocrine organ to appear in mammalian development. It is formed from both the endodermal cells of the primitive pharynx, known as the median anlage, and from neural crest cells from the lateral anlagen or ultimobranchial bodies.^{3, 23–25}

MEDIAN ANLAGE

The median anlage (Figure 53.3) develops from a midline thickening of the ventral surface of the endodermal epithelium of the primitive pharynx between the first and second branchial arches adjacent to the developing myocardium. A diverticulum forms from this thickening at about the sixteenth or seventeenth gestational day. This out-pouching expands laterally at its distal tip to form a rudimentary bilobed structure. It is pulled into position by the descent of the heart and reaches its final location, immediately anterior to the trachea, in the seventh gestational week. Initially the descending thyroid remains attached to the pharyngeal floor by a tubular stalk. During the seventh to tenth week the lumen of the stalk becomes filled with cords of thyroid progenitor cells but eventually fragments and disappears before birth. The residuum of the attachment of the stalk forms the foramen caecum in the midline at the junction of the posterior third and anterior two-thirds of the tongue.²⁵

LATERAL ANLAGEN (ULTIMOBANCHIAL BODIES)

The two lateral anlagen (Figure 53.3), also known as the ultimobranchial bodies, are thought to develop as evaginations of the fourth pharyngeal pouches.^{25, 26} They become separated from them by attenuation and rupture from the common pharyngo-branchial duct. The ultimobranchial

bodies fuse with the median thyroid anlage by the sixth week of development, contributing approximately 10% of the mass of the thyroid gland.^{25, 27} It is thought that rarely the ultimobranchial bodies can fail to fuse resulting in a true 'lateral thyroid lobe', although this has been disputed.²⁸ The ultimobranchial bodies also contribute the calcitonin-producing parafollicular cells (C cells). The exact origin of these cells in humans remains controversial although they are thought to migrate from the neural crest.^{23–25}

HISTOGENESIS OF THE THYROID FOLLICLE

Histological differentiation of follicular cells can be seen to pass through three stages, defined by their production of colloid.²³

1. The 'precolloid stage' (7–13 weeks) is from the first appearance of immature follicular cells to the beginning of differentiation into cells that are capable of producing colloid.
2. In the second stage (13–14 weeks) an intracellular structure known as the canaliculus begins to dilate. This structure is thought to be an extension of the smooth endoplasmic reticulum and is associated with the accumulation of increasingly electron-dense material. This material is then discharged into the extracellular space where it is retained by the intracellular connections to form a central colloid space.
3. In the third stage there is an increase in colloid production and storage with a consequent increase in size of the follicles. The follicular cells also show an increase in the number of lysosomes representing endocytosis of the colloid in preparation for storage and release of the thyroid hormones into the circulation.

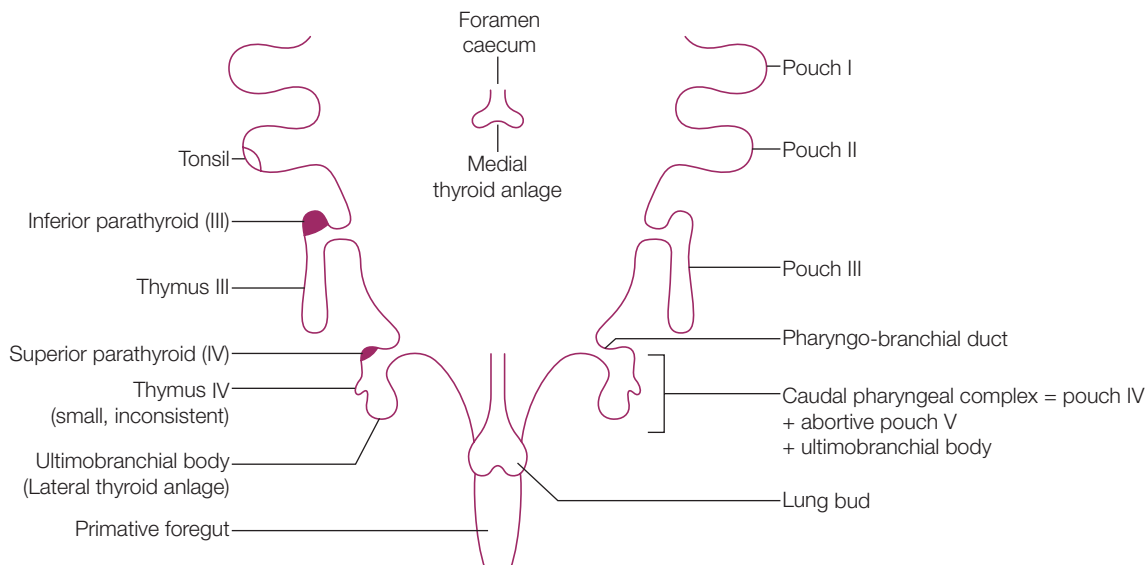

Figure 53.3 Schematic representation of the early development of the median and lateral anlagen of the thyroid gland and the parathyroid glands.

TABLE 53.1 Timeline of development of thyroid gland in humans

Gestational age	Development
Embryonic day 10	Endodermal thickening seen
Embryonic day 16–17	Median and lateral anlagen discernible
Embryonic day 24	Median anlage has developed a thin, flask-like diverticulum, extending from the floor of the buccal cavity down to the fourth branchial arch
Embryonic day 30	Formation of bi-lobulated structure
Embryonic day 40	Median and lateral anlagen have fused Degeneration of thyroglossal duct into fibrous stalk
Embryonic day 50	Lateral expansion Descent of the heart and thyroid reaches its final location, immediately anterior to the trachea Precolloid phase starts
Embryonic day 60	Definite shape Follicle formation Onset of thyroglobulin expression
Gestational week 10	Colloid phase Thyroid hormone receptors detectable in brain Fibrous thyroglossal stalk disappears
Gestational week 11	Histogenesis of the thyroid is virtually complete Foetal thyroid is capable of trapping and oxidizing iodide Thyroglobulin present in foetal thyroid Thyroxine can be detected in foetal serum
Gestational week 16	Increasing TSH secretion the principal regulator of thyroid hormone biosynthesis and secretion Significant increase of thyroid hormone receptors in foetal brain
Gestational week 17.5	Structural maturity of thyroid gland
Gestational week 20	Increasing organification of iodide and foetal T4 secretion
Gestational week 24	T3 detectable
Birth	Gland weight 1.5 g

Thyroxine can be detected in foetal serum at 11 weeks.²⁹ Structural maturity of the foetal thyroid gland is achieved at 17.5 weeks (Table 53.1).³⁰

Anatomical variations and pathological conditions resulting from developmental abnormalities of the thyroid gland

ASYMMETRIES AND COMMON NORMAL VARIANTS

Asymmetries of the gland are frequently found with the right side being larger than the left.¹² A third conical protrusion known as the **pyramidal lobe** is present in 12–81% of cases. The prevalence depends on the method of identification, i.e. autopsy, ultrasonography, CT, scintigraphy, intra-operative finding, the presence of pathology and possibly the population studied.^{31–33} Most authors report the pyramidal lobe to originate more commonly on the left side, from either the medial aspect of the upper poles or the isthmus (40–60%),³⁴ but it can also arise from the midline of the isthmus or the right lateral lobe. Reported as being between 3 mm and 63 mm in length,³⁴ it can extend superiorly as a short stump or a long process that can reach the upper border of the thyroid cartilage or even the hyoid bone^{32, 34, 35} (Figure 53.1). Its high prevalence indicates that this is a normal variant and represents the persistence of the distal part of the embryonic thyroid and

thyroglossal duct.^{34, 36} Its apex may be replaced by fibrous or fibromuscular tissue when it is then known as the ‘levator of the thyroid gland’.³⁶

KEY POINT

The prevalence of the pyramidal lobe is high enough to warrant exploration in every case of thyroid surgery. If a pyramidal lobe is present on the side of surgery, it should be removed with the main lobe to avoid leaving behind functioning thyroid tissue.³⁴

The **tubercle of Zuckerkandl** is a lateral or posterior projection of the thyroid lobe which can be identified in up to 60% of surgical dissections.^{14, 37, 38} It is thought to represent the point of embryological fusion of the ultimobranchial body and median anlage.

KEY POINT

The surgical importance of the tubercle of Zuckerkandl is threefold:

- the recurrent laryngeal nerve most often runs medial to it
- the superior parathyroid gland is usually attached to its cranial aspect
- when enlarged as part of the goitre, a significant portion of thyroid tissue may be inadvertently left behind if subtotal thyroidectomy is performed.

ABNORMAL DESCENT AND DEVELOPMENT OF THE THYROID GLAND

Rarely the migration of the thyroid may become arrested anywhere along the descent pathway from the foramen caecum to low in the neck.³⁹ The most common abnormality is a lingual thyroid. Ectopic thyroid tissue may also be found in the sublingual, high cervical and mediastinal regions or within the cardiac endothelium.³⁹ Hemiagenesis with absence of a lobe or lobe and isthmus can be rarely encountered.^{40, 41} The left lobe is more commonly absent (5:1) than the right.⁴¹

More commonly the descending thyroid stalk can persist anywhere between the foramen caecum and thyroid isthmus. Subsequent infection of adjacent lymphoid tissue to the tract is thought to stimulate the epithelial remnants so that they undergo cystic change.⁴² Typically thyroglossal duct cysts are midline with 25% being paramedian; 60–80% are found below the hyoid bone.^{28, 43–45} The tract is in close proximity to the hyoid bone, lying within the periosteum or even passing through the bony substance. During development, the point of origin of the embryonic thyroid is situated anteriorly to the second branchial arch so the thyroglossal tract ends up running ventrally to the developing hyoid bone. As the hyoid matures it rotates to assume its adult position. During this rotation the thyroglossal tract is drawn posteriorly and cranially around the inferior edge of the bone. It then continues descending downward and anteriorly to thyroid membrane.⁴² A persisting thyroglossal tract may become entrapped in the midline mesenchymal condensation that is now thought to form the body of the hyoid bone in the midline.^{46, 47}

Lateral aberrant thyroid rests

Normally the ultimobranchial bodies fuse with the expanding lateral lobes of the median thyroid and differentiate into thyroid tissue, which is usually indistinguishable from the rest of the thyroid gland. Aberrant follicular thyroid tissue or gland has been identified lateral to the main body of the thyroid gland and situated lateral to the internal jugular vein and not associated with any lymphoid tissue. The majority of these deposits or nodules are likely to represent metastatic follicular or follicular variant papillary thyroid carcinoma and perhaps should be managed as such.⁴⁸ On rare occasions a few follicles of normal thyroid tissue can also be found within the capsule of cervical lymph nodes situated in the central compartment of the neck. Again, the majority are likely to represent metastatic deposits but on rare occasions with no evidence of a carcinoma in the thyroid gland on painstaking histological examination they have to be attributed to ectopic tissue.⁴⁸

Solid cell nests

These are irregularly shaped clusters of inter-follicular cells delineated by basal lamina within the thyroid gland. The dominant cell component comprises polygonal to fusiform cells with an epidermoid appearance.⁴⁹ Less commonly they show glandular morphology and may be microcystic, micropapillary and/or mucinous.⁴⁹ They may

be found in approximately 25% of resected thyroid glands and are thought to represent remnants of the ultimobranchial apparatus.^{9, 31, 50} They are more prevalent in the thyroid of infants and children and gradually decline with advancing age. Their biological significance remains controversial but there is some evidence that they harbour stem cells with capacity for self-renewal and end differentiation. They can be a source of confusion in thyroid pathology as they can mimic a number of pathological conditions.⁵¹

Medullary carcinoma

Normally the calcitonin-producing parafollicular cells (C cells) migrate to become distributed throughout the thyroid gland. However, they often remain more numerous near the point of fusion between the two anlagen.^{52, 53} There is therefore a tendency for medullary carcinomas to develop in the central portions of the middle and upper thirds of the thyroid lobes.⁵³

Struma ovarii (thyroid tissue within the ovary)

This is not a developmental anomaly of the thyroid but a germ-cell tumour, i.e. a monodermal teratoma. It accounts for approximately 5% of ovarian teratomas and the teratoma must comprise more than 50% of thyroid tissue to be classed as Struma ovarii. The thyroid tissue in this condition rarely functions but there have been rare instances of thyrotoxicosis (5–8%)⁵⁴ and malignancy with peritoneal and distant metastases.^{55–57}

PARATHYROID GLANDS

Macroscopic and microscopic anatomy

The parathyroid glands are generally found in close proximity to the posterior surface of the thyroid gland. They are small, yellowish-brown, oval or bean-shaped and their colour often darkens with age. In most cases (84%) there are four parathyroid glands.⁵⁸ The size of each gland can vary but on average they are 6 mm in craniocaudal dimension and 3–4 mm in transverse diameter. They are usually paired and named superior and inferior glands. Around 85% of superior glands are within a 2 cm diameter of a point 1 cm above the crossing of the inferior thyroid artery and recurrent laryngeal nerve.^{58–60} The inferior glands are frequently situated below the artery level or within 1 cm of the lower pole of the thyroid gland.

The parathyroid glands are enveloped by a thin fibrous capsule which extends into the parenchyma partitioning the gland into lobules. The parenchymal cells are arranged in clusters or cords nourished by a rich capillary network. Within the fibrovascular stroma there are other cells including adipocytes, macrophages and mast cells. They are likely to be involved in parathyroid hormone (PTH) secretion, signalling functions and as a detoxification storage site for lipophilic agents such as Vitamin A. The amount of stromal fibroadipose tissue increases with age, eventually comprising 50% of the gland substance in the elderly.⁶¹

The dominant cell type within the parathyroid glands are known as chief cells or principal cells. They produce PTH and together with calcitonin and an active metabolite of vitamin D, 1,25-dihydroxyvitamin D₃, play an essential role in calcium homeostasis. Tight regulation of serum calcium levels is essential for neural transmission, muscle contraction and relaxation, exocrine secretion, blood clotting and cellular adhesion. Chief cells undergo morphological changes corresponding to different stages of the secretory cycle. They range from being cuboidal in shape in the inactive phase to oval or polygonal in the active phase.⁴ They are characterized by their rather scant, slightly eosinophilic cytoplasm. This is in contrast to the other main cell type, the oxyphil cells. Oxyphil cells are much less prevalent and are found singly or in small clusters. They can be identified by their larger size, eosinophilic cytoplasm due to their high mitochondrial content, prominent nucleoli and randomly enlarged nuclei.² Oxyphil cells are thought to be derived from chief cells and their numbers increase with age or after excessive functional stress (e.g. long-term stimulation of the parathyroid glands or chronic kidney disease).⁴ Their function is not fully understood but they have the potential to produce PTH, PTH-related protein (PTHrP) and calcitriol. They may also have autocrine and paracrine functions.⁶² A further cell type known as parathyroid water-clear cells can occasionally be found in normal parathyroid glands. They are much more prevalent in hyperfunctional parathyroid states associated with hyperplasia and parathyroid adenomas.⁶³

Developmental anatomy

In humans the parathyroid primordia first appear at about 32 days of embryonic development.⁵⁹ Each superior parathyroid gland is derived from the endoderm of the dorsal part of the fourth pharyngeal pouch together with the ultimobranchial body.⁴ It is commonly referred to as Parathyroid IV (PIV) in the embryological literature to indicate its site of origin. Each inferior parathyroid gland (Parathyroid III (PIII)) develops from endodermal cells from a common parathyroid/thymus primordium found in the third pharyngeal pouch (Figure 53.3). The dorsal/anterior part of the common primordium contributes the parathyroid component while the ventral/distal part contributes to the thymus component. PIII migrates with the thymus and PIV migrates together with the ultimobranchial bodies respectively at about 44 days (Figure 53.4).

Figure 53.4 Schematic representation during development of relative positioning of the parathyroids and ultimobranchial body during fusion.

Later in development the inferior glands separate from the thymus and come to lie caudal to the superior parathyroids.

Anatomical variations and pathological conditions resulting from developmental abnormalities of the parathyroid glands

GLAND NUMBERS, SIZE AND POSITION

Although four parathyroid glands is the commonest number present, the number can range from two to six with some authors reporting as many as twelve glands.⁶⁴ Each gland weighs 30–40 mg, giving a combined weight of the glands in adults of 120 ± 3.5 mg in men and 142 ± 5.2 mg in women.⁶⁵ If a single gland's weight is greater than 60 mg, it is considered pathological.

As the thymus has a longer course of descent into the superior mediastinum, the accompanying inferior parathyroids have a more variable location, and a higher chance of ectopic location. They are responsible for supernumerary glands most commonly found in the cervical thymus (39%) or within the mediastinal thymus itself (6%).⁶⁰ Normal superior parathyroids can occasionally be found in the posterior neck, retropharyngeal–oesophageal space, carotid sheath and posterior mediastinum (1–4%). Parathyroid adenomas are found in posterior locations in 40% of cases. Most 'intrathyroidal' parathyroids reported on histological resections are located within indentations of the thyroid gland surrounded by perithyroidal fat.² Intravagal parathyroid tissue has been documented in 6% of cases in autopsy reports.⁶⁶

KEY POINTS

- In most cases (84%) there are four parathyroid glands but the number can vary between two and six.
- 85% of superior parathyroid glands are within a 2 cm diameter of a point 1 cm above the crossing of the inferior thyroid artery and recurrent laryngeal nerve.
- The inferior glands have a more variable position but are frequently situated below the artery, level or within 1 cm of the lower pole of the thyroid gland.
- Ectopic or supernumerary glands can be found in the thymus gland, posterior neck, retropharyngeal – oesophageal space, carotid sheath and posterior mediastinum.

SEARCH STRATEGY AND EVIDENCE BASE

This chapter was prepared from anatomy and physiology texts and supported by a Medline search using the keywords anatomy, endoscopic, pituitary and cavernous sinus. The anatomical studies quoted constitute level 3 evidence.

EMBRYOLOGY

The adenohypophysis is derived from the placodal ectoderm of the stomodeum roof. The neurohypophysis is derived from an evagination of the floor of the forebrain and the third ventricle.

There is a saccular depression in the roof of the stomodeum immediately in front of the oropharyngeal membrane. This saccular depression evaginates to form the pouch of Rathke. This area remains in close contact with the ventral surface of the forebrain. The pouch of Rathke develops into the adenohypophysis. The anterior part becomes the pars anterior and the posterior part, in

contact with the forebrain, becomes the pars intermedia. The section of the forebrain in close contact with the pars intermedia becomes the neurohypophysis (Figure 54.1). In foetal life and childhood the vestige of Rathke's pouch remains as the hypophyseal cleft separating the pars anterior and pars intermedia. The pars intermedia is rudimentary in humans and is of little functional significance. Remnants of Rathke's pouch may persist below the sphenoid in the roof of the nasopharynx forming a pharyngeal pituitary. The clivus and the dorsum sellae of the future sphenoid bone are formed from mesenchymal condensations surrounding the hypophysis.¹ The cavernous sinus is derived from the primary head vein (Figure 54.1).

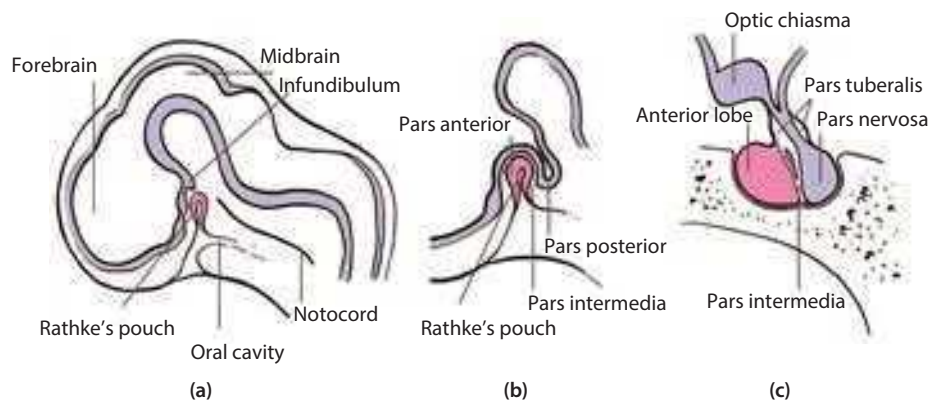

Figure 54.1 Embryological development of the hypophysis.

ENDOSCOPIC ANATOMY OF THE SPHENOID AND ANTERIOR SELLA WALL

The anatomical considerations for the endoscopic pituitary surgeon are:

- the degree of pneumatization of the sphenoid and the localization of the anterior sella wall
- the position of the intra-sphenoid sinus septae
- the positioning of the carotid arteries and optic nerves in the posterior sphenoid wall.

The degree of pneumatization of the sphenoid was originally described by Hammer and Radberg in 1961.² They divided the sphenoid sinus into three types: sellar, pre-sellar and conchal. In the sellar type the sphenoid is well pneumatized and the floor of the pituitary fossa (sella) performs an easily identifiable bulge in the posterosuperior aspect of the sphenoid sinus. In most series this arrangement is found in approximately 80% of sinuses. The posterior wall of the sphenoid sinus is in the same plane as the midpoint of the pituitary fossa or more posteriorly placed. In a small subgroup the pneumatization can be described as 'post-sella' whereby the entire sella floor protrudes down from the roof of the sphenoid sinus. In 'pre-sella' pneumatization (approximately 20%), the posterior wall of the sphenoid sinus is in the same plane as the anterior wall of the sella. In these cases it may be difficult to delineate the anterior bulge of the anterior sphenoid wall and intra-operative radiology or navigation systems may be needed to help the endoscopic surgeons. In 2% of cases there is no pneumatization of the sphenoid. This arrangement is much more common in Asian populations where it may occur in up to 28% of cases.³

Intra-sphenoid sinus septae

The arrangement of the septae is highly variable. The standard textbook depiction of a single septum running in the midline from the rostrum of the sphenoid back to the anterior pituitary fossa wall is found in only 14% of individuals. Almost any arrangement of septae can be encountered by the surgeon. The commoner arrangements are of a single septum (48%) or two septae (48%) rather than multiple septations. The septae may be incomplete or complete whereby they extend from the anterior to the posterior wall of the septum. Anteriorly, a complete septum is usually inserted in the midline, but its posterior attachment is variable. Midline posterior attachment occurs in only 14% of individuals and more commonly the arrangement is that the posterior attachment is laterally placed close to the paraclival carotid eminence. In 87% of cases at least one septum will be inserted posteriorly close to the carotid.⁴ Care is therefore needed when drilling down these septae to gain surgical access (Figure 54.2).

Transverse septations as well as vertical septations are also encountered. Where there are horizontal sphenoid

Figure 54.2 Endoscopic view of sphenoid. Single intra-sphenoid septum (1) inserting into the left carotid artery eminence (2).

septae, this is due to posterior ethmoids pneumatizing over the top of sphenoid sinuses. This can be surgically relevant: if they are not opened, the surgeon may not be able to visualize and reach all of the anterior wall of the pituitary fossa.

Carotid arteries and optic nerves

In a well-pneumatized sphenoid the pituitary fossa will form a bulge in the midline in the posterosuperior aspect of the sinus. Figure 54.3 shows that inferolateral to the fossa is the paraclival carotid (a). Lateral to the fossa is the bulge formed by the carotid as it curves anteriorly then posteriorly as it ascends in the cavernous sinus (b). Superolateral to the fossa is the position of the optic nerve (c), although this is visible in only a small proportion of the sphenoid sinuses. The small fossa bounded by the

Figure 54.3 Endoscopic view of posterior wall of sphenoid. Indentations caused by the internal carotid artery (1,2) and optic nerve (3), lateral opticocarotid recess (4) and medial opticocarotid recess (5).

optic nerve superomedially and the carotid artery inferomedially is termed the lateral opticocarotid recess (LOCR) and it corresponds to the anterior clinoid process intracranially. The triangular depression bounded by the optic nerve superolaterally, the carotid inferomedially and the the pituitary fossa medially is termed the medial opticocarotid recess (MOCR) and that corresponds to the medial clinoid intracranially.

The bony covering over the sella is thin, usually less than 0.5 mm. In cases where an adenoma is present, the bony covering may be absent. The carotico-optic recess is triangular in shape and is limited by the optic nerve superiorly, the carotid artery inferomedially and the oculomotor nerve laterally. The carotid protuberance or C shape of the carotid artery is immediately lateral to the pituitary fossa and is formed by the serpentine carotid artery as it bends forwards in the cavernous sinus before curving backwards as it ascends before entering the anterior cranial fossa medial to the anterior clinoid process.

The optic nerves and the cavernous sinuses are usually covered by bone, although a dehiscence over the carotid artery is present in up to 5% of cases.⁵

PITUITARY GLAND ANATOMY

The pituitary gland or hypophysis cerebri is an ovoid body measuring approximately 8 mm in the anteroposterior diameter by 12 mm transversely by 4 mm high. By the age of puberty it weighs approximately 100–500 mg. It doubles in size during pregnancy and usually remains larger in females. The adenohypophysis constitutes two-thirds of the volume.

There are two major parts to the hypophysis:⁶

- **adenohypophysis:** includes the pars anterior, pars intermedia and pars tuberalis
- **neurohypophysis:** includes the pars posterior, infundibular stem and median eminence.

Both these parts include parts of the infundibulum and are referred to the old terms anterior and posterior lobes (Figure 54.4).

Adenohypophysis

This structure is highly vascular and consists of epithelial cells arranged in follicles and cords between which lie thin-walled, vascular sinuses. This arrangement is supported by a delicate skeleton of reticular tissue.

Traditionally, cell types of the adenohypophysis have been divided up by their staining characteristics into chromophil (acidophilic, basophilic) and chromophobe cells. Modern immunohistochemical techniques allow us to identify cells by the hormones that they produce, as follows.

- **Somatotrophs:** (acidophilic), the largest and most abundant chromophil cells, these secrete the protein somatotrophin or growth hormone (GH).

Figure 54.4 Lateral view of the hypophysis in the sella turcica. The intercavernous venous sinuses are indicated in blue.

- **Mammotrophs:** (acidophilic), secrete the polypeptide hormone prolactin (PRL). They become the dominant cell during pregnancy and lactation.
- **Mammosomatotrophs:** (acidophilic) secrete growth hormone and prolactin simultaneously.
- **Corticotrophs:** (basophilic), produce the precursor molecule pro-opiomelanocorticotropin (POMC), which is broken down into adrenocorticotropin (ACTH), beta-lipotropin and beta-endorphin.
- **Thyrotrophs:** (basophilic), secrete thyroid-stimulating hormone (TSH).
- **Gonadotrophs:** (basophilic) secrete follicle-stimulating hormone (FSH) and luteinizing hormone (LH).
- **Chromophobe cells:** these small cells constitute the majority of the cells in the adenohypophysis. They include stem cells and degranulated secretory cells.
- **Folliculostellate (FS) cells:** these are the supporting cells of the adenohypophysis, with growth factor and cytokine activity. Their expression of cytokeratins supports the theory that the adenohypophysis is derived from Rathke's pouch.⁷
- **Pars tuberalis:** this contains large number of blood vessels as well as the secreting cells listed above. In some species this area is rich in receptors for the pineal hormone melatonin.

Neurohypophysis

Axons with their cell bodies in the supraoptic and paraventricular nuclei of the hypothalamus run to the neurohypophysis. Some terminate in the median eminence from where they can influence the action of the adenohypophysis (see below); others run down through the stalk of the hypophysis to the main mass of the neurohypophysis where they terminate close to the sinusoids. The latter transport polypeptide hormones in conjunction

with a glycoprotein (neurophysin) to the neurohypophysis where they are stored prior to release. The two hormones secreted in this way are:

- anti-diuretic hormone (ADH) or vasopressin
- oxytocin.

Blood supply of the hypophysis

The arterial supply of the hypophysis is from single inferior hypophyseal arteries and several superior hypophyseal arteries on each side, all of which are branches of the internal carotid. The superior hypophyseal arteries supply the median eminence and the infundibulum. The inferior hypophyseal arteries anastomose to form an arterial ring around the infundibulum, which gives fine branches supplying the capillary bed of the neurohypophysis. The adenohypophysis does not have a direct arterial supply but is supplied by long and short portal vessels, which run from the median eminence and the lower infundibulum respectively to the capillary bed of the adenohypophysis (Figure 54.5).

The hormones of the adenohypophysis are secreted by exocytosis into the nearby sinusoids. The major signal for this secretion involves the release of specific releasing factors from neurones in the median eminence, which are then transported to the adenohypophysis by the portal system.⁸

The venous drainage of the hypophysis is less clear but has important implications in understanding the control of pituitary hormone secretion. Possible drainage is via:

- long and short portal vessels to the infundibulum
- large inferior hypophyseal veins into the dural venous sinuses
- the median eminence to the hypothalamus
- reversible flow between the adenohypophysis and neurohypophysis.

Pituitary gland capsule

The gland has a capsule made up of soft fibrous tissue that is in continuity with the fibrous connective tissue of the gland. The gland appears to be loosely attached to the surrounding connective tissue, which forms a smooth nest for the hypophysis. Bridging veins, capsular arteries and fibrous bundles cross this space.⁹

SELLA TURCICA

The sella turcica or Turkish saddle is the deep depression in the body of the sphenoid bone. It contains the hypophysis cerebri, dural layers and the intercavernous sinuses. The hypophysis fills 50–85% of the fossa.

The bony landmarks around the fossa are as follows (Figure 54.6):

- The **optic canal** lies between the roots of the lesser wing and the body of the sphenoid medially. It descends slightly anterolaterally, and it contains the optic nerve, ophthalmic artery and meninges.
- The **anterior clinoid process** is the posterior projection from the lesser wing of the sphenoid.
- The **tuberculum sellae** is a midline ridge in the anterior slope of the sella turcica.
- The **dorsum sellae** is the posterior wall of the sella turcica. The superolateral projections of the dorsum form the posterior clinoid processes.
- The **groove for the internal carotid artery** is formed as the artery turns anteriorly from the foramen lacerum. The groove can be seen on the sphenoid lateral to the sella turcica.
- The **middle clinoid process** is a small elevation in the median edge of the groove. In approximately 10% of skulls the middle and anterior clinoid processes are joined to form a continuous ring called the carotico-clinoid foramen.¹⁰

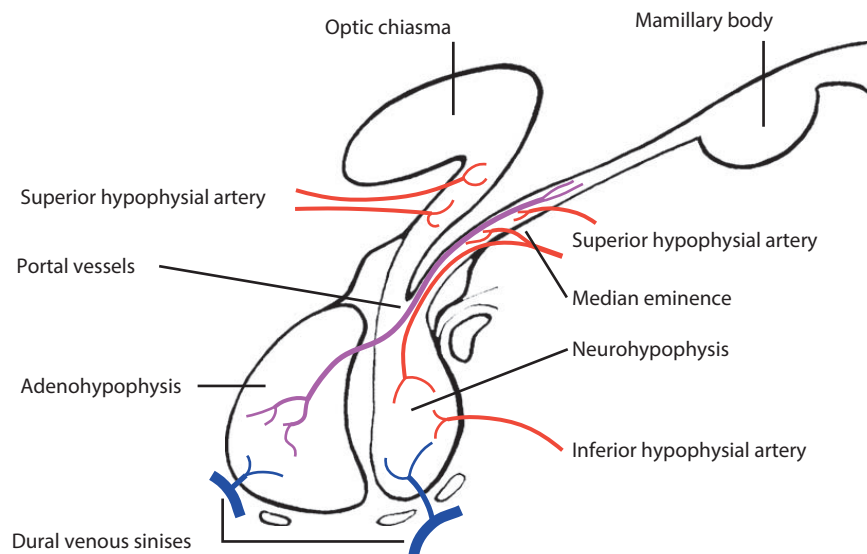

Figure 54.5 Vasculature of the hypophysis.

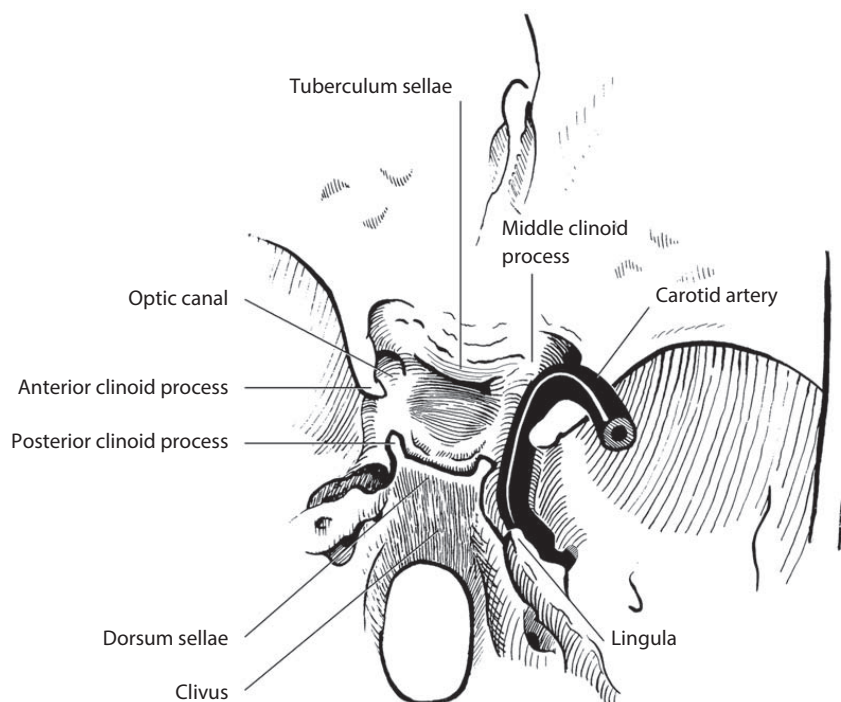

Figure 54.6 Posterosuperior view of the sella turcica of a skull. The position of the right internal carotid is demonstrated.

- The **lingula** is a small projection arising on the posterolateral aspect of the carotid groove.
- The **clivus** is made up of the body of the sphenoid bone behind the dorsum sellae and the basioccipital bone. The upper part of the pons lies adjacent to the clivus.

In approximately 2% of skulls there is a bony bridge joining the anterior clinoid and posterior clinoid processes called the tinea interclinoidea. In approximately 1% of skulls there is a bony projection in the floor of the sella called the sella spine. It is a bony spicule that projects from the junction of the anterior and inferior walls of the sella towards the middle of the hypophyseal fossa and it is usually 1 mm in diameter and 2–5 mm in length. It probably represents an ossified remnant of the notochord.¹¹

Dural reflections

The diaphragmatica sella is a sheet of dura mater that forms the roof of the sella turcica. This small, flat, horizontal circular sheet covers over the fossa between the clinoid processes and is continuous with the roof of the cavernous sinus. There is a central defect in the diaphragm called the foramen diaphragmatis to allow through the pituitary stalk or infundibulum. It is of variable diameter up to 5 mm.¹² In the region of the foramen of the dura, arachnoid and pia mater fuse with each other and with the capsule of the pituitary gland to form one fibrous layer that lines the hypophyseal fossa. In the fossa it is not possible to differentiate the fibrous layers and there are no subdural or subarachnoid spaces. Therefore there is no cerebrospinal fluid (CSF) in the normal pituitary fossa. The diaphragmatica sella separates the contents of the

pituitary fossa from the CSF in the region of the foramen. The barrier may be very thin and consist of only arachnoid mater.¹³

The tentorium cerebelli is the main dural sheet that loops around the brain stem and separates the cerebral hemispheres from the cerebellum, forming the floor of the middle cranial fossa. It arises from the anterior clinoid processes and has a U-shaped free border looping posteriorly. The peripheral attachments of the tentorium run from the anterior clinoid process backwards as a ridge of dura mater to the apex of the petrous temple bone. This ridge is at the junction of the roof and the lateral part of the cavernous sinus. From here the attachment runs backwards to the posterior clinoid process, forming the roof of the cavernous sinus, and is continuous with the diaphragmatica sella. The remainder of the peripheral attachment of the tentorium is to the superior surface of the petrous temporal bone in the region of the superior petrosal sinus and to the occipital bone in the region of the transverse sinuses.

Intercavernous venous sinuses

The two cavernous sinuses are connected across the floor of the pituitary fossa by the intercavernous venous sinuses. Some texts indicate that there is a single anterior and single posterior vein in the floor of the fossa, hence the old term 'inferior circular sinus of Winslow'. Cast studies have shown, however, that the arrangement is much more variable, with multiple interconnections across the floor possible. The superior and inferior connections may be found behind the anterior wall of the fossa and the connections may widen out laterally as they enter the cavernous sinuses (Figure 54.4).¹⁴

Relations of the pituitary fossa

Superior:

- The diaphragmatica sella
- The pituitary stalk and infundibulum
- The optic chiasm anterior to the infundibulum; 5–10 mm above the diaphragm
- Anterior cerebral artery and anterior communicating artery anterior to the optic chiasm
- Internal carotid artery/middle cerebral artery lateral to the infundibulum
- CSF surrounds the above structures above the diaphragmatica sella
- The third ventricle lies above the infundibulum

Posterior:

- Lamellar bone of the dorsum sella
- Dura mater of the poster fossa, behind the lamellar bone
- Basilar artery, behind the dura mater
- CSF

Lateral:

- Upper part of the cavernous sinus containing:
 - horizontal portion of the internal carotid artery
 - oculomotor, trochlear and abducens nerves

Anterior and inferior:

- Sphenoid sinus
- Intra-sphenoid sinus septum

ENDOSCOPIC ANATOMY OF THE PITUITARY FOSSA

There is a thin layer of bone (<0.5 mm) over the anterior surface of the pituitary fossa. In pathological cases where a macro-adenoma is present the bone may be dehiscent or thinned.

In a cadaver study, the average dimensions of the anterior sella wall were measured.¹⁵ The distance between the medial margins of the optic nerves at the level of the carotico-optic recess was found to be 12 mm; the width of the pituitary fossa between the carotid prominences was 21 mm; and the height of the anterior sella wall was 8 mm. Inside the pituitary fossa the height of the pituitary gland was 7 mm and the average separation of the superior aspect of the gland from the optic chiasm was 5 mm. There is, however, great variation in the normal anatomy of this region and the inter-carotid distance can be much narrower (Figure 54.7). The pathological processes will also distort the anatomy and macroadenomas can result in the intra-carotid distance being increased to up to 3 cm.¹⁶

During the endoscopic surgical approach to the fossa the first layer encountered will be the bony covering of the anterior sella wall, followed by a layer of dura lining the fossa. This is a single layer of dura except where it splits to accommodate the intercavernous sphenoid

Figure 54.7 Coronal MR scan. The optic chiasm (1) and the pituitary gland (2) between medially placed carotid arteries (3).

sinuses (see above). Inside the dural layer is the substance of the gland itself. *In vivo* normal healthy pituitary gland tissue is slightly yellowish in appearance. There is a clear plane of dissection between the substance of the gland and its soft fibrous capsules. If the pituitary gland is removed *in vivo*, it is possible to see the diaphragm bulging down from above. The diaphragm is an easily identifiable sheet of fibrous tissue. Laterally the soft fibrous tissue of the medial wall of the cavernous sinuses is visible.

CAVERNOUS SINUSES

These sinuses lie on the lateral aspect of the sphenoid body and are the lateral relations of the sella turcica. The term ‘cavernous’ was adopted when it was thought that these sinuses were a single cavern with a few trabeculae. Work using corrosion casts has established that these sinuses are plexiform in nature, i.e. they are made up of an intertwined network of thin-walled venous channels of varying sizes that divide and coalesce and incompletely surround the carotid arteries.¹⁷

The sinuses are approximately 1 cm wide and 2 cm long and are wider at the roof than at the base. They extend forwards from the apex of the petrous temporal bone to the superior orbital fissure. The carotid arteries have a variable course inside the sinuses. They enter posteroinferiorly, having passed through the carotid canal, and then turn anteriorly, passing horizontally through the sinus before turning superiorly to enter the anterior cranial fossa medial to the anterior clinoid processes. The horizontal portion of the artery is usually the lateral relation of the hypophysis. There is significant individual variation and the artery may be up to 7 mm away from the gland with the intervening space filled with venous plexus or it may be

as close as 1 mm with little intervening venous tissue. The lateral wall of the cavernous sinus is a thick sheet of dura mater; the medial wall is much thinner. There is no thick dural sheet and the capsule of the pituitary is the only barrier to spread of adenoma from the pituitary fossa.

The oculomotor nerve, trochlear nerve and ophthalmic division of the trigeminal nerve are closely related to, but not in, the lateral wall of the sinus as they pass anteriorly towards the superior orbital fissure.¹⁸ The abducens nerve runs inferolaterally to the carotid artery in its horizontal portion. The sympathetic plexus runs with the carotid artery.

The sinus receives tributaries from the superficial middle cerebral vein, inferior cerebral vein, sphenoparietal sinus, inferior ophthalmic vein and sometimes the central retinal vein and frontal tributaries of the middle meningeal vein. The sinus then drains into the internal jugular vein via the inferior petrosal sinus, to the transverse sinus via the superior petrosal sinus, and small emissary veins drain through the foramen lacerum and foramen ovale to the pterygoid plexus.

ENDOSCOPIC ANATOMY OF CAVERNOUS SINUSES

If the bone of the posterior sphenoid sinus is taken down laterally to the anterior sella wall, the anterior aspect of the cavernous sinus is exposed. The prominent anatomical feature is the bulge of the C-shaped curve of the intra-cavernous portion of the internal carotid artery (Figure 54.8a). The nerves in the cavernous sinus are all placed laterally to the carotid artery and the carotid artery needs to be displaced medially in order to identify these (Figure 54.8b). Along the lateral wall of the cavernous sinus the oculomotor, trochlear and abducens nerves may be seen. In addition, the ophthalmic and occasionally the maxillary divisions of the trigeminal nerves may be visible. The oculomotor nerve is large and easily recognizable. It is located superiorly closest to the optic nerve, the trochlear nerve is smaller and is found just below the oculomotor nerve, and the abducens nerve is located more medially and inferior to the carotid artery.¹⁹

Figure 54.8 Endoscopic view of the sella and cavernous sinus in a frozen cadaver. (a) The right ascending carotid (1) is behind its bony covering. Bone, dura and the diaphragm have been removed over the pituitary fossa and left cavernous sinus up to the roof of the sphenoid (2). The left ascending carotid (3), optic nerves (4), chiasm (5), pituitary stalk (6) and the pituitary gland (7) are exposed. The anterior bulge of the left carotid artery (8) is seen in the cavernous sinus. **(b)** The left carotid artery (8) is displaced medially to show the cavernous sinus (9) and the oculomotor nerve (10) in its lateral wall.

KEY POINTS

- Intra-sphenoid septae are highly variable and often inserted close to the carotid artery on the posterior sphenoid wall.
- Endoscopic view allows good visualization of the posterior sphenoid wall and the landmarks of the carotid arteries and optic nerves are often visible.
- The lateral optico-carotid recess corresponds to the anterior clinoid process intracranially.
- Understanding the variable, tortuous course of the carotid artery in the sphenoid and cavernous sinus is the key to performing safe pituitary surgery.
- The pituitary fossa does not normally contain CSF but does contain small inter-cavernous venous sinuses.

Physiology of the thyroid gland	619	References	627
Physiology of the parathyroid glands	623		

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: thyroid, parathyroid glands, hypothyroidism, thyrotoxicosis, thyroid-stimulating hormone (TSH), thyroglobulin, thionamides, neutropenia, osteoporosis, vitamin D.

The information in this chapter summarizes the physiology of the thyroid and the parathyroid glands, with a focus on aspects that are important for the endocrine surgeon.

INTRODUCTION

The thyroid is the largest endocrine organ, weighing 10–25 g. The highly vascular gland is located in front of the trachea in the anterior neck and consists of a left and a right lobe, connected by the isthmus. The parathyroid glands can vary in number and location, but in over 80% of humans there are four glands which are most commonly located posterior to the thyroid, although the location especially of the inferior glands can be more variable. Importantly, apart from sharing anatomical neighbourhood and part of the name, thyroid and parathyroid glands are independent endocrine organs that share no obvious functional similarities. However, due to the close anatomical location, surgery of the thyroid can impair parathyroid function transiently or permanently.

At the beginning of modern thyroid surgery in the 1860s, the mortality associated with thyroidectomy was high,^{1,2} mainly related to thyroid storm in thyrotoxic patients, as well as post-surgical hypothyroidism and hypocalcaemia. ‘Cachexia strumipriva’ in patients after total thyroidectomy, as described by Kocher in 1883,³ was later causally linked to surgical hypothyroidism. Tetany was thought to be caused by ‘hysteria’. The parathyroid glands in humans were discovered in 1880 by Sandstrom,⁴ but the fact that hypocalcaemia was the definitive cause of tetany was not accepted until decades later.²

Improved insights in the physiology of thyroid and parathyroid glands have made a major contribution to

transforming surgery of these organs to relatively low-risk routine procedures. The aim of this chapter is to provide a brief overview of the physiology of the thyroid and parathyroid glands, with a focus on aspects that are relevant to the ENT surgeon.

PHYSIOLOGY OF THE THYROID GLAND

Hormones secreted by the thyroid are critical for the development of the foetus and newborn, with key influences on the development of the brain and normal growth. In adults, major roles of the thyroid include involvement in the regulation of energy homeostasis.⁵ Thyroid hormones influence the function of various target organs, primarily by stimulating cell metabolism and activity. Both over- and under-function of the thyroid influence the well-being of the patient, with major dysfunction in both directions being potentially life-threatening.

Key controlling factors of thyroid hormone synthesis include the availability of external iodine; and regulation by the hypothalamic–pituitary axis (HPA).

The thyroid produces and releases tetraiodothyronine (T4) and triiodothyronine (T3), which are essential hormones for the regulation of metabolic processes. Iodine from dietary sources is absorbed and carried to the thyroid as iodide, where it is actively concentrated via the sodium (sodium) iodide symporter (NIS) and transported

TABLE 55.1 Effects and key functions of thyrotoxic or hypothyroid states in adults

	Thyrotoxicosis	Hypothyroidism
Energy metabolism	Increased basal metabolic rate Heat intolerance Weight loss*	Decreased basal metabolic rate Cold intolerance Weight gain
Carbohydrate metabolism	Stimulation of carbohydrate metabolism	
Lipid metabolism	Stimulation of lipolysis, T3 mediated down regulation of SREBP1c mRNA;47 reduction in body fat mass ¹	Reduced lipolysis, increase in body fat mass
Protein metabolism	Protein degradation, reduction of body lean mass	Decreased protein synthesis, increased body mass
Cardiovascular	Increased efficacy of catecholamines, tachycardia, tremor, peripheral vasoconstriction (skin) with increased central blood flow	Decreased efficacy of catecholamines, bradycardia, reduced exercise tolerance and myocardial contractility, exacerbated heart failure
Central nervous system	Enhanced catecholamine activity	Impairment of intellectual activity, movement and speech, impaired memory, delayed tendon reflexes, muscle weakness
Bone	Increased bone turnover, osteopaenia, osteoporosis [†]	Decreased bone turnover
Various	Turnover of vitamins, increased gut motility, erythropoiesis, involvement in the regulation of the menstrual cycle	Dry/coarse skin, hair loss, breathlessness, oligomenorrhea/amenorrhea, menorrhagia, normocytic anaemia

* In some 10% of patients, weight loss can be observed in the thyrotoxic state, related to increased appetite which may override the catabolic metabolic state.

[†] Related to activation of osteoclasts.

into thyroid follicles. The endoplasmic reticulum of the thyrocyte produces thyroglobulin (Tg) and thyroid peroxidase (TPO). Iodide is then attached to Tg via TPO, resulting in the production of mono-iodothyronine (MIT) and di-iodothyronine (DIT), with subsequent production of T3 and T4 via enzymatic coupling.

Thyroid hormone release is a complex process, involving endocytosis of Tg-containing vesicles and fusion with follicular epithelial phagolysosomes, proteolytic digestion and cleavage of Tg, intra-cellular deiodination of MIT and DIT and reuse of iodide, and finally release of T3 and T4 from the basolateral membrane into the circulation.^{5,6} Almost all of these steps are influenced by thyroid-stimulating hormone (TSH).⁷ **Table 55.1** summarizes some of the key functions of thyroid hormones in adults.

Hormones secreted by the thyroid

The thyroid produces thyroid hormones T4 and T3 and releases them into the circulating blood. Approximately 80% of thyroid hormone is secreted as T4 and peripherally converted via deiodination into T3, which shows around fivefold more potency. The half-life of circulating T3 is $\cong 1.5$ days, as compared with $\cong 7$ days of T4. Combined, this results in $\cong 40$ -fold higher plasma concentrations of T4 versus T3.⁵ T3 production is reduced in acute illness and starvation. Locally produced T3 plays important roles in several fundamental mechanisms, including thyroid homeostasis, energy balance and glucose metabolism.⁸

Thyroid hormones are bound to binding proteins in the peripheral blood. In circulating blood, only the free hormones (fT3 and fT4) exert relevant physiological actions. To assess the function of the thyroid, it is usually sufficient to measure plasma fT4, along with TSH. However, the

measurement of plasma fT3 can be valuable in situations where there is suspected excess production and release of T3, i.e. in patients with a toxic thyroid adenoma.

Synthesis of thyroid hormones

Iodine is a crucial component of thyroid hormones, which are iodothyronines. By weight, iodine comprises 65% of T4 and 58% of T3. Ingested iodine is absorbed in the small intestine and transported via the plasma to the thyroid follicular cells, where it is concentrated. Thereafter, iodine is rapidly oxidized and bound to tyrosyl residues in Tg. This is followed by intra-colloidal modification of Tg, which comprises iodination of tyrosine residues; formation of iodothyronines by oxidative coupling of two iodotyrosines; and storage of iodinated Tg as colloid. The next steps include endocytosis of iodinated Tg, merging with lysosomes and finally, mediated via TPO, conversion of the respective iodinated tyrosine residues MIT and DIT to the thyroid hormones T3 (from MIT + DIT) and T4 (from DIT + DIT) (**Figure 55.1**).^{6,9}

Selenium is another essential element for thyroid hormone synthesis. It is involved in synthesis of various enzymes, especially glutathione peroxidase.¹⁰

Antithyroid drugs interfere with the synthesis of thyroid hormones. The most important inhibitory drugs of thyroid hormone synthesis are the thionamides: methimazole and, more widely used in the UK, its prodrug carbimazole; and propylthiouracil. Propylthiouracil shows a less favourable side-effect profile compared with the thiamazoles in terms of possible agranulocytosis (not dose-dependent) and hepatic reactions, but it is preferred during the first trimester of pregnancy, due to the extremely rare possible side effect of aplasia cutis of the scalp in the foetus that has been observed with treatment with carbimazole.

**Figure 55.1 Thyroid hormone synthesis.**

Following the uptake of iodide into the follicular thyroid cell, thyroid peroxidase drives the iodination of tyrosine residues within the thyroglobulin matrix. Iodothyronines are formed by peroxidase coupling of iodothyrosyl residues, with 2 di-iodothyrosines (DIT) forming T4 and 1 MIT + 1 DIT forming T3. P, thyroid peroxidase.

Control of thyroid hormone synthesis

Release of thyroid hormones into the circulating blood involves the negative feedback system of the HPA.¹¹ A decrease in circulating T3 concentrations or a low metabolic rate signal the hypothalamus to secrete thyrotropin-releasing hormone (TRH), which in turn stimulates the secretion of TSH from the anterior pituitary gland. On the contrary, elevated circulating T3 concentrations inhibit the release of TRH and TSH directly.⁷ T4 plays an indirect role, exerting inhibitory roles mainly after conversion to T3 within the pituitary or hypothalamus. **Figure 55.2** depicts the feedback inhibition of thyroid hormones on the release of TRH and TSH.⁶

Figure 55.2 Feedback inhibition of thyroid hormones. The anterior pituitary gland increases the secretion of thyroid-stimulating hormone (TSH) when stimulated by hypothalamic thyrotropin-releasing hormone (TRH). The action of TRH is inhibited either directly by circulating T3, or indirectly, after conversion of T4 to T3, by the hypothalamus and pituitary.

TSH is a glycoprotein hormone from the anterior pituitary that influences almost all steps in both the synthesis and the release of thyroid hormones. The α -subunit is similar to that of luteinizing hormone, follicle-stimulating hormone and human chorionic gonadotropin, whereas the β -subunit is unique to TSH. It stimulates the TSH receptor (TSH-R) on thyroid follicular cells. The effects on thyroid hormone secretion appear to be mediated through the cAMP cascade, whereas the effects on synthesis are mediated by the Gq/phospholipase C cascade.⁷ TSH stimulates the expression of NIS, TPO and Tg, the generation of hydrogen peroxide (H_2O_2), and the formation of T3.⁷ Further functions of TSH involve altering the priority of iodination and hormonogenesis among tyrosyls and promoting the rapid internalization of Tg by thyrocytes. These steps are interrelated and have the net effect of increasing available iodine to the cells and finally of producing and releasing an increased amount of biologically active T3.⁷

Stimulation of TSH-R also increases the vascularity of the thyroid, an effect that is mediated via vascular endothelial growth factor (VEGF) secretion by the follicular cells. Presence of stimulating TSH-R antibodies explains that patients with Graves' disease can show excessive vascular flow in the thyroid. Although TSH is the primary regulator of thyroid function, there is evidence for additional autoregulation of the thyroid, mainly related to iodine transport and organification.

Normal range for TSH

Expert opinion on the normal range for TSH varies widely. Some assays give excessively wide 'normal ranges' from 0.35–6 mU/L, which is in part related to the use of not well-characterized cohorts from cross-sectional studies, including assumed healthy individuals with occult thyroid disease.^{12, 13} The American Association of Clinical Endocrinologists (AACE) defines a normal range for TSH

of 0.3–3.0 mU/L and the National Academy of Clinical Biochemistry of 0.4–2.5 mU/L.¹⁴ Notably, the population mean for TSH in various ethnicities appears to be lower, at 1–2 mU/L.^{15–18} Even higher normal TSH levels (>2.5 mU/L) may be related to adverse outcomes, which include associations with parameters of metabolic risk.¹⁹ After thyroidectomy, it appears reasonable titrating TSH within the ideal range in most patients. In subjects with moderate or high risk differentiated thyroid carcinomas, where TSH suppression is indicated, fT4 should be titrated towards the upper normal range. Importantly, TSH suppression is sufficient, whereas over-treatment resulting in excess fT4 levels is unnecessary and should be avoided due to risks of palpitations, atrial fibrillation and depletion of bone mass.

Iodine

Iodine is an essential mineral and the main substrate involved in thyrocyte metabolism. Potassium iodide is a man-made salt compound of iodine with increased absorption in the intestine. The normal human thyroid maintains a concentration of iodide that is 20–50 times higher than plasma concentrations, depending on the amount of available iodine and the activity of the gland.²⁰

The thyroid concentrates iodide from the extracellular fluid by an active, energy-dependent and saturable process via NIS, which is located at the basolateral membrane of the acinar cell.⁶ Iodide then diffuses via pendrin channels from the cell to the lumen at the apical membrane. Several types of control have been identified, which involve rapid and transient TSH-mediated stimulation of iodide efflux, TSH-induced blunted capacity of the active iodide transport, and transient inhibition of thyroid blood flow by iodide.⁹ The rate of uptake of iodide by the thyroid normally exceeds the rate of its incorporation into amino acids (organification) and diffusion back to the extracellular fluids, which ensures high intra-thyroidal iodide concentrations.

Adequate dietary intake of iodine is essential for thyroid hormone synthesis. The daily iodine intake of adult humans varies from less than 10 µg in areas of extreme deficiency to several hundred milligrams. In the United States, urine iodine concentrations indicate generally sufficient intake of iodine²¹, but intake in most of Europe appears to be lower. The Institute of Medicine has set the Recommended Dietary Allowance (RDA) for iodine in adults at 150 mcg/day. The minimum daily requirement to prevent goitre from iodine deficiency is thought to be 50–75 mcg/day. Both under- and over-supply of iodine influence thyroid function. Low supply with iodine is common and leads to impaired production of thyroid hormones, causing increased TSH secretion and possibly goitre in a compensatory attempt.⁷ Various other iodine deficiency disorders of the thyroid have been reported.²²

Excess iodide acutely inhibits the synthesis of thyroid hormones, the Wolff–Chaikoff effect.²³ Possible mechanisms include inhibiting the production of H₂O₂ and thus blocking the iodination of TG.²⁴ Importantly, this effect is typically short-lived, often lasting for several days only (escape from the Wolff–Chaikoff effect). Thereafter, in patients with pre-existing goitre, excess iodine can cause

severe thionamide-resistant thyrotoxicosis. Blocking an overactive thyroid with high-dose iodine before surgery is therefore not encouraged by all centres; if this procedure is chosen, thyroid surgery should be performed within the next few days. Thyrotoxic effects of excess iodine can also be observed in thyrotoxicosis type-1 induced by amiodarone (an antiarrhythmic drug that contains 75 000 µg of iodine per tablet) and in patients with goitre following the use of iodine-containing contrast medium when performing computer tomographic (CT) scans.

Thyroglobulin

Tg is the most abundant protein in the thyroid gland, with up to 200–300 g/L being stored in the follicular lumen. The main function of Tg is to provide the polypeptide backbone for the synthesis and storage of thyroid hormones.⁷ Further functions include depot capacity for the storage of iodine, thereby compensating for fluctuations in the supply of external food derived iodine. Thyroid hormones that are bound to Tg are biologically inactive.

Given that Tg is exclusively produced in thyroid, it can serve as a tumour marker after complete removal of the thyroid (total thyroidectomy followed by radioiodine treatment in patients with differentiated thyroid cancer). However, the presence of anti-Tg antibodies needs to be excluded. Interference of these antibodies with various assays can lead to either false positive and false negative results, possibly delaying the detection of a relapse, or resulting in unnecessarily repeated investigations involving radiation.

Thyroid peroxidase

TPO is produced in the endoplasmic reticulum of the thyrocytes. TPO oxidizes iodine, thereby facilitating the formation of T3 and T4 (Figure 55.1). The presence of TPO antibodies increases the risk of developing autoimmune thyroiditis.

Release of thyroid hormones

Unlike most other endocrine organs, which do not store relevant amounts of hormone, the thyroid contains the supply of Tg-bound thyroid hormones for several weeks.⁶ Upon stimulation by TSH, iodothyronines are released from Tg due to effects of lysosomal proteases, with fT4 and fT3 diffusing from the thyroid cell into the bloodstream. Both iodide and TG normally remain in the thyroid cells and are reused for hormone resynthesis.⁶ After variable periods of storage in thyroid follicles, Tg is proteolysed and the released hormones are secreted into the circulation, where specific binding proteins, most notably thyroxine-binding globulin (TBG), transport them to their respective target tissues.

Thyroxine-binding globulin in plasma (TBG)

In circulating blood ≈80% of T4 and T3 are bound to TBG and other binding proteins, which help maintain

TABLE 55.2 Effects of various factors on circulating thyroxine-binding globulin (TBG)

Circulating TBG	Causal factors
Increased TBG	Pregnancy Hepatitis Acute intermittent porphyria Drugs (i.e. oestrogen, tamoxifen, opiates, etc.) Hereditary TBG excess
Decreased TBG	Genetic reasons Chronic liver disease Nephrotic syndrome Malnutrition Cushing's disease Drugs (i.e. androgens, steroids, etc.) Acromegaly

serum free T3 and T4 concentrations within a tight range. Only unbound thyroid hormone is available to the tissues and therefore biologically active. T3 is less strongly bound than T4 and has a more rapid onset of action.

Oestrogens stimulate the expression of TBG in the liver. Therefore, from about 20 weeks of gestation, pregnant women with hypothyroidism need their L-thyroxine replacement doses to be increased to avoid hypothyroidism (Table 55.2).

Action of thyroid hormones at the tissue level

At the tissue level, the biological activity of thyroid hormone is regulated by deiodinases (DIO). DIO-1 and DIO-2 are responsible for the generation of T3 from T4, whereas DIO-3 is the major inactivating enzyme, leading to an increase of reverse T3 (rT3).²⁵ The ratio between T3 and rT3 (T3/rT3-ratio) is a sensitive indicator of peripheral thyroid hormone metabolism. The ratio is positively influenced by DIO-1 and DIO-2 and negatively by DIO-3. The T3/rT3-ratio is relatively independent of both thyroidal T4 production and thyroid hormone-binding protein variation in serum.²⁵

Calcitonin

Calcitonin is produced by the neural crest cell-derived parafollicular C-cells. The role of calcitonin in humans is not completely understood.

Calcitonin (and, less specific, carcinoembryonic antigen – CEA) can be used as tumour markers in medullary thyroid carcinoma (MCT), a rare ($\cong 4\%$ of all thyroid cancers) and frequently aggressive cancer that is often located in the upper central lobe of the thyroid gland. C-cell hyperplasia defines a MTC *in situ*, with better prognostic features. Around 80% of MCT occur sporadically. The remaining 20% are inherited syndromes such as multiple endocrine neoplasia (MEN) types 2A, 2B, or MTC only. Catecholamine-producing pheochromocytomas are a concern in MEN-2, with important implications when preparing for safe thyroid surgery.

FUTURE RESEARCH

- To develop uniform evidence-based recommendations for the follow-up of patients with differentiated thyroid cancers, with respect to risk assessment (low, medium or high risk)
- Advanced strategies to avoid inadvertent damage to the parathyroids in patients requiring total thyroidectomy
- Potential differences between thyroid hormone action in circulating blood, as compared to cellular and tissue levels
- Influence of age and developmental status on thyroid function
- Further defining risk assessment in patients with thyroid nodules
- Molecular treatment approaches for different histotypes of thyroid cancer

KEY POINTS

- TSH is the best overall parameter for assessing thyroid function and for monitoring replacement therapy.
- In medium- to high-risk thyroid cancer, TSH suppression with high normal fT4 is the aim.
- Replacement with L-thyroxine (T4) is standard. Replacement with Liothyronine (T3) is more likely to result in fluctuations of thyroid function tests and side effects, but it may be needed in rare conditions with impaired conversion of T4 to T3 or for preparation of radioiodine treatment if recombinant TSH is not available.
- Thyroid hormones should be taken at least 30 min before breakfast and isolated from caffeine-containing beverages and other tablets to facilitate more reliable absorption.
- TSH can react slowly to changes in hormone supply, especially after longer term dysfunction. Here, monitoring of fT4 (or fT3, if appropriate) gives more timely information.
- Thionamides are the treatment of choice to control thyrotoxicosis prior to surgery.
- Replacement of vitamin D before total thyroidectomy reduces the risk of severe hypocalcaemia related to inadvertent damage to the parathyroid glands.
- Screening for catecholamine-producing tumours is mandatory before performing surgery for MCT.

PHYSIOLOGY OF THE PARATHYROID GLANDS

The main function of the parathyroids is the regulation of calcium homeostasis via the secretion of PTH. There are usually four (40 mg each) parathyroid glands. Five per cent of the population have only three glands and an additional fifth gland can be found in 12–15%, with six or more glands being occasional findings.²⁶ The secretion of PTH is under negative feedback regulation by ionized calcium in the extracellular fluid. However, PTH remains detectable even when serum calcium is excessively raised, indicating that further factors contribute to the regulation of PTH secretion.

Calcium homeostasis

Calcium homeostasis is a complex process, involving serum calcium, phosphate, 1,25-dihydroxyvitamin D₃ (synonyms: 1,25(OH)₂ vitamin D₃, 'active' vitamin D, or calcitriol) and PTH. The main involved organs are the parathyroid glands, bones, kidneys and the intestine; the skin, kidneys and liver regulate vitamin D metabolism.

More than 99% of the human calcium reserve ($\cong 1.1$ kg) is stored in the bones and teeth. 'Free' ionized calcium, comprising $\cong 50\%$ of body calcium, has crucial physiological roles including cell signalling, the functioning of the heart and the nervous system, the contraction of muscles and the clotting of blood.⁶ The remainder of the calcium pool is protein-bound (40%) or forms soluble complexes with phosphate and citrate (10%). Most protein-bound calcium is attached to albumin and influenced by the pH, with acidosis increasing and alkalosis decreasing ionized calcium levels.⁵

Serum calcium concentrations are tightly regulated (normal range 2.14–2.6 mmol/L, assay-dependent). Even relatively mild acute changes can be symptomatic. Major changes in both directions can be life-threatening.

Parathyroid hormone (PTH)

The parathyroid glands secrete parathyroid hormone (PTH) after cleavage from pre-pro-PTH (115 amino acids) to pro-PTH (90 amino acids) and finally the active peptide hormone (84 amino acids). PTH is released when calcium sensors on the surface of the parathyroid glands detect low circulating serum calcium concentrations, and rapidly increases serum calcium levels. The release of PTH is inversely proportional to serum calcium, with small calcium fluctuations producing large changes in PTH secretion.²⁶ PTH blocks the renal reabsorption of phosphate in the proximal tubule and facilitates the reabsorption in the ascending loops of Henle, distal tubules and collecting tubules. In addition, PTH activates the enzyme 1-hydroxylase in the proximal renal tubules, thereby converting 25-OH vitamin D to its active metabolite, calcitriol.

In the bone, PTH promotes the absorption of calcium via a rapid and a slow phase.²⁷ The rapid phase appears to be mediated at the level of the bone cells. In response to hypocalcaemia, PTH concentrations change within 1 min, peak in 4–10 min and decline again within 60 min. The half-life of PTH is approximately 3 min. The slow phase of bone resorption is regulated via activation and proliferation of osteoclasts, with effects taking several days. These actions appear to be mediated by the differentiation of osteoclast precursors which, unlike mature osteoclasts, possess vitamin D and PTH receptors; or via cytokines that are released by activated osteocytes and osteoblasts.²⁷ Feedback inhibition of PTH release occurs primarily by direct effects of circulating calcium at the level of the parathyroid gland.

In humans, PTH fluctuates episodically at a frequency of 6–7 bursts per hour. Non-pulsatile secretion accounts for $\cong 70\%$ of total PTH secretion. Patients with excess PTH secretion (i.e. primary hyperparathyroidism, PHPT) show

both pulsatile and tonic excess secretion but unchanged pulse frequency. Constantly elevated PTH has detrimental effects on bone mass density and bone structure,²⁸ primarily due to up-regulation of nuclear factor κ B ligand (RANKL) and inhibition of osteoprotegerin expression, leading to an increase in osteoclast formation and activity.²⁹ In contrast, intermittent administration of recombinant PTH stimulates bone formation, explaining its pharmacological use for the treatment of osteoporosis.³⁰ In hypercalcaemic states, measurement of PTH is the most important measure to distinguish between PHPT and other causes of hypercalcaemia where circulating PTH is typically low, i.e. in patients with Vitamin D intoxication or malignancy (where hypercalcaemia can result from PTH related peptide (PTHrp) excess; osteolytic bones metastases; immobilization or dehydration). Importantly, patients with raised PTH together with low or lower end of normal adjusted calcium concentrations have secondary hyperparathyroidism (frequently caused by vitamin D deficiency or insufficiency), which is a physiological reaction of the parathyroids to increased serum calcium levels. Here, imaging of the parathyroids or surgical intervention would be inappropriate.

Vitamin D

Vitamin D₃ (colecalfiferol, previously cholecalciferol) is formed in the skin when a cholesterol precursor, 7-dehydroxycholesterol, is exposed to ultraviolet light (UV-B). 'Active' vitamin D (1, 25-(OH)₂ vitamin D₃) occurs after (i) 25-hydroxylation in the liver and (ii) 1-hydroxylation in the kidney (**Figure 55.3**), with major effects on calcium homeostasis. Compared with PTH, vitamin D exerts much slower but long-acting regulatory effects on calcium balance.

Active vitamin D is calciotropic, raising serum calcium by several mechanisms. These include promoting the absorption of calcium in the intestine and stimulating the formation of calcium-binding protein in the intestinal epithelial cells. Further functions include increasing bone resorption and renal calcium reabsorption, actions that are in part shared with those of PTH. Vitamin D also promotes intestinal absorption of phosphate. In bone, vitamin D may play a synergistic role with PTH in stimulating osteoclast proliferation and bone resorption, with high PTH and low phosphate levels as stimulating and with low PTH and high phosphate as inhibiting factors.⁶

Recent research also links calcitriol precursors to various physiological functions. The exact mechanisms of how increased vitamin D₃ intake inhibits PTH secretion need further investigation but are unlikely to be exclusively dependent on circulating calcitriol.^{31–34} Local mRNA and protein expression of 1-alpha hydroxylase has been described in human parathyroid glands, and this expression appears to be altered in various disorders of the parathyroids.^{33, 35, 36} Further proposed mechanisms include non-1,25(OH)₂ vitamin D-mediated effects of colecalfiferol or other vitamin D metabolites on PTH production, or stimulation of parathyroid tissue vitamin D receptors.^{32–34} Further actions may include vitamin D-mediated regulation of the expression of the calcium-sensing receptor (CaSR).^{31, 37, 38} Treatment of

Figure 55.3 Vitamin D metabolism and replacement drugs. Unlike calcitriol, alfacalcidol is a prodrug that is inactive prior to hydroxylation in the liver. This process can be impaired in patients with liver disorders.

vitamin D deficiency appears to reduce circulating PTH in patients with PHPT, without adverse effects on serum calcium concentrations.³¹ Various factors support the replacement of vitamin D deficiency in patients with PHPT: suboptimal dietary intake of vitamin D stimulates parathyroid adenoma growth and reduces the calcemic response to PTH.³¹ Apart from elevated markers of increased bone turnover,^{39, 40} patients with coexisting PHPT and vitamin D deficiency are more likely to have a larger parathyroid adenoma and higher PTH levels.^{34, 41} Recent guidelines encourage vitamin D replacement to serum 25-OH vitamin D concentrations above 50 nmol/L in all monitored patients with pHPT.⁴²

Post-operative hypoparathyroidism

Post-operative hypoparathyroidism can result in severe hypocalcaemia. Early symptoms may include anxiety, tingling of the fingers and toes, or peri-oral numbness. Acute and severe hypocalcaemia may result in papilloedema, tetany, seizures and even death. In patients with MEN type 1, all parathyroids should be removed, although autotransplantation of half a gland into the sternocleidomastoid muscle or forearm is advised to avoid severe hypocalcaemia and often major fluctuations in serum calcium levels despite replacement with active vitamin D. Post-operative hypoparathyroidism happens accidentally, for example during total thyroidectomy for thyroid cancer, Graves' disease, or surgery for multinodular goitre. It is more often temporary but can be permanent. Frequency of this complication is usually reported as 5%, but could be as high as 20% after combined thyroidectomy and radical neck dissection.^{2, 43} Treatment

with radioiodine may play a role as well, but is considered to be a rare cause of symptomatic hypocalcaemia.

Post-operative hypoparathyroidism is most frequently caused by disruption of the fine vessels that supply the parathyroids, rather than by accidental removal of all parathyroid glands.² The risk of accidental devascularization can be reduced by dissecting close to the thyroid capsule and by ligating the branches of the inferior thyroid artery on the thyroid capsule distal to their supply of the parathyroid glands, rather than by ligating the inferior thyroid artery as a single trunk.²

There is an increased risk of severe and potentially life-threatening hypocalcaemia in patients with combined PHPT and vitamin D deficiency following parathyroidectomy.⁴¹ Correcting vitamin D deficiency has been shown to reduce both the incidence of post-operative hypocalcaemia and the length of stay in hospital.⁴⁴

Calcium-sensing receptor

The calcium-sensing receptor (CaSR) is a class C G-protein coupled receptor which senses extracellular levels of calcium ions. In the parathyroid gland CaSR controls calcium homeostasis by regulating the release of PTH. Mutations that inactivate the CaSR gene cause familial hypocalciuric hypercalcaemia (FHH), which generally is asymptomatic and does not require treatment. Therefore, it is important to distinguish this benign disorder from PHPT. Not all patients with PHPT require surgical treatment, and there is consensus that asymptomatic patients with adjusted calcium concentrations below 3 mmol/L and absence of end-organ damage related to longer-term PTH excess such

as osteoporosis can be safely observed. Calcimimetics are a class of drugs with calcium-sensing receptor agonist properties that act directly on the parathyroid gland and decrease PTH release and serum calcium levels, and may also beneficially influence parathyroid tumour growth. Calcimimetics can be useful in patients with PHPT who are not eligible for surgical intervention.

Calcitonin

Calcitonin counteracts many of the functions of PTH in various species. However, in humans the biological role of calcitonin is not well defined, with both lack of calcitonin after thyroidectomy and excess of calcitonin in medullary thyroid carcinoma exerting no obvious effects on serum calcium or bone mass. Calcitonin of some other species (e.g. that of salmon, which is >15-fold more potent) is used pharmacologically for the treatment of osteoporosis and malignant hypercalcaemia.⁶ Calcitonin acts in response to acute changes in serum calcium concentrations by inhibiting calcium resorption from the bones and tubular reabsorption in the kidneys.⁵ Physiological stimuli of calcitonin secretion include hypercalcaemia and high circulating levels of gastrin.

SUMMARY OF CONSIDERATIONS OF PATIENTS WITH DISORDERS OF THE THYROID OR PARATHYROIDS

Patients undergoing surgery of the thyroid should be euthyroid. Correction of thyrotoxicosis is assessed by measurement of serum fT3 (and more slowly reacting fT4, due to longer plasma half-life; note that fT4 will show delayed decrease when the conversion of fT4 to fT3 is pharmacologically blocked), whereas a suppressed TSH alone does not define risk and may need weeks to normalize. Hypothyroidism should be treated before surgery, if possible. In emergency situations, intravenous treatment with thyroid hormones for patients with severe hypothyroidism can be provided during surgery. In patients with thyrotoxicosis and contraindications against thionamides drugs (i.e. due to carbimazole-induced agranulocytosis, with known cross-reactivity of at least 50% with all other drugs in this class), urgent surgery is mandatory to save the patient's life. Measures to reduce risk in this

situation may include high-dose treatment with propranolol (>140 mg/day are needed to block conversion T4 to T3), high-dose hydrocortisone, low-dose lithium (400–500 mg daily) (unlicensed use; with various inhibiting effects on thyroid hormone synthesis and release;⁴⁵ higher doses are discouraged and increase the rate of side effects only); or iodine, although with the latter the situation may worsen in patients with multinodular goitre related to pre-existing iodine deficiency; and surgery must be performed within the next few days.

Following total thyroidectomy, the replacement dose of L-thyroxine is usually $\cong 1.6 \mu\text{g}/\text{kg}$ body weight, to be taken first thing in the morning and at least 30 minutes before food, caffeine-containing beverages and any other tablets or supplements to facilitate more reliable absorption. Initially smaller doses with stepwise increases are advised, especially in geriatric patients and patients with risk factors such as atrial fibrillation. When TSH needs to be raised transiently (typically to >30 mU/L) prior to radioiodine treatment, the preferred choice is administration of recombinant TSH over 2 days. Alternatively, L-thyroxine can be paused and replaced by Liothyronine (T3; 20% of the dose of L-thyroxine), which is eliminated more rapidly after withdrawal. Although more cost-efficient, this method results in significant morbidity related to overt hypothyroidism, which can include severe weight gain and clinically relevant depression.

Measurement of serum-adjusted calcium, 25-OH vitamin D and PTH concentrations, and pre-operative replacement of vitamin D are recommended in patients undergoing total thyroidectomy or surgery of the parathyroid glands. Endoscopic or indirect laryngoscopy should be performed to exclude potentially asymptomatic pre-existent lesions of the vocal cords. In patients following removal of parathyroid gland(s) or in patients who underwent total thyroidectomy, close monitoring of serum calcium levels and appropriate replacement with active vitamin D preparations is crucial to avoid significant morbidity.

In patients with PHPT due to MEN 1, all parathyroid glands need to be explored and thymectomy considered, particularly when fewer than four parathyroid glands are identified.⁴⁶ Leaving a viable remnant or performing autotransplantation is recommended to avoid major swings in serum calcium levels following surgery. Patients with MTC require pre-surgical assessment (and treatment, if appropriate) for possible coexisting catecholamine excess.

FUTURE RESEARCH

- Additional strategies for preserving parathyroid function in patients undergoing total thyroidectomy; and improved strategies for the long-term treatment of patients with permanent hypoparathyroidism and hypocalcaemia
- Improved methods for the pre-operative identification of small parathyroid adenomata
- Further improvement of decision pathways for performing surgery vs. an observational approach in patients with PHPT
- Improved diagnostic and therapeutic strategies for patients with parathyroid carcinoma

KEY POINTS

- PTH concentrations are altered within 1 min, peak in 4–10 min and decline in 60 min. Absence of PTH (e.g. after inadvertent damage to the parathyroids) can result in major problems including life-threatening hypocalcaemia.
- Additional vitamin D deficiency in patients with PHPT may introduce additional (secondary) stimulation to the parathyroid glands, with further negative effects on bone mass.
- Correcting vitamin D deficiency before parathyroid surgery and total thyroidectomy can reduce both the incidence of post-operative hypocalcaemia and the length of stay in hospital.
- Alfacalcidol is a prodrug and may not work effectively in hypoparathyroid patients with impaired liver function.
- Patients with MEN 1 generally have tumours in several or all four parathyroid glands and may have additional ectopic glands (e.g. in the thymus). Minimally invasive parathyroidectomy is not recommended. Leaving a viable remnant or performing autotransplantation is recommended to avoid major swings in serum calcium levels following surgery.

Data in this chapter may be updated by a PubMed search using the keywords: pituitary hormones, growth hormone (GH), prolactin (PRL), adrenocorticotrophic hormone (ACTH), thyroid stimulating hormone (TSH), luteinising hormone (LH), follicle stimulating hormone (FSH), arginine vasopressin (AVP) and oxytocin.

INTRODUCTION

The existence of the pituitary gland (also referred to as hypophysis cerebri, derived from the Greek words *hypo*, meaning under, and *physis*, meaning growth) was known before the time of Aristotle, but its role in physiology puzzled scientists for many centuries. In AD 150, the Greek physician and philosopher Galen described the pituitary gland in detail, proposing that its role was to drain the phlegm from the brain to the nasopharynx. The gland was named with this in mind – from the Greek *ptuo* (to spit) and the Latin *pituita* (mucous) and *pituitarius* (mucous-secreting). The pituitary gland's true functions emerged over the 19th and 20th centuries, when its function as an endocrine organ was finally recognized.¹

The pituitary gland is usually less than 8 mm in length when measured in the craniocaudal plane. However in certain physiological conditions, such as puberty and pregnancy, it can be enlarged (reaching 10–12 mm). It is quite remarkable that such a small organ controls diverse and complex functions of the whole body. Although the pituitary gland is often referred to as the 'master gland' of the body (since many other endocrine glands depend on hypophyseal stimulation), the hypothalamus is the true superior regulator of the hormonal system.¹ The hypothalamus (forming the most ventral part of the diencephalon or 'midbrain') is a key regulator of homeostasis, controlling not only the release of pituitary hormones

but also a range of autonomic and behavioural functions including temperature regulation, food and water intake, sleep, circadian rhythms and mediation of emotion. The various nuclei located within the hypothalamus allow signals to pass between the nervous and endocrine system, via the pituitary gland. The hypothalamus receives both hormonal and neural input from the periphery and the brain, and it exerts its action via neural as well as humoral pathways. There are extensive vascular (long portal vessels) and neural (axons in the pituitary stalk) connections between the hypothalamus and the anterior and posterior lobe of the pituitary, as well as a vascular connection between the anterior and posterior lobe via the short portal vessels.²

Control of the endocrine system is primarily achieved by negative feedback loops, which not only act as the main form of regulation but are also important in fine-tuning the functions of the hypothalamic–pituitary–peripheral organ axis. The interplay of stimulatory and inhibitory hormones from the hypothalamus and the pituitary hormones is influenced by negative feedback loops between the periphery and central organs, as well as between the pituitary and the hypothalamus (Figure 56.1). Positive feedback also exists, primarily in the gonadal axis at the time of puberty and ovulation.³

Diagnosing pituitary tumours is often challenging, as symptoms can initially be rather non-specific. In later stages the pituitary mass may lead to local tumour effects,

Figure 56.1 Interplay of stimulatory and inhibitory hormones from the hypothalamus and the pituitary hormones. Primary hormone deficiency results from the damage of the peripheral gland or its function, which usually leads to elevated pituitary stimulatory hormone levels. For example, primary hypothyroidism results in high TSH, adrenal failure leads to high ACTH levels, etc. Secondary hormone deficiency is due to damage to the pituitary, such as a pituitary lesion destroying the gland. Tertiary deficiency is due to damage to the hypothalamus. Blue arrows show inhibition; red arrows show stimulatory effects.

Abbreviations: GHRH: growth hormone-releasing hormone; SS: somatostatin; TRH: thyrotrophin-releasing hormone; GnRH: gonadotrophin-releasing hormone; CRH: corticotrophin-releasing hormone; AVP: arginine vasopressin; GH: growth hormone; TSH: thyroid-stimulating hormone; PRL: prolactin; FSH: follicle-stimulating hormone; LH: luteinizing hormone; ACTH: adrenocorticotrophic hormone; IGF-1: insulin-like growth factor 1; T3: triiodothyronine; T4: thyroxine.

such as headaches and characteristic visual field defects if the tumour is large enough to compress nearby tissues, particularly the optic chiasm.

ANTERIOR LOBE OF THE PITUITARY GLAND

The anterior lobe of the pituitary, the adenohypophysis, comprises approximately 75% of the total pituitary volume. It is functionally linked to the hypothalamus by blood vessels in the pituitary stalk which transmit regulatory hypothalamic hormones to the pituitary. These stimulate or inhibit the synthesis and release of pituitary hormones. The anterior pituitary consists of five major cell types (each secreting specific hormones), organized into cords of cells located around venous sinusoids. The six major hormone products of the anterior pituitary (Table 56.1) are secreted into the sinusoids from which they enter the circulation.

Other less common cells in this area include somatomammotrophs, a rare cell type that secretes both growth hormone (GH) and prolactin (PRL) and a unique star-shaped, non-endocrine cell type, the so-called folliculostellate cell. These cells have been shown to be important for cell-to-cell interaction and regulation within the pituitary.⁴ More recently, a few stem cell-like cells have also been discovered in the adult pituitary located mostly at the border of the anterior and posterior lobe ('marginal zone') and their role in pituitary tumorigenesis is currently under investigation.^{5, 6}

The growth hormone axis

The existence of a hormone responsible for growth was first proposed by Cushing in the early 1910s but the hormone itself was not isolated until 1956.⁷ Growth hormone (GH) is a 191-amino acid polypeptide synthesized by the somatotroph cells, which make up 40–50% of anterior pituitary cells. The main functions of GH are to stimulate growth and regulate cell turnover and repair. At a cellular level, this results in enhanced protein synthesis, facilitating amino-acid transport, mobilizing free fatty acids from adipose tissues, decreasing glucose uptake and increasing gluconeogenesis. The most notable targets of GH are the growth plates of long bones leading to the characteristic increases in bone length seen during childhood, but GH also regulates soft-tissue growth. GH excess in childhood results in overly increased linear bone length and gigantism, while in adults (in whom the epiphyseal plates are now fused, preventing further elongation of the long bones) increases in bone width occur instead, resulting in the characteristic facial and hand/foot changes associated with the diagnosis of acromegaly. Other clinical features of acromegaly include prominent soft-tissue swelling of internal organs, such as the heart, bowels and liver. Cartilaginous enlargement also occurs, leading to rheumatological problems and altered laryngeal anatomy, with resultant deepening of the voice. Finally, as the skull enlarges, the paranasal sinuses also increase in size, particularly the frontal sinuses, and the jaw enlarges with resultant malocclusion and prognathism.

GH acts via the GH receptor (GHR), which belongs to the type I cytokine receptor family. GH binding to the dimerized GHR activates Janus kinase 2 (JAK2) and signal transducer and activator of transcription (STAT) (Figure 56.2). While

TABLE 56.1 Main cell types of the anterior pituitary gland

Cell type	Percentage of total pituitary cells (%)	Hypothalamic regulatory hormone	Hormone secreted	Main target organs
Somatotrophs	45–50	Stimulation: growth hormone releasing hormone (GHRH) and ghrelin Inhibition: somatostatin (SST)	Growth hormone (GH)	Liver, muscle, bone, cartilage, adipose tissue
Thyrotrophs	5	Stimulation: thyrotrophin releasing hormone (TRH)	Thyroid-stimulating hormone (TSH)	Thyroid gland
Lactotrophs	10–30	Stimulation: TRH Inhibition: dopamine	Prolactin (PRL)	Mammary gland
Gonadotrophs	10–15	Stimulation: gonadotrophin releasing hormone (GnRH)	Follicle-stimulating hormone (FSH) Luteinizing hormone (LH)	Ovary and testis
Corticotrophs	10–20	Stimulation: corticotrophin releasing hormone (CRH), arginine vasopressin (AVP)	Adrenocorticotrophic hormone (ACTH)	Adrenal gland (cortex)

Figure 56.2 GH action. Ligand binding to the pre-formed GHR dimer results in internalization and relative rotation of the subunits in the homodimer, subsequently causing JAK2 phosphorylation (P) and signal transduction. GH signalling may be mediated by JAK2-independent signalling (Src/ERK) pathways. GH targets include IGF-I, c-fos, genes involved in cell proliferation, glucose metabolism and cytoskeletal proteins. IGF-I may also block GHR internalization, acting in a feedback loop. The GHR antagonist pegvisomant used in the treatment of acromegaly, blocks GHR signalling via inhibitory rotation.

Abbreviations: GH: growth hormone; GHR: growth hormone receptor; JAK2: Janus kinase 2; P: phosphor group; STAT: signal transducer and activator of transcription; SHC: SH2-containing protein; IRS: insulin receptor substrate; CoAA: nuclear receptor coactivator AA; IMP α/β : importin α/β ; MAPK: mitogen-activated protein kinases; PI3K: phosphatidylinositol 3-kinase; ERK: extracellular signal-regulated kinase; MEK: MAP kinase kinase; RAS: rat sarcoma protein family; RAF: rapidly accelerated fibrosarcoma protein kinase family; c-fos: Fos Proto-Oncogene; AP-1: Transcription Factor Subunit; IGF-1: insulin-like growth factor 1.

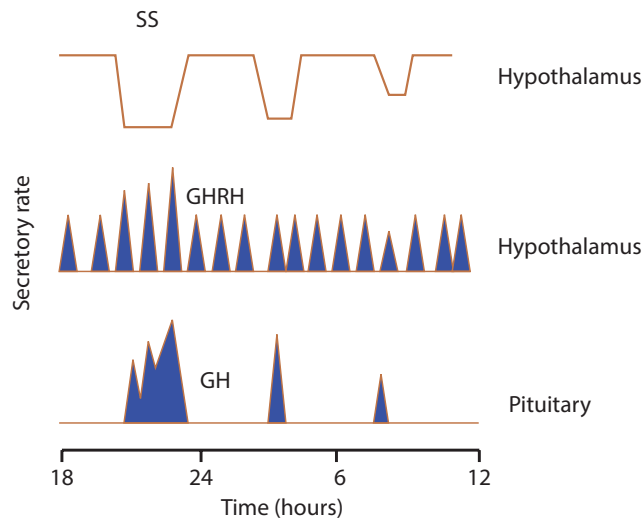

Figure 56.3 Secretion of growth hormone. A simplified schematic representation of pulsatile secretion of growth hormone (GH) in response to growth hormone-releasing hormone (GHRH) and growth hormone inhibitory hormone (SS, somatostatin) impulses. (Adapted from Hartman et al. Temporal structure of *in vivo* growth hormone secretory events in humans. Redrawn from ref.)⁹

GH exerts its direct metabolic effects via this pathway, other effects are exerted through insulin-like growth factor type 1 (IGF-1), synthesized not only in the liver but in all local tissues, and responsible for the growth effects of the hormone. IGF-1 binds to the type 1 IGF receptor, which belongs to the membrane-bound tyrosine kinase receptor family.⁸

GH is secreted in a pulsatile manner (Figure 56.3)⁹ in response to an interplay of hypothalamic hormones. GH release is stimulated by both growth hormone-releasing hormone (GHRH) and ghrelin (the brain-gut peptide, mainly synthesized by neuroendocrine cells in the gastric mucosa) while somatostatin (SS) is inhibitory in action. Animal data suggest that ghrelin-induced GH release has a role in maintaining glucose levels during fasting.¹⁰ GHRH, SS and ghrelin act by binding G-protein coupled receptors: the GHRH receptor, five major subtypes of SS receptors and the type 1a growth hormone secretagogue receptor (also called ghrelin receptor). Animal data suggest that a tightly regulated network of somatotroph cells, known as ‘clusters’, allows rapid, large increases in circulating GH levels.

GHRH has a complex regulatory function on GH:

- It causes immediate release via activation of cAMP and Ca²⁺ in somatotrophs.
- GHRH triggers GH synthesis by stimulating the transcription factor POU class 1 homeobox 1 (PUOF1, previously called Pit1).
- It increases GH cell number.
- It stimulates the formation of GH cell clusters.

An understanding of the second messenger pathway of the GHRH receptor is important, since several genetic defects involving this pathway can result in excess GH secretion and its associated complications (Figure 56.4). The stimulatory subtype of the alpha subunit of the G protein (G α) activates adenylyl cyclase, following which

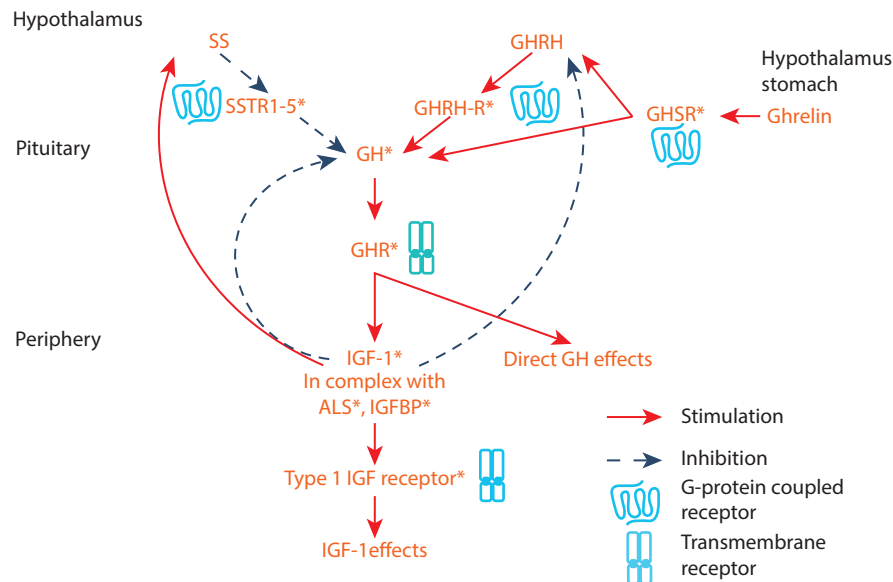

Figure 56.4 Growth hormone axis. A simplified scheme of the growth hormone (GH) axis. Inhibitory somatostatin (SS) and stimulatory growth hormone-releasing hormone (GHRH) impulses coming from the hypothalamus regulate GH release from the pituitary. GH exerts its effects either directly or via IGF-1. GH stimulates IGF-1 synthesis in all peripheral tissues. Circulating IGF-1 primarily represents liver IGF-1 synthesis. Ghrelin is also a potent GH-releasing hormone. IGF-1 regulates GH release via negative feedback to the hypothalamus and the pituitary.

Abbreviations: GH: growth hormone; GHRH: growth hormone releasing hormone; GHRH-R: growth hormone releasing hormone receptor; SS: somatostatin; SSTR1-5: somatostatin receptors 1-5; IGF-1: insulin-like growth factor 1; IGFBP: insulin-like growth factor binding protein; ALS: acid labile subunit.

*Mutations in these components of the pathway have been described in patients presenting with short stature.

Figure 56.5 Signal transduction in the growth hormone cell. Following ligand binding, the alpha subunit of the Gs protein dissociates from the beta and gamma subunits and activates AC. cAMP is synthesized, and this binds to and inhibits the regulatory subunit (R) of protein kinase A (PKA). The catalytic subunit (C) is now free to enter the nucleus and phosphorylate the CREB, which upregulates GH synthesis. A gain of function mosaic (McCune-Albright syndrome) or somatic mutation (seen in 40% of sporadic acromegaly adenomas) in the Gs alpha subunit (GSP) leads to GHRH-independent upregulation of the pathway. In Carney complex there is a loss of function in the regulatory subunit of PKA, or gain of function of the catalytic subunit leading to cAMP-independent activation of PKA. Alterations are marked with yellow leading to different disease conditions.

Abbreviations: Gs: G-protein adenylate cyclase stimulator; AC: adenylate cyclase; cAMP: cyclic adenosine monophosphate; PDE: phosphodiesterase; PKA: protein kinase A; CREB: cAMP response element binding protein; GH: growth hormone; GHRH: growth hormone releasing hormone; GHRH-R: growth hormone releasing hormone receptor; ATP: adenosine triphosphate; Puof1: pituitary-specific positive transcription factor 1; GSP: stimulatory G protein.

*Mutations in these components of the pathway have been described in patients presenting with short stature.

synthesized cAMP binds and inhibits the regulatory subunit of protein kinase A. The catalytic subunit of protein kinase A phosphorylates the cAMP response element binding protein which in turn upregulates PUOF1 and GH synthesis (Figure 56.5).¹¹

GH levels change throughout life. The highest levels occur during puberty, after which there is a gradual decline (Figure 56.6).¹² GH levels also show circadian variation with the highest levels occurring during the night, and low, often undetectable levels during the day. We clinically utilize this circadian rhythm when serial GH samples are taken in the diagnostic workup of GH-excess or GH-deficient patients.¹³ IGF-1 circulates in a complex with IGF-binding proteins (mostly IGFBP3). The acid labile subunit and IGF-1 levels are steady during the day and a gradual decline is seen with age, therefore age-specific normal ranges should be used to assess circulating hormone levels.

The regulation of growth and the GH axis is a complex process. It is influenced by various activities such as sleep (GH levels are high during the night), calorie intake (GH levels increase at fasting), exercise (increases GH release) and inflammation (chronic inflammation reduces the activity of the growth axis). Oestrogen stimulates GH release

both via the hypothalamus and by direct action on the pituitary gland but it inhibits GH effects via upregulating an inhibitor of GH receptor signalling pathway SOCS2 (suppressors of cytokine signalling 2).¹⁴ Overall, females need higher GH levels to achieve the same IGF-1 level.

The thyroid axis

Thyroid-stimulating hormone (TSH) is synthesized in the thyrotroph cells and its release is triggered by binding of thyrotrophin-releasing hormone (TRH) to the TRH receptor (Figure 56.7). TRH is synthesized in the paraventricular nucleus of the hypothalamus. TSH secretion is inhibited by somatostatin.³ Interestingly, TRH also stimulates prolactin release from the pituitary. This is clinically relevant since in untreated primary hypothyroidism the high TRH level stimulates prolactin release, leading to hyperprolactinaemia and hypogonadism, which could pose a diagnostic problem if the link were not appreciated.³ The glycoprotein hormone TSH is a heterodimer comprising two subunits. The alpha subunit, a protein made up from 89 amino acids, is common to TSH, LH, FSH and human chorionic gonadotrophin (HCG), while the beta subunit (112 amino acids) is specific to TSH. TSH is produced by the thyrotroph cells of

Figure 56.6 The 24-hour integrated concentration of GH. The mean 24-h concentration of growth hormone, designated the integrated concentration levels change throughout life, reaching a peak level during puberty then decreasing by age. Figure adapted from Zadik et al.¹²

Figure 56.7 Thyroid axis. A simplified scheme of the hypothalamo–pituitary–thyroid gland axis. Hypothalamic hormone TRH stimulates TSH release from the pituitary. TSH binds to the TSH-receptor on the thyroid gland and activates thyroid cells, which results in increased iodine uptake, thyroglobulin synthesis, thyroid peroxidase activity and thyroxine release.

Abbreviations: TRH: thyroid releasing hormone; TRH-R: thyroid releasing hormone receptor; TSH: thyroid stimulating hormone; TSH-R: thyroid stimulating hormone receptor.

* Mutations in these components of the pathway have been described in patients presenting with abnormal thyroid function.

the anterior pituitary and is essential for regulating the thyroid gland and consequently the metabolic activity of the body.^{2,3} TSH activates thyroid cells by binding to the TSH receptor, thus stimulating the cAMP pathway, leading to increased iodine uptake, thyroglobulin synthesis, thyroid peroxidase activity and thyroxine release.¹⁵ Iodine is a crucial component of both thyroxine and triiodothyronine, and lack of iodine in the diet can lead to reduced thyroid hormone synthesis, therefore elevated TSH due to negative feedback and significant thyroid enlargement (endemic goitre). Recently, ‘thyrostimulin’, an alternative TSH receptor ligand, has been identified, but its precise physiological role is yet to be elucidated.¹⁶

Circulating TSH is known to exhibit a circadian rhythm with higher levels during the night and its pulsatile secretion is synchronized with hypothalamic PRL

pulses, as TRH has a stimulatory effect on the release of both PRL and TSH.³ The availability of sensitive TSH assays allows us to diagnose subclinical hypo- or hyperthyroidism. Screening for congenital hypothyroidism using the Guthrie-devised heel-prick blood test relies on sensitive TSH measurements to identify hypothyroidism in neonates 2–3 days old. Recent data suggest that women planning pregnancies should have strictly normal TSH levels for the optimal central nervous system development of the foetus. Patients with pre-existing thyroid hormone replacement need usually increase the dose of hormone replacement during early stages of pregnancy.

Thyroid cells synthesize thyroxine (T4) and in smaller amounts its active derivative triiodothyronine (T3), which has a much shorter half-life. Thyroid hormones circulate in the bloodstream in a ratio of approximately 20:1 T4:T3,

bound to thyroglobulin (Tg), which is synthesized by the follicular cells of the thyroid gland. Thyroglobulin levels can be used as tumour markers in patients with papillary or follicular thyroid cancers, hence regular Tg level monitoring may facilitate detection of early recurrence. Sex steroids can alter thyroglobulin synthesis, so measurement of free thyroid hormones (fT4 and fT3) is a better reflection of thyroid status.¹⁷ T4 is converted to the active T3 form in peripheral tissues; T3 is inactivated by conversion to reverse T3 (under the influence of D3 deiodinase enzyme). Deiodinase enzymes contain selenium, therefore dietary selenium insufficiency can result in low T3 levels and there is now evidence that selenium supplements are beneficial for patients with Graves' ophthalmopathy.

Thyroid disease is one of the most common endocrine diseases. A wide range of congenital and acquired aetiologies underlie thyroid disease including: euthyroid goitre (due to mild iodine deficiency), thyroid nodules, thyroid cancer, autoimmune hypothyroiditis (Hashimoto's thyroiditis) or hyperthyroidism (Graves disease), contrast agent- or amiodarone-induced abnormalities, TSH-secreting pituitary tumours and a range of genetic syndromes affecting pituitary transcription factors. Less common causes include sick euthyroid syndrome, where the patient's blood tests demonstrate a pattern of thyroid hormone alterations during non-thyroidal illness with normal TSH, low total T4, fT3 and elevated reverse T3 levels,¹⁸ and Pendred syndrome, a congenital autosomal recessive disease which results from a mutation in the iodine/chloride transmembrane transporter pendrin. In thyroid cells, pendrin transports iodine from the cytoplasm to the colloid, where it is organized into thyroglobulin during thyroid hormone synthesis. Mutations in this transporter cause progressive bilateral high-frequency sensorineural hearing loss (often secondary to minor head trauma) possible vestibular dysfunction and abnormal thyroid hormone synthesis with goitre developing in early puberty/young adulthood.¹⁸ This condition is often associated with Mondini malformation of the cochlea and enlarged vestibular aqueducts.

Prolactin

The lactotroph hormone prolactin (PRL) was discovered in the early 1930s and was named for its effect on lactation and mammary gland development.¹⁹ Both PRL (198 amino acid protein) and its receptor share similarities with GH. Primarily synthesized and secreted by the lactotroph pituitary cells,²⁰ PRL is also secreted by extrapituitary sites such as the mammary gland, placenta, uterus and T lymphocytes.²¹ The most prominent effects of prolactin are the effect on milk production, inhibition of the gonadal axis and regulation of immune function. Its hypothalamic control is different from other pituitary hormones. The hypothalamus has a primary inhibitory input on prolactin synthesis and release, therefore any damage to the hypothalamus or pituitary stalk can result in hyperprolactinaemia.¹⁹

Prolactin levels in maternal blood rise from the fifth week of pregnancy and peak at parturition. Loss of placental oestrogen and progesterone disinhibits the milk ejection response to suckling.^{2, 20} Basal prolactin level typically

returns to normal within a couple of weeks after the delivery, but each nursing episode results in temporarily increased PRL secretion.² Prolactin exerts its inhibitory action on the gonadal axis via inhibiting kisspeptin release from the kisspeptin neurons.²³ Furthermore, it has been shown to counteract the effects of dopamine on sexual arousal (dopamine rises during intercourse and decreases rapidly afterwards), which may explain the decreased libido frequently reported by patients suffering from hyperprolactinaemia. TRH stimulates prolactin release and this is of clinical importance in primary hypothyroidism, since mild hyperprolactinaemia frequently accompanies primary hypothyroidism.¹⁹⁻²¹

Although high prolactin is a typical sign of a prolactin-secreting pituitary adenoma (prolactinoma), the differential diagnosis of hyperprolactinaemia is broad. High prolactin levels occur physiologically during pregnancy, stress and exercise. PRL can be elevated by administering dopamine antagonist drugs including psychotropic drugs (used to treat depression and schizophrenia), as well as verapamil, metoclopramide, opiates, cocaine and protein inhibitors, even after short-term use. It is also affected by some medicinal herbs, such as star anise, fenugreek, fennel seeds and red clover.² Other causes of raised prolactin levels include polycystic ovary syndrome (PCOS), herpes zoster infection of the chest, thoracic surgery, renal failure and liver cirrhosis.^{24, 25} PRL levels can double due to stress, increase to 5 times the upper limit of normal due to stalk effect (pituitary stalk compression), increase 5–10 times due to small microadenomas or drugs, and 10–100+ times due to larger adenomas. Pituitary-dependent hyperprolactinaemia can result from a prolactinoma or an adenoma (endocrinologically active or inactive) compressing the pituitary stalk, preventing dopamine (prolactin release inhibiting hormone) reaching lactotrophs.^{26, 27} Prolactin-secreting tumours lead to inhibition of the gonadal axis and can induce galactorrhoea and cause local tumour effects. Small adenomas (microprolactinomas, <1 cm) are more commonly identified in females, while males usually harbour macroprolactinomas (>1 cm) at presentation. In the majority of the cases dopamine agonist drugs (cabergoline or bromocriptine) have an excellent effect both on hormone reduction and on tumour shrinkage.^{24, 25} Prolactinomas can be part of multiple endocrine neoplasia type 1 syndrome (MEN1) which is associated with hyperparathyroidism and pancreatic adenomas.

The gonadal axis

Luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are glycoprotein hormones. Although they are both synthesized in the gonadotroph cells and regulated by the same stimulatory hypothalamic hormone gonadotroph-releasing hormone (GnRH), their levels vary considerably during the female cycle. The frequency of GnRH pulses is the main determinant of this differential regulation with slow pulses leading to FSH release and rapid pulses to LH release.³ Numerous further factors regulate the system (Figure 56.8). Pulsatile GnRH secretion is an important hallmark of gonadal regulation. If continuous GnRH secretion is present, the GnRH receptors in the

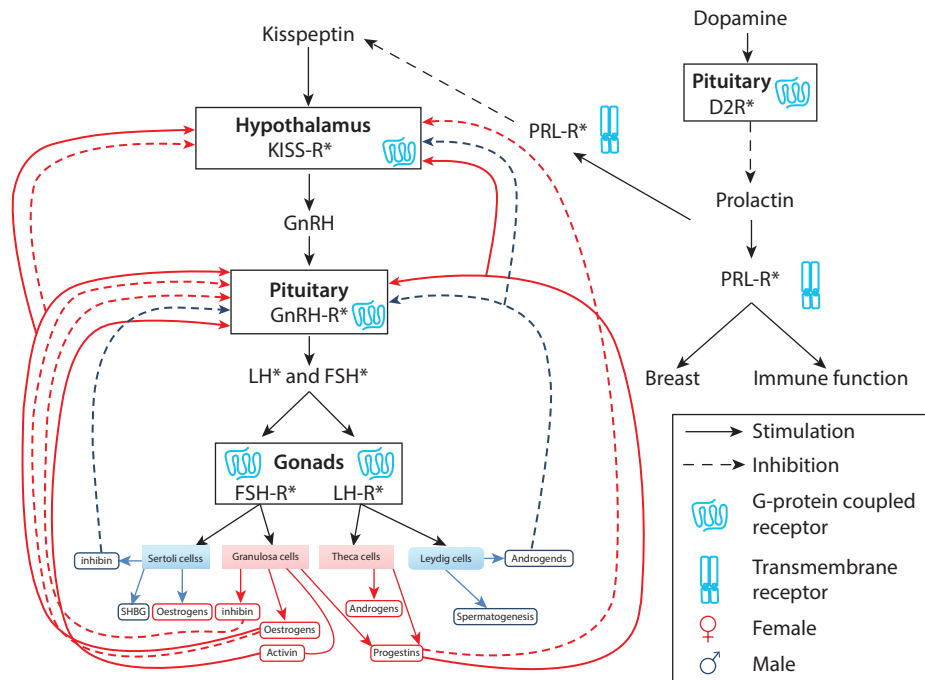

Figure 56.8 Gonadal axis. A simplified scheme of the gonadal axis. Hypothalamic hormone GnRH stimulates LH and FSH release from the pituitary gland. Prolactin inhibits the gonadal axis by inhibiting kisspeptin release from the kisspeptin neurons in the hypothalamus. As shown in the diagram, there are differences between male (blue lines) and female (red lines) with respect to signalling and feedback loops. SHBG (in the testis, also called androgen binding protein).

Abbreviations: KISS-R: kisspeptin receptor (also known as GPR54); GnRH: gonadotrophin releasing hormone; LH: luteinising hormone; LH-R: luteinising hormone receptor; FSH: follicle stimulating hormone receptor; SHBG: sex hormone binding globulin; D2R: dopamine receptor 2; PRL-R: prolactin receptor.

*Mutations in these components of the pathway have been identified in patients with abnormal gonadal hormone synthesis.

pituitary desensitize and the gonadal axis is turned off. This phenomenon is utilized in treatment of some diseases where gonadal steroids need to be inactivated, such as prostate cancer, breast cancer and endometriosis, or when premature puberty needs to be delayed.²⁸ Patients with tertiary hypogonadism (hypogonadotropic hypogonadism) can be treated with pulsatile GnRH treatment using a pump device.²⁸

Secretion of GnRH is primarily regulated by 17β -oestradiol (E_2) acting via oestrogen receptor alpha ($ER\alpha$). However, as GnRH neurons do not express $ER\alpha$, regulation of hypothalamic function by oestradiol is mediated by kisspeptin neurons, which do express this receptor and are thought to relay information regarding oestrogen levels directly to the GnRH neurons.²⁹ In addition, the inhibitory feedback of prolactin on the gonadal axis occurs via kisspeptin, as GnRH neurons do not express prolactin receptors either, therefore rendering them insensitive to circulating prolactin levels.³⁰ Kisspeptin and its receptor KISS-R (G-protein-coupled receptor 54, GPR54) are recently identified members of the gonadotroph axis. Kisspeptin is synthesized in several hypothalamic nuclei including the arcuate nucleus and the preoptic area. More recently, a gonadotrophin inhibitory hormone (GnIH) has been described in birds.³¹ The role of its mammalian counterpart RFamide-related peptide (RFRP) and its putative G-protein coupled receptor OT7T022 (also known as neuropeptide FF receptor type 1) is currently under investigation.

There is an interesting interface between the gonadal axis and the olfactory system. During embryogenesis, GnRH cells are located at the top of the nasal cavity together with cells of the olfactory system. GnRH cells then migrate to the hypothalamus. Patients with loss-of-function mutations in peptides involved in this migration develop hypothalamic hypogonadism. When this condition occurs in combination with decreased sense of smell, either partial (hyposmia) or total (anosmia), the underlying condition is referred to as Kallmann syndrome.³² From an ENT perspective, the condition is associated with craniofacial defects such as cleft palate and sensorineural hearing loss.

LH

In females, LH is responsible for follicular development, ovulation and development of the corpus luteum, while in the male it acts on Leydig cells within the testis, stimulating testosterone production.² Binding to the G-protein-coupled transmembrane receptor, the luteinizing hormone receptor (LH-R) exerts its effects on the ovarian theca cells to enhance oestrogen production of the granulosa cells. At the beginning of the cycle, FSH stimulates these granulosa cells, leading to elevated oestrogen levels and follicular maturation. Elevated oestrogen levels may lead to ovulation by a positive feedback effect on arcuate kisspeptin neurons that stimulate GnRH, thus leading to sudden LH release. This 'LH surge' acts as the trigger for

ovulation, resulting in the egg leaving the follicle and the follicle beginning to become the corpus luteum, secreting progesterone to make the endometrium ready for implantation.²

Slightly elevated LH levels are observed in polycystic ovary syndrome and precocious puberty. Marked elevation is typically due to the lack of gonadal negative feedback, which results in excessive production of LH and FSH in the anterior pituitary, such as in primary ovarian failure and the menopause. Low LH levels are associated with hyperprolactinaemia, eating disorders and certain congenital conditions where patients present with infertility. Synthetic LH-analogues (such as human chorionic gonadotropin – better known as HCG) are commonly used for ovulation induction and managing male infertility.

FSH

FSH stimulates follicular growth. Its level drops after the follicle has reached full maturation but rises slightly again at the end of the menstrual cycle, contributing towards the initiation of the next cycle. In males, FSH stimulates the gonadal Sertoli cells to produce spermatozoa as well as inhibin, which in both females and males inhibits FSH production. Low FSH secretion can be observed in conditions resulting in infertility and loss of gonadal functions.² High FSH is an early sign of the menopause or primary gonadal damage (e.g. autoimmune or cytostatic-induced). Synthetic FSH is available for ovulation induction or induction of spermatogenesis.

The hypothalamic–pituitary–adrenal axis

Adrenocorticotrophic hormone (ACTH), secreted by corticotroph cells, is derived from the pro-hormone pro-opiomelanocortin (POMC). Typically produced in response to stress, ACTH functions to increase production and release of corticosteroids. It stimulates cortisol synthesis and release from the adrenal cortex (but it also has some effect on aldosterone and androgen secretion) (Figure 56.9).² ACTH release from the pituitary is regulated by corticotrophin-releasing hormone (CRH) and arginine vasopressin (AVP), both synthesized in the paraventricular nucleus. The latter hormone reaches the anterior pituitary gland via the short portal vessels.²

Nearly all types of stress, physical or emotional, and food intake lead to immediate and significant increase in ACTH and cortisol secretion.² There is a prominent circadian rhythm operating in the HPA axis, with high hormone levels in the early morning hours. This is followed by a gradual reduction in hormone levels through the day such that cortisol levels during the night are undetectable.²

In addition, ACTH secretion has a superimposed pulsatile release pattern. The increase in cortisol is crucial for the appropriate stress response of the body and, if the hypothalamic–pituitary–adrenal (HPA) axis is compromised, cortisol treatment is life-saving in stress situations such as infection or surgery. Since ACTH is derived from POMC, conditions that lead to synthesis of large amounts of ACTH will also result in accumulation of other POMC-derived peptides. Raised levels of the alpha melanocyte-stimulating hormone lead to characteristic

Figure 56.9 Hypothalamic–pituitary–adrenal (HPA) axis. A simplified scheme of the hypothalamic–pituitary–adrenal (HPA) axis. The hypothalamic hormone CRH stimulates ACTH release. Arginine vasopressin (AVP), which is also a hormone of the posterior pituitary and has a role in regulating water balance, is another significant stimulator of ACTH. Its main effect is acting synergistically with CRH, but it also has a direct effect on the pituitary. It has been suggested recently that CRH is the basis of constant basal release of ACTH, while AVP adds peaks in stress situations. ACTH binds to its receptor MC2R and stimulates cortisol release. Cortisol may undergo alteration via the 11 beta hydroxysteroid dehydrogenase type 1 and 2 (11HSD1&2) before binding the glucocorticoid receptor.

Abbreviations: CRH: corticotrophin releasing hormone; CRH-R: corticotrophin releasing hormone receptor; POMC: pro-opiomelanocortin; ACTH: adrenocorticotrophic hormone; MC2R: melanocortin 2 receptor; GC: glucocorticoid; HSD: hydroxysteroid dehydrogenase enzymes.

* Mutations in these components of the pathway have been identified in patients with abnormal HPA axis hormone synthesis.

darkening of the skin. This phenomenon is seen in adrenal insufficiency, ectopic ACTH-secreting tumours and Nelson syndrome.

Abnormalities can occur in the HPA axis at several levels. Depression can cause chronic central stimulation of the HPA axis. ACTH-secreting adenomas, ectopic ACTH-secreting tumours and adrenal cortisol-secreting tumours lead to Cushing's syndrome. Cushing's syndrome is a hormone disorder that results from high levels of cortisol in the blood, while Cushing's disease refers to one specific cause of Cushing's syndrome, a corticotroph adenoma in the pituitary gland that produces large amounts of ACTH. POMC mutations lead to glucocorticoid deficiency together with altered skin colouring and obesity due to the lack of ACTH and alpha melanocyte-stimulating hormone. Damage to the adrenal gland (causes include autoimmune and infective, e.g. tuberculosis) results in Addison's disease (primary adrenal insufficiency). Familial glucocorticoid deficiency arises secondary to mutations in the *MC2R* or its accessory protein MRAP (*MC2R* accessory protein), and further genes have been recently identified in the steroidogenic pathway. Abnormalities in the steroid synthesis pathway (as seen in congenital adrenal hyperplasia) may lead to glucocorticoid deficiency in some cases. Finally, abnormalities in the pre-receptor metabolism of cortisol or mutations in the glucocorticoid receptor itself will also lead to abnormalities in the HPA axis.

The most common and clinically relevant situation regarding the HPA axis occurs in patients receiving exogenous glucocorticoid treatment, usually in the form of prednisolone or dexamethasone. In these patients the endogenous HPA axis is suppressed and they do not exhibit a normal stress hormone response. For infections, doubling the standard glucocorticoid replacement dose is advisable; for surgery, intra-muscular 100 mg hydrocortisone every 8 hours for 24 hours and then oral treatment in gradually decreasing doses is recommended.

POSTERIOR LOBE OF THE PITUITARY GLAND

The posterior lobe of the pituitary gland, the neurohypophysis, consists of nerve fibres originating from the supraoptic and paraventricular nuclei of the hypothalamus. The supraoptic and paraventricular nuclei synthesize two cyclic nonapeptides. The resulting hormones are known as arginine vasopressin (AVP, previously known as antidiuretic hormone, ADH) and oxytocin, respectively (Figure 56.10). The hormones are transported to the posterior lobe of the pituitary gland via the pituitary stalk, loosely bound to their carrier protein neurophysin. Within the posterior lobe of the pituitary, nerve axon terminals are located close to blood vessels. Upon activation, the secretory granules rapidly release the hormones by a calcium-dependent exocytic process,² allowing them to diffuse into the local capillary network. The role of AVP in rapid ACTH release has been well described.²

Arginine vasopressin (AVP)

Oxytocin

Figure 56.10 The chemical structure of arginine vasopressin (AVP) and oxytocin. Both AVP and oxytocin are nine amino acid peptide hormones (nonapeptides) released from the posterior lobe of the pituitary gland. Their structural similarity (they have all but one amino acid in common) may be the reason behind their functional similarities.

Arginine vasopressin

Arginine vasopressin (AVP) is primarily produced in response to reductions in plasma volume and/or increased plasma osmolality.² The plasma half-life of AVP is relatively short (15–30 minutes) therefore plasma levels can vary greatly over short periods of time.³³ AVP regulates renal excretion of water and is the primary determinant of urine concentration. Very small amounts of AVP can have a significant inhibitory action on water excretion in the kidneys, an effect known as antidiuresis. AVP is released from the posterior hypothalamus in response to increases in plasma osmolality (Figure 56.11). As more water is reabsorbed, the urine becomes more concentrated. Certain drugs can modify AVP plasma levels: for example, ethanol, mineralocorticoids and glucocorticoids decrease AVP level, while selective serotonin reuptake inhibitors (SSRIs), nicotine and carbamazepine can increase its level in peripheral blood.

The precise mechanism by which increased plasma osmolality triggers AVP release is yet to be elucidated; however, it is suggested that osmoreceptor cells release water upon higher fluid concentration via osmosis, ultimately leading to increased AVP production and secretion in the hypothalamus and neurohypophysis.² In addition to increasing osmolality, carotid, aortic and pulmonary baroreceptors detect the resulting hypotension, which stimulates vasopressin release (Figure 56.12).²

In patients with complete absence of AVP, the collecting tubules and ducts are almost impermeable to water resulting in daily fluid loss of up to 20 litres via the urinary tract.^{2, 34}

Insufficient AVP or reduced AVP action results in production of excessive amounts of inappropriately dilute urine, a hallmark of diabetes insipidus (DI). This disease can be either central (hypothalamic) or nephrogenic. In central DI there is a defect in AVP synthesis or secretion, typically due to pituitary stalk damage, head trauma,

Figure 56.11 Signal transduction in the renal collecting duct cell. Following the binding of AVP by the V2R, the alpha subunit of the Gs protein dissociates from the beta and gamma subunits and activates adenylyl cyclase. cAMP is synthesized, which binds to and inhibits the regulatory subunit (R) of protein kinase A (PKA). The catalytic subunit (C) can enter the nucleus and phosphorylate the cAMP binding element (CREB), which upregulates aquaporin 2 synthesis. Four AQP2 molecules assemble to create a water channel at the luminal border, allowing water to be reabsorbed from the collecting duct back to the cell, and then via AQP3 and AQP4, from the cell back to the plasma.

Abbreviations: AVP: arginine vasopressin; V2R: vasopressin type 2 receptor; AC: adenylyl cyclase; GTP: guanosine triphosphate; ATP: adenosine triphosphate; cAMP: cyclic adenosine monophosphate; PKA: protein kinase A; CREB: cAMP binding element; AQP2: aquaporin 2.

*Mutations in these components of the pathway have been identified with abnormal function.

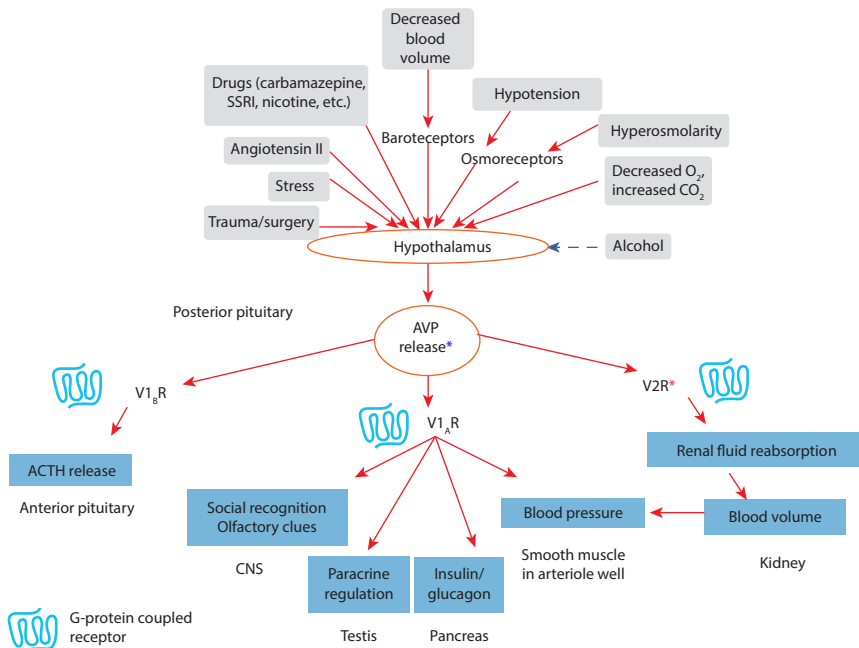

Figure 56.12 Regulation of AVP release. AVP release stimulators increase AVP release from the posterior pituitary. AVP then acts via three receptor subtypes: V1AR, V1BR and V2R. V1AR and V1BR are responsible for the vasoconstrictive effect, and V2R for the antidiuretic effect.

Abbreviations: AVP: arginine vasopressin; VR: vasopressin receptors 1A, 1B and 2; CNS: central nervous system; ACTH: adrenocorticotrophic hormone.

*Mutations in these components of the pathway have been identified with abnormal function.

infection or tumour or mutation in the AVP gene; in nephrogenic DI the kidneys are unable to respond to AVP because of renal disease or a mutation in the vasopressin type 2 receptor (V2R) or in aquaporin 2 (AQP2).

Central DI is managed by administering an exogenous AVP analogue. The analogue used in clinical practice is desmopressin, which, with its strong antidiuretic but relatively low vasopressive effect, is a good therapeutic option not only in central DI but also as treatment for enuresis in children. In nephrogenic DI, thiazide diuretics can be beneficial (inhibiting reabsorption of sodium (Na⁺) and chloride (Cl⁻) ions from the distal convoluted tubules in the kidneys by blocking the thiazide-sensitive Na⁺-Cl⁻ symporter as well as increasing calcium reabsorption at the distal tubule). In contrast, the syndrome of inappropriate antidiuretic hormone (SIADH or Schwartz-Bartter syndrome) is characterized by excessive release of AVP from the posterior pituitary gland or from neuroendocrine tumours, typically small-cell carcinoma of the lung. This is treated using V2R antagonists, which block the V2R receptors in the collecting duct and therefore result in aquaresis (excretion of water that is free of electrolytes). V2R blockers must be used cautiously since rapid reversal of hyponatraemia carries a risk of severe central nervous system complications.

Oxytocin

Oxytocin was first discovered by British pharmacologist Sir Henry Dale in 1906.³⁵ The name (derived from the Greek words meaning ‘quick birth’) refers to its well-known role in stimulation of uterine-contraction during delivery.³⁵ Oxytocin acts via receptors which activate the phospholipase signalling pathway.^{36–38} Plasma oxytocin levels are markedly elevated in late pregnancy and during labour, but sexual activity and stress also stimulate its release. In addition to its role in inducing uterine contractions during labour, oxytocin also plays a major role in the process of milk-ejection of the breasts. The trigger for oxytocin secretion is the suckling itself. Activation results in release of oxytocin that acts on myoepithelial cells that lie around the alveoli of mammary glands, triggering contraction (Figure 56.13). Approximately 30–60 seconds after suckling starts, milk begins to flow. This whole process is referred to as the ‘let-down reflex’.² Despite the fact that suckling is a unilateral stimulus, both breasts will start to produce milk. The importance of emotional cues are clear from observations that hearing the baby crying (or even cuddling the baby) provides sufficient emotional signal to the hypothalamus to trigger milk ejection.² Oxytocin released during breastfeeding also plays a role in reduction of uterine size after birth by stimulation of contractions.

KEY POINTS

- Pituitary function affects multiple aspects of growth and metabolism.
- Pituitary hormones usually work in tightly controlled feedback loops.

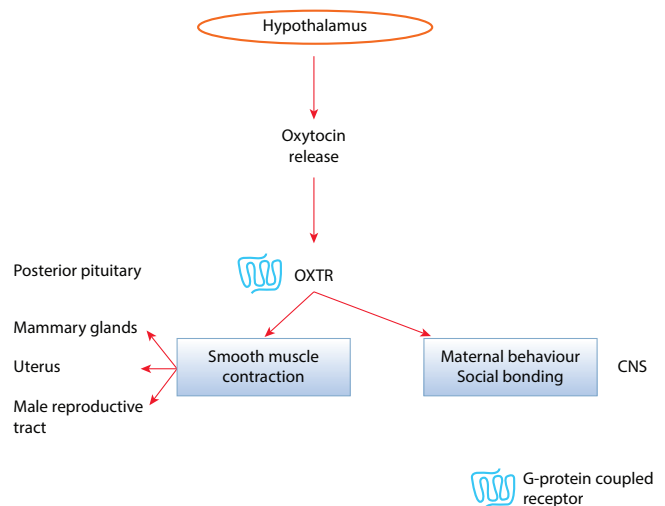

Figure 56.13 Oxytocin effects. Upon hypothalamic stimulation, the posterior pituitary releases oxytocin that binds to its receptor on target smooth muscle cells of the mammary glands and uterus, leading to their contraction. This results in lactation and uterine contractions. It has also been observed that oxytocin in the central nervous system (CNS) plays a role in social bonding and maternal behaviour, and more recently it has been referred to as the ‘love hormone’.

Abbreviations: OXTR: oxytocin receptor; CNS: central nervous system.

Extensive research over the past few years has revealed the role of oxytocin in social recognition, pair bonding, maternal behaviour and sexual interaction as well as social anxiety.³⁹ Oxytocin has gained fame as the ‘love hormone’, with recent studies implying that it has a determining role in bonding between mothers and their babies,^{40, 41} as well as in establishing long-term relationships and falling in love.⁴² Recent human studies showed that intra-nasal oxytocin induces increased eye contact and trustful behaviour.^{43, 44} CNS effects modulating both the neuronal and behavioural processes associated with alcohol, cocaine and opiate administration in rodents were described,^{45, 46} extending possible therapeutic indications to various psychiatric disorders, including drug addiction.³⁶ A large number of studies have outlined the possible use of intra-nasal oxytocin in behavioural and neural disorders with minimal side effects.⁴⁷

CONCLUSION

The pituitary gland is the central regulator of peripheral hormones. Due to the vicinity of the cells regulating different pathways, abnormalities in the gland can result in a complex pattern of signs and symptoms providing diagnostic and therapeutic challenges.

- Both hormone excess and deficiency can lead to complex endocrine disease with multi-system effects.

THYROID GLAND

INTRODUCTION

Ultrasound (US) is the primary imaging modality used to assess size, morphology and pathology of the thyroid gland, and it is the best method for assessing thyroid nodules and possible thyroid cancer. In addition it has the benefit of being able to assess neck lymphadenopathy, and guide appropriate fine-needle aspiration (FNA) for cytological diagnosis.

Since US cannot penetrate bone or air-containing structures, computed tomography (CT) is used to assess the degree of retrosternal extension of thyroid masses. It is also used to image the chest in cases of thyroid malignancy. Magnetic resonance imaging (MRI) is rarely used to assess the thyroid but can occasionally help assess potential tracheal cartilage invasion by cancer.

Positron emission tomography (PET-CT) is sometimes used in the follow-up imaging of thyroid cancer. Thyroid scintigraphy is used less commonly to assess thyroid nodules, with the majority of nuclear isotope scans being therapeutic ¹³¹I to treat potential thyroid cancer metastases.

Thyroid nodules and thyroid cancer

Nodules within the thyroid are ubiquitous. Palpable nodules occur in up to 4% but are seen on imaging studies in up to 60–70% of patients, the incidence increasing with age.

US is the best imaging method to assess thyroid nodules. No single US sign has high enough sensitivity or specificity to confirm or exclude malignancy, but a combination

of signs or US features can be used in summation to provide an excellent guide to the risk of underlying malignancy. Multiple papers confirm the ability of US to ‘risk stratify’ nodules and provide an accurate assessment, firstly of whether an FNA is required and secondly which nodule should be sampled.^{1,2} Further technology such as US elastography, assessing how firm or compressible a nodule is, have been shown in some studies to assist in this regard.

Features associated with benign nodules³ are cysts, predominantly cystic nodules with thin septations, cysts with thin peripheral isoechoic tissue, spongiform nodules (microcystic spaces comprising over 50% volume of a nodule), isoechoic well-defined nodules and multiple nodules similar in appearance to isoechoic largely replacing the normal thyroid parenchyma.

Indeterminate or follicular lesions tend to be well defined and iso- to hyperechoic, usually with a thin, low echogenicity halo and often increased internal blood flow. These lesions are usually benign (follicular adenoma), but cytology/biopsy cannot exclude a follicular carcinoma and diagnostic hemithyroidectomy should be considered.

There are a number of US features strongly associated with malignancy: a solid hypoechoic appearance, ill-defined nodule margins, a taller-than-wide shape, and microcalcifications all suggest papillary thyroid cancer and are considered suspicious US features. By using these four characteristics as a guide to FNA of nodules, we can reach a NPV for presence of thyroid cancer of 97%,⁴ without undertaking biopsy of the majority of thyroid nodules. If we then consider FNA of well-defined hyperechoic nodules with a peripheral halo (i.e. follicular lesions),

our performance is even better. Abnormal neck nodes, either cystic or containing microcalcification, also raise the likelihood of thyroid cancer and usually warrant FNA.

Nodule size and nodule growth have been shown to have poor correlation with underlying thyroid cancer and should not be used as a guide for FNA, but rather the nodule appearances should guide management.

Medullary cancers look very similar to papillary cancers (i.e. solid, hypoechoic, ill-defined), but calcifications are described as more globular in nature. Follicular carcinomas are diagnosed on pathology post excision, not imaging or cytology. Anaplastic cancers, thyroid lymphoma and thyroid metastases from alternate primaries all appear as large, low-echogenicity masses, often with a rapidly progressive history.

Scoring systems, such as the Mayo Clinic Thyroid Ultrasound Chart and the new British Thyroid Association guidelines for the management of thyroid cancer⁵ can assist in risk stratifying nodules and improve patient care by reducing unnecessary FNA, speeding up patient pathways and reducing costs.⁶

Benign thyroid disorders

GRAVES' DISEASE

The thyroid gland appears diffusely hyper-reflective on US without nodules. An increase in intrinsic blood flow is seen on Doppler imaging.

HASHIMOTO'S THYROIDITIS

The thyroid is diffusely hypoechoic, often with hyper-echoic fibrous bands seen between the areas of affected thyroid. The gland may be of normal size or enlarged. Increased internal blood flow may be seen.

MULTINODULAR GOITRE

The role of imaging in multinodular goitre is to identify the extent of thyroid enlargement (retrosternal extension, superior and inferior extent), tracheal deviation or narrowing, and the presence of any suspicious nodules or masses to suggest whether there may be a thyroid malignancy present.

Ultrasound outperforms CT and MRI in the assessment of the nodules within a goitre. The presence of multiple isoechoic nodules throughout both lobes, with varying degrees of cystic change, is almost certainly due to benign disease and does not represent the pattern of thyroid cancer.

Malignant thyroid disease

Papillary carcinoma is the most common thyroid malignancy. On US, papillary cancer demonstrates four cardinal signs: solid and hypoechoic, ill-defined margins, microcalcifications and a 'taller-than-wide' shape. If none of these four features is present, then the negative predictive value (NPV) for absence of thyroid cancer is in excess of 97%.⁴ Papillary cancers may be multifocal and occasionally may be partially cystic; in this setting, it is the

appearance of the solid portion of the mass that should be assessed with US.

CT and MRI less reliably show the features of thyroid cancer and rely on extrathyroidal extension or a large ill-defined thyroid mass.

Nodal metastases may be detected by US, CT or MRI. Typically, abnormal nodes from metastatic thyroid cancer show microcalcification or have a propensity for cystic change.

FOLLICULAR CANCER

Unlike papillary cancer, follicular cancer tumours are solitary. Lesions tend to be well defined and iso- to hyper-echoic to normal thyroid, with a well-defined peripheral low-echogenicity halo and often prominent internal blood flow.

Metastatic lymph nodes are uncommon. Tumours tend to metastasize to bone and lungs. Tumours tend to take up ¹³¹I, and this can be used to treat and follow up metastatic deposits.

ANAPLASTIC THYROID CANCER

Almost exclusively seen in older patients, anaplastic carcinoma has a poor prognosis due to its rapid progression. On US, a large, ill-defined solid low-echogenicity mass with extra thyroidal spread and nodal metastases is typical.

THYROID LYMPHOMA

Extranodal lymphoma of the thyroid may occur following long-standing thyroiditis. Appearances are of a large, hypoechoic mass, which can be indistinguishable from anaplastic carcinoma, requiring core biopsy to differentiate between the two pathologies.

PARATHYROID GLANDS

The parathyroid glands are derived from the third (lower) and fourth (upper) pharyngeal pouches. There are normally four glands, but up to 25% of individuals have more than this. The superior glands are more constant in position, lying posterior to the upper pole, near the recurrent laryngeal nerve (RLN). The lower glands have a more varied position: more commonly glands lie posterior to the lower pole, near the vascular pedicle, but they can vary in location from the level of the hard palate superiorly down to the superior mediastinum.

The role of imaging in hyperparathyroidism is to localize abnormal or hyperfunctioning glands, in order to guide surgical exploration and removal. The major imaging modalities can all be used with varying degrees of success.

Ultrasound

- **Benefits** of US are that it can visualize abnormal parathyroid glands in the region of 10 mm diameter. Abnormal glands appear of low echogenicity compared to adjacent thyroid. Reported sensitivities and specificities vary,

but range between 40% and 80%, with specificity up to 98%.⁷ US is operator-dependent, but in experienced hands it can outperform nuclear medicine.⁸

- **Limitations** of ultrasound imaging include ectopic glands (ultrasound cannot visualize mediastinal lesions and struggles with tracheoesophageal lesions) and glands lying posterior to a multinodular goitre.

Nuclear medicine

Nuclear medicine scintigraphy utilizes radioactive substrates that are taken up by both thyroid and parathyroid glands. Technetium (^{99m}Tc) sestamibi is taken up by both thyroid and abnormal parathyroid glands but these have different speeds of washout. Subtraction of the images from one another allows visualization of abnormal parathyroid glands.

- **Benefits** of nuclear medicine are that multiple glands may be visualized in multigland disease, and ectopic glands in the mediastinum may be seen. Reported sensitivity of sestamibi scanning is 70–100%.
- **Disadvantages** include uptake by thyroid nodules/adenoma and poor spatial resolution. The latter has been improved by combining (fusing) the nuclear medicine scan with a low-dose CT study for anatomical and functional detail.

In many centres, the initial investigation may be ultrasound or nuclear medicine, and a combination of the two is a very common method of investigation.

Computed tomography

Contrast enhanced CT is a newer imaging technique for visualization of abnormal parathyroid glands. Adenomas show arterial phase enhancement, with rapid washout of contrast, whereas adjacent lymph nodes show gradual increasing enhancement. Polar feeding vessels may also suggest adenomas.

- **Benefits** include accurate anatomical detail, aiding surgical exploration, and accurate visualization of multigland disease and ectopic glands. Reported sensitivity and specificity appears high, and anatomical information is greater than with US or nuclear medicine techniques.
- **Disadvantages** of CT are radiation doses, as the scan utilizes multiple phases of scanning (typically three or four scans). For this reason, multiphase CT is usually limited to patients with failed surgical exploration or recurrent disease, or where clinical and biochemical suspicion is high and US and nuclear medicine have not provided a potential abnormal gland.

PITUITARY GLAND

The pituitary gland is contained within the sella turcica, a concave depression within the sphenoid bone (basisphenoid). The gland is composed of two lobes, the anterior pituitary or adenohypophysis (AH) and posterior pituitary or neurohypophysis (NH).

The **anterior pituitary** comprises 75–80% of the gland, and it produces somatotropin (growth hormone), prolactin, TSH, FSH, LH and ACTH. The **posterior pituitary** comprises 20–25% of the gland and is an inferior extension of the hypothalamus. The pars nervosa secretes ADH and oxytocin that are both produced by the hypothalamus.⁹ The posterior pituitary is subdivided into the large **pars nervosa** and smaller **infundibulum** (pituitary stalk).

Imaging techniques

The best technique for multiplanar imaging of the pituitary gland is high-resolution MRI. A standard pituitary MR imaging study is 3 mm thick coronal and sagittal images pre- and post-contrast. The coronal images are best for simultaneously visualizing the sellar and parasellar structures and the position of the infundibulum in relation to the pituitary gland. The sagittal images demonstrate the midline structures and anterior and posterior extent of any related lesion. Axial T2W images of the brain 5 mm thick aid in excluding any other brain pathology and 3 mm thick coronal T2W images are also acquired to aid in differentiating types of pathology and consistency of any lesion.

ENHANCEMENT PATTERNS

The pituitary gland and infundibulum lack a blood–brain barrier therefore enhance rapidly and intensely after contrast is given.

In patients unable to undergo an MRI study, multislice CT (1 mm) pre- and post-contrast enhancement is an alternative. This can then be reconstructed in coronal and sagittal planes as required.

PRE-OPERATIVE EVALUATION

In those patients suitable for surgery to this region, a pre-operative CT scan is performed to delineate the bony anatomy of the adjacent paranasal sinuses to facilitate a transnasal, endoscopic operative approach.

PITUITARY TUMOURS

Pituitary adenomas constitute 10–15% of all intra-cranial tumours. Small adenomas occur in up to 15% of glands at autopsy and more than 20% of imaging studies. They usually occur in adults and are mostly benign. Tumours less than 1 cm are microadenomas and those greater than 1 cm are macroadenomas (**Figures 57.1** and **57.2**).

Around 25% of pituitary tumours lack hormone activity and are often diagnosed later than hormone-secreting tumours only when they compress adjacent structures (e.g. visual field defects from optic nerve compression or cranial nerve deficits from cavernous sinus invasion) (**Figures 57.3** and **57.4**). Up to 10% of pituitary adenomas invade the cavernous sinus. Clinical signs occur late, as cavernous sinus cranial nerves are lateral to the ICA. An adenoma that extends inferiorly may present as a sphenoid sinus mass.

Figure 57.1 Coronal T1W image illustrates a bulky left side of the pituitary gland. There is a slight inferior slope of the sella floor also on the left. The round, dark areas either side of the pituitary gland are due to 'flow voids' which are normally seen due to the cavernous part of the internal carotid artery within the cavernous sinuses.

Figure 57.2 Post-contrast coronal T1W image demonstrates the non-enhancing microadenoma within the left side of the pituitary gland. The rest of the pituitary gland enhances normally.

Figure 57.3 Coronal post-contrast image shows a large pituitary macroadenoma. The suprasellar extension causes compression of the optic chiasm in this case. There is also invasion of the adjacent cavernous sinuses.

Figure 57.4 Sagittal post-contrast image of the same pituitary macroadenoma shows superior extension up to the optic chiasm and slight posterior extension into the pre-pontine cistern. There is also anterior and inferior extension and inferiorly causing a slight depression of the sella floor.

Most pituitary tumours are sporadic, only 5% being familial. The four inherited familial tumour syndromes are MEN1 (multiple endocrine neoplasia type 1, where pituitary tumours are present in 15–40%), Carney complex, McCune–Albright syndrome and FIPA (familial isolated pituitary adenoma syndrome).⁹

Adenomas originate from the anterior pituitary. The two most common types are prolactinomas and growth hormone (GH)-secreting tumours, which are usually present laterally. TSH, ACTH, LH/FSH-secreting tumours tend to occur in the midline. The most common functioning adenomas are prolactinomas. Clinical symptoms include amenorrhoea, galactorrhoea, infertility and loss of libido or impotence and hence they are more likely to present earlier in premenopausal women than in men and postmenopausal women.

The next most common pituitary tumours produce ACTH and GH. GH-secreting tumours cause gigantism in children and acromegaly in adults. ACTH secretion causes Cushing's disease. 'Dynamic post-contrast' scans are useful in the investigation of microadenomas caused by suspected Cushing's disease. This utilizes the property of microadenomas having a slower uptake of contrast than the normal pituitary gland. A microadenoma is then visualized as a filling defect (dark) within the rest of the normally enhancing gland. Serial images are acquired of the pituitary gland during intravenous contrast injection to demonstrate the microadenoma. The range of times for optimum detection varies from 30–50 seconds to 1–2 minutes post contrast. Soon after this the contrast within the pituitary gland reduces and the adenoma becomes no longer visible.¹⁰ Cases with known high prolactin levels and a normal-sized gland with or without a filling defect on a normal post-contrast study are treated medically and hence would not require dynamic post-contrast imaging.

Macroadenomas often extend superiorly through the opening of the diaphragm sellae. Cysts and/or foci of haemorrhage are seen in approximately 50% of cases. Most macroadenomas enlarge slowly over years. Imaging features are those of an intrasellar or intra- and suprasellar mass where the pituitary gland cannot be separated from it. Bony CT can show an enlarged sella turcica due to remodelling of the bone. A 'giant' or very large macroadenoma can erode and appear to invade the skull base.

On MRI macroadenomas are usually isointense with cortex and enhance well but heterogeneously with contrast. Tumours that have hyperintense foci on T2W images may be soft or partially necrotic. This knowledge pre-operatively is useful in pre-surgical counselling as a soft tumour can be easily removed compared to a lesion with a more fibrous nature (Figure 57.5).

Differential diagnosis

A number of features help to distinguish sellar masses:

- location: is the mass intrasellar, suprasellar, infundibular or a combination of these locations?
- connection: is the mass separate from the pituitary gland or not?
- age of the patient.

Figure 57.5 Coronal T2W image demonstrates a pituitary macroadenoma with hyperintense foci within it indicating the tumour is 'soft' or partially necrotic. It is extending up to and compressing the optic chiasm which is draped over its superior aspect.

MENINGIOMA

This tumour is rare in children and usually seen as separate from the pituitary gland. Most arise from the undersurface of the diaphragma sellae but they can also arise from the walls or floor of the sella. Meningiomas more commonly arise from the parasellar regions and project into the sella turcica.¹¹ Intrasellar meningiomas are rare.¹²

MRI demonstrates these lesions to be hypointense to grey matter on T1W and T2W images. They enhance rapidly and avidly and have a 'dural tail'. The most useful feature in allowing differentiation of a sella meningioma from an adenoma is identifying the pituitary gland as separate from the sella mass (Figure 57.6). Also hyperostosis of adjacent bone is seen in 34% of cases. These lesions are benign but can be locally aggressive and recur after incomplete resection. They can encase and eventually occlude the internal carotid artery (ICA). Because most are very vascular tumours, pre-operative embolization is used in some cases to reduce intra-operative blood loss.

METASTASIS

Metastases to the infundibulum and/or pituitary gland are infrequent. They most commonly arise from lung and breast.¹³ The posterior pituitary is generally most affected but breast metastases tend to affect the anterior pituitary. It can be difficult to differentiate these lesions from pituitary adenomas. Imaging features that may help to distinguish a pituitary metastasis are: thickening of the infundibulum, loss of high T1W signal from the posterior pituitary,

Figure 57.6 Sagittal T1W post-contrast image demonstrates a sella and suprasellar meningioma. The lesion enhances avidly and can be seen separate from the non-enhancing, normal-appearing pituitary gland seen within the posterior aspect of the sella. A 'dural tail' is seen as linear enhancement along the floor of the anterior cranial fossa.

Figure 57.7 Axial T2W image illustrates the high signal intensity cystic components in a suprasellar craniopharyngioma. The posterior aspect of the lesion has some solid material within it which is seen as intermediate signal intensity.

isointense signal on T1W or T2W images, invasion of the cavernous sinus and sclerosis around the sella turcica. These appearances, however, are not specific for pituitary metastasis.

CRANIOPHARYNGIOMA

These tumours arise from epithelial remnants of Rathke's pouch. In children these are the most common suprasellar mass. They have a bimodal age distribution with one peak at 5–10 years of age and another at 50–60 years. Most are suprasellar lesions but a quarter have an intrasellar component. Intrasellar craniopharyngiomas are rare. They can measure from a few millimetres to several centimetres. The large lesions can extend to the anterior and middle cranial fossa (Figures 57.7 and 57.8). Two types exist: 90% are adamantinomatous and 10% papillary.

The common type of craniopharyngioma is a multilobulated, mainly cystic suprasellar mass with a solid component. It may contain cysts that are full of viscous 'machinery oil' fluid due to the cholesterol content. Calcification is common and most enhance. The papillary type has a smoother surface and is often solid. Any cysts contain a clear fluid. These tumours rarely calcify. They occur in adults with a peak at 40–44 years. Imaging features are those of a partially calcified, mixed solid and cystic mass. The pituitary can sometimes be seen as separate from the mass.

Figure 57.8 Sagittal post-contrast image demonstrates the same lesion as in Figure 57.7. The partially solid, posterior, retrosellar component exhibits patchy enhancement. The anterior and superior cystic components are non-enhancing. A thin rim of pituitary tissue is seen compressed within the sella floor, which is also depressed.

RATHKE CLEFT CYST

Craniopharyngiomas need to be differentiated from Rathke cleft cysts (RCCs). The latter do not calcify, which helps distinguish them. RCCs are a remnant of the embryonic Rathke cleft. Approximately 40% are intrasellar and 60% suprasellar.⁹

If they cause symptoms, patients with an RCC can present with pituitary dysfunction, visual disturbance and headache. MRI signal varies according to the cyst contents, which are mainly mucoid but can be serous.¹⁰ Those which contain mucoid fluid may be indistinguishable from cystic craniopharyngiomas on MRI, with both being hyperintense on T1W and T2W images. They are usually

hyperintense on FLAIR imaging. The serous cysts have imaging features of typical benign cysts, that is, low signal (dark) on T1W and high signal (bright) on T2W images. After contrast they have an enhancing rim or 'claw sign' of compressed pituitary gland around the non-enhancing cyst. Around 40–75% of RCCs have an intracystic nodule (Figures 57.9 and 57.10).

NON-ADENOMATOUS PITUITARY TUMOURS

These are rare, WHO grade 1 tumours and are classified as pituicytoma, spindle cell oncocytoma and granular cell tumour.⁹ They can also present with visual loss and endocrine disturbance.

Figure 57.9 Coronal FLAIR image of a Rathke cleft cyst with mucoid fluid within it. This fluid does not 'suppress' like water or CSF on FLAIR imaging and therefore appears hyperintense.

Figure 57.10 Sagittal post-contrast image of a Rathke cleft cyst illustrates the rim-enhancing cystic lesion which has suprasellar and retrosellar extension. There is a normally enhancing pituitary gland within the sella seen separate from the lesion.

KEY POINTS

- Best imaging technique is thin-section multiplanar MRI with a small field of view obtained before and after contrast.
- To distinguish the different types of sellar masses, first consider the location – is the mass intrasellar, suprasellar, infundibular or a combination of these locations?
- Is the mass separate from the pituitary gland or not?
- The age of the patient; as certain lesions are common in adults but not in children.
- Further imaging features of whether the mass is cystic, calcified and its signal intensity on MRI are also helpful.

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: benign thyroid disease, thyroid cancer, thyroiditis, benign parathyroid disease, parathyroid cancer, fine needle aspiration cytology and frozen section examination.

INTRODUCTION

The endocrine pathology discussed in this chapter is that affecting the extracranial endocrine system, viz. the thyroid and parathyroid glands found in the anterior triangle of the neck bilaterally. The chapter is not intended to be an encyclopaedic treatise, more a summary overview with selective consideration of clinically important differential diagnoses. Surgical pathology is a visual subject, therefore no apology is offered for the liberal use of illustrations to supplement the text.¹

THYROID GLAND

The normal thyroid gland

The term 'thyroid gland' was first coined by Thomas Wharton in the 17th century to describe the gland in close proximity to the shield-shaped (scutiform or scutate) thyroid cartilage.²

The thyroid gland is the largest of the discrete endocrine organs typically weighing between 15 g and 25 g (roughly 0.4% of body mass), being slightly larger in women,² dependent upon age, nutritional and hormonal status. Macroscopically the normal thyroid gland presents a bilobate structure with a reddish-brown colour. The two lobes are connected by a central isthmus. A vestigial, accessory pyramidal lobe is present in 40% of the population.

EMBRYOLOGY

Embryologically, the thyroid gland develops from the median anlage and the two lateral anlagen. The median anlage starts as a thickening of the endodermal epithelium in the foregut between the 1st and 2nd branchial arches at the base of the tongue close to the developing myocardium,^{2,3} which in later life constitutes the foramen caecum. The cells proliferate to form the thyroid bud and then a diverticulum, which expands and migrates from the base of tongue to lie anterior to the trachea. The track between the thyroid gland and base of tongue typically disappears by birth. The two lateral anlagen (known as the ultimobranchial bodies) develop from the caudal aspect of the 4th pharyngeal pouch supplemented by migratory neural crest elements and fuse with the median anlage as the thyroid gland descends in the neck. The median anlage forms the thyroid follicular cells and the lateral anlagen form the clear parafollicular cells (C-cells).⁴

CAPSULE

There is no clearly defined anatomical thyroid capsule proper, rather a thin investing fibrous pseudocapsule, which is continuous with the pre-tracheal fascia. This capsule is discontinuous or focally interrupted in approximately 60% of individuals and extracapsular thyroid tissue is present in almost 90% of glands. A variety of pericapsular inclusions, sometimes intra-thyroidal, such as parathyroid tissue, heterotopic thymus, lymph nodes and autonomic paraganglia,

Figure 58.1 Intrathyroidal mature adipocytes intermingled with normofollicular thyroid gland parenchyma. The slender anatomical thyroid gland pseudocapsule is barely discernible at this magnification (*H&E stain, low magnification*).

are considered normal. Mesenchymal-derived inclusions within the thyroid gland include stromal adipocytic, skeletal muscular and cartilaginous elements⁵ (Figure 58.1). Awareness of potential comorbid pathological changes in perithyroidal structures is helpful, for example medial calcification of arteries (Monckeberg's sclerosis), which may also occasionally synchronously affect vasculature within the thyroid gland and rarely be encountered in lesional tissue itself.

Breach of this pseudocapsule by tumour constitutes extrathyroidal extension (ETE), defined by infiltration into perithyroidal tissues, typically eliciting inflammatory and/or desmoplastic response. Where discernible grossly to the unaided eye, this is described as macroscopic (or extensive/major/massive/marked). If only appreciable during microscopy, this is designated microscopic (or minimal/minor/limited). This distinction is important prognostically – macroscopic ETE portends a higher recurrence rate and lower disease-free survival than microscopic ETE. Direct infiltration into parathyroid gland is rare but may be arbitrarily regarded as minimal ETE owing to close proximity.

MICROSCOPICAL APPEARANCE

Microscopically, the functional unit of the thyroid gland is the follicle, which in the euthyroid state consists of a monolayer of cuboidal or flattened epithelial cells (thyrocytes) surrounding a central lumen containing stored colloid. The follicles are loosely aggregated into lobules (thyromeres), each containing around 20–50 follicles separated by slender connective tissue septula (Figure 58.2). Intracoloidal birefringent oxalate crystals (Figure 58.3), brown cytoplasmic lipofuscin ('wear and tear') pigment and haemosiderin pigment are usually of incidental portent, though these may be increased with age and in certain disease states.

The C-cells form a minor cell subpopulation, accounting for less than 10% by number, and are typically concentrated at the junction between the middle and upper thirds of the lateral lobes in a hypothetical central longitudinal

Figure 58.2 Normal thyroid gland demonstrating a lobular architecture with uniform, round/ovoid follicles. The latter contain plentiful stored colloid with fine marginal vacuolation. The parallel linear marks in the colloid ('ripple' or 'wave' effect) are an artefact of microtomy. The C-cell population is typically inconspicuous (*H&E stain, low magnification*).

Figure 58.3 Thyroid gland parenchyma with intrafollicular rhomboidal and petaloid oxalate crystals. (a) Viewed under non-polarized brightfield light showing apparent empty geometrical spaces within the stored colloid (*H&E stain, medium magnification*). (b) Identical field illuminated by cross-polarized light disclosing many more strongly birefringent crystals against a dark background (*H&E stain, medium magnification*).

axis, corresponding to the planes of medial and lateral anlagen fusion – solid cell nests, C-cell hyperplasia and medullary thyroid carcinoma, therefore, do not ordinarily occur in the isthmus. C-cells are usually larger, more rounded, polyhedral or fusiform in shape, with paler cytoplasm than follicular epithelium.

Solid cell nests

So-called solid cell nests (SCNs) are collections of non-follicular cells, found in approximately 25% of resected thyroid glands, which probably represent remnants of the ultimobranchial apparatus. They are present in greater numbers in infants and children and gradually decline with advancing age. The role of SCNs in the normal structure and function of the thyroid gland is incompletely understood and their biological significance remains a source of controversy and debate. SCNs may harbour minimal properties of a stem cell phenotype with capacity for self-renewal and end differentiation.

SCNs comprise irregularly shaped clusters of interfollicular cells delineated by basal lamina. The dominant cell component (main cell) comprises polygonal to fusiform cells disposed in solid array sometimes with an epidermoid appearance, though generally non-keratinizing and devoid of intercellular bridges (prickles). They less commonly show a glandular morphology and may paradoxically be microcystic, micropapillary and/or mucinous. SCNs co-express cytokeratins, carcinoembryonic antigen (CEA, CD66e), galectin-3 and many pan-neuropeptides such as chromogranin A, synaptophysin and somatostatin, but they are negative for markers of terminal differentiation, viz. thyroglobulin (Tg), thyroid transcription factor-1 (TTF-1) and calcitonin (Figure 58.4). They also contain a minor subpopulation of C-cells, which show a partially differentiated immunophenotype. SCNs consistently stain for p63, a homologue of p53, a nuclear transcription factor that induces expression of cytokeratin 5 (CK5) and cytokeratin 14 (CK14). The gene for p63 is universally

expressed in basal cells of stratified epithelia and plays a major role in triggering the maturation of these into squamous epithelium.

Solid cell nests are postulated to be precursors of certain thyroid gland neoplasms, notably papillary thyroid carcinoma. They may also play a role in the histogenesis of Hashimoto's thyroiditis, which is also associated with papillary thyroid carcinoma. Papillary thyroid carcinoma and Hashimoto's thyroiditis may therefore be linked in pathogenesis via a common population of pluripotent p63 positive embryonal stem cell remnant progenitors.⁶

Fine-needle aspiration cytology

Fine-needle aspiration cytology (FNAC) is generally recognized as a valuable and cost-effective first-line investigation in the evaluation of a thyroid swelling.⁷⁻¹⁰ In experienced hands, FNAC of the thyroid gland is accurate with a sensitivity of 65–98%, a specificity of 72–100%, a false-positive rate of 1–8% and false-negative rate of 1–11%.^{7,11} The non-diagnostic or inadequate rate can be as high as 28%¹¹ but targeting by ultrasound (US) guidance can reduce the incidence of a non-diagnostic FNAC.¹² US guidance is recommended in nodules with a higher chance of non-diagnostic FNAC by simple palpation. These include cystic nodules and smaller or non-palpable lesions.¹⁰ Thus, as a screening test FNAC is highly sensitive, but it lacks specificity: approximately 15–40% of aspirates designated suspect of a follicular neoplasm ultimately prove to be malignant, ergo the remaining 60–85% or so of nodules are benign in the final analysis. Immediate assessment of samples for adequacy at the time of aspiration (rapid on-site evaluation, ROSE) can reduce the rate of unsatisfactory specimens and aid collection of material for ancillary tests.

FNAC is substantially a screening/triage procedure for follicular carcinoma, identifying those patients who require further investigations, and a primary diagnostic test for other thyroid malignancies, principally papillary

Figure 58.4 Solid cell nests. (a) Ultimobranchial apparatus rests (solid cell nests) disposed as discrete conglomerates of squamoid (epidermoid) cells without keratinization, discovered incidentally in a thyroidectomy specimen indicated for partially treated Graves' disease (H&E stain, medium magnification). (b) Such cell rests typically express pan-neuroendocrine immunomarkers but not thyroglobulin and they are thus shown here in negative relief (thyroglobulin IHC, medium magnification).

thyroid carcinoma, medullary carcinoma, undifferentiated (anaplastic) carcinoma and lymphoma.

The results of FNAC may reassure that a lesion is benign, triage patients for diagnostic surgery, or provide a definitive diagnosis of selected thyroid malignancies, thereby expediting single-stage therapeutic intervention.^{9, 10} There is plentiful experience based upon the traditional wet-fixed and air-dried direct smear methodology, aspirate washings and cyst fluid samples, supplemented by cell concentration techniques, such as centrifugation, filtration and cell blocks. Newer liquid-based technology is favoured by some centres, dependent upon local resources and experience, furthermore handling of FNAC specimens may be influenced by the prospect of ancillary investigations. The success of thyroid FNAC is demonstrably operator-dependent – the cytopathologist can only ever be as good as the quality of the aspiration sample that he or she receives.

Despite acknowledged cytodiagnostic pitfalls, some outlined below, the use of FNAC in the preliminary evaluation of solitary or dominant nodules reduces the use of surgery by approximately one-third, doubles the proportion of malignancies among surgical resections and increases cost-effectiveness. FNAC may be employed in the investigation of suspect lymph nodes and measurement of thyroglobulin in needle wash samples may augment diagnostic accuracy. Molecular studies may also refine the diagnostic process in thyroid FNAC samples. Serious diagnostic delay due to false-negative FNAC is uncommon where there is appropriate clinical follow-up.¹³

Historically, the diagnostic criteria and reporting nomenclature employed internationally have varied somewhat though these have ultimately evolved to broad consensus, aimed at national standardization, stratified for risk of malignancy with corresponding evidence-based recommendations for further patient management.¹⁴ These are epitomized by the North American National Cancer Institute (Bethesda) terminology (2007),¹⁵ Italian (2007, 2014), Australian (2014), Japanese (2013) and British Thyroid Association/Royal College of Pathologists (2002, 2007, 2016) guidelines.¹⁶ The terminology for non-diagnostic, benign, malignant and suspect for malignancy is similar across each of these classifications with minor differences in emphasis for the equivocal/indeterminate category. These schemata and the anticipated rates of malignancy attributed to each diagnostic category are outlined in [Table 58.1](#). It is sometimes salutary when deliberating management options during multidisciplinary team conferences to remind participants of the reciprocal likelihood of benignity for each category to maintain a sense of perspective.

The shorthand alpha-numeric diagnostic category codification intrinsic to some of these systems is not intended to supplant a focused narrative cytology report or stymie more comprehensive communication, where appropriate. Additionally, the vernacular habit of grouping together non-diagnostic/unsatisfactory and non-neoplastic/benign aspirates under the rubric of negative reports should be dispelled. As a fundamental principle, it is emphasized that, while the presence of malignant cells is diagnostic, a lack of malignant cells can never be wholly exclusionary – absence of evidence is not *prima facie* evidence of absence.

LIMITATIONS OF FNAC OF THE THYROID GLAND

The follicular-patterned lesion is the most commonly encountered type of thyroid FNAC specimen in clinical practice. Distinction between a hyperplastic (adenomatoid) nodule in a multinodular goitre and a follicular-patterned neoplasm may not always be achievable. The presence of dispersed colloid, monolayered sheets of bland thyrocytes and macrofollicular structures are more typical of hyperplasia. Dense colloid globules, paucity of colloid and microfollicular configuration ([Figure 58.5](#)) tend to support neoplasia. It is necessary to focus on the predominant cyto-architectural pattern, rather than a minor subpopulation of microfollicles, with the proviso that this approach is predicated upon adequate cell sampling. The agreed criterion for this is that samples from solid lesions should contain at least six groups of thyroid follicular epithelial cells across all the submitted slides, each composed of at least ten well-visualized epithelial cells. Note that this constitutes a minimum standard, that the degree of diagnostic confidence should increase with higher yield samples and that this threshold does not necessarily preclude a positive diagnosis of malignancy if a lesser quantum of characteristic cells is present.

Reliable discrimination between a benign adenoma and differentiated follicular carcinoma on subjective morphological grounds is now realized to be always difficult, often impossible. While the presence of high cellularity, cell crowding, tri-dimensional (acervate) groups, nucleomegaly, cytonuclear atypia, three or more nucleoli per cell, irregular karyoplasm and necrosis are individually not absolute, in aggregate they tend to favour a diagnosis of malignancy. Follicular variant of papillary thyroid carcinoma (FVPTC) enters the differential diagnosis, where a scrupulous search for its characteristic nuclear morphology is indicated. The diagnosis of non-invasive follicular thyroid neoplasm with papillary-like nuclear features (NIFTP) is not sustainable from SNAC appearances alone. The separation of minimally invasive from widely invasive follicular carcinoma on FNAC, contingent upon extent of extracapsular invasion is obviously untenable *ab initio*.

Oncocytic (oxyphil) cell lesions are problematic on FNAC. Hashimoto's thyroiditis and oncocytic (oxyphil) metaplasia in multinodular hyperplasia are generally separated by conspicuous lymphocytosis in the former ([Figure 58.6](#)) though the degree of inflammatory cell infiltrate varies with the natural history of the disease and paucilymphocytic variants are described. The cytological distinction between Hürthle cell adenoma and carcinoma is unreliable – benign oncocytic (oxyphil) cells may display extreme pleomorphism and, paradoxically, there is often less cytonuclear variation in Hürthle cell neoplasms. Confident recognition of the rare oncocytic (oxyphil) variant of papillary thyroid carcinoma on FNAC is extremely difficult. The conclusion oncocytic (oxyphil) cell lesion or neoplasm, not otherwise specified, is occasionally the best that can be achieved with a recommendation for excision, as clinically indicated. A solitary thyroid nodule composed of predominantly oncocytes on FNAC merits excision because oncocytic (oxyphil) thyroid neoplasms show on average a 30% malignancy rate based on histology. Moreover, the larger an oncocytic tumour,

Figure 58.5 FNAC. (a) Cellular FNAC specimen suggestive of a follicular neoplasm. Note several microfollicular structures (defined as 12 or fewer circumferential thyroid epithelial cells, in contrast to macrofollicles composed of 20 or more peripheral cells).¹⁵ Structures of normofollicular configuration are defined within these two extremes (*Pap stain, high magnification*). (b) Similar microfollicles seen on its companion air-dried smear. There is sparse colloid in some of the follicles (*MGG stain, high magnification*).

Figure 58.6 FNAC from Hashimoto's thyroiditis. Loosely cohesive, monolayered clusters of mildly pleomorphic oncocyctic (oxyphil or Hürthle cell) thyrocytes can be seen admixed with polymorphous small lymphocytes (*Pap stain, medium magnification*).

the greater the likelihood of invasive malignancy: there is a 65–80% chance of malignancy in oncocyctic neoplasms exceeding 4cm maximum dimension.

Aspirates from cystic lesions may not be fully diagnostic, particularly if there is limited or degenerate epithelial sampling. Cysts of any type tend to contain variform inflammatory cells, foam cells, pigmented macrophages and cytolytic debris (Figure 58.7). Copious dispersed colloid favours benignity, though in the absence of adequate epithelial cell content the possibility of a cystic neoplasm or cystic degeneration in a neoplasm, of which papillary thyroid carcinoma is paradigmatic, cannot be completely ruled out on FNAC microscopical appearances in isolation since up to 10% of thyroid carcinomas missed on FNAC harbour a cystic component.

The diagnosis of high-grade non-Hodgkin lymphoma is generally straightforward with adequate FNAC material.

Figure 58.7 Fine-needle aspiration cytology. (a) FNAC from a benign thyroid cyst showing monolayered sheets (honeycomb or frog spawn) of cohesive, isomorphic epithelial cells amidst foam cells and pigmented macrophages with minimal necrotic debris (*Pap stain, medium magnification*). (b) FNAC of the contents of a benign colloid cyst/nodule illustrating abundant, evenly dispersed, tessellated (cracked or 'parched earth') colloid. There is no cell sampling in this field.

Recognition of low-grade non-Hodgkin lymphoma, typically extranodal marginal zone lymphoma ('MALToma'), however, is sometimes fraught, especially if arising in the context of autoimmune thyroiditis where monomorphism of the neoplastic lymphocytes, which triggers the suspicion of neoplasia, is diluted or obscured by reactive lympho-proliferative elements. Histological examination is typically advised, particularly if more definitive subclassification is desired.

FNAC-INDUCED IATROGENIC CHANGE

Although FNAC is popularly considered to be a comparatively atraumatic procedure, the technique is known to induce histological changes, which may modulate or even obscure the underlying pathology and potentially mislead the unwary.

Several studies propose an incidence for FNAC-induced iatrogenic changes of close to 100%.¹⁷ Relevant factors include the nature and size of the target lesion, the calibre of the needle used, the number of passes attempted, the precise FNAC technique employed, how meticulously

such effects are sought and the interval between FNAC and excision surgery. The retrospective nature of such audit is prone to underestimate the true frequency.

The resultant secondary damage may broadly be classified into tissue damage and repair effects, tumour and tissue infarction, and epithelial dislodgement/displacement phenomena. The acronym WHAFFT ('worrisome histologic alteration following fine-needle aspiration of the thyroid gland') was originally proposed and has further been divided into acute WHAFFT and chronic WHAFFT.¹⁸

The tissue damage and repair aspect includes haemorrhage, fibrovascular granulation tissue organization and regenerative/degenerative atypia. Haemorrhagic needle tracks and associated proliferation of fibroblasts/myofibroblasts are typically pericapsular and radiate to the centre of the lesion, perpendicular to the capsule. The influx of inflammatory cells, siderophages, linear fibrosis/hyalinization, cholesterol granulomata, dystrophic mineralization, epithelial metaplasia and epithelial and endothelial atypia may on occasion be so exuberant and kaposiform as to closely mimic a sarcoma (so-called post-FNAC spindle cell nodule) (Figure 58.8).

Figure 58.8 FNAC-induced iatrogenic changes. (a) Recent FNAC needle tracks in a follicular neoplasm. The crossed swords ('double skewer') sign indicates that at least two passes of the needle in different directions were conscientiously made by the aspirator. The rectilinear, subcapsular configuration is typical. (b) This haemorrhagic recent FNAC needle track, however, appears more curvilinear. (c) Circumscribed encysted haematoma post-FNAC. (d) Another follicular neoplasm showing post-FNAC linear haemorrhagic infarction with early macrocystic change. (Continued)

Figure 58.8 (Continued) FNAC-induced iatrogenic changes. (e) Established macrocystic degeneration with localized mural vascular granulation tissue response and limpid, mucoid contents. (f) Globally infarcted oncocytic (oxyphil) cell neoplasm, not further subclassifiable, following FNAC displaying complete yellow ischaemic type necrosis. (g) Obvious healing rectilinear FNAC artefact perpendicular to the capsule with a retracted, cuneiform, fibrous pericapsular scar in an otherwise minimally invasive follicular carcinoma. (h) Post-FNAC linear fibrous scar traversing an oncocytic (Hürthle cell) neoplasm, contiguous with wedge-shaped, retracted capsular defect. (i) Post-FNAC artefact manifest as radial scar-like, central fibroblastic granulation tissue and haemorrhage distorting surrounding lesional parenchyma (*H&E stain, low magnification*). (j) Another example of an older post-FNAC radial scar presenting a haemosiderotic, hyalosclerotic nidus with centripetal contracture deformity of lesional architecture (*H&E stain, ultra-low magnification*). (Continued)

Figure 58.8 (Continued) FNAC-induced iatrogenic changes.

(k) Post-FNAC spindle cell nodule composed of richly vascularized myofibroblastic (kaposiform) stroma bordering encysted haematoma (H&E stain, medium magnification).

The thyroid gland is a richly vascularized organ (receiving approximately 2% of total cardiac output) and post-FNAC vascular effects include venous thrombosis, recanalization and papillary endothelial hyperplasia, sometimes to an extent to resemble angiosarcoma (pseudangiosarcomatoid). Mitochondrion-rich oncocytic (oxyphil) cell lesions are exquisitely sensitive to ischaemia, and therefore characteristically susceptible to partial or global infarction, either spontaneously or post-FNAC. Where extensive, such infarction may render definitive histological evaluation difficult or impossible and a diagnosis of oncocytic neoplasm, not further specified, may be the best that can be proffered under these circumstances. However, a minor population of better-preserved tissue, the ghost-like outlines of devitalized papillae, necrotic cells or psammoma bodies, together with review of the original FNAC material, may yield some insight into the underlying pathology. Immunocytochemical positivity for certain epitopes persists for a surprising time after infarction – leukocyte common antigen (CD45) and CD20 staining, for example, may reproducibly define lympho-proliferation long after tumour cells have cytolysed, though antibodies such as carcinoembryonic antigen (CD66e) is more capricious and stains fields of necrotic tissue and abscess cavitation indiscriminately.

Angulated follicles and reparative stromal response, accompanied by nuclear hyperchromasia, fusiform epithelial morphology and squamous metaplasia, may appear infiltrative (pseudo-infiltration), and therefore merit serious consideration of follicular carcinoma, squamous cell carcinoma or muco-epidermoid carcinoma.

Epithelial displacement and/or tumour implantation along FNAC needle tracks into soft tissues or skin does occur, though apart from the uncommon sarcomas such deposits usually disintegrate and viable tumour seeding is rarely of serious clinical importance. Fields of reactive papillary endothelial hyperplasia (Masson's pseudotumour) in pericapsular vasculature may closely mimic lymphovascular involvement by papillary thyroid carcinoma. Mechanical tumour cell dislodgement into blood vessels may resemble vascular invasion. Rigorous criteria are recommended, notably the presence of a protruberant

connection with the vessel wall, partial or complete endothelialization of the tumour tissue and/or admixture of tumour cells with blood/thrombus, all indicative of a vital response. Opinion is divided as to whether immunostaining (e.g. CD31, CD34 for vascular and D2-40 for lymphatic endothelium) ought to be routinely or selectively utilized. Pericapsular defects in various stages of healing must not be misconstrued as capsular infiltration (pseudoinvasion) or evidence of extrathyroidal extension.

Developmental conditions

Developmental conditions involve the presence of normal thyroid tissue in sites outside the normal thyroid gland (heterotopia or ectopia, hamartoma and choristoma). This includes lingual thyroid, mediastinal thyroid, benign lymph node inclusions, so-called 'lateral aberrant thyroid gland' and sequestered (parasitic) thyroid nodules. Mature adult cystic teratoma (dermoid cyst) of the ovary may show a preponderance of thyroid tissue (struma ovarii) sometimes with carcinoid elements (strumal carcinoid). The same repertoire of pathological conditions that affect eutopic thyroid gland may also be rarely encountered at these other sites (Figure 58.9).

THYROGLOSSAL TRACT ANOMALIES

Thyroglossal duct remnants persist due to failure of involution of the thyroglossal duct following embryological descent of the thyroid gland. They are the commonest cause of a congenital neck mass and the second most common cause of a cervical mass in childhood.¹⁹

Thyroglossal duct remnants can occur at almost any site from the base of the tongue to the suprasternal region, predominantly at four locations, namely intralingual, suprahyoid, thyrohyoid and suprasternal²⁰ (Figure 58.10). Cysts predominate with fewer sinuses and fistulae. Counterintuitively, follicular thyroid tissue is not a prerequisite for diagnosis. Thyroglossal duct carcinoma is rare, estimated as occurring in no more than 1% of thyroglossal duct cysts and, when it supervenes, it is usually a subtype of papillary thyroid carcinoma.

Figure 58.9 Developmental conditions. (a) Adult cystic ovarian teratoma (dermoid cyst). The solid component is substantially follicular thyroid tissue with clinically unsuspected fields of minimally invasive (angioinvasive) follicular carcinoma microscopically. (b) Minimally invasive follicular carcinoma ex-ovarian teratoma (struma ovarii). The endothelialized tongue-like angioinvasion is identical to that seen in such tumours occurring in eutopic thyroid gland (*H&E stain, medium magnification*). (c) Lymphovascular invasion in well-differentiated papillary thyroid carcinoma, classical pattern ex-struma ovarii. Again, this is identical to that occurring in eutopic thyroid gland proper (*H&E stain, medium magnification*).

Figure 58.10 Whole mount preparation of a Sistrunk's procedure specimen. It shows hyoid bone, closely associated connective tissue plus a nubbin of normofollicular thyroid tissue representing thyroglossal duct remnants (*H&E stain, ultra-low magnification*).

SQUAMOUS DIFFERENTIATION

The presence of squamous epithelium is not uncommon. It is usually either an acquired, adaptive response (metaplasia) due to inflammation, or related to developmental rests of cells (heteroplasia)^{21, 22} though it may also occur in some neoplasms (differentiation) (Figure 58.11 and Table 58.2).

Non-neoplastic squamous epithelium is usually microscopically bland though may sometimes show an alarming degree of reactive/repairative cytonuclear atypia. Benign squamous epithelium generally presents the same immunophenotype as elsewhere, viz. cytokeratins (notably CK5 and CK14), epithelial membrane antigen (EMA) and p63 positivity, usually with thyroglobulin, thyroid transcription factor-1 (TTF-1) and carcinoembryonic antigen (CEA, CD66e) negativity. Malignant squamous differentiation, however, may not conform to this profile and anomalous epitope expression (e.g. CD 56) may be confounding.

ONCOCYTIC CHANGE

Oncocytic (oxyphilic) cells are characterized by swollen, granular, mitochondrion-rich cytoplasm and may occur in both endocrine tissues and non-endocrine organs, including pituitary, parathyroid, thyroid, adrenal, lacrimal and salivary glands, kidney, pancreas, intestine, lung

Figure 58.11 Squamous differentiation. (a) Papillary thyroid carcinoma exhibiting isolated areas of squamous differentiation (squamous morulae), which are seen focally in up to 50% of cases. The squamoid cells do not show the typical nuclear features that define PTC (*H&E stain, medium magnification*). (b) Carcinoma with thymus-like elements (CASTLE) showing smooth-contoured lobules of non-keratinizing squamoid epithelial cells demarcated by a central broad fibrous septum, percolated by lymphocytes and plasma cells (*H&E stain, medium magnification*).

TABLE 58.2 Conditions associated with squamous epithelium in the thyroid gland

Non-neoplastic	Neoplastic
Nodular hyperplasia (goitre)	Papillary carcinoma
Chronic lymphocytic thyroiditis and variants	Squamous cell carcinoma, primary or secondary
Hashimoto's thyroiditis	Mucoepidermoid carcinoma, primary or secondary
Following FNAC, core biopsy or contralateral lobectomy	Carcinoma with thymus-like elements (CASTLE)
Developmental solid cell nests and thymic rests	Teratoma

and sinonasal tract. The incidence of oncocytic change increases with advancing age and may be extensive at any one site (oncocytosis). When such cells occur in the thyroid, they are termed Hürthle cells (Askanazy cells). It is a purely descriptive term and does not in itself indicate biological potential – oncocytic cells occur in both non-neoplastic and neoplastic (benign and malignant) conditions (mitochondriomas) (Table 58.3).

Oncocytic metaplasia is believed to occur in response to pathological or physiological stress and the oxygen-sensitive nature of the mitochondria renders the cells unusually susceptible to traumatic/ischaemic injury. There is ongoing debate as to whether such oncocytic transformation is a form of metaplasia or more correctly represents a process of transdifferentiation.²³ The pathogenetic mechanisms underpinning oncocytic change are complex. The genetic events driving oncocytic change involve mutations in mitochondrial DNA and somatic mutations that affect mitochondrial function. Importantly, these changes are largely unrelated to the genetic events that result in proliferation and neoplastic transformation of thyroid follicular epithelial cells.

There is hallmark concomitant nuclear enlargement often with striking nuclear pleomorphism, coarse karyoplasm and conspicuous nucleolation, even in benign oncocytes.

TABLE 58.3 Conditions associated with oncocytic (oxyphilic) epithelium in the thyroid gland^{24, 25}

Non-neoplastic	Neoplastic
Hashimoto's thyroiditis	Follicular adenoma
Nodular hyperplasia	Follicular carcinoma
Graves' disease	Papillary thyroid carcinoma
Post-irradiation	Medullary carcinoma
Ageing	Anaplastic carcinoma

The distinction between oncocytic hyperplasia and neoplasia can be difficult, particularly in the context of thyroiditis. Note that, in autoimmune thyroid disease, oncocytic change is not restricted to Hashimoto's thyroiditis but may also be encountered in long-standing Graves' disease. Oncocytic change occurring in follicular nodules and/or multinodular goitre is conventionally regarded as hyperplastic, whereas clonality studies have demonstrated that many of the larger nodules are in fact monoclonal, thus the biologically correct approach would be to regard these as follicular adenomas.

The mitochondria themselves stain with the phosphotungstic acid haematoxylin (PTAH) method. Positive immunostaining for cytokeratins (notably CK14), vimentin, anti-mitochondrial antibody and weakly for thyroglobulin (TG) is typical. Carcinoembryonic antigen (CEA/CD66e) reactivity is variable. Electron microscopy demonstrates abnormally configured mitochondria (Figure 58.12).

Thyroiditis

The various manifestations of thyroiditis are summarized in Table 58.4. These may be either non-autoimmune or autoimmune, the latter typified by Hashimoto's thyroiditis and Graves' disease and their variants. Drug-induced thyroiditis is associated with the use of a number of drugs including amiodarone, lithium, interferon-alpha and interleukin-2 (Figure 58.13).

Figure 58.12 Transmission electron micrograph of several tumour cells from a poorly differentiated oncocyctic (oxyphil) carcinoma of the thyroid gland. Note the cytoplasmic expansion by scores of swollen mitochondria and paucity of other cell organelles. Two prominent osmiophilic macronucleoli are also plainly seen (TEM, ultra-high magnification).

TABLE 58.4 Classification and features of thyroiditis^{20, 22}

Characteristics	Hashimoto's thyroiditis (chronic lymphocytic or chronic autoimmune thyroiditis)	Painless Postpartum thyroiditis (subacute lymphocytic thyroiditis)	Painless Sporadic thyroiditis (subacute lymphocytic thyroiditis)	Painful Subacute thyroiditis (de Quervain's, giant-cell, pseudo-granulomatous thyroiditis)	Suppurative Thyroiditis (infectious, bacterial, pyogenic thyroiditis)	Riedel's thyroiditis
Age	All ages, peak 30–50	Childbearing age	All ages, peak 30–40	20–60	20–40	30–60
Sex ratio	8–9:1		2:1	5:1	1:1	3–4:1
Cause	Autoimmune	Autoimmune	Autoimmune	Unknown	Infectious	Unknown
Thyroid function	Hypothyroidism	Can be thyrotoxic, hypothyroid or both	Can be thyrotoxic, hypothyroid or both	Can be thyrotoxic, hypothyroid or both	Euthyroid	Euthyroid
TPO status	High	High	High	Low	Absent	Present
ESR	Normal	Normal	Normal	High	High	Normal
Gross pathological features	Symmetrical diffuse enlargement of the thyroid gland Firm consistency, pale colour and multilobulated	Firm to hard, tan white appearance and nodules of varying size	Firm to hard, tan white appearance and nodules of varying size	Firm to hard, tan white appearance and nodules of varying size	Variable appearance including focal or diffuse enlargement and abscess formation Can appear normal	Thyroid replaced by dense, tan-white, firm to hard tissue

Figure 58.13 Thyroiditis. (a) FNAC sample in granulomatous thyroiditis, suspect of tuberculosis. Part of an epithelioid histiocytic granuloma is shown with characteristic overlapping, tangled, angulated ('hockey sticks') and elongated (smear or streamed) nucleoplasm plus an adjacent dissociated polykaryocytic giant cell. There is no colloid content and no obvious necrosis (Pap stain, medium magnification). (b) Complimentary FNAC smear from the same case. Several epithelioid histiocytic granulomata are noted with more numerous plurinucleate giant cells. Again, there is minimal colloid. Care must be taken to discriminate between multinucleate giant cells, often of Langhans' type, of mononuclear/macrophage/histiocyte lineage and aspirated intact tri-dimensional thyroid follicles (pseudo-giant cells) (MGG stain, medium magnification). (Continued)

Figure 58.13 (Continued) Thyroiditis. (c) Non-necrotizing granulomatous thyroiditis typical of subacute (De Quervain's) thyroiditis. There is folliculocentric lymphohistiocytic inflammation, loose epithelioid granuloma formation with multinucleate giant cell transformation, follicle destruction and localized colloidophagy. There is little fibrosis in this early phase of the disease (*H&E stain, medium magnification*). (d) Riedel's thyroiditis (Riedel's struma, ligneous thyroiditis), acute phase illustrating destructive, non-granulomatous fibroinflammatory tissue percolating beyond thyroid gland pseudocapsule into perithyroidal fat with occasional lymphoid aggregates. Phlebitis and nodular fibro-occlusive vasculopathy were seen throughout this thyroid gland (*H&E stain, low magnification*). (e) Replicate section of Riedel's thyroiditis stained for IgG4, highlighting excess numbers of positive plasma cells plus more diffuse background reactivity, presumably of serum origin, supportive of IgG4-related sclerosing disease. Both the IgG4 positive plasma cell count per high-power field and the IgG4:IgG plasma cell ratio were elevated, though not uniformly throughout the specimen (*IgG4 IHC, high magnification*).

Lateral aberrant thyroid tissue

Lateral aberrant thyroid (LAT) tissue or gland describes anomalous deposits of follicular thyroid tissue in the lateral neck. Originally believed to indicate persistent lateral thyroid anlage, the modern view is that the overwhelming majority, but not all, actually represent metastatic follicular thyroid carcinoma or follicular variant of papillary thyroid carcinoma (PTC), the cytonuclear morphology of which may be so deceptively bland as to be virtually indistinguishable from normal or hyperplastic thyroid parenchyma proper.²³

Pragmatically, any such deposits lateral to the carotid sheath ought to be regarded as metastatic disease until otherwise proven. Those extracapsular deposits medial to the carotid sheath may represent either benign sequestered (parasitic) thyroid nodules (Figure 58.14), which generally recapitulate the appearances in the body of the main gland proper, or metastatic tumour. Benign thyroid tissue inclusions in cervical lymph nodes are rarely encountered and are difficult to confirm with certainty.

Hyperplastic nodules

Historically, multiple nodules as part of multinodular goitre, either incompletely capsulated or unencapsulated,

are designated hyperplastic (adenomatoid or cellular colloid) nodules. One or more may predominate, thereby simulating a solitary nodule clinically and/or radiologically (Figure 58.15). They do not normally compress the adjacent gland, which oftentimes displays a similar growth pattern. Secondary retrogressive changes frequently present, sometimes extensive, include coarse fibrosclerosis (sometimes resembling a radial scar), cystic degeneration, calcification, infarction, fresh haemorrhage, haemosiderosis, siderophages, foam cells, cholesterol granulomata, endarteritis obliterans and localized inflammation. Squamous, lipocytic, chondroid, osseous and oncocytic (oxyphil) metaplasia are occasionally seen. Simple papillae (papillary hyperplastic nodule) do rarely occur and the papillae tend to radiate towards the centre of the lesion (Figure 58.16).²⁵ Exhaustive efforts to exclude papillary thyroid carcinoma must be pursued under these circumstances.

The concept of thyroid follicular epithelial dysplasia remains theoretical. Up to 70% of hyperplastic nodules are in fact clonal proliferations and can express various markers of malignant follicular-patterned thyroid tumours. However, no morphological, immunohistochemical or molecular study to date has been able to discriminate between adenomatoid nodules, follicular adenoma and follicular carcinoma with absolute sensitivity and specificity.²⁶

Figure 58.14 Lateral aberrant thyroid tissue. (a) Pericapsular thyroid nodule protruding outside the confines of the anatomical thyroid pseudocapsule, impinging upon perithyroidal fat with an expansile contour. This is the formative stage of sequestration (*H&E stain, low magnification*). (b) Extraglandular sequestered (parasitic) thyroid nodule, completely detached from eutopic thyroid gland proper, but still within the confines of the central neck compartment (*H&E stain, low magnification*).

Figure 58.15 Total thyroidectomy specimen showing a protruberant, well-circumscribed, ovoid mass arising from the left lower pole, clinically excised as a solitary thyroid nodule. This proved to be a dominant hyperplastic (adenomatoid) nodule arising in chronic lymphocytic (Hashimoto's) thyroiditis with several smaller intraparenchymal nodules throughout the main body of the gland bilaterally.

Figure 58.16 Hyperplastic nodules. (a) The edge of a papillary hyperplastic nodule showing localized intracystic mural papillary proliferation immersed in colloid. The papillary projections are simple in contour and tend to project towards the epicentre of the lesion (*H&E stain, low magnification*). (b) Part of a different intracystic papillary hyperplastic nodule, also illustrating arborescent centrifugally projecting papillae. The epithelial cells are monolayered, well-polarized and bland. There were no cytonuclear or architectural features to indicate papillary thyroid carcinoma despite a rigorous search (*H&E stain, medium magnification*).

Secondary tumours

Follicular adenoma

The WHO (4th edition, 2017) classification of tumours of the thyroid gland is reproduced in [Table 58.5](#).²⁷ Follicular adenoma classically occurs as a solitary benign, encapsulated tumour, which shows follicular epithelial differentiation with no evidence of either capsular or vascular invasion and neither architectural nor cytonuclear features of papillary thyroid carcinoma ([Figure 58.17](#)). It possesses a circumferential, smooth-contoured or gently undulating, slender, fibrous delimiting capsule, usually displaying little variation in thickness – fields of capsular augmentation warrant a conscientious search to exclude a carcinoma, especially if FNAC has not previously been attempted. Surrounding native gland may be compressed and/or atrophic.^{8, 22} Internally, there may be a variety of growth patterns, such as normofollicular, microfollicular (foetal), macrofollicular (colloid), solid, trabecular and organoid, though the architecture tends to be fairly uniform within any individual example. Mitoses are few. Degenerative stromal changes, particularly post-FNAC, are identical to multinodular hyperplasia but squamous metaplasia is uncommon and, where present, merits consideration of papillary thyroid carcinoma, follicular variant (FVPTC).

Histological subtypes of adenoma include solid, foetal, oxyphilic (oncocytic), clear cell, signet ring cell ([Figure 58.18](#)) and lipoadenoma, defined according to the predominant growth pattern (accounting for over 75% of the overall tumour). These, however, do not differ clinically or in biological behaviour from conventional follicular adenoma. There is some commonality in architecture and cytological pattern across the follicular tumours, both adenomas and carcinomata ([Box 58.1](#)).

Atypical adenoma (follicular tumour of uncertain malignant potential, FT-UMP) is used to describe follicular neoplasms that display some worrisome microscopical features though falling short of unequivocal capsular or vascular infiltration.²⁸ These include irregularly thickened capsule, partial thickness incursions into, but not completely through, the capsule, hypercellularity, increased mitoses and/or abnormal forms and nuclear atypia ([Figure 58.19](#)).

Figure 58.17 The cut surface of a benign follicular adenoma showing a largely solid, fleshy texture with localized cystic change. The perimeter is evenly contoured and the investing capsule is uniformly slender.

Figure 58.18 Follicular adenoma. (a) Clear cell variant of follicular adenoma. Virtually the entire tumour was composed of colloid filled follicles bounded by thyrocytes possessing abundant faintly reticulated, optically clear cytoplasm (*H&E stain, medium magnification*). (b) Signet ring variant of follicular neoplasm. The individual cells are bloated by dense eosinophilic cytoplasm sometimes displacing and/or compressing the nucleus to the cytoplasmic periphery (signet ring appearance) (*H&E stain, high magnification*).

BOX 58.1 Histological variants of follicular neoplasms

- Hyalinizing trabecular adenoma and carcinoma
- Signet ring adenoma and carcinoma
- Mucinous variant
- Clear cell follicular neoplasm (lipid-rich adenoma)
- Follicular adenoma with papillary hyperplasia
- Encapsulated papillary oncocyctic neoplasm (follicular adenoma and carcinoma, oncocyctic variant with papillary growth)
- Glomeruloid variant
- Meningioma-like tumour of the thyroid
- Follicular neoplasm with lipomatous stroma (adenolipoma/lipoadenoma/thyrolipoma)
- Follicular neoplasm with cartilaginous metaplasia
- Atypical adenoma
- Follicular adenoma with bizarre nuclei
- Hyperfunctioning follicular tumours ('hot nodules')

Figure 58.19 Atypical follicular adenoma. (a) A cross-sectional slice through an atypical adenoma (follicular tumour of uncertain malignant potential, FT-UMP). Despite the widespread capsular fibrosis and multiple, irregular, virtually full-thickness internal incursions, at no point can convincing complete transcapsular infiltration be demonstrated. (b) Whole mount preparation of the same lesion. Circumferentially, tumour does not invade beyond the original capsular contour (*H&E stain, ultra-low magnification*).

Hyalinizing trabecular tumours

Hyalinizing trabecular tumours (HTTs) are a group of neoplasms originally regarded as adenomas (hyalinizing trabecular adenoma/HTA, paraganglioma-like adenoma of the thyroid/PLAT). It has subsequently transpired that the supposed characteristic organoid growth

pattern with interstitial perivascular hyalinization may also be seen focally in nodular hyperplasia plus a number of other benign and malignant thyroid neoplasms, many, though not all, showing histological features of papillary thyroid carcinoma, including *RET/PTC* gene rearrangements. In those examples of pure HTT architecture without papillary carcinomatous morphology

Figure 58.20 Hyalinizing trabecular tumour. (a) Minimally invasive hyalinizing trabecular carcinoma demonstrating the typical organoid nested and trabecular architecture separated by hyalinized interstitium, richly endowed with blood vessels. Elsewhere, this example showed mushrooming transcapsular growth. There are no features to suggest papillary thyroid carcinoma in this neoplasm but there was synchronous classical papillary thyroid carcinoma separately in the specimen (*H&E stain, medium magnification*). (b) The same tumour illustrating universal Ki67 (MIB-1) immunoreactivity. Note that this is peculiarly membranous and cytoplasmic in distribution and is antibody clone/manufacturing source dependent. Ki67 is conventionally used as a proliferation marker where, in other circumstances, it stains the nuclei only of those cells in certain phases of the cell cycle (*Ki67 IHC, medium magnification*).

there appears to be a spectrum of biological potential ranging from adenoma to carcinoma, both minimally invasive and widely invasive by conventional criteria.²⁹ A proportion of such neoplasms exhibit characteristic, peculiar, avid cytoplasmic Ki67 (MIB-1) immunostaining (Figure 58.20). Immunopositivity for cytokeratins, thyroglobulin and vimentin generally with negative pan-neuroendocrine marker and calcitonin staining discriminates HTT from paraganglioma proper and medullary thyroid carcinoma.

Follicular carcinoma of the thyroid

Follicular thyroid carcinoma (FTC) is a malignant epithelial tumour arising in both eutopic thyroid gland and/or heterotopic thyroid tissue, showing follicular cell differentiation and bereft of the characteristic features of papillary thyroid carcinoma (PTC). It accounts for 5–15% of all thyroid cancers in iodine-sufficient regions. It spreads via haematogenous routes, preferentially to bone and lung with metastatic disease as a presenting feature in 11% of patients. It is divided into two basic categories defined by the extent of capsular infiltration and/or presence of vascular invasion (Table 58.6) and meticulous examination of the tumour capsule and interface with native gland is consequently of paramount importance.

Minimally invasive follicular carcinoma (MIFC) is the common variant and is characterized by microscopical transcapsular invasion and/or pericapsular vascular infiltration.³⁰ With experience, obvious capsular violation and/or accompanying fibrous capsular thickening may be appreciated in the gross specimen by the unaided eye (Figure 58.21), but not more subtle capsular transgression or vascular permeation.

Widely invasive follicular carcinoma (WIFC) is readily identified grossly by infiltrative, destructive or sometimes multinodular growth, the latter separated by fibrous bands, expanding into surrounding native gland. This may be so strikingly obviously nodular as to be mistaken for multinodular hyperplasia by the unwary, particularly if there is no clearly identifiable vestige of pre-existing capsule for reference.

The interpretation of capsular invasion remains somewhat controversial. Most authorities require full-thickness capsular transgression beyond the original lesional contour (capsular invasive MIFC), whereas a dwindling minority of authors accept a given neoplasm as MIFC if it shows only partial-thickness capsular penetration. Full-thickness violation manifests as multiple foci, less commonly a single nidus, of mushrooming herniation bulging into and displacing surrounding native follicles, without infiltrative/permeative growth. Lateral fibrous capsular thickening (buttressing) and neocapsule formation along the advancing tumour to gland interface are paradigmatic,

TABLE 58.6 Classification of follicular thyroid carcinoma²⁷

Traditional	AFIP 2015		WHO 2017
Minimally invasive	Minimally invasive	With capsular invasion	Minimally invasive
		With limited vascular invasion (<4 vessels)	Encapsulated angioinvasive
		With extensive vascular invasion (≥4 vessels)	Widely invasive
Widely invasive	Widely invasive		Widely invasive

Figure 58.21 Minimally invasive follicular carcinoma. (a) Obvious mushrooming, full-thickness, transcapsular herniation qualifying as minimally invasive follicular carcinoma, easily discernible to the unaided eye during dissection. There is slight lateral capsular buttressing but negligible neocapsule formation along the advancing margin in this example. Note that there is no universally endorsed maximum size limit for this phenomenon. (b) The same area viewed histologically corroborates streaming impingement into perilesional native gland with no tentacular/permeative infiltration and neither significant host inflammatory nor stromal response (*H&E stain, low magnification*).

but not invariable. Incomplete capsular encroachment includes areas of irregular, serratiform and/or undulating inner capsular contour, perpendicular dentate capsular incursions and horizontally disposed (entrapped) intracapsular follicles, which do not qualify, though they should prompt further detailed scrutiny, as should any unexplained area of capsular expansion. Circumscribed extracapsular (satellite) nodules may represent MIFC visualized outside the plane of connection with the body of the tumour (though such a pedicle may sometimes be impossible to demonstrate) or a sequestered (parasitic) congeries of benign follicles. Comparison of the cytonuclear features with the main tumour bulk may aid discrimination here. Current recommendation is that, unless there is identifiable connection with the main tumour mass, such satellitosis should not be regarded as definite evidence of capsular violation.

Artefactual capsular puncture, healing and distortion following FNAC should be interpreted with caution and the entry/exit site of normal capsular blood vessels, where there is typically smooth curvilinear capsular interruption, not misconstrued. Well-sampled tumours that fall short of these criteria are termed follicular tumour of uncertain malignant potential (FT-UMP).

There are studies indicating that both the existence and the extent of vascular invasion are of portentous significance. Whilst there is a general consensus as to what defines angioinvasion (grossly encapsulated angioinvasive MIFC), there remains some dissent. The majority opinion is that tumour penetration should be into medium-calibre or large-calibre intracapsular or extracapsular blood vessels and polypoidal intraluminal growth should be endothelialized with/or without thrombus, though not necessarily adherent (**Figure 58.22**). Tumour invasion and obturation of large calibre veins is sometimes a feature, extending beyond the confines of the thyroid gland, in a pattern akin to infiltration of the renal vein/vena cava by clear cell carcinoma of the kidney. A point of attachment of tumour to vessel wall is a prerequisite for some observers. Free-lying

nests of tumour cells may represent artefactual dislodgement. Tumour cells occupying capillary-sized intracapsular vessels are of no proven clinical importance and should be discounted. Tumour within intralesional or subcapsular vessels does not qualify. Reactive vascular endothelial hyperplasia may simulate angioinvasion and, when recognized, ought to prompt a rigorous search for vascular invasion proper. Immunostaining for vascular endothelial markers (e.g. CD31, CD34) and lymphatic endothelium (e.g. D2-40) may be helpful in selected instances. Cognizant that absolute discrimination between blood vessel invasion and lymphatic space infiltration may ultimately be impossible, the RCPATH defines vascular invasion as involvement of any definite endothelial-lined space and the current College of American Pathologists (CAP) protocol recommends merging the two and reporting under the unifying designation of lymphovascular invasion.³²

Figure 58.22 Pericapsular angioinvasion qualifying as encapsulated (angioinvasive) minimally invasive follicular carcinoma. There is a broad tongue of endothelialized tumour unequivocally protruding into a large-calibre intracapsular vessel (*H&E stain, low magnification*).

Capsular invasive MIFC without lymphovascular invasion portends an extremely low risk of metastasis (less than 1%), justifying the option of a conservative management approach with treatment by lobectomy, acknowledging that there is a small risk of undertreatment in a minority of cases. The term grossly encapsulated angioinvasive follicular carcinoma has been proposed for encapsulated tumours with any foci of lymphovascular invasion, based on the premise that access to even one or a few endothelial-lined vessels confers the capacity for more aggressive behaviour with heightened risk of recurrence, thereby offsetting a designation of minimal invasion. Encapsulated angioinvasive MIFC with limited (minimal) vascular invasion, defined as a few microscopic foci (up to 4 foci) is said to show a low risk of metastasis (approximately 5%). MIFC with more extensive lymphovascular infiltration (defined as 5 or more foci) is said to portend a higher likelihood of metastasis (up to 42%)^{33, 34} and the term grossly encapsulated follicular carcinoma with extensive angioinvasion acknowledges this. Specifying a precise threshold for the number of foci of lymphovascular invasion is, however, controversial, not least because a histological section is a two-dimensional representation of a tri-dimensional system and inadvertent replication by counting infiltration potentially into the same vessel visualized in close proximity and/or in a different plane of section is of dubious biological validity and reproducibility.

WIFC is an aggressive neoplasm with a high risk of distant secondaries (29–66%). It displays infiltrative growth within and beyond the anatomical thyroid pseudocapsule proper, sometimes in the form of successive generations of herniating capsular transgression (**Figure 58.23**). Vascular penetration is common and the more widespread it is, the worse the prognosis.

Extrathyroidal extension (ETE) describes involvement of perithyroidal soft tissues by primary thyroid carcinoma. This may be further subdivided into microscopic (minimal/minor/limited) ETE and macroscopic (extensive/major/massive/marked/gross) ETE. As previously noted, the thyroid pseudocapsule is not a discrete anatomical structure, is incomplete or focally absent in a majority of individuals,

Figure 58.23 The cut surface of a widely invasive follicular carcinoma demonstrating successive generations of capsular transgression to the point where the original lesional capsule becomes almost obscured.

is additionally fenestrated by lymphovascular channels and contains small nerve radicles. The histological evaluation of minimal ETE into immediate peri-thyroidal soft tissue is consequently subjective, prone to poor reproducibility and, owing to its limited prognostic value, has been expunged from the UICC/TNM (8th edition, 2017) staging schema.³⁵ Importantly, both adipocytes and skeletal muscle bundles may be normally encountered within the thyroid gland and may also be a component of a variety of pathological thyroid conditions. The identification of a desmoplastic response, adipocytic and/or muscular impingement in close proximity to large-calibre, thick-walled vessels and/or large nerve trunks, on the other hand, may be more helpful, as such would not be expected within the confines of the thyroid gland proper. Extensive ETE is characterized by direct infiltration well beyond the limits of the thyroid gland into anterior strap musculature (sternohyoid M, sternothyroid M, thyrohyoid M and/or omohyoid M), subcutis, neighbouring viscera including larynx, trachea, oesophagus, recurrent laryngeal nerve, carotid artery or mediastinal vasculature. Extensive ETE is invariably obvious, typically identified by the surgeon perioperatively.

The prognosis for those carcinomas with minimal ETE worsens referenced against those without ETE. Similarly, the survival prospects for those suffering carcinomas with extensive ETE are significantly diminished in comparison with minimal ETE.

Gross or microscopic involvement of surgical margins informs the TNM R stage of a tumour and is of prognostic significance. There is no evidence-based definition for the distance required for complete excision, simply that non-neoplastic tissue is interposed between tumour and excision plane. The exercise of measuring the distance of tumour to closest resection margin is therefore somewhat arbitrary.^{33, 36} Initial studies suggesting that a microscopically positive posterior margin poses a significantly higher risk of recurrence than a positive anterior margin merits further scrutiny.³³

Oncocytic (oxyphil) cell tumours

Follicular neoplasms comprising 75% or more oncocytic (oxyphil) cells are designated as such and are subclassified according to the same criteria as their non-oncocytic counterparts based upon morphology, immunohistochemical profiling and molecular markers as oncocytic (oxyphil) adenoma, oncocytic (oxyphil) tumour of uncertain malignant potential, minimally or widely invasive oncocytic (oxyphil) carcinoma (Hürthle cell carcinoma). Oncocytic variants of papillary thyroid carcinoma, poorly differentiated thyroid carcinoma, undifferentiated (anaplastic) carcinoma and medullary thyroid carcinoma are recognized. Focal clear cell change is common in oncocytic tumours and, where this constitutes over 75% of the lesion, it is traditionally designated as clear cell carcinoma. Under such circumstances, it is imperative to exclude metastatic carcinoma (e.g. renal or adrenal),³⁷ malignant melanoma, intrathyroidal parathyroid gland neoplasms and clear cell variant of medullary thyroid carcinoma.

Grossly, they are usually single nodules (solitary oxyphil follicular tumour, SOFT) (**Figure 58.24**), although they may be multiple (multiple oxyphil follicular tumour, MOFT) and

Figure 58.24 A small, benign solitary oncocytic (oxyphil) cell follicular tumour (SOFT), occurring sporadically in a background of chronic lymphocytic (Hashimoto's) thyroiditis. Despite its lack of capsule and occasional rudimentary papillae, there were no diagnostic features to suggest papillary thyroid carcinoma (H&E stain, low magnification).

are sometimes associated with Hashimoto's thyroiditis and/or conventional papillary thyroid carcinoma (PTC). A higher proportion of oncocytic (oxyphil) tumours are malignant than other follicular lesions, and when staged comparably there is some experience that they fare worse than their non-oncocytic counterparts, possibly a sequela of their low avidity for radioiodine. The incidence of malignancy in oncocytic (oxyphil) cell neoplasms increases with size, with 17%, 23% and 65% or more associated with maximum dimensions of less than 1 cm, between 1 cm and 4 cm and larger than 4 cm respectively.³⁸ Most examples are sporadic. Familial examples are rare and may indicate a germline mutation.³⁹

Macroscopically they are classically mahogany brown tumours with a propensity for ischaemic infarction, either spontaneously or post-FNAC. They may show numerous histological patterns, including papillary areas, which may morphologically overlap with oncocytic (oxyphil) papillary thyroid carcinoma (PTC). They are typified by cytonuclear atypia and mitoses, though in isolation these do not reproducibly predict biological behaviour.

Oncocytic (oxyphil) parathyroid gland neoplasms should always be considered when evaluating a potential oncocytic (oxyphil) thyroid neoplasm, as they may be indistinguishable by routine orthodox microscopy without recourse to immunostaining.

Papillary thyroid carcinoma

Papillary thyroid carcinoma (PTC) is a malignant epithelial tumour showing follicular cell differentiation with characteristic nuclear features. It accounts for approximately 80% of all thyroid cancer and is also the commonest paediatric thyroid malignancy. In adults it typically occurs between the ages of 20 and 50 years with a female preponderance with less pronounced gender bias in patients over 50 years old. It normally carries an excellent prognosis, especially in younger patients. In areas of adequate dietary iodine, papillary thyroid carcinoma usually presents as a solitary thyroid nodule. In regions of iodine

Figure 58.25 The cut surface of a classical papillary thyroid carcinoma illustrating a solid, granular appearance with adjoining encysted elements distended by inspissated colloid. The yellow punctate structures represent psammoma calcification and imparted a gritty texture.

insufficiency multinodular goitre is common and papillary thyroid carcinoma can present as a more prominent or distinctive nodule. It has a propensity for lymphatogenous spread, initially to locoregional lymph nodes.

The potential macroscopical and microscopical manifestations of PTC are protean. Prototypically, it is invasive with irregular outline and either a scirrhous or granular, gritty texture often with multiloculated cystic change and colloid contents (Figure 58.25). The encapsulated follicular variant of PTC (EFVPTC, Lindsay tumour) is usually well circumscribed possessing a solid, fleshy cut-surface, closely resembling an adenoma.

The principal defining feature of PTC is its nuclear morphology by light microscopy (Figure 58.26), thus the diagnosis of PTC is sustainable even in the absence of invasive growth. Crucially, however, the distinctive appearances may be very localized and, in an appropriate context, the diagnosis may still be entertained in their absence. Ordinarily, there is at least focal nucleomegaly, nuclear crowding and nuclear overlap ('basket of eggs'). Homogenization of karyoplasm ('ground glass' nuclei) with margination of chromatin (likened to the empty-looking, pupil-less eyes of Harold Gray's cartoon strip characters, most famously the waif Little Orphan Annie and her canine companion Sandy) is characteristic, but not pathognomonic. It is not invariable, it is rarely present in FNAC and frozen sections, it may be encountered in other non-neoplastic conditions (notably Hashimoto's thyroiditis, Graves' disease and dyshormonogenetic goitre), it may be simulated by sub-optimal tissue fixation (bubbly or pseudo-clear artefact) and is subject to vagaries of inter-observer and intra-observer reproducibility. Longitudinal nuclear grooves ('coffee beans'), nucleolemmal scalloping ('rat bites'), rents and irregularity formed by redundant, folded nuclear membrane and intranuclear cytoplasmic inclusions (pseudo-inclusions) formed by cytoplasmic herniation are typical and may be visualized on both FNAC and frozen section (Figure 58.27), but these again are not exclusive and may be mimicked by emptier looking intranuclear bubble artefact (pseudo-pseudo-inclusions,

Figure 58.26 Papillary thyroid carcinoma. (a) The characteristic nuclear enlargement, nuclear crowding, nuclear overlap (basket of eggs) and optically clear karyoplasm (Little Orphan Annie eye) of papillary thyroid carcinoma. A few nuclear grooves (coffee beans) and isolated intranuclear cytoplasmic inclusions are also present.

(b) For comparison, this depicts pseudo-clear (bubbly) nuclear artefact, consequent upon suboptimal tissue fixation and processing. Although there is some anisonucleosis and margination of chromatin, there is no real nuclear crowding or overlap. The nucleoplasm is polyvacuolated with conspicuous nucleolation. Pseudo-inclusions (vacuoles or holes) are numerous, much less densely staining than the thyrocyte cytoplasm and they lack any sharply delimiting nucleolemmal rim. Furthermore, these changes are strikingly zoned, seen towards the centre of a dominant hyperplastic nodule and gradually merged with propitiously preserved follicles more peripherally (H&E stain, high magnification).

(c) Dysmorphogenetic goitre from an adolescent with Pendred's syndrome. Again, there is apparent homogenization of chromatin with plentiful nuclear grooves ('coffee beans'), albeit with evenly disposed nuclei and preponderant follicular-patterned growth. The very comprehensive, bilateral and diffuse distribution of these changes throughout the entire gland with preserved lobular architecture militates against malignancy here, with the proviso that this may be a vexatious differential diagnosis (H&E stain, high magnification).

Figure 58.27 FNAC preparation illustrating numerous rounded intranuclear cytoplasmic inclusions and several longitudinal nuclear grooves (coffee beans) in papillary thyroid carcinoma (MG stain, high magnification).

vacuoles, holes). The latter is often unduly widespread and lacks the discrete nuclear membrane rimming of true intranuclear cytoplasmic inclusions in *forme pleine*.

A papillary architecture is typical though by no means universal. The papillae are often well vascularized and complexly arborescent, sometimes oedematous (hydropic), hyalinized, fibrocellular, calcified or micropapillary in configuration (Figure 58.28). Follicles are usually present, albeit with an elongated, tortuous or crenated outline ('twisted' follicles) sometimes with rudimentary or abortive papillae and colloid is often more densely hyper eosinophilic compared to autochthonous follicles. Intrafollicular multinucleated giant cells of macrophage/histiocyte lineage phagocytosing colloid (colloidophagy) are more often seen in PTC than in other lesions (Figure 58.29).

Psammoma bodies (laminated calcospherites) are present in roughly 50% of PTCs histologically, less frequently on FNAC and are virtually pathognomonic. They probably represent mineralized stromal cores and, therefore, must be stromal in location, in contradistinction to calcified, inspissated intrafollicular colloid (psammomatoid calcification or pseudo-psammoma bodies) seen in normality and other

Figure 58.28 FNAC tissue microbiopsy from a papillary thyroid carcinoma. Despite its thickness, obscuring much cytonuclear detail (a few nuclear inclusions and nuclear grooves are nonetheless visible), the branching vascularized fronds are a useful diagnostic feature. Colloid, where present, tends to be globular or in strands ('chewing gum' or stringy colloid) (*Pap stain, medium magnification*).

disease states (such as oncocytic tumours) (Figure 58.30). Importantly, psammoma bodies may also be seen in other neoplastic and non-neoplastic conditions, both within and outside the thyroid gland. Rarely, psammoma bodies or linear scoring artefact following microtomy provide the only presumptive evidence of regressed or infarcted PTC. Multicentric PTC is common and represents either intrathyroidal lymphatic spread or synchronous primary tumourgenesis with different *RET/PTC* translocations.

Numerous variants of PTC have been described, none mutually exclusive within an individual tumour (Box 58.2). A single tumour is classified according to its predominant histological pattern. Most subtypes are of no prognostic

(a)

Figure 58.29 Several intrafollicular multinucleate giant cells, of macrophage/monocyte lineage, phagocytosing vacuolated colloid (colloidophagy) in a PTC. This phenomenon is often seen in PTC, but not exclusively so (*H&E stain, high magnification*).

significance, although tall cell, diffuse sclerosing, diffuse follicular, solid, trabecular, hobnail/micropapillary and dedifferentiated variants (Figure 58.31) are biologically more aggressive in contrast to the encapsulated variant (where conventional infiltrative growth may not be apparent), which portends a highly favourable outcome. Increased mitoses (over two mitoses per ten high-power fields) and tumour necrosis signify worse survival in PTC. PTCs measuring less than 1 cm are associated with an excellent prognosis and the outlook worsens for those tumours exceeding 4 cm. Positive lymph nodal metastasis in PTC is usually an indication for radioactive iodine therapy and the presence of extranodal extension heightens risk of distant metastasis and death. Areas of squamous differentiation (morulae) occur in approximately 50% of cases

(b)

Figure 58.30 Psammoma bodies. (a) Psammoma bodies in papillary thyroid carcinoma. These concentrically laminated concretions are stromal in location. They are often said to represent mineralized tombstones to a mummified cell or papilla, the latter forming the initial nidus for mineral encrustation. They may occasionally be large and complex in configuration. Some of these have splintered during microtomy. Any calcified deposits or other hard objects are prone to dislodgement by the microtome blade and being swept across the tissue section to give parallel linear score artefact (*H&E stain, medium magnification*). (b) Psammoma body within fibroblastic interstitium encountered as part of retrogressive change in multinodular hyperplasia. There was no evidence of neoplasia (*H&E stain, high magnification*).

(Continued)

Figure 58.30 (Continued) Psammoma bodies. (c) FNAC from a papillary thyroid carcinoma showing two concentrically lamellated psammoma bodies mantled by vacuolated epithelial cells. Psammoma bodies are seen in 40–60% of papillary thyroid carcinomas in histological sections but in only 20% of cases in FNAC specimens³⁶ (*H&E stain, high magnification*). (d) Three psammomatoid spheruliths (concretions or pseudo-psammoma bodies) occupying follicular lumina, again composed of inspissated, partially mineralized intrafollicular colloid in a case of PTC, but also commonly a feature of oncocytic (oxyphil or Hürthle cell) neoplasms (*H&E stain, high magnification*).

Figure 58.31 PTC variants. (a) Tall cell variant of papillary thyroid carcinoma. The cells are columnar, their height being at least three times greater than their width, and they are not hyperstratified, in contradistinction to columnar cell carcinoma (*H&E stain, high magnification*). (b) Solid variant of papillary thyroid carcinoma. The small cell nests demonstrate the distinctive nuclear features. This example behaved extremely aggressively (*H&E stain, high magnification*). (Continued)

Figure 58.31 (Continued) PTC variants. (c) Hobnail variant of PTC characterized by a significant proportion of the cells showing reverse nuclear polarity with protruberant apical nuclei and/or luminal blebs (snouting) of cytoplasm (*H&E stain, high magnification*). (d) Contiguous tubulocribriform arcs of thyrocytes of the pattern seen in cribriform-morular variant PTC (*H&E stain, medium magnification*). (e) Papillary thyroid carcinoma, Warthin tumour-like variant, microscopically resembling Warthin's tumour (adenolymphoma) of salivary gland (usually parotid gland) derivation. The epithelium is oncocytic (Hürthle cell) and there is marked reactive lymphocytosis expanding papillary stromal cores (*H&E stain, low magnification*). (f) Diffuse sclerosing variant of PTC dominated by dense, acellular, paucivascular sclerohyaline stroma. Psammoma body formation and associated parallel linear microtomy score marks traversing the section are exemplary (*H&E stain, medium magnification*).

and the distinctive PTC nuclear morphology is absent from such areas (Figure 58.11a). The WHO definition of tall cells in PTC is merely a preponderance of tumour cells whose height is at least threefold (previously twofold) greater than their width, and this pattern should not be confused with columnar cell carcinoma. Note that there is presently no unanimous agreement on the percentage of tall cell morphology required to define an entire PTC as tall cell variant. The appellation solid variant is reserved for tumours displaying 50% or more solid growth pattern.

PTC stains immunohistochemically for cytokeratins (CKs), thyroglobulin (Tg) and thyroid transcription factor-1 (TTF-1) but not pan-neuroendocrine markers. Areas of squamous differentiation lose their Tg and TTF-1 reactivity. A plethora of markers have been proposed to aid discrimination between follicular variant of PTC and other follicular lesions, notably high molecular weight cytokeratins (HMWCKs), low-molecular weight cytokeratin

(cytokeratin 19/CK19), Hectort Battifora mesothelial-1 antibody (HBME-1), galectin-3 (GAL-3), neural cell adhesion molecule (NCAM), (CD56), Leu7 (CD57), LeuM1 (CD15), fibronectin-1 (FN-1), platelet-derived growth factor (CD44), p63 protein, trophoblastic cell surface antigen (TROP2), paired box gene 8 (PAX8), Thyroid transcription factor-2 (TTF-2), thyroperoxidase (TPO), BRAF mutation specific antibody and *RET* among others. None, individually or in combination, is entirely sensitive or specific for PTC: they may be capricious even in classical PTC, and a number of inflammatory and other neoplastic conditions may yield ambiguous and/or spurious results. CK19 staining in isolation has a low specificity and low sensitivity. The panel of cytokeratin 19 and HBME-1 has a higher exclusionary power than positive predictive power: if both markers are negative, this militates against a diagnosis of PTC, whereas positivity of either, or both, is supportive but not conclusive (Figure 58.32). CD56 is expressed by normal thyrocytes,

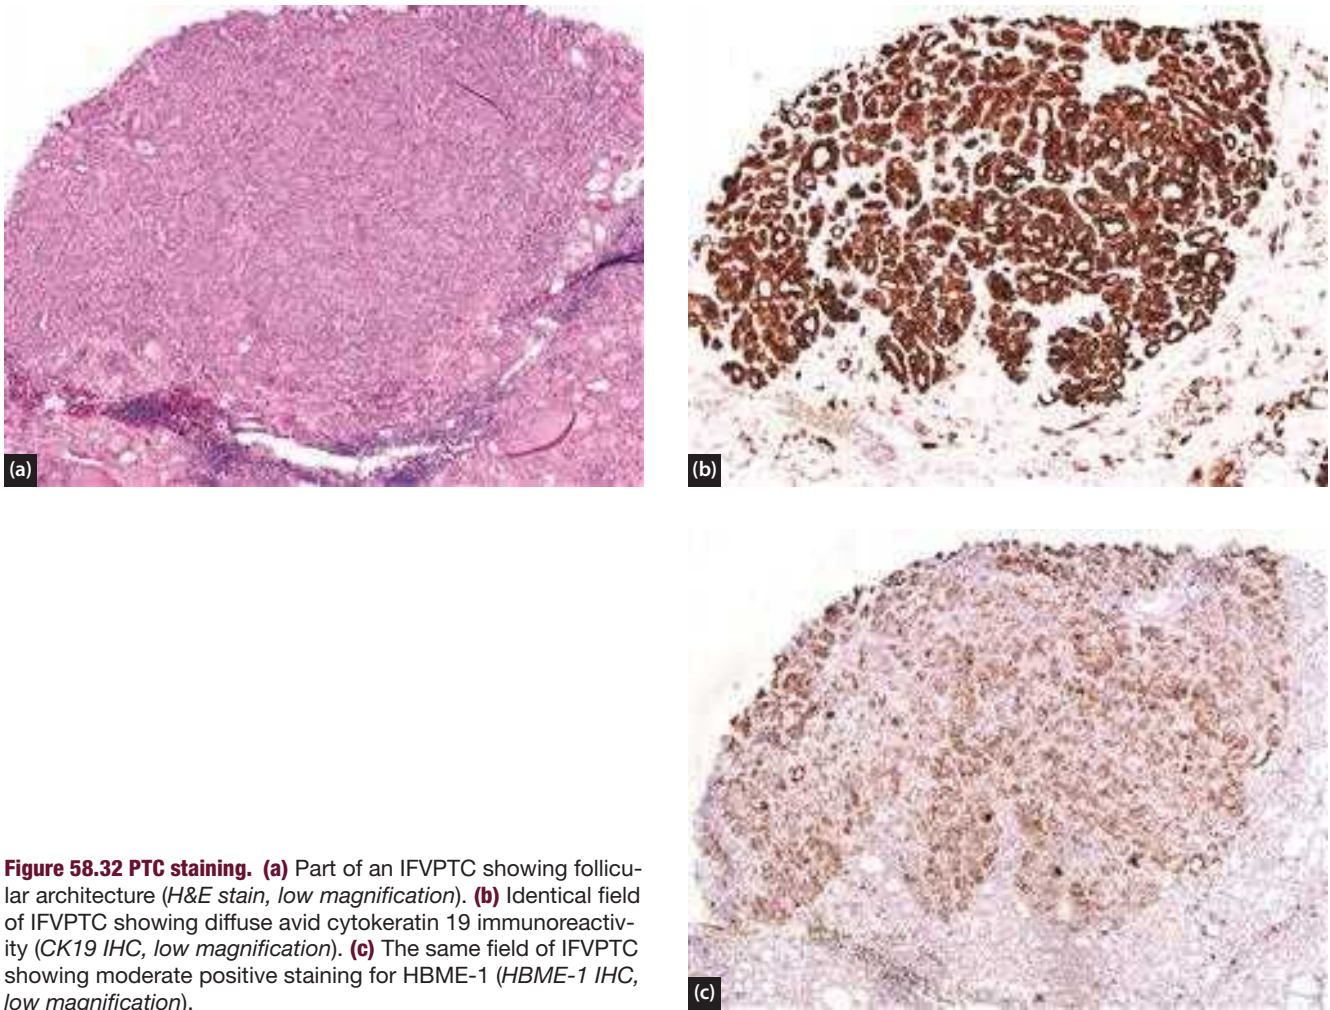

Figure 58.32 PTC staining. (a) Part of an FVPTC showing follicular architecture (H&E stain, low magnification). (b) Identical field of FVPTC showing diffuse avid cytokeratin 19 immunoreactivity (CK19 IHC, low magnification). (c) The same field of FVPTC showing moderate positive staining for HBME-1 (HBME-1 IHC, low magnification).

benign and malignant follicular lesions but generally not by PTC. Absent, or low, CD56 expression (typically less than 5% or so, confined to the tumour-native tissue interface) in a follicular-patterned neoplasm is claimed to be consistently specific and extremely sensitive for PTC, more so than CK19. In the appropriate context, CD 56 immunonegativity, or loss of CD56 expression in various degrees, is supportive of malignancy and may compliment diagnostic accuracy of PTC when used as a panel in conjunction with CK19, p63 protein and/or HBME-1 antibodies. However, undue reliance should not be placed upon immunostaining in isolation.

Three independent molecular pathways are recognized in the tumorigenesis of PTC with distinct gene expression profiles, namely activation of the proto-oncogene receptor tyrosine (*RET*) kinase, mutation of the gene for B-raf (*BRAF*) and *ras* mutation. *RET* kinase activation consequent upon chromosomal translocation is collectively referred to as *RET/PTC* translocation and occurs in up to 60% of PTCs. *RET/PTC 1* fusion correlates to classical PTC and papillary microcarcinoma. *RET/PTC 3* fusion is seen in tall cell and solid PTC variants plus irradiation-induced tumours. *RET/PTC* expression is not a feature of follicular carcinoma, poorly differentiated carcinoma or undifferentiated (anaplastic) carcinoma. Mutation of the gene for B-raf (*BRAF*) accompanies

29–69 % of PTCs, more prevalent in classical PTC, tall cell, Warthin tumour-like and oncocytic (oxyphil) variants. FVPTC harbours *ras* gene mutations and may show *PAX8/PPAR γ* translocation, but rarely *RET/PTC* translocation or *BRAF* mutations, a profile akin to that of follicular adenoma and follicular carcinoma.⁴

Follicular-patterned tumours of uncertain malignant potential

Perhaps the most controversial development relating to thyroid pathology over the past two decades has been the recognition and incorporation into mainstream classification of a group of well-differentiated follicular-patterned neoplasms (intermediate or borderline) that lie morphologically and behaviourally between follicular adenoma and follicular carcinoma/FVPTC – tumours of uncertain malignant potential (atypical adenoma, adenoma with atypia, well-differentiated tumour of uncertain behaviour). Whether these lesions constitute distinct entities, and if so, whether they qualify as carcinoma/neoplasms of low malignant potential has yet to be categorically determined.

Historically, limited follow-up data, compounded by subjective judgement and well recognized poor inter-observer concordance and intra-observer variation has

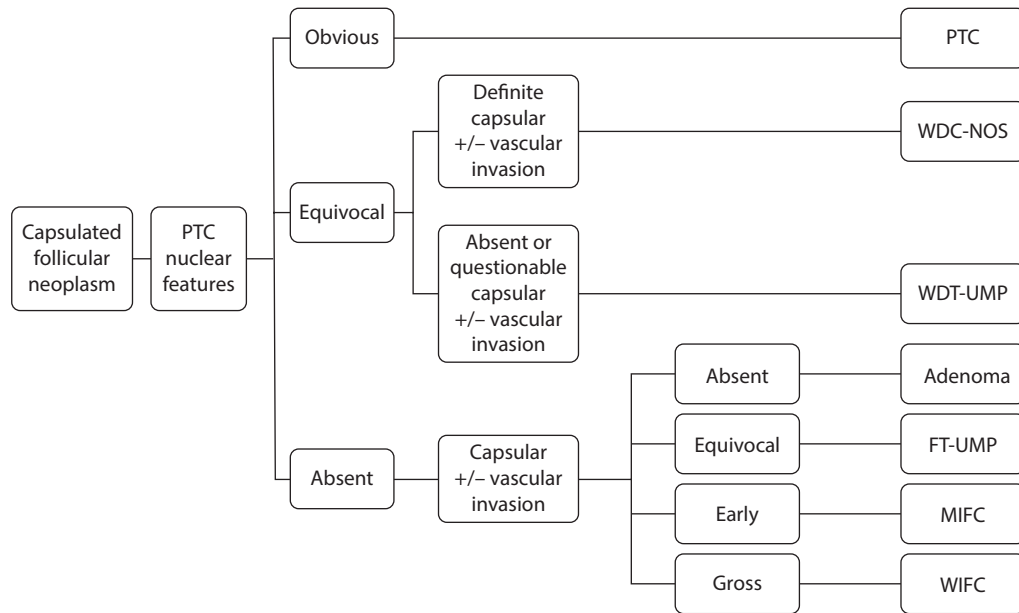

Figure 58.33 Chernobyl Pathologists’ Group nosology and diagnostic algorithm for resolution of the differential diagnosis of encapsulated follicular-patterned lesions of the thyroid gland. PTC: papillary thyroid carcinoma; WDC-NOS: well-differentiated carcinoma, not otherwise specified; WDT-UMP: well-differentiated tumour of uncertain malignant potential; FT-UMP: follicular tumour of uncertain malignant potential; MIFC: minimally invasive follicular carcinoma; WIFC: widely invasive follicular carcinoma.

been problematical, prompting recourse to a pragmatic *ipse dixit* diagnosis.²⁵ Furthermore, RET/PTC expression in some cases of FVPTC shows multicentric rather than diffuse alterations, suggestive of carcinomatous transformation ex-adenoma, though by convention it is recommended that the entire encapsulated lesion is arbitrarily regarded as PTC for staging purposes.²⁶

In recognition of these difficulties, the Chernobyl Pathologists’ Group proposed alternative nomenclature to accommodate this diagnostic uncertainty and this is summarised in Figure 58.33. For more than a decade this provided a more descriptive schema, which could be invoked in the minority of cases where diagnostic equivocation was irresolvable by conventional morphology and the stigma of malignancy was potentially unjustifiable and equally undesired. Until recently, however, this approach was not wholly accepted into mainstream diagnostic practice. The Armed Forces Institute of Pathology (AFIP) fascicle 2015 did embrace this philosophy and adopted the terminology into its classification (Table 58.7). Subsequently, the WHO (4th edition, 2017) classification has refined this further (Table 58.8).²⁷

For encapsulated follicular-patterned tumours indeterminate between follicular adenoma and follicular

carcinoma, lacking nuclear features of PTC, where capsular invasion is equivocal, the WHO (4th edition, 2017) classification retains the descriptor *follicular tumour of uncertain malignant potential (FT-UMP)*, but has expanded its scope to include equivocal vascular invasion.²⁷

For encapsulated, or well circumscribed, follicular-patterned tumours with well-developed or equivocal nuclear features of PTC, the term *well-differentiated tumour of uncertain malignant potential (WDT-UMP)* was also adopted by the AFIP fascicle 2015. The WHO (4th edition, 2017) classification further recognizes that non-invasive encapsulated FVPTC is associated with an excellent prognosis and possesses molecular features more akin to follicular adenoma/carcinoma than those of conventional PTC – the term *non-invasive follicular thyroid neoplasm with papillary-like nuclear features (NIFTP)* has been introduced to encompass non-invasive encapsulated follicular-patterned tumours previously called encapsulated FVPTC as well as *WDT-UMP*.²⁷ The designation *WDT-UMP* is reserved in this classification for well-developed or incompletely developed PTC-type nuclei and questionable capsular or vascular invasion.

Where diagnostic distinction between invasive follicular carcinoma and invasive PTC is difficult, the generic

TABLE 58.7 AFIP recommended nomenclature for encapsulated well-differentiated follicular-patterned tumours based on the presence or absence of PTC nuclear features and capsular invasion, AFIP fascicle 2015.³²

		Capsular invasion		
		Present	Questionable	Absent
Nuclear features of PTC	Present	Follicular variant of PTC

		Capsular or vascular invasion		
		Present	Questionable	Absent
Nuclear features of PTC	Present	Invasive encapsulated follicular variant of PTC	Well-differentiated tumour of uncertain malignant potential	Non-invasive follicular thyroid neoplasm with papillary-like nuclear features
	Questionable	Well-differentiated carcinoma, NOS		
	Absent	Follicular carcinoma	Follicular tumour of uncertain malignant potential	Follicular adenoma

rubric *well-differentiated thyroid carcinoma, not otherwise specified (WDT-NOS)* may still rarely be employed, though every effort to sub-classify more precisely should be expended.⁴⁰

NON-INVASIVE FOLLICULAR THYROID NEOPLASM WITH PAPILLARY-LIKE NUCLEAR FEATURES

The follicular variant of papillary thyroid carcinoma (FVPTC) is the most prolific variant of PTC, accounting for around 30% of all PTCs. Small variations in outcome (dependent upon the presence/absence of invasion) notwithstanding, the long-term prognosis is near universally excellent, supporting the notion that these tumours are biologically indolent. Discounting the rare diffuse follicular and macrofollicular variants of PTC and encapsulated papillary carcinoma (the latter denoting classical PTC bounded by a thick capsule but with dominant papillary rather than follicular architecture), further subclassification into invasive follicular variant (IFVPTC), encapsulated follicular variant with invasion (EFVPTC) and encapsulated follicular variant without invasion (non-invasive follicular thyroid neoplasm with papillary-like nuclear features, NIFTP), is clinically useful.

In terms of follicular growth and nuclear morphology, IFVPTC is identical to EFVPTC, except that capsulation is typically incomplete and it shows wide infiltration into adjacent parenchyma with commensurate risk of locoregional recurrence and likelihood of metastasis, behaviour more analogous to classical PTC.

Both EFVPTC (which encompasses non-capsulated and incompletely capsulated but circumscribed tumours) and NIFTP are associated with an excellent outcome when managed conservatively, with disease persistence/recurrence rates of 3% and less than 1% in the first 15 years, respectively, such that NIFTP is not now considered a malignant neoplasm. This terminology is intended to encourage more conservative management and to spare the psychological burden of cancer diagnosis for indolent tumours that may be adequately managed by lobectomy or hemi-thyroidectomy alone. This proposed nomenclature and shift in emphasis has been provisionally accepted internationally, justifying inclusion in the revised WHO (4th edition, 2017) classification of thyroid tumours ('blue book').²⁷

An algorithm has been proposed along with standards to stringently define this NIFTP subset, stipulating inclusion and exclusion criteria (Figure 58.34) supplemented by an objective nuclear scoring schema (Table 58.9). There is

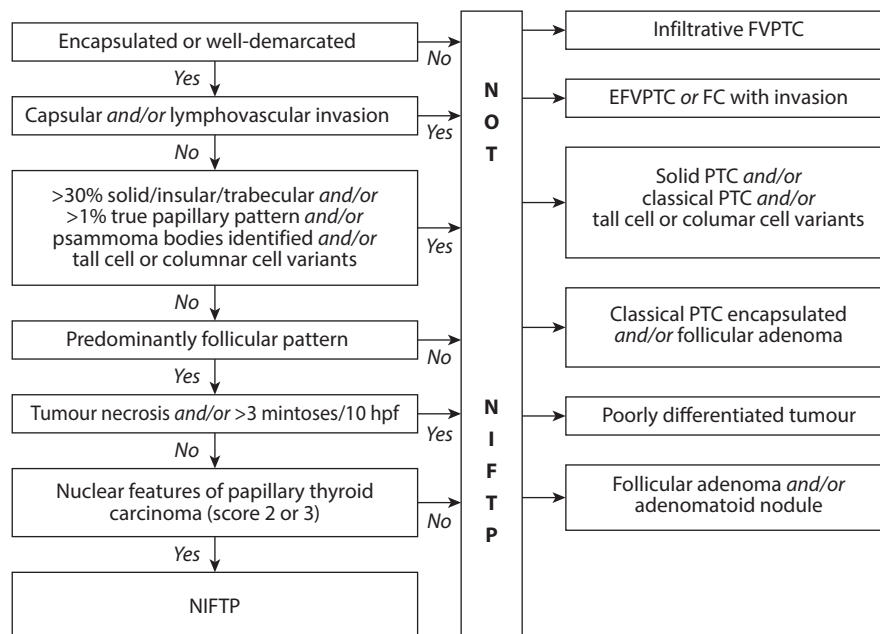

**Figure 58.34** Algorithm aiding the subclassification of a follicular-patterned thyroid lesion where NIFTP is a consideration.³⁸

TABLE 58.9 Nuclear morphology scoring system intended to enhance reproducibility in the diagnosis of NIFTP^{41, 42}

Three-point scoring criteria for the nuclear features of papillary thyroid carcinoma		
Nuclear features	Score = 0	Score = 1
1. Size and shape Enlargement, elongation, crowding, overlapping	Absent or only slightly expressed	Present or well-developed (1 point for each feature)
2. Membrane irregularities Irregular contours, grooves, folds, intranuclear cytoplasmic inclusions		
3. Chromatin characteristics Chromatin clearing, margination to the nuclear membranes, glassy nuclei, fine-even delicate chromatin		
Total score: 0 or 1: Not diagnostic		
Total score: 2 or 3: Diagnostic of PTC nuclei		

no prescribed minimum size criterion and the terminology is not fully validated for sub-centimetre or incidentally discovered tumours, indeed it may be challenging to apply the diagnostic criteria to neoplasms measuring less than 0.5 cm. Equally there is no prescribed upper size limit, with the proviso that the collective experience of NIFTP exceeding 4 cm maximum dimension is restricted. Importantly, where possible the entire lesional capsule should be submitted for microscopic scrutiny. Careful fixation and tissue processing are obligatory. A conclusive diagnosis of NIFTP is not feasible on frozen section or FNAC examination.⁴¹

Major inclusion criteria include sharp demarcation, majority capsulation, dominant follicular growth (less than 1% papillae), less than 30% other architecture (solid, trabecular or insular) and papillary nuclear characteristics (scored for size and shape, membrane irregularity and chromatin characteristics). Minor inclusion features are listed as dark colloid, follicular irregularity and haphazardly scattered microfollicles (sprinkling sign) often displaying artefactual retraction clefts (Figure 58.35). Exclusion criteria dictate any capsular or vascular invasion, true papillae (exceeding one percent of the tumour), psammoma bodies,

infiltrative interface, coagulative necrosis (excepting ischaemic FNAC injury), increased mitoses (at least 3 per 10 hpf), features of some other aggressive PTC variant (tall cell, columnar cell, cribriform-morular, hobnail/micropapillary, diffuse sclerosing or dedifferentiated) and oncocytic (Hürthle cell) lesions.⁴² Lymph node metastasis at presentation is incompatible with a diagnosis of NIFTP, cognizant that central cervical compartment lymph nodal micro-metastasis might represent spread from a different occult primary thyroid carcinoma and that heterotopic (ectopic) lymphadenoidal inclusions enter the differential diagnosis.

Papillary thyroid microcarcinoma

Papillary thyroid microcarcinomas (papillary microtumours) are by definition less than 10 mm in diameter, constituting pT1a disease. They may be an incidental finding in thyroid glands removed for other pathology or serendipitously detected on imaging of the thyroid gland (latent carcinoma).⁴³ Alternatively, they may be found retrospectively in patients presenting with metastatic disease from an initially unsuspected small primary lesion (occult/cryptic/covert carcinoma). Historical subdivision into tumours less

Figure 58.35 Non-invasive follicular thyroid neoplasm with papillary-like nuclear features. (a) A congeries of small follicles displaying PTC nuclear features nested between larger non-descript follicles in NIFTP (sprinkling sign). There is limited artefactual perifollicular clefting (shrinkage artefact) (H&E stain, medium magnification). (b) A similar nidus of small follicles displaying PTC nuclear characteristics in NIFTP, albeit with very florid, diffuse follicle-stromal interface retraction artefact (H&E stain, high magnification).

Figure 58.36 Papillary thyroid microcarcinoma. (a) Multicentric papillary thyroid microcarcinoma each deposit measuring less than 10 mm in diameter. These show a sclerotic morphology. (b) Microscopical deposit of papillary microcarcinoma. This is poorly demarcated and is eliciting no stromal or inflammatory response whatsoever. Such foci are readily overlooked on cursory or low-power examination (H&E stain, medium magnification).

than 5 mm ('minute') and 5 mm to 10 mm ('tiny') maximum dimension is of no clinical relevance. Occult and latent papillary carcinomas may or may not be microcarcinomas. Follicular and medullary microcarcinomas are independently recognized though less frequently encountered.

Most studies report a prevalence for latent papillary microcarcinomas of around 5% to 10%, but figures as high as 30% or so are acknowledged. Despite their propensity for multifocality in one lobe (23%), bilaterality (17%) and locoregional lymph node metastasis (16%), they almost always pursue an indolent clinical course with excellent prognosis, usually not requiring aggressive intervention.⁴³ Exceptionally, however, papillary microcarcinomas behave more aggressively and the presence of two or more foci, lymphovascular invasion, extrathyroidal extension and higher risk morphology (e.g. tall cell features) may prompt more comprehensive treatment, despite limited long-term vindication for this. A significant number of sub-centimetre PTCs occurring in children and adolescents harbour extrathyroidal extension and/or distant metastasis, prompting the CAP recommendations to restrict use of the term papillary thyroid microcarcinoma to those over 19 years of age.³³

Morphologically, papillary microcarcinomas are usually either infiltrative and sclerotic or circumscribed but unencapsulated, located between native follicles without discernible host response (Figure 58.36). Such microscopical foci therefore are easily missed on cursory histological screening and are apt to mimic solid cell nests or even heterotopic thymic rests on scanning magnification.

Poorly differentiated thyroid carcinoma

Poorly differentiated carcinoma of the thyroid (PDCAT) encompasses a spectrum of heterogeneous tumours showing limited evidence of follicular cell differentiation associated with biological behaviour intermediate between differentiated (follicular and papillary) thyroid carcinoma and undifferentiated (anaplastic) carcinoma.⁴⁴

Poorly differentiated carcinomas typically arise *de novo*, but they may occur through transformation of differentiated carcinoma (Figure 58.37). They may progress to undifferentiated (anaplastic) carcinoma either *ab initio* or after recurrence (Figure 58.38).

PDCAT may be defined mainly on the basis of growth pattern. Insular (primordial) carcinoma represents the archetype and is composed of large solid nests (insulae) punctuated by occasional primitive follicles (Figure 58.39). Minor elements of classical papillary thyroid carcinoma and/or follicular carcinoma may be recognized. Conversely, an insular growth pattern is by no means exclusive to poorly differentiated carcinoma and important differential diagnoses include medullary thyroid carcinoma, solid variant papillary thyroid carcinoma and undifferentiated (anaplastic) carcinoma.

Figure 58.37 Transverse slice through a total laryngopharyngectomy and bilateral radical neck dissection specimen for advanced stage, poorly differentiated thyroid carcinoma. The bulk of the specimen comprises heterogeneous tumour largely encasing upper trachea and cervical tubular oesophagus. Microscopically this showed intermingled areas of papillary thyroid carcinoma, follicular carcinoma and insular carcinoma with localized squamous differentiation.

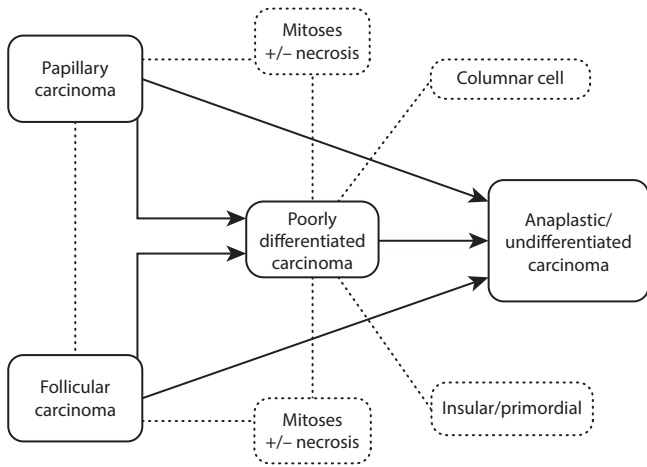

Figure 58.38 Schematic outlining the theoretical developmental relationships between differentiated, poorly differentiated and undifferentiated (anaplastic) thyroid carcinomas.

Alternatively, PDCAT may be specified according to mitotic state (exceeding 5 mitoses per 10 high-power fields $\times 400$) and/or comedo-like tumour necrosis. These portend a survival rate of 60% at 5 years, irrespective of tumour architecture. Furthermore, the combination of solid growth and the presence of at least one of convoluted nuclei, tumour necrosis and/or over 3 mitoses per 10 high-power fields is a powerful predictor of poor outcome. This group constitutes the major cause of radioiodine refractory positron emission tomography (PET)-positive incurable thyroid carcinomas. Some authors propose a so-called ‘high-grade carcinoma’ of the thyroid as a malignancy in which there are recognizable elements of differentiated thyroid carcinoma but which also show histological and cytological features placing the lesion into a ‘high-grade’ category. However, this concept has yet to be endorsed in the WHO (4th edition, 2017) classification and most would classify such neoplasms under the rubric of PDCAT.²⁷

Confusingly, the term poorly differentiated carcinoma is also applied by some observers to differentiated carcinomas showing a solid, trabecular or scirrhous pattern, to tall cell papillary carcinomas and to columnar cell carcinomas. There are insufficient data to determine whether the spectrum of PDCAT should be widened to incorporate a small subset of tumours that exhibit high-risk pathological and clinical features despite low-grade histomorphology.⁴⁹ This lack of consensus may explain conflicting data as to whether a minority component of insular carcinoma in an otherwise differentiated carcinoma is an independent prognostic factor or not and, if so, at what threshold this begins to be a clinically valid observandum. When such poorly differentiated carcinoma comprises the majority of tumour mass (greater than 50%), pragmatically the lesion is best classified as poorly differentiated overall.³⁶ The response of PDCAT to radio-iodine is generally poor.

Unsurprisingly, the tumour cells demonstrate cytokeratins (CK), thyroglobulin (Tg) and thyroid transcription factor-1 (TTF-1) immunopositivity but negative pan-neuroendocrine markers and calcitonin.

Figure 58.39 Classical poorly differentiated (insular) thyroid carcinoma displaying the characteristic solid tumour cell islands (insulae) separated by narrow fibrovascular septa. There is no hint of follicular or other differentiation here (H&E stain, medium magnification).

Columnar cell carcinoma

Columnar cell carcinoma is a rare thyroid neoplasm, which once invasive pursues a more aggressive course than other differentiated thyroid carcinomas. Where it remains encapsulated, however, there appears to be little risk of metastasis.⁴⁴ There is disagreement as to whether it is best classified as a distinct entity rather than a variant of papillary thyroid carcinoma. There is indeed morphological overlap between columnar cell carcinoma, the cribriform-morular variant of papillary thyroid carcinoma and also so-called FAP-associated thyroid carcinoma, remembering that thyroid carcinomas of conventional pattern also occur in familial adenomatous polyposis (FAP) patients.

This notwithstanding, the typical architecture resembles that of intestinal and endometrioid carcinomas with complex glandular, cribriform and solid growth. The individual cells are tall and columnar but striking nuclear pseudostratification and hyperchromasia enable separation from tall cell variant of papillary thyroid carcinoma (Figure 58.40). Immunohistochemically, it is usually CK, Tg and TTF-1 positive.

Undifferentiated (anaplastic) carcinoma

Undifferentiated (anaplastic) carcinoma is a highly malignant tumour typically seen in elderly patients with preponderance in females. It accounts for approximately 2–10% of all malignant thyroid neoplasms,⁴⁵ with a predilection for iodine-deficient regions though its overall incidence is declining.⁴⁶ Undifferentiated (anaplastic) thyroid carcinoma is usually widely invasive at presentation and inoperable in roughly half of cases. It carries a high mortality and accounts for nearly half of all deaths associated with thyroid malignancy.⁸ The overall median survival is 4 months and the 5-year survival rate is less than 10%.

All undifferentiated (anaplastic) thyroid carcinomas are arbitrarily UICC/TNM staged as pT4 due to their anticipated

Figure 58.40 Columnar cell carcinoma illustrating the classical, complex glandular growth pattern resembling gastric, colorectal or endometrial adenocarcinoma. The tumour cells are columnar with characteristic nuclear pseudo-stratification (*H&E stain, high magnification*).

aggressive behaviour, classically showing widespread infiltration of surrounding structures, regional lymph node metastases and distant metastasis to any site.⁸ Presentation with early, intracapsular anaplastic carcinoma, which is more amenable to surgical extirpation, portends a slightly more favourable outlook but is uncommon. Where there is any focus of anaplasia within a differentiated tumour, the lesion is conventionally classified overall as undifferentiated (anaplastic) carcinoma thereby by default becomes stage T4 disease. Conversely, the presence of better-differentiated elements may mitigate the poor prognosis of undifferentiated (anaplastic) carcinoma to some extent.

Undifferentiated (anaplastic) carcinoma can arise *de novo* but the presence of synchronous better-differentiated carcinomatous elements in over 50% of cases is taken as evidence of de-differentiation of a pre-existing neoplasm.⁴⁵ Ergo, there may be a history of long-standing thyroid disease complicated by a recent phase of accelerated growth. The histological features are tremendously variable with two main patterns being pleomorphic epithelioid (giant cell) and spindle cell (sarcomatoid) (**Figure 58.41**). A variety of other microscopical

Figure 58.41 Undifferentiated (anaplastic) carcinoma. (a) A cross-sectional slice through a thyroid lobectomy specimen substantially replaced by undifferentiated (anaplastic) thyroid carcinoma. The solid, dense, featureless and infiltrative nature is paradigmatic. (b) FNAC specimen from undifferentiated (anaplastic) thyroid carcinoma showing a tri-dimensional, acervate clump of pleomorphic, high-grade malignant spindle cells (*Pap stain, medium magnification*). (c) A field of fibrosarcoma-like undifferentiated (anaplastic) thyroid carcinoma composed of fasciculated, malignant fusiform cells (*H&E stain, medium magnification*). (d) Undifferentiated (anaplastic) thyroid carcinoma showing highly pleomorphic epithelioid tumour cells with numerous bizarre giant cells and monster cells ('monstrocytes'), some polykaryocytic (*H&E stain, medium magnification*).

TABLE 58.10 Recognized histological variants of undifferentiated (anaplastic) thyroid carcinoma and their mimics. Note that any individual tumour may present a mixture of appearances in any combination or permutation

Pattern	Major differential diagnosis
Epithelioid	Poorly differentiated (insular) carcinoma Papillary carcinoma, solid variant Metastatic carcinoma
Sarcomatoid	Sarcoma proper
Angiomatoid	Angiosarcoma
Osteoclastic	Pleomorphic sarcoma
Rhabdoid	Rhabdomyosarcoma
Lymphoepithelioma-like	CASTLE
Paucicellular/fibrosing	Riedel's thyroiditis
Carcinosarcomatoid	Osteosarcoma Rhabdomyosarcoma
Adenosquamous	Metastatic carcinoma Sclerosing mucoepidermoid with eosinophilocytosis
Squamous cell carcinoma	Metastatic disease Direct extension Papillary thyroid carcinoma CASTLE

patterns are recognized and are renowned for troublesome differential diagnosis (Table 58.10). Angiolymphatic penetration is characteristic and a brisk inflammatory response is often encountered.

While the term carcinoma is conventionally applied, compelling proof of epithelial differentiation is not always forthcoming by light microscopy, morphologically or immunophenotypically, and the diagnosis ultimately rests upon an acceptable histological pattern allied to an appropriate clinicoradiological context. Immunohistochemical staining for cytokeratin and vimentin are at least focally positive in around 90% of cases with epithelial membrane antigen reactivity in 50% of examples. Tg, TTF-1, calcitonin and pan-neuroendocrine epitopes are typically negative; diffusion of thyroglobulin from destroyed follicles, however, may give rise to spurious immunopositivity. The thyroid lineage marker PAX 8 is retained in roughly half of all cases and immunopositivity may assist in the exclusion of metastatic giant cell lung cancer, which is generally negative. Endothelial markers (CD31, CD34 and factor VIII) may be focally demonstrated in some tumours presenting an angiosarcomatoid morphology, which may rarely prevail. EDRF, VEGFR and ALK may be expressed with the prospect of targeted protein kinase inhibitor therapy. Occasional cases are completely immunoinert and ultrastructural studies are seldom rewarding. Where appropriate, a haematolymphoid immunopanel should always be considered, particularly on FNAC and needle core biopsies, so as not to overlook high-grade or anaplastic non-Hodgkin lymphoma.

Medullary thyroid carcinoma

Medullary thyroid carcinoma (MTC) is a malignant tumour displaying parafollicular C-cell differentiation,⁴⁷

which secretes calcitonin and often a variety of other neuropeptides.⁴⁸ It is an uncommon tumour accounting for 5–8% of all thyroid cancers.⁵⁰ It may occur sporadically or against a background of an inherited autosomal dominant trait related to a mutation of the *RET* proto-oncogene, which causes multiple endocrine neoplasia (MEN) types 2A or 2B or familial MTC (FMTC).

Sporadic MTC is more common in females and presents at a mean age of 50 years. MEN 2A presents in adolescence or young adults, while MEN 2B presents in infancy or childhood.⁸ Sporadic tumours are usually single whereas hereditary tumours are often multicentric and/or bilateral. FMTC arises from C-cell hyperplasia, which is considered a precursor lesion and can be identified histologically with due diligence.

Regional lymph node metastasis and distant lymphatogenous spread are found in 20% and 8% of cases at presentation, respectively. Secondary sites of predilection include lung, liver, adrenal and bone. MEN 2B MTC generally pursues a more aggressive course than MEN 2A MTC, which in turn portends a less favourable prognosis than sporadic MTC, though for those with neoplasms confined to within the thyroid gland, overall long-term survival approaches 95%, and many patients survive for years despite secondary systemic involvement.⁴ Micro-MTCs (defined as smaller than 1cm maximum dimension) detected through screening are associated with a better outcome than those examples over 1cm.

MTCs may be well demarcated or infiltrative, sometimes encapsulated (Figure 58.42). They are commonly located in the middle third of the lateral lobes, where C-cell concentration is greatest. Microscopically, they comprise solid sheets, nests and trabecula of cells separated by slender fibrovascular septa (Figure 58.43). A panoply of histological variants is seen, most of no clinical importance other than they may masquerade as other tumours (Box 58.3). There is often a mixed pattern in any individual example. There is usually only modest nuclear pleomorphism but necrosis may be a feature. Amyloid protein deposition is present in around 80% of cases (Figure 58.44) and may mineralize or elicit a foreign body granulomatous response.

Figure 58.42 The cut surface of multicentric medullary thyroid carcinoma occurring in MEN2B demonstrating widespread effacement of thyroid tissue by infiltrative, solid, white tumour, which abuts and focally violates anatomical thyroid capsule.

Figure 58.43 Medullary thyroid carcinoma. (a) The typical nested or pseudo-alveolar (Zellballen) architecture of medullary thyroid carcinoma, *type ordinaria*. These tumour cells are largely epithelioid and monotonous (H&E stain, high magnification). (b) This field shows mild pleomorphism and a more fusiform cell morphology (H&E stain, high magnification).

BOX 58.3 Histological variants of MTC

- Follicular (glandular/tubular)
- Oncocytic (oxyphilic)
- Giant cell (anaplastic)
- Pigmented
- Papillary (pseudo-papillary)
- Neuroblastoma-like
- Paraganglioma-like
- Small cell
- Clear cell
- Spindle cell
- Squamous melanotic
- Amphicrine
- Angiosarcoma-like (Pseudo-angiosarcomatoid)
- Carcinoid-like
- Medullary microcarcinoma (latent carcinoma)
- Encapsulated ('C-cell adenoma')

Figure 58.44 MTC. (a) FNAC preparation from medullary thyroid carcinoma, depicting loosely cohesive, moderately pleomorphic, plasmacytoid tumour cells together with several globules of amorphous amyloid protein (MGG stain, high magnification). (b) Medullary thyroid carcinoma with conspicuous amorphous, dense, pink/red amyloid protein stroma separating groups of tumour cells (Congo red stain, low magnification). (c) The identical field viewed under high intensity, cross-polarized light corroborates anomalous red/green colouration (sometimes incorrectly termed 'apple green birefringence') highly characteristic of amyloid protein (Congo red stain, high magnification).

Figure 58.45 Small cell variant MTC. (a) Calcitonin-poor, small cell variant of medullary thyroid carcinoma. Note the insular growth pattern (H&E stain, intermediate magnification). (b) The same tumour exhibiting carcinoembryonic antigen (CEA, CD66e) positivity. This example was negative for calcitonin and only weakly positive for chromogranin A, reflecting a paucity of intracytoplasmic storage granules, despite raised circulating serum calcitonin levels (CEA IHC, high magnification).

The usual immunophenotype is positive for CK, calcitonin, TTF-1, CEA, (CD66e) and pan-neuroendocrine markers. Calcitonin-depleted tumours may behave more aggressively, but almost invariably stain for CEA (Figure 58.45). Other neuropeptides may be demonstrated including calcitonin gene-related peptide, somatostatin, ACTH, serotonin, gastrin, bombesin and histaminase amongst others. An S100 protein-positive subpopulation of sustentacular cells is more commonly seen in hereditary cases (Figure 58.46), potentially overlapping morphologically with paraganglioma, though paragangliomas (with the rare, anomalous exception of those involving the cauda equina) are cytokeratin negative. It is wise to be aware that neuroendocrine neoplasms other than MTC may sometimes express aberrant calcitonin immunoreactivity, for example laryngeal and bronchopulmonary atypical carcinoid

tumours, although the latter are typically immunonegative for CEA (CD66e) and there is more often than not normocalcaemia.

Electron microscopy identifies membrane-bound electron-dense storage granules ranging from 100–300 nm in diameter with augmented rough endoplasmic reticulum and Golgi apparatus (Figure 58.47).

C-cell hyperplasia and neoplasia

FMTC develops in a milieu of C-cell hyperplasia and there is no recognized benign C-cell adenoma counterpart. Reactive (physiological) C-cell hyperplasia occurs with advancing age, in thyroiditis, in hyperparathyroidism, in close proximity to other thyroid neoplasms or solid cell nests and in hypergastrinaemia. There is no unanimously accepted definition of nodular (neoplastic, MTC *in situ*)

Figure 58.46 Medullary thyroid carcinoma in MEN2 showing typical S100 protein reactive, spindly sustentacular cells mantling small nests of secretory tumour cells (S100 IHC, high magnification).

Figure 58.47 Transmission electron micrograph depicting several tumour cells from a medullary thyroid carcinoma, occurring in a child with known MEN2B. Numerous dense, membrane-bound neurosecretory vesicles are present in the cytoplasm (TEM, ultra-high magnification).

Figure 58.48 C-cell hyperplasia. (a) Early nodular (neoplastic) C-cell hyperplasia in MEN2, readily identified on routine staining. There is expansion of C-cells within the follicular basement membrane but no destructive or infiltrative growth (*H&E stain, medium magnification*). (b) More marked and multicentric nodular (neoplastic) C-cell proliferation with follicular obliteration and interstitial expansion. This probably amounts to at least medullary carcinoma *in situ*, if not medullary thyroid microcarcinoma (microtumour) proper (*calcitonin IHC, high magnification*).

C-cell proliferation but over 50 C-cells per $\times 100$ field has been proposed,⁵¹ where there is obliteration of follicular spaces by solid, intrafollicular C-cell growth delimited by basement membrane, as demonstrated by immunostaining for collagen IV (Figure 58.48). Once there is violation of basement membrane and/or tumour-derived basal lamina reduplication, that intuitively constitutes MTC proper, although the distinction between medullary microcarcinoma (minute MTC) and intrathyroidal spread of MTC may be impossible.

C-cells cannot be reliably identified by morphology on routine histological slides without recourse to calcitonin or pan-neuroendocrine immunophenotyping. This has, however, assumed less importance with the advent of more sensitive and specific molecular analysis looking for *RET* proto-oncogene germline mutations in the diagnosis of hereditary MTC syndromes.

Tumours displaying joint follicular and C-cell differentiation

The concept of mixed follicular–parafollicular carcinoma (mixed medullary and follicular thyroid carcinoma, MMNFTC) is enigmatic. Collision (combined) tumours include follicular carcinoma plus MTC and papillary carcinoma plus MTC. True follicular–parafollicular carcinoma (differentiated carcinoma of intermediate type) occurring as a genuine hybrid (composite/compound/biphasic) neoplasm is exceptionally rare. Theoretically, the two cell populations may either share origin from a common stem cell or be of dual clonality. The follicular component is sometimes non-neoplastic, thereby raising the possibility of implicated follicles within a slowly growing MTC. False-positive Tg staining may result from passive diffusion out of nearby native follicles or following active pinocytosis by tumour cells, rather than endogenous synthesis proper. The conventional ontogenetic

explanation proposing different origins for follicular cells and C-cells, however, fails to reconcile the observation of apparent genuine coexpression of both Tg and calcitonin by the same tumour cell.⁴

An appreciation of primary small cell thyroid tumours and allied variants, with or without neuroendocrine features, is however emerging. What was initially described as small cell primary non-neuroendocrine thyroid carcinoma has more recently been redesignated carcinoma of the thyroid with Ewing family tumour elements (CEFTE) on the basis of *EWSR1/FLI1* gene rearrangement studies, and as such may overlap with so-called adamantinoma-like Ewing tumours. Rare examples of non-medullary primary neuroendocrine carcinoma closely resemble small cell neuroendocrine carcinoma of lung, also with absent C-cell differentiation. There is some immunophenotypic overlap between this and non-small cell calcitonin-free medullary carcinomas (calcitonin-negative neuroendocrine tumours of the thyroid). Some authors have postulated that this phenotype is a manifestation of least differentiated tumours of C-cell histogenesis that have lost the capacity to secrete calcitonin but maintain calcitonin gene-related peptide expression, thereby potentially providing a developmental pathway to explain the controversial concept of so-called mixed medullary–follicular/papillary carcinoma.⁵²

Other neoplasms and tumour-like lesions

Rare, but distinct forms of primary thyroid carcinoma may morphologically simulate tumours of salivary gland derivation, notably muco-epidermoid carcinoma, muco-epidermoid carcinoma with eosinophilia and secretory carcinoma/mammary secretory analogue carcinoma. There are very many other less common or incredibly rare neoplasms affecting the thyroid gland of epithelial, mesenchymal, haematolymphoid, thymic, parathyroid gland and developmental origin, together with a few tumour-like lesions (Box 58.4). The list

BOX 58.4 Uncommon or rare tumours and tumour-like lesions described in the thyroid gland

Squamous cell carcinoma	Fibromatosis
Mucoepidermoid carcinoma	Granular cell tumour
Mucoepidermoid carcinoma with eosinophilcytosis	Synovial sarcoma
Mucinous carcinoma	Haemangiopericytoma
Spindle cell tumour with thymus-like differentiation (SETTLE)	Lipoma
Carcinoma showing thymus-like differentiation (CASTLE)	Liposarcoma
Malignant lymphomas and leukaemias	Chondrosarcoma
Extramedullary plasmacytoma	Osteosarcoma
Langerhan's cell histiocytosis	Haemangioma
Angiosarcoma	Lymphangioma
Solitary fibrous tumour	Rhabdomyoma
Smooth muscle neoplasms	Epithelioid haemangioendothelioma
Peripheral nerve sheath tumours	Small cell neuroendocrine carcinoma
Paraganglioma	IgG4-related sclerosing disease/inflammatory pseudotumour
Teratoma	

is not exhaustive and a few may arguably be reclassified differently in the light of modern thinking.

Metastatic tumours

The thyroid gland is commonly affected by metastases either by direct extension from neighbouring structures,

haematogenous or lymphatic spread. Local structures include the larynx or lymph nodes and common non-head and neck primary sites include bronchopulmonary, breast, malignant melanoma and renal cell carcinoma ([Figure 58.49](#)). The latter may occur metachronously following an interval of up to 19 years or be a synchronous presenting feature of the disease.³⁷

Figure 58.49 Metastatic tumours. (a) Thyroid lobectomy specimen corticated by squamous cell carcinoma, secondary to direct contiguous infiltration from an advanced stage, upper aerodigestive tract primary site. (b) Metastatic clear cell renal carcinoma colonizing nodules in a pre-existing hyperplastic multinodular goitre. This was accompanied by characteristic radiological imagery. (c) Needle core biopsy of metachronous, metastatic clear cell renal carcinoma presenting as a mass in the thyroid gland some 13 years after nephrectomy for clear cell carcinoma. Its true nature was completely unsuspected clinically – there was no mention of a previous operation in the clinical records. Nonetheless, the pathological findings were unequivocal and the previous kidney specimen was eventually retrieved from the archives of a neighbouring hospital for comparison and review (*H&E stain, medium magnification*).

Intra-operative frozen examination

The use of peri-operative frozen section examination to assist in the diagnosis of thyroid lesions has dwindled in recent years. The widespread adoption of FNAC has enabled broad pre-operative categorization of many lesions, which by their very nature cannot be further refined by frozen section assessment, for example follicular lesion, follicular neoplasm and oncocytic (oxyphil) neoplasm. Frozen section examination on a lesion, definite for malignancy on FNAC, is also unlikely to confer any significant benefit – if the distinction between high-grade lymphoma and undifferentiated (anaplastic) carcinoma has not already been made on FNAC or needle core biopsy, then frozen section is equally unlikely to resolve this. Fleshy, solitary encapsulated lesions are likely to represent follicular adenoma, MIFC, EFVPTC or even MTC, but attempts to comprehensively sample the capsule in the fresh state should be resisted pending tissue fixation with

a view to proper paraffin sections in order to obviate artefactual disruption and distortion of the all important pericapsular tissue planes. The indications for peri-operative frozen section examination of thyroid gland lesions are best agreed by the relevant multidisciplinary team at a local level, taking into consideration local circumstances, individual experience and preferences, together with clinical expectations.⁵³

Thyroid cancer staging

The UICC/AJCC TNM classification of malignant tumours is internationally ratified, currently in its 8th edition (2017) (Table 58.11).⁵⁴ Most importantly, the definition of T3 has been revised for papillary, follicular and medullary thyroid carcinomas, compared to the 7th edition (2009) and the age threshold for a poor prognosis has been amended from over 45 years to over 55 years.

TABLE 58.11 UICC/TNM 8th edition staging schema for thyroid carcinoma^{54, 55}

THYROID GLAND (ICD-o-3 C73.9) ⁵⁴	
Rules for Classification	
The classification applies only to carcinomas. There should be microscopic confirmation of the disease and division of cases by histological type.	
The following are the procedures for assessing T, N, and M categories:	
<i>T categories</i>	Physical examination, endoscopy, and imaging
<i>N categories</i>	Physical examination and imaging
<i>M categories</i>	Physical examination and imaging
Regional Lymph Nodes	
The regional lymph nodes are the cervical and upper/superior mediastinal nodes.	
TNM Clinical Classification	
T – Primary Tumour*	
TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
T1	Tumour 2 cm or less in greatest dimension, limited to the thyroid
T1a	Tumour 1 cm or less in greatest dimension, limited to the thyroid
T1b	Tumour more than 1 cm but not more than 2 cm in greatest dimension, limited to the thyroid
T2	Tumour more than 2 cm but not more than 4 cm in greatest dimension, limited to the thyroid
T3	Tumour more than 4 cm in greatest dimension, limited to the thyroid with gross extrathyroidal extension invading only strap muscles (sternohyoid, sternothyroid, or omohyoid muscles)
T3a	Tumour more than 4 cm in greatest dimension, limited to the thyroid
T3b	Tumour of any size with gross extrathyroidal extension invading strap muscles (sternohyoid, sternothyroid, or omohyoid muscles)
T4a	Tumour extends beyond the thyroid capsule and invades any of the following: subcutaneous soft tissues, larynx, trachea, oesophagus, recurrent laryngeal nerve
T4b	Tumour invades prevertebral fascia, mediastinal vessels, or encases carotid artery
Note: *Including papillary, follicular, poorly differentiated, Hürthle cell and anaplastic carcinomas.	
N – Regional Lymph Nodes	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
N1a	Metastasis in Level VI (pretracheal, paratracheal, and prelaryngeal/Delphian lymph nodes) or upper/superior mediastinum
N1b	Metastasis in other unilateral, bilateral or contralateral cervical (Levels I, II, III, IV or V) or retropharyngeal

(Continued)

TABLE 58.11 (Continued) UICC/TNM 8th edition staging schema for thyroid carcinoma^{54, 55}

THYROID GLAND (ICD-o-3 C73.9)⁵⁴			
M – Distant Metastasis			
M0	No distant metastasis		
M1	Distant metastasis		
pTNM Pathological Classification			
The pT and pN categories correspond to the T and N categories. pM1 denotes distant metastasis microscopically confirmed. Note that pM0 and pMX are not valid categories – the MX category is considered to be inappropriate as clinical assessment can be based on physical examination alone (the use of MX may result in exclusion from staging). The categories M1/pM1 may be further specified employing dedicated codes denoting anatomical site(s) of metastasis, i.e. pulmonary, osseous, hepatic, brain, lymph nodes, bone marrow, pleura, peritoneum, adrenals, skin and others.			
pN0	Histological examination of a selective neck dissection specimen will ordinarily include 6 or more lymph nodes. If the lymph nodes are negative, but the number ordinarily examined is not met, classify as pN0.		
Histopathological Types			
The four major histopathological types are:			
<ul style="list-style-type: none"> • Papillary carcinoma (including those with follicular foci) • Follicular carcinoma (including so-called Hürthle cell carcinoma) • Medullary carcinoma • Anaplastic 			
Stage			
Separate stage groupings are recommended for papillary and follicular (differentiated), medullary, and anaplastic (undifferentiated) carcinomas:			
Papillary and Follicular* under 55 years			
Stage I	Any T	Any N	M0
Stage II	Any T	Any N	M1
Papillary or Follicular 55 years and older			
Stage I	T1a, T1b, T2	N0	M0
Stage II	T3	N0	M0
	T1, T2, T3	N1	M0
Stage III	T4a	Any N	M0
Stage IVA	T4b	Any N	M0
Stage IVB	Any T	Any N	M1
Medullary			
Stage I	T1a, T1b	N0	M0
Stage II	T2, T3	N0	M0
Stage III	T1, T2, T3	N1a	M0
Stage IVA	T1, T2, T3	N1b	M0
	T4a	Any N	M0
Stage IVB	T4b	Any N	M0
Stage IVC	Any T	Any N	M1
Anaplastic			
Stage IVA	T1, T2, T3a	N0	M0
Stage IVB	T1, T2, T3a	N1	M0
Stage IVB	T3b, T4a, T4b	N0, N1	M0
Stage IVC	Any T	Any N	M1
Note: *Including papillary, follicular, poorly differentiated, and Hürthle cell carcinomas.

Essential	Pre- and post-operative calcitonin and CEA	Age	Extent of resection
Additional	MEN Germline mutation Calcitonin doubling time		
New and promising	Molecular profile		

PARATHYROID GLANDS

Normal parathyroid glands

Most individuals possess at least two pairs of parathyroid glands (PTG). The cephalad pair are embryologically derived from the 4th branchial cleft and are usually located over the posterior surface of the thyroid gland close to the point of entry of the inferior thyroid artery. The caudad glands are of 3rd branchial pouch origin and typically lie over the lower thyroid gland pole, though they are more variably placed and may be found within the mediastinum or even the pericardium, consequent upon co-migration with the thymus, which is similarly of 3rd branchial pouch ontogeny. Supernumerary or heterotopic (ectopic) glandular tissue may consist of less well-formed, more diffuse cell aggregates within cervical soft tissues (parathyromatosis) often in close proximity to eutopic glands and this pattern also characterizes surgically implanted gland tissue.⁵

The parathyroid glands secrete parathyroid hormone (parathormone, PTH), which elevates serum calcium via direct effects on kidney and bone and indirectly through the intestine. To the unaided eye, the glands are a yellow-brown colour. At operation, brown fat, yellow fat, sequestered thyroid tissue, thymus, lymph node and autonomic ganglia may all mimic these appearances and these are not infrequently submitted for frozen section examination in lieu of parathyroid gland proper. Microscopically, in the normal state, the glands are lobulated, richly vascularized and composed of nests and/or trabecula of polygonal parenchymal cells, viz. a mixture of chief (principal) cells, water-clear cells and oncocyctic (oxyphil) cells, interspersed with adipocytes (Figures 58.50 and 58.51). The number, size and

composition of the glands, however, are subject to wide normal and abnormal variation (Table 58.12) influenced by age, gender, nutritional and hormonal status. With advancing age, congeries of oncocyctic (oxyphil) cells are increasingly encountered.

Hyperparathyroidism

Hyperparathyroidism is defined by elevated serum PTH and is the commonest pathological condition affecting the parathyroid glands. It is classified into primary, secondary and tertiary forms dependent upon the identification of a driving stimulus (Table 58.13) though the end result is an absolute increase in parenchymal cell mass affecting one or more glands (Figure 58.52). Parathyroid proliferative disease (PPD) is a collective term encompassing all histological causes of hyperparathyroidism.

In primary parathyroid gland hyperplasia, all of the parathyroid glands are enlarged, albeit unevenly in some cases. In parathyroid gland adenoma, paradigmatically only a single gland is enlarged, the remaining glands being of normal size or small. This is typically accompanied by marked diminution in intraglandular adipocytes and reduced or absent intracytoplasmic lipid droplets (Figure 58.53), though rarely the latter may paradoxically be more abundant in chief cells located between hyperplastic nodules. Additionally, foci of irregularly distributed stromal fat cells may persist, recapitulating a rim of normal glandular tissue which, when juxtaposed to a fat depleted hyperplastic nodule, may lead to erroneous interpretation as an adenoma. The most reliable discrimination between hyperplasia and adenoma is achieved through histological examination of multiple glands augmented by multiple sections through larger glands. If only one parathyroid gland is available for

Figure 58.50 Normal parathyroid glands 1. (a) An intrathyroidal parathyroid gland presenting a normal vascularized, lobular microarchitecture comprising parenchymal cells interspersed with a normal complement of mature fat cells that are of haphazard distribution and density. Note its clear circumscription and delicate fibrous capsule (*H&E stain, low magnification*). (b) A replicate section immunostained with anti-PTH antibody showing intense parenchymal positivity, in sharp contrast to the surrounding negative thyroid gland follicles acting as an internal control (*PTH IHC, low magnification*).

Figure 58.51 Normal parathyroid glands 2. (a) Nests and trabeculae of isomorphic chief cells forming occasional glandular lumina or so-called microfollicular/pseudofollicular growth pattern (*H&E stain, high magnification*). (b) Clusters of water-clear cells displaying their characteristic clear, generally univacuolar cytoplasm with eccentrically displaced nuclei (*H&E stain, high magnification*). (c) Nodular sheets of oncocytic (oxyphil) cells illustrating their hallmark, copious, granular and densely eosinophilic cytoplasm, attributable to plentiful mitochondria. A minor degree of random nuclear pleomorphism is often encountered (*H&E stain, high magnification*).

examination and proves to be enlarged and/or hypercellular, definitive pathological distinction between hyperplasia and adenoma cannot always be reliably achieved.

The term lipohyperplasia may be used to designate the extremely rare occurrence of hyperplastic glands with plentiful fat, in which the glands are enlarged albeit with

predominant lipocytes and limited parathyrocyte cell content.

Parathyromatosis is a rare cause of persistent or recurrent hyperparathyroidism characterized by multiple nests of hyperfunctioning parathyroid tissue throughout the neck and mediastinum. These may range in size from

TABLE 58.12 Attributes of normal and abnormal parathyroid glands in man⁴

Characteristic	Normal range	Abnormal
Number	Usually 4, but ranges from 1–12	
Size	Length 3–6 mm Width 2–4 mm Depth 0.5–2 mm	>6 mm in any plane
Weight	Each gland approx. 30 mg – the inferior glands are often heavier than the superior ones Total parathyroid gland mass 120 ± 3.5 mg in males 142 ± 5.2 mg in females	Any individual gland >60 mg
% fat	17–50% Male average 20.5% Female average 15.6%	Complete absence or very marked reduction
Intracytoplasmic lipid	Abundant	Absent or sparse

TABLE 58.13 Classification of hyperparathyroidism

Type	Definition	Causes	Pathological changes
Primary	Overproduction of PTH due to intrinsic abnormality of one or more glands causing elevated serum calcium with depressed serum phosphate	PTG adenoma 85% PTG carcinoma 1% PTG hyperplasia 14% <ul style="list-style-type: none"> • Sporadic • MEN 1 • MEN 2 • Familial isolated hyperparathyroidism • Familial hypocalcaemic hypercalcaemia 	Adenoma or carcinoma changes Chief cell hyperplasia Reduced or absent intra-parenchymal fat Diffuse or nodular changes
Secondary	Compensatory hyperplasia of parathyroid glands due to decreased serum calcium, usually resulting in normocalcaemia	Chronic renal failure Malabsorption Vitamin D deficiency Renal tubular acidosis	Hyperplasia of all glands May be indistinguishable from primary hyperparathyroidism Multinodular or diffuse
Tertiary	Autonomous parathyroid gland hyper-function following secondary hyperparathyroidism	Any cause of secondary hyperparathyroidism	Very similar to secondary hyperparathyroidism though glands are typically larger and multinodular May rarely be associated with adenoma or carcinoma

Figure 58.52 Left and right upper and lower parathyroid glands in quadriglandular hyperplasia of secondary hyperparathyroidism following renal transplantation. These each weighed between 0.5 g and 1.2 g and were incised bivalvate peri-operatively to disclose the variegated, multinodular cut surfaces seen here to be irregular, both within and between glands. The lower glands are often asymmetrically larger than the upper glands.

Figure 58.53 A hyperplastic gland in hyperparathyroidism, secondary to chronic renal disease, displaying hypercellularity with hugely reduced stromal fat cell content. The multinodular appearance is due to proliferation of groups of cells with different cytological features, mostly chief cells here with, unevenly distributed, water-clear cell and oxyphil cell nodules (H&E stain, ultra-low magnification).

microscopical congeries of cells within skeletal muscle and fat to larger soft yellow/white nodules visible to the unaided eye. Primary parathyromatosis is associated with the MEN syndromes, most commonly MEN 1. Secondary parathyromatosis occurs as a sequela of surgical exploration of the neck, supposedly due to inadvertent contamination of the operative field following spillage (seeding) of cells. It may mimic invasive carcinoma to the unwary.

Only primary and tertiary hyperparathyroidism are associated with hypercalcaemia and its attendant systemic sequelae, but all three forms may manifest with bone disease. Aberrant PTH-related peptide secretion may occur as a paraneoplastic phenomenon (humoral hypercalcaemia of malignancy) in some malignant neoplasms, notably squamous cell carcinoma of primary bronchopulmonary, upper aerodigestive tract and female genital tract origin, sometimes with renal cell carcinoma. Approximately 50% of metastatic prostatic adenocarcinoma deposits evince anomalous PTH immunopositivity, cross-reacting with PTH-related protein, which may prove to be a source of differential diagnostic confusion. Hypercalcaemia directly related to the osteolytic effects of bone metastasis, independent of PTH-related protein, may occur in mammary carcinoma and haematological malignancies. Lithium therapy prescribed for psychiatric disorders may induce a form of primary hyperparathyroidism, which abates on cessation of the drug, though parathyroidectomy may still be indicated.

Parathyroid gland adenoma

The WHO (4th edition, 2017) classification of parathyroid gland tumours is reproduced in [Table 58.14](#).²⁷ Parathyroid

TABLE 58.14 WHO classification of tumours of the parathyroid glands²⁷

Parathyroid carcinoma
Parathyroid adenoma
Secondary, mesenchymal and other tumour

gland adenoma is the predominant cause of primary hyperparathyroidism. It may occur spontaneously or within the context of various syndromes. Irradiation of the neck is a potential risk factor with a latency/interval period in the order of 30–40 years. Excision of the abnormal gland is curative and results in normalization of biochemical indices and increased bone mineral density. Up to 10% of patients relapse, sometimes after an interval of many years. Adenomas are not usually palpable clinically, unless cystic, and rarely cause compressive symptoms. Haemorrhagic infarction, either post-FNAC or spontaneously, complicated by haematoma, may result in an acutely painful neck lump.

The morphological spectrum of parathyroid adenomas occurring in supernumerary glands and in heterotopic sites such as mediastinum, thyroid gland or oesophagus is identical to that in eutopic locations. However, not only may they lead to unsuccessful cervical exploration, they may mimic thyroid gland adenomas or medullary thyroid carcinoma histologically.

Double adenomas may rarely occur (responsible for between 1.7% and 12% of cases of primary hyperparathyroidism) and are usually bilateral. All of the patients are symptomatic and show a higher PTH level and tumour weight compared to solitary adenoma and parathyroid gland hyperplasia. Distinction from asymmetrical parathyroid gland hyperplasia, particularly in the context of MEN, is extremely difficult. The diagnosis is therefore only considered conclusive when follow-up after removal of two abnormal glands shows no recurrence. Gene profiling studies indicate that multiple gland neoplasia represents a distinct molecular entity.

Parathyroid gland adenomas occur more frequently in the lower parathyroid glands. The mean weight is 0.55 g but tumours weighing as much as 53 g are recorded and, generally, the more severe the hypercalcaemia, the bulkier the adenoma. Macroscopically, parathyroid gland adenomas are well marginated, soft and vary from yellow-red to orange-brown in colour ([Figure 58.54](#)), more blue tinged if toluidine blue has been used as an aid to peri-operative

Figure 58.54 (a) The external surface of a parathyroid gland adenoma, weighing 1.2 g in primary hyperparathyroidism, demonstrating a delicate capsule with ramifying surface blood vessels. (b) When transected, its variegated, multinodular texture is very similar to a hyperplastic gland, though in this instance it was the only abnormal gland of those recovered at operation.

localization. The oncocytic (oxyphil) cell variant presents a so-called mahogany brown cut surface, characteristic of such mitochondria-rich tumours at many sites. Secondary haemorrhage and/or cystic change (Figure 58.55) may be encountered, either spontaneously occurring or post-FNAC. The remaining, uninvolved parathyroid glands should be normal or reduced in size.

Microscopically, parathyroid gland adenomas are circumscribed and may be lobulated or nodular. They are hypercellular and substantially or completely bereft of intraglandular adipocytes, with the exception of lipoadenoma. An attenuated, part-circumferential mantle of normal or compressed parathyroid gland tissue is identified in 50% or so of cases, dependent upon the planes of section examined (Figure 58.56), often near the vascular hilum of the gland, with the caveat that a compressed tissue rim is occasionally encountered around hyperplastic nodules.

The tumour cells may be disposed in solid sheets, cords, acini, follicle-like and/or microcystic configuration. Glandular structures may contain eosinophilic colloid-like secretions (pseudo-follicular growth). These are dPAS-positive but immunonegative for thyroglobulin. Intrafollicular or interstitial amyloid protein may rarely be deposited.

Most adenomas are composed of chief (principal) cells, though oncocytic (oxyphil) cells and/or water-clear cells are often present, either dispersed or in nodular aggregates. The chief cells of an adenoma are usually larger than their non-neoplastic counterparts present in the uninvolved rim of parathyroid tissue, where present, and in the remaining, non-neoplastic glands. They also typically possess less intracellular fat than the uninvolved tissue and the other suppressed glands. Mitoses usually number less than 1 per 10 high-power fields without abnormal forms. There may be random nuclear pleomorphism and/or multinucleation

Figure 58.55 (a) This adenoma shows scattered collections of interstitial siderophages containing phagocytosed, coarsely granular, golden brown haemosiderin pigment, indicative of antecedent haemorrhage (*H&E stain, intermediate magnification*). (b) Another example displays focal cystic change with accompanying fibrocollagenous scar tissue plus part-circumferential, dystrophic, mural calcification (*H&E stain, low magnification*).

Figure 58.56 (a) View of the edge of a parathyroid gland adenoma. Note its sharp demarcation, hypercellularity and absence of intratumoural lipocytes. There is a peripheral nubbin of attenuated-looking parathyroid glandular tissue with preserved intraglandular fat cells for comparison (*H&E stain, ultra-low magnification*). (b) Perimeter of another parathyroid gland adenoma depicting extrinsic atrophic looking parathyroid gland remnant with juxtaposed vascular hilus (*H&E stain, ultra-low magnification*).

Figure 58.57 The presence of bizarre giant cell transformation (monster cells), some polykaryocytic, possessing enlarged hyperchromatic nuclei, albeit without mitoses or other worrisome features, against a background of bland-looking cells should not be taken as evidence of malignancy (*H&E stain, medium magnification*).

sometimes with bizarre, hyperchromatic giant cells (Figure 58.57), though in the absence of other indicators of potential malignancy these should not be misconstrued as evidence portending aggressive behaviour. Flow cytometry is of limited assistance in discriminating between parathyroid gland adenoma and carcinoma because aneuploidy is found in up to 25% of histologically and clinically benign tumours.

VARIANTS OF PARATHYROID GLAND ADENOMA

In addition to their fundamental cytological and architectural patterns, parathyrocyte proliferations, including adenomata, are susceptible to a host of engrafted secondary phenomena, mostly retrogressive, none

entirely specific diagnostically. These include inflammation, infarction, haemorrhage, haemosiderosis, Gamna–Gandy nodulosis, hydrops, necrosis, hypervascularity and peliosis-like (pseudo-angiomatoid/telangiectatic) change, microcystic and macrocystic degeneration, fibrosis/hyalinosis, lipometaplasia, metaplastic ossification, mineralization and pseudo-invasion (Figure 58.58). These may occur *de novo* or in response to trauma, such as FNAC. The following histological subtypes, however, are recognized.

- **Cystic adenoma** may be cystic *ab initio* or secondarily as a consequence of subsiding haematoma post-infarction. Morphologically, it may mimic a benign simple parathyroid cyst but should not be confused with adenoma *type ordinaire* displaying a minority cystic growth pattern.
- **Lipoadenoma (parathyroid hamartoma)** is a very rare occurrence showing admixture of parenchymal cells with copious mature adipocytes and/or brown fat cells, the fat content variably accounting for 20–90% of the tumour (Figure 58.59). There may be accompanying inflammation, mineralization and mucomyxoid change (myxoid lipoadenoma) and, where dominant, the term myxoadenoma is sometimes invoked.⁵⁶ Distinction should be drawn diagnostically between lipoadenoma, benign lipoma thymolipoma and lipohyperplasia. Approximately 50% of lipoadenomas are associated with hypercalcaemia. The uninvolved parathyroid glands are normal.
- **Papillary variant** is rare and apt to be mistaken for papillary thyroid carcinoma.
- **Water-clear adenoma** is substantially or wholly composed of water-clear cells. The histological differential diagnosis includes adenoma composed of hydropic and/or vacuolated chief cells (rather than ultrastructurally distinct water-clear cells proper) and water-clear cell

Figure 58.58 (a) Pseudo-follicular growth in a parathyroid adenoma closely resembling normofollicular and macrofollicular thyroid gland follicles with stored colloid-like secretions, even mimicry of marginal vacuoles (*H&E stain, medium magnification*). (b) Parathyroid gland adenoma showing sequelae of prior haemorrhage, i.e. localized haemosiderosis with adjacent Gamna–Gandy body. These fibrosiderotic nodules consist of degenerate elastin fibres encrusted with iron and calcium salts upon a hyalinized background. They are by no means exclusive to either haemoglobinopathies or the spleen and may occasionally be encountered in tumours at other sites, for example cardiac myxoma (*H&E stain, medium magnification*). (Continued)

Figure 58.59 (a) The cut-surface of a parathyroid gland lipoadenoma illustrating its multinodular architecture comprising solid parenchymal elements interspersed with yellow fat. (b) The same lesion histologically confirms solid parathyrocyte nodules intimately admixed with mature lipocytes (white fat cells), all within the confines of the delimiting capsule (H&E stain, low magnification). (c) The pericapsular region of a different lipoadenoma showing similar features, albeit with brown fat cells predominant (H&E stain, low magnification). (d) Myxoid lipoadenoma comprising prominent loose mucomyxomatous interstitium enclaving discrete islands and sheets of parathyroid cells. A minority cluster of mature adipocytes is evident within the right lower quadrant of this particular field and these provide a clue to the diagnosis (H&E stain, medium magnification).

hyperplasia. It may be mistaken for a clear cell neoplasm of the thyroid gland, including metastasis, and paraganglioma.

- **Follicular variant** shows a predominant pseudo-follicular (acinar) architecture often with intraglandular secretions and may be misinterpreted as a follicular-patterned thyroid neoplasm.
- **Oxyphil adenoma (oncocyctic adenoma)** is comprehensively composed (at least 90% of the cell population) of mitochondria-rich oncocyctic (oxyphil) cells and may or may not be functional. It must be distinguished from nodular oxyphilic cell change with advancing age and, when intrathyroidal, from oxyphil (Hürthle) cell neoplasms of the thyroid gland. Commensurate nuclear pleomorphism with polykaryocytosis and bizarre giant cell transformation (monster cells) often feature and, in isolation, should not be overinterpreted as evidence suggestive of malignancy.
- **Microadenoma** is defined as a single lesion of less than 6 mm maximum dimension, weighing no more than 0.1 g, occurring in an otherwise grossly normal parathyroid gland. It may present as an unencapsulated micronodule wholly or partially within the substance of the gland, as a hypercellular proliferation affecting an entire gland or as an area of hypercellular growth showing poor demarcation from juxtaposed normal glandular parenchyma. Demonstration of these may be surgically and pathologically challenging.
- **Parathyroid adenoma with prominent lymphocytic infiltrate** is an unusual histological phenomenon, not necessarily associated with autoimmune response. There may, or may not, be background chronic lymphocytic parathyroiditis of adjacent remnant parathyroid tissue, where glandular destruction may be seen, at least focally. Caution must be exercised to exclude lymphoma.⁵⁶ Very rarely parathyroid gland adenoma

may present with granulomatous infiltration, not associated with sarcoidosis, underlying infection or other primary granulomatous conditions, themselves associated with hypercalcaemia independent of parathyroid gland disease (Figure 58.60).

- **Atypical parathyroid gland adenoma (*parathyroid neoplasm of uncertain malignant potential*)** is a descriptive term attributed to a parathyroid gland tumour that displays equivocal, worrisome, borderline or suspicious features of parathyroid carcinoma, though falls short of fulfilling the first-order criteria for a confident designation of malignancy. This rubric acknowledges the limitations of predicting the behaviour of an individual tumour based upon conventional histomorphological assessment (it is the pathologist who is uncertain, not the tumour) and it is not proffered as a distinct clinicopathological entity. Only a small minority of such atypical adenomas are expected to recur and/or metastasize and the rank importance of second-order criteria in quantifying this small risk of more aggressive behaviour has yet to be established.

Atypical parathyroid gland adenomas are generally indistinguishable from adenoma of usual type by the unaided eye (Figure 58.61). The commonest microscopical features, ranked according to frequency, however, include intracapsular entrapment (87%), intratumoural fibrosis (75%), haemosiderosis (58%), cyst formation (50%), mitoses (25%) and peritumoural fibrosis (25%). The Ki67 proliferative index typically lies intermediate between adenoma and frank carcinoma. The value of ploidy studies in predicting local recurrence is based upon small studies. Nonetheless, the use of this terminology serves to highlight those patients who merit closer surveillance, such as regular serum calcium measurements, while avoiding the stigma of a firm label of malignancy, wholly unjustified in most cases.⁴

Figure 58.60 (a) Parathyroid adenoma variant with prominent lymphocytic infiltrate, demonstrating sheets of chief cells and nodules of water-clear cells intimately associated with a population of lymphocytes and mature plasma cells. Two lymphoid follicles, one with reactive germinal centre formation, are present (H&E stain, low magnification). **(b)** Parathyroid adenoma associated with non-necrotizing granulomatous inflammation. Three sharply circumscribed epithelioid histiocytic granulomata, each containing multinucleate giant cells, one of Langhans' type, are visible. This is a rare occurrence and should prompt efforts to exclude comorbid systemic granulomatous disease (H&E stain, medium magnification).

Figure 58.61 This atypical parathyroid gland adenoma is macroscopically indistinguishable from adenoma *type ordinaire*. The cut surface displays subtle capsular irregularity and localised fibrous thickening. First-order criteria of malignancy were absent.

Immunohistochemistry is occasionally valuable in the differential diagnosis between parathyroid gland adenoma and other neoplasms, notably of the thyroid gland, and it also has a role in differentiating between atypical adenoma and parathyroid carcinoma. Parathyrocytes are cytokeratin-positive and stain for many pan-neuroendocrine markers, both membrane-bound peptide products, such as PTH, chromogranin A and synaptophysin, and cytosol epitopes including neuron-specific enolase. Chief cells show nuclear immunoreactivity for thyroid transcription factor-1. Reciprocal negative staining for thyroglobulin may also be helpful. Typically, nuclear parafibrin immunoreactivity is globally or focally lost in parathyroid carcinoma. Atypical adenomata expressing parafibrin are said to behave as adenomata, in contradistinction to those with loss of immunopositivity, which portend a heightened risk of recurrence. Immunostaining for anti-mitochondrial antibody highlights oncocyctic (oxyphil) differentiation, but in itself it does not discriminate between oncocyctic parathyroid gland tissue and oncocyctic change in other tissues. Staining for fat on frozen section is seldom of diagnostic help.

Molecular genetic studies by X-linked restriction fragment length polymorphism provide evidence for monoclonality in many parathyroid gland adenomas. Tumour-specific DNA alterations are present in the PTH gene in some cases. A minority of cases demonstrate pericentric inversion of chromosome 11, which causes translocation of the cyclin D1 gene with the PTH gene resulting in overexpression of cyclin D1 and cell proliferation. Cyclin D1 expression is identified by immunohistochemistry more frequently than this cyclin D1 gene rearrangement, suggesting that other molecular factors are operant in cyclin D1 deregulation. Cyclin D1 is also common in parathyroid hyperplasia and parathyroid carcinoma.

The germline mutation underlying MEN 1 is associated with some sporadic parathyroid gland adenomas. The *RET* proto-oncogene germline mutation underlying MEN 2 does not appear to be involved in the genesis of sporadic parathyroid gland adenomas. Other chromosomal abnormalities are detected by comparative genomic hybridization and fluorescence *in situ* hybridization (FISH) techniques.

Parathyroid carcinoma

This is defined as a malignant neoplasm of parathyroid parenchymal cells and is responsible for approximately 0.5–2% of all cases of primary hyperparathyroidism, though some series report as high as 5%. It occurs most frequently in the fifth and sixth decades (i.e. roughly a decade younger than adenomas) with no gender predilection. Most patients are severely hypercalcaemic with active bone and renal disease at presentation, they tend to suffer worse symptoms attributable to this compared to those with adenoma and there is more often a palpable neck mass, though this presentation is by no means invariable. Initial designation as adenoma may be revised at a later time following recurrence and/or metastasis.⁵⁷

Parathyroid carcinoma tends to invade local structures, is slow-growing and metastasizes late. Complete surgical excision at first operation affords the best opportunity for cure, though this relies upon early recognition of its malignant nature, which cannot always be achieved. Following surgery, approximately 30% of patients suffer local recurrence, usually within 3–5 years. Roughly 30% develop metastasis, typically late in its course, generally to regional lymph nodes (30%), lungs (40%), liver (10%) and bone. Survival is 60–85% and 40–70% at 5 years and 10 years respectively with an average survival following recurrence of 7–8 years. Non-functioning examples may behave more aggressively than functioning ones. Death is usually attributable to the metabolic complications of hypercalcaemia rather than overwhelming tumour burden. Repeated surgery may palliate and adjuvant radiotherapy has a limited role. The response to chemotherapy is poor. The hypercalcaemia may become refractory to medical management and specialist anti-PTH immunotherapy has proven beneficial in very severe cases (Figure 58.62), occasionally eliciting a direct anti-tumour effect.⁵⁸

Figure 58.62 Metastatic parathyroid carcinoma in the lung, following anti-PTH immunotherapy for refractory, severe hypercalcaemia. Note the vigorous granulomatous inflammatory response, secondary to Freund's complete adjuvant, which was used to intensify the immune response, closely associated with the nests of residual tumour cells (H&E stain, medium magnification).

The tumour size is generally larger than that of parathyroid gland adenoma with an average weight between 6.7g and 12g, although smaller tumours are being identified earlier in recent times. It may be encapsulated or obviously infiltrative. There may be a soft, brown appearance indistinguishable from adenoma, or a firm, grey-white texture. Troublesome intra-operative dissection, owing to adherence to contiguous structures, should alert the perceptive surgeon to a possibility of malignancy.

Microscopically, parathyroid carcinomas may be deceptively bland or overtly malignant and anything in between. It is the biological behaviour, however, which ultimately defines parathyroid carcinoma. In rare cases, there may be no histomorphological clues to indicate potential aggressiveness. Nonetheless, first-order morphological criteria of malignancy (absolute criteria) include invasion into adjacent tissues and/or histologically documented metastasis. When these are absent or inconclusive, a combination of second-order facultative features (features associated with malignancy), each in themselves not fully diagnostic, are invoked (Table 58.15).

The capsule is often thickened and is classically contiguous with broad internal fibrous septula, dividing the tumour into irregular nodular compartments. (This must be differentiated from scarring in an adenoma, secondary to spontaneous infarction, FNAC or previous surgery.) Invasion beyond the delimiting capsule (Figure 58.63) may or may not be obvious (and can be mimicked by pseudo-infiltration, sequestration/benign entrapment and/or implantation of benign tissue following rupture of a parathyroid adenoma capsule). Fibrosis and haemosiderin deposition may be encountered in hyperplasia, degenerate adenomas and carcinomas. Pericapsular vascular invasion (Figure 58.64) is virtually diagnostic of malignancy (though artefactual dislodgement of cells simulating tumour embolus must be considered) but is present in only 10–15% of cases. Perineural infiltration is also diagnostic of malignancy but is also an uncommon finding. There may be a variety of growth patterns and a trabecular or rosettoid architecture favours malignancy (but it is not common and not entirely specific). Diffuse growth of isomorphic cells with elevated nucleus–cytoplasmic ratio is

TABLE 58.15 Microscopical criteria for the diagnosis parathyroid carcinoma²³

First-order criteria	Second-order criteria
Presence of either or both of the following: <ol style="list-style-type: none"> Invasion into surrounding tissues <ul style="list-style-type: none"> Thyroid Oesophagus Nerves Connective tissue Histologically documented locoregional or distant metastasis 	In the absence of first-order criteria, at least two or more of the following: <ul style="list-style-type: none"> Capsular invasion Vascular invasion Mitoses >5 per 10 hpf Broad intralesional fibrous septa with division into nodules Coagulative-type necrosis Diffuse growth with elevated nucleus to cytoplasmic ratio Diffuse cellular atypia Abundant macronucleoli

Figure 58.63 (a) Whole mount preparation of an oncocyctic parathyroid carcinoma in a patient with MEN2 demonstrating irregular, thick fibrous capsulation contiguous with conspicuous internal fibrous septa. This gland was adherent to surrounding structures at operation and dissected out with some difficulty (*H&E stain, ultra-low magnification*). (b) The edge of another parathyroid carcinoma depicting an irregular, thick peripheral capsule, together with coarse intratumoural fibrous bands separating the expansile tumour nodules. This presents a broad advancing margin with surrounding soft tissues, rather than direct tentacular, permeative infiltration (*H&E stain, low magnification*).

Figure 58.64 (a) A pericapsular neurovascular bundle showing endothelialized intravascular tumour invasion characteristic of parathyroid carcinoma (H&E stain, medium magnification). (b) Angioinvasion of a medium-calibre blood vessel at the perimeter of a parathyroid carcinoma, exemplified by parathyrocytes enveloped in endoluminal fibrin clot (H&E stain, high magnification).

Figure 58.65 Parathyroid carcinoma composed of monotonous tumour cells showing raised nucleus-cytoplasmic ratio, nuclear hyperchromasia, coarse chromatin, macronucleolation and focal multinucleolation. A solitary mitosoid body is present towards the upper left-hand corner (H&E stain, high magnification).

a toxin (Figure 58.65), as is generalized nuclear pleomorphism (in contrast to focal, random cytonuclear atypia). Macronucleolation may be conspicuous. Areas of coagulative necrosis may be seen (and should not be mistaken for ischaemic damage or haemorrhage). The interpretation of mitoses has proven controversial: mitoses are present in both hyperplasia and adenoma, though generally below 1 mitosis per 10 high-power fields (obversely, mitotic figures may be completely absent in some metastasizing carcinomas and care must be taken to distinguish mitoses in endothelial and other stromal elements from those in tumour cells). The presence of very many mitoses and/or abnormal forms, however, is usually taken as presumptive evidence of

malignant potential. The proposed UICC/AJCC TNM staging classification³⁵ for parathyroid carcinomas is given in Table 58.16. T staging predicated upon size criteria has also been proposed.⁵⁹

The immunohistochemical proliferation marker Ki67 (MIB-1) is slightly higher in parathyroid carcinoma than adenoma, though there is overlap, with a proliferative index greater than 5% suggestive of malignancy. Ki67 may also help in discriminating genuine mitotic figures from pyknotic nuclei (mitosoid bodies) in equivocal cases. An immunopanel comprising Ki67 in combination with galectin-3, parafibromin and PGP9.5 augments both specificity and sensitivity, compared to a single marker. Alternative studies, including retinoblastoma protein, cyclin D1, bcl-2, adenomatous polyposis coli antibody and p27 immunostaining, are presently of limited diagnostic and/or prognostic utility. Cytokeratin 14 (CK14) immunoreactivity has been reported as positive in oncocytic (oxyphil) adenomas but never in oncocytic carcinomas.

An increased incidence of parathyroid carcinoma is reported in some hereditary hyperparathyroidism syndromes. Familial hyperparathyroidism represents a clinically and genetically heterogeneous group of disorders that includes multiple endocrine neoplasia type 1 (MEN 1), multiple endocrine neoplasia type 2 (MEN 2), familial hypocalcaemic hypercalcaemia (FHH), hyperparathyroidism-jaw tumour (HPT-JT) syndrome and familial isolated hyperparathyroidism (FIHP). Parathyroid carcinoma is seen in 10–15% of the autosomal dominant HPT-JT syndrome but it is exceptionally rare in MEN 1 and MEN 2. Early studies of FIHP suggested an increased risk of parathyroid carcinoma, but the inclusion of some patients with HPT-JT syndrome casts doubt upon this conclusion. There are no reported cases of parathyroid carcinoma with FHH.

TABLE 58.16 Proposed TNM staging schema for parathyroid carcinoma

T – Primary Tumour	
TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
Tis	Atypical parathyroid neoplasm (neoplasm of uncertain malignant potential)
T1	Localized to the parathyroid gland with extension limited to soft tissue
T2	Direct invasion into the thyroid gland
T3	Direct invasion into laryngeal nerve, oesophagus, trachea, skeletal muscle, adjacent lymph nodes, or thymus
T4	Direct invasion into major blood vessels or spine
N – Regional Lymph Nodes	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
N1a	Metastasis to Level VI (pretracheal, paratracheal, and prelaryngeal/Delphian lymph nodes) or upper/superior mediastinal lymph nodes
N1b	Metastasis to unilateral, bilateral or contralateral cervical (Levels I, II, III, IV, or V) or retropharyngeal nodes
M – Distant Metastasis	
M0	No distant metastasis
M1	Distant metastasis
Stage	
There are not enough data to propose a formal staging system at this time.	

Source: Adapted from AJCC Cancer Staging Manual, 8th edition, 2017. Note that there are insufficient data to enable stage group stratification.³⁵

Other parathyroid gland tumours

Paraganglioma may rarely occur at this site. Tumour-like lesions, which may on occasion enter the differential diagnosis, include parathyroid cysts, branchiogenic cysts and amyloidosis. Secondary neoplasms may be the result of direct extension from adjacent structures, such as larynx or thyroid, or from distant metastatic disease, most commonly of primary mammary, haematolymphoid, renal, malignant melanoma or bronchopulmonary derivation. Despite their close proximity, metastasis to parathyroid gland from a primary thyroid carcinoma is uncommon (Figure 58.66).

Frozen section examination

Intra-operative frozen section examination of parathyroid gland tissue in cases of hyperparathyroidism is intended to establish the nature of the excised tissue and ascertain whether it is normal or abnormal. Without knowledge of the status of the remaining glands, a more definitive diagnosis of hyperplasia or adenoma (very rarely carcinoma) cannot always be proffered. Incisional biopsies render the task more difficult, as do freezing (ice crystal) artefact, other technical constraints and sampling error. The process is inevitably subject to inter-observer variation. Some workers advocate routine lipid stains as an adjunct to assessing intracytoplasmic fat; others do not. Oncocytic (oxyphil) cells, however, contain minimal lipid and occasional non-oncocytic hyperplastic and adenomatous

parathyrocytes may retain significant lipid content. This notwithstanding, the overall accuracy of frozen section evaluation is surprisingly high and demonstrates good concordance with subsequent paraffin sections in experienced hands (Figure 58.67). The frozen section diagnosis of parathyroid carcinoma is understandably seldom sustainable, although alerting the surgeon to the possibility may alter pre-operative management should there be other suspect features.

Figure 58.66 Parathyroid gland of normal size, albeit with diminished fat content, containing an intracapsular deposit of metastatic papillary thyroid carcinoma. There was no contiguity with similar tumour elsewhere in the neck (H&E stain, low magnification).

Figure 58.67 (a) The external surface of a fresh parathyroid gland nodule, weighing 1.8g, sent for intra-operative frozen section examination – see Figure 58.54 for comparison with the appearances of a similar fixed specimen. (b) The same nodule bivalved in the unfixed state to demonstrate ill-defined parenchymal multinodularity. (c) Frozen section histology confirms hypercellular parathyroid gland tissue devoid of intraglandular fat. The entire consultation was completed in less than 5 minutes following receipt of the specimen in the laboratory. The linear striations and folds/rents in the section are artefactual. Without knowledge of the status of the remaining parathyroid glands, this could represent either an adenoma or hyperplasia. This notwithstanding, the findings supported the clinical impression of an adenoma. Subsequent paraffin sections on routinely processed tissue served as a quality audit (*H&E stain, medium magnification*).

Based on the premise that most primary hyperparathyroidism is due to single gland disease, there is sound rationale for unilateral neck exploration to remove the adenoma and visualize and/or biopsy any ipsilateral gland(s). Furthermore, advances in pre-operative localization techniques now facilitate targeted minimally invasive parathyroidectomy (MIP), variously through a mini incision, video-assisted surgery or endoscopic operation alone. Intra-operative frozen section or cytology examination merely confirms tissue nature rather

than functional status. Intra-operative quick assay of intact parathyroid hormone (IOPTH) can be undertaken prior to and post removal of a gland – a significant reduction in parathormone concentration predicts extirpation of abnormally functioning tissue, indicative of cure. Radioguided parathyroidectomy is guided by pre-operative radionuclide injection and radioguidance is helpful in second-look parathyroidectomy. MIP is, however, unsuitable in individuals with discordant imaging and/or comorbid thyroid disease.

KEY POINTS

- Accurate and timely pathological tumour subtyping, tumour grading and tumour staging underpin subsequent effective clinical management of thyroid gland and parathyroid gland neoplasia.
- Morphology remains the gold standard of histocytological diagnosis, increasingly facilitated, but not yet supplanted, by advances in ultrastructural, immunohistochemical, molecular and genetic understanding of normality and disease states.
- Advancement in diagnostic pathology has traditionally evolved along heuristic lines, assimilating observational studies with careful clinico-pathologico-radiological and treatment outcome correlation at population and individual case study levels. This has enabled recognition of new entities and clinically relevant reclassification and/or subclassification of existing conditions with time.
- There is a new era of pathological, clinical and molecular integration informing our understanding of thyroid disease and enabling patient management and clinical treatment decisions to be guided by evidentially based risk stratification with de-escalation of therapy in differentiated thyroid carcinoma.
- The apparently limited repertoire of thyroid gland disease belies its subtlety, masking some of the most highly contentious fields in any area of current surgical pathology.
- Fine needle aspiration cytology (FNAC) of the thyroid gland is a generally accepted first-line investigation for triage of solitary thyroid nodules, is helpful in evaluating diffuse, non-toxic goitre, aids the diagnosis of clinically suspected malignancy and potentially discriminates between treatable lymphomas and poor prognosis undifferentiated (anaplastic) carcinoma.
- Papillary thyroid carcinoma in its numerous guises accounts for approximately 80% of all thyroid malignancies.
- It generally portends an excellent prognosis, particularly in younger patients, modulated by both patient-specific and tumour-specific variables.
- The capsule of any follicular-patterned neoplasm should be comprehensively sampled specifically searching for both capsular and lymphovascular microinvasion.
- Oncocytic (oxyphil, Hürthle cell) change is a cellular adaptive process occurring in a wide variety of non-neoplastic and neoplastic conditions. It is subject to its own molecular basis, independent to that of any underlying tumour.
- There remain a number of unresolved issues in the histopathological diagnosis of thyroid carcinomas. Large clinico-pathological studies subject to long-term follow up are still required with anticipation that many of these controversial areas will be ultimately resolved with evidential basis.
- The role of ancillary immunohistochemical, molecular and genetic studies in the determination of malignancy of the thyroid gland is evolving and has yet to be fully realized in routine diagnostic practice.
- All patients newly diagnosed with medullary thyroid carcinoma should be offered genetic testing given its association with multiple endocrine neoplasia syndromes.
- The value of peri-operative frozen section examination of thyroid gland lesions is disputed amongst pathologists and surgeons. The indications for such are best agreed by the local multi-disciplinary team according to local circumstances, preferences and experience.
- Parathyroid carcinoma is rare, slow growing and metastasizes late in its natural history. The diagnosis is predicated upon clinical, biochemical, imaging and pathological criteria.

CLINICAL EVALUATION OF THE THYROID PATIENT

Andrew Coatesworth and Sebastian Wallis

Introduction	705	Miscellaneous others	706
Functional disorders	705	References	707
Structural disorders	706		

SEARCH STRATEGY

Data in this chapter may be updated by on a PubMed search using the keywords: hypothyroidism, hyperthyroidism, Grave's disease, thyrotoxicosis and thyroid nodule.

This chapter succinctly covers the various clinical presentations of differing thyroid pathologies. More detail of specific presentations is available in chapters specific to those presentations.

INTRODUCTION

Thyroid disorders are common; serious or sinister problems are rare. They can broadly be divided into disorders of function, and disorders of structure, with a few miscellaneous others.

Thyroid disorders are managed by primary care and endocrine physicians, and endocrine and ENT surgeons.

FUNCTIONAL DISORDERS

Endocrine thyroid disorders affect approximately 2% of the adult population, with a 10:1 female to male ratio. Hypothyroidism is predominantly diagnosed and treated in primary care. Hyperthyroidism is primarily managed by physicians, with a surgical opinion generally being sought in cases where medical treatment has failed. It is therefore rare for a patient with an endocrine disorder to present *de novo* to an ENT clinic in the UK.

Symptoms and signs of hypothyroidism

The majority of patients with an underactive thyroid will have little or no symptoms or signs. The commonest symptoms are fatigue, weight gain with a poor appetite, and feeling cold.¹ Other recognized symptoms are poor concentration and memory, hoarse voice, shortness of breath, abnormal sensation, and a change in menstruation.¹ Constipation and

dyspepsia are also recognized.² Coma is a rare life-threatening state of extreme hypothyroidism. Untreated congenital hypothyroidism can result in cretinism.

Signs of hypothyroidism are: dry coarse skin, cool extremities, hair loss and bradycardia. Reinke's oedema, myxoedema, delayed tendon reflexes, carpal tunnel syndrome, pleural effusion, ascites and pericardial effusions have all been described, but these are generally rare and late features.¹ Reinke's oedema is far more commonly associated with smoking.

Symptoms and signs of hyperthyroidism

Graves' disease, toxic multinodular goitre and toxic adenoma are the commonest causes of thyrotoxicosis. Overactivity of the thyroid gland can cause a wide range of symptoms. These include: weight loss, often in the presence of an increased appetite; nervousness, anxiety and irritability; sweating, palpitations and tremor; thin skin, thin hair and muscle weakness; gastrointestinal and menstrual disturbance. Eye symptoms are a feature of Graves' disease, with bulging eyes, a staring appearance and diplopia. In severe cases, a thyroid storm may occur with tachydysrhythmia, pyrexia, vomiting, diarrhoea and mental agitation. This is a medical emergency which has a 20–50% mortality even when treated.³

Signs of thyrotoxicosis are: agitation, evidence of weight loss, perspiration, tremor, palmer erythema and proximal muscle wasting. Thin skin and thin hair, tachycardia and/or atrial fibrillation can also be found.

Thyroid ophthalmopathy is a feature of Graves' disease, and is strongly associated with smoking. Axial proptosis with lid lag (von Graeffe sign), lid retraction (Dalrymple sign), and conjunctival injection (Goldzeiher's sign) can be elicited. Diplopia, particularly on upward gaze in abduction, occurs with increased pressure at the orbital apex. In severe cases optic neuropathy can occur.³

Graves' disease can also cause dermatopathy, with pretibial myxoedema and thyroid acropachy. Pre-tibial myxoedema presents with waxy indurated skin that itches. It can extend onto the dorsum of the foot, and rarely affects other parts of the body.⁴ Thyroid acropachy is characterized by soft-tissue swelling of the hands which can be in association with clubbing.⁵

STRUCTURAL DISORDERS

Thyroid nodules are common in adults and may be palpated in 3–7% of cases.⁶ If ultrasound is used, the prevalence is nearer 70%.⁷ The majority of thyroid nodules are solitary, but they may be part of a multinodular goitre. A focal or diffuse goitre can occur physiologically, and in association with thyroiditis. A first-degree relative with thyroid cancer, and prior exposure to radiation, increase the likelihood of malignancy.⁷

Symptoms and signs of thyroid swellings

The commonest presentation of a thyroid nodule is with an asymptomatic lump. Increasingly referrals are arising as incidental findings from radiological investigations. Pain, rapid increase in size, hoarse voice and the presence of a lateral neck mass are all features that raise concern about a malignant underlying pathology, but the commonest cause for a sudden painful thyroid nodule is bleeding into a pre-existing cyst, and the commonest presentation of a differentiated thyroid cancer is an asymptomatic nodule.⁸ Prior exposure to ionizing radiation is a risk factor for developing thyroid cancer. Patients may also have a relevant family history.

With increasing size, goitres can cause compressive symptoms; these are usually at or above the level of the thoracic inlet, causing cervical dysphagia, exertional dyspnoea, inspiratory or biphasic stridor, and venous congestion of the superior vena caval territory.⁹

A thyroid nodule can often be diagnosed when the patient swallows on their way into the clinic room. Berry first described the fascial attachments of the thyroid to the trachea.¹⁰ This means that thyroid swellings elevate with swallowing.

A hard mass that is tender to touch is more likely to indicate malignancy or Riedel's thyroiditis. Associated cervical lymphadenopathy and fixation to surrounding structures are also highly worrisome findings. Tracheal deviation can be elicited by examining the neck from the anterior aspect. The lower extent of a retrosternal goitre cannot be felt when the neck is examined from behind and the patient swallows. Percussion of the anterior chest wall to elicit the lower extent of a retrosternal goitre is largely of historical interest with the emergence of readily available

cross-sectional imaging techniques. A large retrosternal goitre can cause venous congestion of the head, neck and upper torso. When venous congestion is impending, it can be elicited by asking the patient to raise both arms until they touch the side of their face, and holding that position for a minute (Pemberton's sign). There may also be cyanosis and respiratory distress induced by this manoeuvre.⁹

Flexible nasendoscopy can reveal a vocal cord palsy, Reinke's oedema, tracheal deviation and, in severe cases, tracheal compression. Direct invasion of the upper aerodigestive tract may also be seen.

MISCELLANEOUS OTHERS

Structural thyroid disorders can arise as part of an underlying systemic disorder.

Medullary thyroid cancer is part of multiple endocrine neoplasia syndrome type 2 (MEN2) in 20% of cases, along with pheochromocytoma. In those cases not diagnosed through genetic screening, medullary thyroid cancer is the commonest initial manifestation.¹¹ With MEN2a, parathyroid hyperplasia occurs causing primary hyperparathyroidism. With MEN2b mucosal neurofibromas and Marfanoid features may be evident.

Lymphoma of the thyroid gland can occur in isolation, or as part of wider haematological malignancy. As such, it can be associated with lymphadenopathy in the axilla and groins, and hepatosplenomegaly. The patient may also have the 'B' symptoms of lymphoma, with fever, unintentional weight loss, and drenching night sweats.¹²

BEST CLINICAL PRACTICE

- ✓ Clinical evaluation of the thyroid patient starts when the patient enters the clinic room. Features of hormone dysfunction and the presence of a goitre may be apparent before the patient sits down.
- ✓ The history should cover systemic as well as locoregional symptoms, and also elicit any family and past history of relevance, including prior exposure to ionizing radiation.
- ✓ ENT examination covers the upper aerodigestive tract and neck, including flexible nasendoscopy. There are systemic signs of thyroid disease in a minority of cases that are evaluated by the ENT surgeon.

KEY POINTS

- Thyroid disorders are common.
- They are often asymptomatic but can be associated with a diverse range of locoregional and systemic signs and symptoms.
- They are managed by a wide range of clinicians.
- They can broadly be broken down into functional and structural disorders.
- Thyroid nodules are common.
- Rapid growth, pain and hoarseness are worrying symptoms for thyroid cancer. The commonest cause for a rapidly enlarging painful swelling, however, is bleeding into a pre-existing cyst, and the commonest presentation of thyroid cancer is with an asymptomatic nodule.

INVESTIGATION OF THYROID DISEASE

Anthony P. Weetman

Introduction	709	Determining the nature of structural lesions	713
Investigation of thyroid dysfunction	709	References	714
Determining the cause of thyroid dysfunction	711		

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords hyperthyroidism, hypothyroidism, thyroid function, thyroid nodule and thyroid cancer, and published guidelines which are cited in the chapter.

INTRODUCTION

Clinical signs and symptoms are inadequate to diagnose the presence of any thyroid disorder. Even sophisticated scoring systems are unable to categorize around 40% of euthyroid individuals,¹ and there is considerable inter-user variation in the findings made from thyroid palpation.² The investigation of thyroid disease can be broken down into three sets of tests aimed at: (i) determining whether there is biochemical thyroid dysfunction (i.e. hypothyroidism or thyrotoxicosis); (ii) determining the cause of any thyroid dysfunction and (iii) determining the nature of any structural lesion in the thyroid, most typically nodular thyroid disease. This chapter will not cover the use of fine-needle aspiration biopsy (FNAB) to evaluate thyroid nodules but it is worth recording here that FNAB can also be a useful investigative tool in rare non-neoplastic circumstances, for instance where there is an unexplained diffuse enlargement of the thyroid gland or to obtain material to diagnose acute (suppurative) thyroiditis.

INVESTIGATION OF THYROID DYSFUNCTION

Measurement of thyroid-stimulating hormone

Current sandwich immunoassays, employing two monoclonal thyroid-stimulating hormone (TSH) antibodies to

immobilize and identify TSH, are highly reliable and capable of measuring TSH levels as low as 0.01 mU/L, although not all available assays perform equally well.³ Serum TSH levels show a log-linear relationship to serum free thyroxine (FT4) levels and this makes the TSH the most sensitive test to detect primary dysfunction of the thyroid.⁴ A number of factors can affect TSH levels and need to be taken into consideration in interpreting TSH measurements (**Box 60.1**).

Elevation or suppression of the TSH level, outside the reference range, may be associated with normal levels of

BOX 60.1 Factors affecting the measurement of serum TSH levels

Serum FT3 and FT4; TSH is inversely proportional to free thyroid hormone levels

Physiological factors: intra-individual variation is ± 0.5 mU/L (and there is an insignificant diurnal variation) but inter-individual variation is greater due to the effects of age, genetic factors and obesity

Pituitary or hypothalamic disease; TSH ↓

First trimester of pregnancy; TSH ↓ due to thyroid-stimulating effects of human chorionic gonadotrophin

Non-thyroid illness, including psychiatric disorders; typically TSH ↓, but depends on phase of illness

Drugs; TSH ↓ by dopamine, somatostatin and high dose glucocorticoids

Assay-specific artefacts, especially interference by heterophilic antibodies

free tri-iodothyronine (FT3) or FT4. These are the biochemically defined states of subclinical hypothyroidism and subclinical thyrotoxicosis⁵ and their recognition depends therefore on the cut-off levels used to define the TSH reference range. This is an area that has provoked recent debate, with some data suggesting that the reference range for TSH should be narrowed from around 0.4–4.5 mU/L to 0.4–2.5 mU/L.⁶ On balance, however, the arguments for lowering the upper limit of the reference range in iodine-replete populations are insufficient to warrant a change.^{7, 8}

Measurement of FT3 and FT4

Over 99% of circulating T3 and T4 is bound to thyroxine-binding globulin, albumin or pre-albumin, and variation in the levels of these binding proteins can thus have a profound impact on measurements of total thyroid hormone levels. To eliminate such artefacts, a number of immunoassays have been devised to measure the concentration of free (active) thyroid hormone, and although these may still give anomalous results in certain circumstances (**Box 60.2**), by and large these assays are robust and reliable.⁹ If a serum FT3 or FT4 measurement is unexpectedly abnormal, especially if it is inconsistent with the serum TSH level, more detailed analysis is necessary, including measurement of total thyroid hormone levels.

Measurement of FT3 is particularly indicated in the following circumstances: (i) diagnosis of T3-toxicosis, the earliest stage of overt thyrotoxicosis in which the TSH is suppressed and FT4 is still normal, and (ii) if the patient is taking propylthiouracil or amiodarone, both of which impair the deiodination of T4 to T3 and so give rise to euthyroid elevations of FT4. On the other hand, FT3 measurement is not indicated in the diagnosis of hypothyroidism as FT3 levels are frequently normal until very late in the disease process, despite low FT4 and elevated TSH levels.

Evaluation of the symptomatic patient

Several guidelines have been produced which address the optimal strategy to diagnose thyroid dysfunction.^{4, 10–12} Local policy will generally dictate whether TSH alone is used as a first-line test, progressing to measurement of FT4 only if the TSH is abnormal; the drawback of this

BOX 60.2 Factors affecting the measurement of serum FT3 and FT4 levels

Thyroid dysfunction; overt primary or secondary hypothyroidism or thyrotoxicosis

Non-thyroidal illness, including psychiatric disorders; typically ↓ FT3, but ↑ FT3 and ↓ or ↑ FT4 possible

Drugs; non-steroidal anti-inflammatory drugs, furosemide, phenytoin, carbamazepine, heparin may rarely affect some assays; propylthiouracil and amiodarone inhibit deiodinase activity, altering the ratio of FT3 to FT4

Pregnancy; FT3 and FT4 ↓ by 30% in the last trimester

BOX 60.3 Causes of an elevated TSH

Primary hypothyroidism

- Subclinical (FT3 and FT4 normal)
- Overt (FT4 ↓; FT3 ↓ in 25%)

Non-thyroidal illness (FT3 and FT4 variable), especially during recovery phase

TSH-secreting pituitary tumour (FT3, FT4 ↑)

Rare cases of thyroid hormone resistance (FT3, FT4 ↑)

TSH assay interference (FT3 and FT4 normal)

BOX 60.4 Causes of a suppressed TSH

Primary thyrotoxicosis

- Subclinical (FT3 and FT4 normal)
- Overt (FT3 ↑, FT4 usually ↑)

Secondary hypothyroidism due to pituitary or hypothalamic disease (FT4 ↓, FT3 normal or ↓)

Non-thyroidal illness (FT3 and FT4 normal)

Treatment with dopamine or glucocorticoids (FT3 and FT4 normal)

First trimester of pregnancy (FT3 and FT4 normal)

Hydatidiform mole, choriocarcinoma (FT3 and FT4 ↑)

Activating TSH-receptor mutations (FT3 and FT4 ↑)

approach is that rare cases of hypothyroidism and thyrotoxicosis which are secondary to pituitary or hypothalamic disease may be missed.¹³ If such an approach of using the TSH level as a screening test is adopted, the limitations of TSH measurement have to be continually borne in mind (**Box 60.1**).¹⁴ In general, however, a normal serum TSH level rules out primary thyroid disease. If the TSH is elevated, the most likely diagnosis is hypothyroidism; other causes are detailed in **Box 60.3**. If the TSH is suppressed, the most likely cause is thyrotoxicosis; other causes are detailed in **Box 60.4**.

Screening for thyroid disease

Given the frequency of thyroid disease in the population, the question arises as to whether population-based screening is worthwhile. At present there seems to be no overall benefit, given that most of the cases identified will have subclinical thyroid dysfunction and the benefits of treating this are not yet clear due to the lack of robust trials.^{11, 15}

The occurrence of postpartum thyroid dysfunction in up to 5% of women after pregnancy, and the association between impaired fetal neurological development and untreated maternal hypothyroidism, have suggested there may be a benefit from screening women prior to conception. However, a recent review has indicated that there is insufficient evidence to recommend for or against universal TSH screening at the first trimester visit¹⁶ and in any case there is no evidence that treatment of unrecognized maternal hypothyroidism improves fetal outcome.¹⁷

There is a stronger case for screening certain high-risk populations for thyroid dysfunction, although formal cost–benefit analysis has not been performed: these include individuals with another associated autoimmune disorder (e.g. Addison’s disease, vitiligo, coeliac disease, pernicious anaemia, type 1 diabetes mellitus) or who are taking drugs which may precipitate thyroid dysfunction (e.g. lithium, amiodarone, alpha-interferon, alemtuzumab, sorafenib, sunitinib). The risk of congenital hypothyroidism is around 1 in 3500 births and routine neonatal TSH screening on heel-prick specimens is now well established in all developed countries.¹⁸ Following irradiation of the neck for cancer, including lymphoma, the frequency of hypothyroidism is very high and annual TSH screening is recommended.¹⁹

Monitoring treatment for thyroid dysfunction

In patients receiving antithyroid drug treatment for hyperthyroidism, persistent suppression of TSH levels may occur during and even after cessation of treatment, which is then associated with a higher risk of relapse.²⁰ As a result, such treatment is best monitored by measuring serum FT4 levels; in patients taking propylthiouracil which blocks T4 deiodination, FT3 levels may be a more accurate indicator of thyroid status. Thyroid hormone levels can fluctuate rapidly in some patients following radioiodine, with transient episodes of thyrotoxicosis or hypothyroidism during the first 6 months.²¹ Routine measurement of serum TSH and FT4 levels should be made around 6 and 12 weeks after first treatment, and then every 3 months until a year after radioiodine. Thereafter annual monitoring is indicated. After subtotal thyroidectomy, serum TSH levels often rise and may indicate either a temporary state in which the thyroid remnant is developing capacity to resume function under TSH stimulation, or permanent hypothyroidism. Recent guidelines recommend near-total or total thyroidectomy for Graves’ disease and toxic multinodular goitre, if surgery is chosen as treatment, and in these circumstances levothyroxine is commenced immediately after the operation without the need for further testing.¹¹

Monitoring the adequacy of levothyroxine replacement in primary hypothyroidism depends on measurement of serum TSH levels, which provide an integrated estimate of the effect of treatment during the preceding weeks.^{12, 22} Measurement of TSH should only be made 2 months after any change in levothyroxine dosage, as the TSH level does not stabilize before then. There is no place for measuring serum FT4 levels in the management of primary hypothyroidism, as TSH provides far more reliable information, but FT4 is the only available method to monitor treatment in secondary hypothyroidism: levothyroxine dosage should be adjusted to give a FT4 level in the upper third of the reference range.²³ Once the dose of levothyroxine is stable, TSH should be measured annually, or prior to conception if a pregnancy is planned between annual tests.

Thyroid function testing in pregnancy

Pregnancy has many effects on thyroid function (Box 60.5). As a result of these changes, it is recommended that trimester-specific reference ranges for TSH and FT4 should be applied during pregnancy; in their absence, the following are recommended for TSH: first trimester 0.1–2.5 mU/L; second trimester 0.2–3.0 mU/L; third trimester 0.3–3.0 mU/L.¹⁶

BOX 60.5 Effects of pregnancy on thyroid function

Increase in human chorionic gonadotrophin during first trimester, reciprocal ↓TSH and ↑FT4 (in some cases, this effect may be so large that it may cause transient gestational hyperthyroidism, often associated with hyperemesis gravidarum)

Increase in thyroxine-binding globulin; ↑ in total T3 and T4

Increase in plasma volume; ↑ T3 and T4 pool size

Placental type III deiodinase; ↑ T3 and T4 degradation

Increase in iodine clearance; ↓ in T3 and T4 depending on iodine intake

Serum FT3 and FT4 ↓ by 20–40% during the last trimester but also prone to assay artefacts depending on methodology

TSH-receptor autoantibodies ↓ leading to remission of Graves’ disease in second half of pregnancy

DETERMINING THE CAUSE OF THYROID DYSFUNCTION

Thyroid antibodies

The diagnosis in the vast majority of cases of spontaneous hypothyroidism is autoimmune hypothyroidism, and in hyperthyroidism, around 60–80% of cases are due to Graves’ disease, caused by TSH-receptor stimulating antibodies. Measurement of serum thyroid antibodies can confirm the aetiology of thyroid dysfunction, but there are two important caveats: (i) thyroid antibodies are found in around 10% of the healthy, euthyroid population, and (ii) measurement of thyroid antibodies is only indicated clinically if it alters management. For instance, if radioiodine is going to be used in a particular hyperthyroid patient, it matters little whether TSH receptor antibodies are positive, whereas it would be futile to consider using a course of antithyroid drug treatment to achieve cure in a hyperthyroid patient unless the diagnosis of Graves’ disease is firmly established.

Thyroglobulin (Tg) and thyroid peroxidase (TPO) antibodies were originally measured by immunofluorescence or haemagglutination methods, but more sensitive and reliable immunoassays calibrated against standard sera are now widely used.^{24, 25} Almost all patients with autoimmune thyroid disease who have Tg antibodies also have TPO antibodies, but the reverse is much less common,²⁶ and therefore some laboratories only offer TPO antibody measurement to diagnose autoimmune thyroid disease.

The main indication for the estimation of Tg antibodies is in patients being followed up after treatment for differentiated thyroid cancer. In these individuals, measurement of Tg (see below) is only reliable in the absence of Tg antibodies, especially when immunometric Tg assays are used.²⁷ There is some evidence that the presence of Tg antibodies, found in 15–20% of such patients, is itself a marker for persistent thyroid tissue and a decline in Tg antibody level over time is a good prognostic sign.²⁸ On the other hand, the presence of Tg antibodies has been associated with a higher risk of malignancy in patients presenting with a thyroid nodule.²⁹

Measurement of the TPO antibodies is helpful in defining the risk of overt hypothyroidism developing in individuals with subclinical hypothyroidism (Figure 60.1).^{30, 31} If a patient presents with subclinical hypothyroidism, the TSH and FT4 should be repeated after 3 months, since an elevated TSH may simply be the result of a non-thyroidal illness and in these cases the elevation is only transient. In those who have an isolated elevated TSH, or isolated TPO antibodies, the annual risk of progression to overt hypothyroidism is 2% per year, but it is 5% per year if both are present. Those with positive TPO antibodies are also more likely to develop hypothyroidism after amiodarone or alpha-interferon treatment, or with other drugs which affect the immune system.^{32, 33}

The availability of new, robust immunoassays for TSH receptor antibodies has improved the diagnosis of Graves' disease, as these have sensitivities of around 95% with nearly 100% specificity.³⁴ Although this test does not distinguish between those antibodies which stimulate the receptor and those which block it, in practice this distinction is readily made by taking into account the biochemical picture: a patient with thyrotoxicosis and positive TSH-receptor antibodies must have Graves' disease,

while those with blocking TSH-receptor antibodies will be hypothyroid. Occasionally patients switch production from one functional type of antibody to the other, with sometimes confusing consequences unless this possibility is recognized.³⁵

The two other clinical situations in which measurement of TSH receptor antibodies can be helpful are (i) in predicting the possibility of neonatal Graves' disease by measuring these antibodies in the serum of pregnant women previously treated for Graves' disease^{16, 36} and (ii) in the diagnosis of euthyroid Graves' ophthalmopathy.³⁷ Persistently raised TSH receptor antibody levels are an adverse feature for a successful outcome after antithyroid drug treatment for Graves' disease, but the results are not sufficiently sensitive or specific for routine use in individual patients.³⁸ High levels of TSH-receptor antibodies are an independent risk factor for the development of ophthalmopathy in patients with Graves' disease.³⁹

Inflammatory markers

The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) measurements are useful in the diagnosis of subacute thyroiditis, although these inflammatory markers may also be raised in acute suppurative thyroiditis and even in occasional patients with Hashimoto's thyroiditis.⁴⁰

Thyroglobulin

The measurement of serum thyroglobulin (Tg), alone or following recombinant TSH stimulation, is most useful in the follow-up of patients with differentiated thyroid cancer.^{28, 41} A low serum Tg level before giving radioiodine to ablate any thyroid remnant has 94% negative predictive value for the absence of disease at future follow-up.⁴²

Figure 60.1 Probability of developing overt hypothyroidism in patients with subclinical hypothyroidism. The risks increase in proportion to the initial TSH at the time of diagnosis of subclinical hypothyroidism and the upper line shows the additional risk conferred by having positive thyroid autoantibodies. From Vanderpump et al. The incidence of thyroid disorders in the community – a twenty-year follow-up of the Whickham survey. *Clin Endocrinol* 1995; **43**: 55-69, with permission.

There is no utility in measuring Tg in the initial evaluation of a thyroid nodule. However, there is a role for its measurement in diagnosing factitious thyrotoxicosis, in which the Tg level is low, rather than elevated as in other types of thyrotoxicosis.⁴³

DETERMINING THE NATURE OF STRUCTURAL LESIONS

Scintiscanning

The use of radioisotope uptake tests and thyroid scintiscanning has declined markedly in the last two decades with the introduction of better blood tests and thyroid ultrasound. In benign thyroid diseases, ^{99m}Tc is the most frequently used isotope for scanning and is particularly useful (i) to localize congenital anatomical defects of the thyroid,⁴⁴ and (ii) to distinguish between thyrotoxicosis caused by destructive thyroiditis (e.g. subacute thyroiditis, postpartum thyroiditis), in which the uptake of isotope is reduced, and hyperthyroidism (e.g. Graves' disease, nodular thyroid disease), in which the uptake is increased (Figure 60.2). Radioisotope uptake is also reduced in factitious thyrotoxicosis and in the presence of excessive stable iodine (e.g. after administration of amiodarone or iodine-containing contrast media).

American guidelines for the management of newly presenting thyroid nodules recommend the use of scintiscanning with ^{99m}Tc or I123, for any nodule associated with a subnormal TSH,⁴¹ as a hyperfunctioning nodule is only rarely associated with malignancy. Others take the view that the role of scintiscanning is limited and do not recommend routine use of scintiscanning in the initial evaluation of thyroid nodules.⁴⁵ The use of isotope scanning in the management of treated thyroid cancer is considered elsewhere (see Chapters 62 and 66).

Ultrasound

Thyroid ultrasound is now the most cost-effective approach to gaining structural information about the

gland and is increasingly being performed by endocrinologists and surgeons, rather than being confined to use by radiologists.^{46, 47} Most benign thyroid diseases can be diagnosed by clinical presentation and appropriate blood tests, but colour-flow Doppler ultrasonography has utility in distinguishing between the hyperthyroid (type 1) and destructive (type 2) forms of amiodarone-induced thyrotoxicosis; blood flow is increased in the former and reduced in the latter.³²

Ultrasound is recommended in the evaluation of all thyroid nodules, including multinodular goitre, as simple palpation is imprecise and insensitive.^{41, 48} Features suggestive of malignancy are shown in Box 60.6 and Figure 60.3. It is important to emphasize that ultrasonography is complementary to FNAB in making a diagnosis; for instance, ultrasound is useful in planning the extent of surgery when FNAB is suggestive of carcinoma.⁴⁹ Furthermore, the increasing use of thyroid ultrasound has led to the detection of a large number of nodules which previously would have been ignored. The population prevalence for thyroid nodules is around 5% by palpation, but 10% of 25 year olds and 55% of women aged over 70 have nodules on ultrasonography: only a small fraction of these will be malignant.⁵⁰ A detailed cost-benefit analysis for the investigation of thyroid nodules found incidentally on neck ultrasound has not been undertaken.

Thyroid ultrasound has an increasingly important role in thyroid cancer follow-up, with the recognition

BOX 60.6 Ultrasonographic features suggestive of (a) a malignant thyroid nodule, and (b) a benign thyroid nodule in decreasing order of specificity

- Microcalcification
 - Irregularity of the border of the nodule
 - Increased blood flow in nodule on colour-flow Doppler
 - Hypoechoogenicity
 - Absence of a halo
- Diameter less than 1 cm (those less than 0.5 cm do not require further intervention)
 - Simple cyst with no solid component
 - Comet tail sign, due to colloid content
 - Honeycomb appearance

that whole-body scintiscanning has low sensitivity. Measurement of serum Tg and cervical ultrasound is the best current method to detect recurrent disease in low-risk patients.^{41, 50} Ultrasound elastography is a technique that assesses nodule consistency by measuring the amount of distortion produced by an external force. Although initial reports have been encouraging, based on the premise that malignant nodules are firm and thus have low elastic strain,⁵¹ other studies have found no improvement over conventional ultrasound, even if the two are combined.⁵² This technique is operator-dependent and at present elastography is inadequate to guide management of thyroid nodules.⁵³

Other imaging techniques

Computed tomography (CT) and magnetic resonance imaging (MRI) have only an ancillary use to ultrasound in the investigation of thyroid disease.⁴⁷ Such scans are useful in the assessment of large goitres to determine whether there is any tracheal compression or substernal

extension.⁴⁸ In the initial phase of acute thyroiditis, CT scanning is as good as ultrasound at demonstrating the inflammatory process but more accurate with regard to anatomical involvement; barium swallow imaging is superior to both in detecting a pyriform sinus fistula when the acute inflammatory process subsides.⁵⁴

¹⁸F-FDG-position emission tomography (PET) has generally been used to localize thyroid cancer recurrence in patients with raised Tg levels but no evidence of disease on whole-body scintiscans. However, its overall impact remains to be defined, and specificity and sensitivity figures are unclear.^{41, 55} Non-malignant false-positive results from FDG-PET may be encountered with reactive lymph nodes, suture granulomas and muscle activity. Additional proposed uses for this technique include (i) the initial work-up of patients, although half of patients with indeterminate nodules on fine needle aspiration biopsy and a positive FDG-PET result have benign lesions,⁵⁶ (ii) staging and follow-up of invasive Hürthle cell carcinoma, and (iii) categorization of risk in patients with known distant metastases.⁴¹

KEY POINTS

- Thyroid dysfunction can be diagnosed and managed by simple blood tests: a normal serum TSH level rules out primary thyroid dysfunction.
- Although modern tests for TSH, FT3 and FT4 are robust, occasional artefacts may be encountered, and the possibility of non-thyroid illness as an explanation for abnormal results should always be considered.
- Autoimmune thyroid disease can be diagnosed by the detection of serum TPO antibodies; robust immunoassays for TSH-receptor antibodies make these the test of choice to diagnose Graves' disease.
- Ultrasound has superseded scintiscanning for the structural evaluation of the thyroid and is recommended for the detailed investigation of thyroid nodules.

Hypothyroidism	733	References	746
Thyroid disease in pregnancy	738		

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: hyperthyroidism, thyrotoxicosis, subclinical hyperthyroidism, Graves' disease, hypothyroidism, myxoedema, subclinical hypothyroidism, thyroiditis, subacute thyroiditis, Hashimoto's thyroiditis, goitre, thyroid nodule and multinodular goitre. Secondary search criteria included thyroid-stimulating hormone, thyroxine, triiodothyronine, antithyroid peroxidase, elastography and fine-needle aspiration cytology. Emphasis has been placed on pathogenesis, diagnosis and treatment with level 1 and 2 evidence reported wherever possible.

INTRODUCTION

Benign thyroid disease is commonly encountered by clinicians. The term encompasses thyroid hormone imbalance, abnormal enlargement of thyroid gland tissue and, less commonly, thyroid tenderness. These abnormalities constitute a significant burden within clinical practice, particularly in relation to the elderly, and often require significant biochemical, immunological, radiological and histological investigations in addition to thorough clinical assessment. Thyroid dysfunction encompasses deficient and excess thyroid hormone production, respectively hypothyroidism and hyperthyroidism, which together affect approximately 2% of women and 0.2% of men.¹ While it is clear that the sequelae of overt thyroid dysfunction affect nearly all body systems and that they are therefore associated with significant morbidity and mortality, the significance of subclinical thyroid dysfunction is yet to be fully elucidated. Enlargement of the thyroid gland, or goitre, whether generalized or focal, augments the burden imposed by thyroid disease and may affect up to 60% of the population, with higher frequencies seen in the elderly and women.² Although the majority of cases of thyroid enlargement may be managed conservatively, the need to first exclude malignant aetiology and the more intensive management of these patients pose significant challenges to the clinician.

HYPERTHYROIDISM

Definitions

Hyperthyroidism refers to hyperfunction of the thyroid gland and is defined by reduced levels of thyroid-stimulating hormone (TSH) and raised free T4 (fT4) and free T3 (fT3) concentrations. It leads to thyrotoxicosis, which is the clinical syndrome resulting from a biochemical excess of fT4, fT3 or both. Hence, biochemical tests of thyroid function may identify hyperthyroidism before it becomes clinically apparent, with a rise in fT3 and fall in TSH concentrations typically seen prior to a rise in fT4. **Thyrotoxicosis** may be a consequence of a disorder of the thyroid gland itself, which is referred to as primary disease, or may be secondary to abnormal production of TSH resulting from pathology of the anterior pituitary gland. **Subclinical hyperthyroidism** is diagnosed in patients for whom TSH levels fall below the normal reference range but who have normal fT4 and fT3 concentrations. This must be in the absence of disease of the pituitary or hypothalamus, ingestion of drugs that inhibit TSH secretion or the presence of non-thyroidal illness (**Box 61.1**).

BOX 61.1 Key definitions in thyroid hormone excess (hyperthyroidism)

Hyperthyroidism	<i>Hyperfunction of the thyroid gland (raised T4 and T3 with suppressed TSH)</i>
Thyrotoxicosis	<i>Clinical syndrome resulting from excess thyroid hormones</i>
Subclinical hyperthyroidism	<i>Normal T4 and T3 in the presence of low TSH</i>

Epidemiology

Hyperthyroidism is approximately ten times more common in women than in men within iodine-replete communities, affecting between 0.5% and 2% of the female population.³ The Third National Health and Nutrition Examination Survey (NHANES III) reported the prevalence of clinically significant hyperthyroidism to be 2 per 1000, whereas the prevalence in older persons is reported between 0.4% and 2.0%.^{4, 5} The reported annual incidence for men and women respectively varies between 0.4–0.8/1000 and 0.1/1000 per year; higher rates are seen in iodine-deficient areas.⁶ Unlike for hypothyroidism, there is no documented increase in the probability of the development of overt hyperthyroidism with age.

Subclinical hyperthyroidism is more common and can be readily diagnosed following the introduction of sensitive assays for determining TSH concentrations. The incidence of subclinical hyperthyroidism is reported to increase with age. In a UK survey of 1210 persons aged over 60 years and registered within a single general practice, 6.3% of women and 5.5% of men were identified to have TSH levels below normal.⁷ The overall prevalence of low TSH levels in the Colorado study of 25 862 individuals was 2.2%.⁸ Of the 13 334 persons enrolled in NHANES III, only 0.8% of randomly selected individuals met criteria for subclinical hyperthyroidism, though this rose to 3% of those aged over 80 years.⁴

Aetiology

There are myriad causes of hyperthyroidism, as summarized in [Table 61.1](#), alongside causes of thyrotoxicosis. The most common is Graves' disease, an autoimmune disorder in which antibodies are directed against and stimulate the TSH receptor. Toxic multinodular goitre is commonly seen and features one or more autonomous thyroid hormone-producing nodule(s) that cause thyroid hormone excess. Inflammation of the thyroid may also result in clinically important thyrotoxicosis, in addition to exogenous ingestion of thyroid hormones, the presence of ectopic thyroid tissue or aberrations of thyroidal autonomy. Each carries a specific clinical presentation and requires specific treatment strategies.

Clinical manifestations

Hyperthyroidism may be accompanied by a constellation of signs and symptoms, the breadth of which is attributable to the diversity of action of thyroid hormones. Apathetic or masked thyrotoxicosis may be seen in some patients

who fail to develop any symptoms of thyroid excess whatsoever.⁹ Older individuals may additionally demonstrate a paucity of symptoms though cardiovascular complaints are seen most frequently; it is therefore appropriate to adopt a low threshold for performing thyroid function testing in older persons.¹⁰ There nevertheless exists a rough correlation between circulating thyroid hormone concentrations and symptom severity. The signs and symptoms of hyperthyroidism are summarized in [Table 61.2](#).

SYMPTOMS

The symptoms of thyrotoxicosis result from both β -adrenergic overactivity and the intracellular action of thyroid hormones. Patients may complain of anxiety, poor

TABLE 61.1 Causes and classification of thyrotoxicosis and hyperthyroidism

	Thyrotoxicosis with hyperthyroidism	Thyrotoxicosis without hyperthyroidism
Common	Graves' disease Toxic multinodular goitre Solitary toxic adenoma	Silent (painless) thyroiditis Postpartum thyroiditis Subacute thyroiditis Exogenous thyroid hormone
Uncommon	TSH-secreting pituitary adenoma Iodine intake Radiographic contrast agents Iodine-containing drugs (amiodarone) Pituitary resistance to thyroid hormone Neonatal Graves' disease Hyperemesis gravidarum Struma ovarii Metastatic follicular thyroid carcinoma	Drug-induced thyroiditis (amiodarone, lithium, interferon- α) Acute infectious thyroiditis Radiation thyroiditis Infarction of thyroid adenoma 'Hamburger' thyrotoxicosis

TABLE 61.2 Clinical manifestations of hyperthyroidism

Symptoms	Signs
Weight loss	Sinus tachycardia
Anxiety	Atrial fibrillation
Agitation	Fine tremor
Irritability	Warm moist skin
Palpitation	Palmar erythema
Fatigue and weakness	Onycholysis
Breathlessness	Hair loss
Heat intolerance	Proximal myopathy
Sweating	Muscle wasting
Increased appetite	High output heart failure
Menstrual irregularity	Thyroid bruit
Hair loss	
Brittle nails	

concentration and irritability. They may report insomnia despite extreme fatigue, and a paradoxical fall in weight may be seen in the presence of increased appetite as a consequence of increased basal metabolic rate. Weight loss in conjunction with depression and agitation in this context has previously been termed ‘apathetic hyperthyroidism’.

Heat intolerance and increased perspiration are common complaints. Stool frequency is also increased yet frank diarrhoea is rare. Oligomenorrhoea and infertility may occur in women, although amenorrhoea is seen only rarely. Men may report reduced libido and painful gynaecomastia.

SIGNS

Clinical findings include agitation, rapid speech, palmar erythema, the presence of a fine tremor and warm, moist skin. Hair may be fine and thin while sympathetic overactivity and thyroid orbitopathy contribute to lid retraction and lid lag. Examination of the neurological system may reveal a fine tremor of the outstretched hands, hyperreflexia and a proximal myopathy. Sinus tachycardia or atrial fibrillation (AF) is frequently noted on cardiovascular examination. Approximately 15% of older persons with new-onset AF have thyrotoxicosis, while a study of 40 628 patients with hyperthyroidism identified a prevalence of AF of 8.3%.¹¹ Consequently, new-onset AF warrants an assessment of thyroid status, particularly in older patients among whom AF is seen more commonly and in whom cerebral emboli or worsening cardiac failure may be readily precipitated by its development.¹²

Thyroid enlargement is commonly noted in patients with hyperthyroidism. There may be a single nodule in patients with an autonomously functioning adenoma or a nodular goitre in those with toxic multinodular goitre. A smooth goitre is seen in many patients with Graves’ disease although the thyroid is impalpable in 30% of those with Graves’ and toxic nodular hyperthyroidism.³ Other features seen in hyperthyroidism include osteoporosis, signs of hypercalcaemia and shortness of breath. Signs relating to the excess production of thyroid hormones, including the development of goitre, may be less evident among older persons.

In rare instances, established or new-onset hyperthyroidism may present as an acute ‘thyroid storm’. This potentially life-threatening condition should be considered in patients with a fever and altered mental state. It commonly comprises psychiatric disturbance such as agitation or psychosis coupled with hyperpyrexia, AF and congestive cardiac failure.¹³ Patients may subsequently become comatose. This condition is commonly precipitated by stressors such as infection, surgery or childbirth.

Thyrotoxicosis may also very rarely be associated with periodic paralysis (thyrotoxic periodic paralysis; TPP), particularly among Asian populations and especially in Chinese and Japanese patients aged between 20 and 40 years.¹⁴ Patients typically experience recurrent episodes of transient skeletal muscle weakness which initially affects the lower limbs prior to afflicting the truncal muscles and then all four limbs. Attacks may last 3–72 hours. Severe cases have been accompanied by total paralysis of respiratory, bulbar and ocular muscles. The hallmark of

TPP is hypokalaemia, which is thought to result from the action of thyroid hormone on Na⁺, K⁺-ATPase activity. Treatment with intravenous potassium during an attack may therefore hasten muscle recovery and reduce the potential risk of cardiac arrhythmia. Prophylaxis against further attacks can be achieved using spironolactone or propranolol yet definitive treatment of hyperthyroidism remains the mainstay of management.

Diagnostic evaluation

A history and examination suggestive of thyroid overactivity requires further investigation prior to the initiation of treatment or further investigation. Laboratory investigations used in the workup of suspected thyrotoxicosis are shown in [Table 61.3](#). The single most important test is the measurement of serum TSH. If TSH is within normal range, a diagnosis of hyperthyroidism can usually be ruled out. Rare cases in which thyrotoxicosis is caused by a pituitary lesion, such as a TSHoma, or syndromes of thyroid hormone resistance stand as the exception to this rule. In these instances serum TSH may be normal or slightly raised in association with raised fT3 and fT4 concentrations.

In most cases of hyperthyroidism the typical picture is of undetectable serum TSH with elevated serum concentrations of fT4 and fT3. A low TSH and a normal fT4 concentration should prompt fT3 measurement as 10% of cases of thyrotoxicosis are so-called ‘T3 toxicosis’. This is most commonly seen in mild cases of toxic nodular hyperthyroidism (either a single autonomous nodule or a multinodular goitre) or early in relapse of Graves’ disease. It is important to note that not all laboratories perform T3 assays unless specifically requested.

A low TSH is not specific for thyrotoxicosis. ‘Non-thyroidal illness’ or treatment with a variety of drugs may lower the TSH below the normal range, although it is still usually detectable in these circumstances. For these reasons it is preferable to measure the TSH in conjunction with serum fT4 and, in specific cases, fT3 as well ([Box 61.2](#)).

TABLE 61.3 Laboratory investigations in suspected thyrotoxicosis

Laboratory test	Findings	Comment
Thyroid function tests	Elevated free T4 and/or free T3 Suppressed TSH	Unless TSH-secreting pituitary adenoma or thyroid hormone resistance
Immunology	Raised TSH-receptor antibodies	Pathognomonic for Graves’ disease
	Raised anti-TPO antibodies	Indicative of underlying thyroid autoimmunity
Biochemistry	Elevated alkaline phosphatase Elevated calcium	
Haematology	Normochromic normocytic anaemia	Long-standing cases
	Raised ESR	Subacute thyroiditis

BOX 61.2 Key considerations in TSH testing

Low TSH is not specific for thyrotoxicosis.
Measurement of serum fT4 should be undertaken if TSH is abnormal.
A low TSH and normal fT4 may mask T3 toxicosis.

The specific patterns seen in thyroid function tests (TFTs), as depicted in [Table 61.4](#), are accompanied by non-specific changes in other laboratory tests. Hypercalcaemia is seen in approximately 10% of patients as a consequence of increased bone turnover and secondary suppression of parathyroid hormone.¹⁵ Levels of alkaline phosphatase may increase and both a raised ESR and normocytic normochromic anaemia seen.

TSH-receptor (TSH-R) antibodies are analysed in the laboratory through binding assays or bioassays.¹⁶ These respectively measure TSH-R levels through respectively quantifying either the degree to which radiolabelled TSH–TSH receptor binding is inhibited by the presence of immunoglobulins, or the effect immunoglobulins have on thyroid cell function. The routine use of TSH-R antibody testing is increasing for the diagnosis of Graves' disease and the presence of these antibodies acts as a specific indicator of the disease. Interestingly, high levels of TSH-R antibodies seen in patients with Graves' disease who are pregnant predict neonatal thyrotoxicosis.¹⁷ The additional presence of thyroid peroxidase (TPO) antibodies is suggestive but not pathognomonic for Graves' disease.

THYROID SCINTIGRAPHY IN THE INVESTIGATION OF THYROTOXICOSIS

In cases in which the aetiology of thyrotoxicosis remains unclear despite history, examination and laboratory investigations, thyroid scintigraphy may be utilized. This technique analyses radioactive iodine uptake by the thyroid gland and can be used to differentiate between 'hot' and 'cold' areas of increased and decreased function respectively. In most hyperthyroid states uptake will be at the higher end of normal or raised and there are specific

scintigraphic appearances associated with different conditions ([Figure 61.1](#)). Uptake is typically low in transient thyroiditis and in iodine-induced hyperthyroidism. Isotope imaging, typically with technetium, can be useful to differentiate between focal uptake in one or more autonomous nodules and diffuse uptake in Graves' disease, but it is less specific than iodide-uptake scans. Radioisotope scanning lacks specificity, with high values also seen in individuals who have a normal thyroid gland in addition to those with iodine deficiency and conditions such as Hashimoto's thyroiditis.

Specific disorders of thyroid hormone excess**GRAVES' DISEASE**

In iodine-replete parts of the world, Graves' disease is the most common cause of thyrotoxicosis ([Figure 61.2](#)). First described in 1835, Graves' disease is a syndrome consisting of hyperthyroidism, moderate diffuse goitre, ophthalmopathy and dermopathy. In many patients, hyperthyroidism and goitre are the only features. It is more common in women than men at a ratio of greater than 5:1. Men are affected later and the disease may be more severe. Its peak incidence is in the twenties and thirties, but the disease can occur at any age, albeit uncommonly before puberty. Graves' disease is both more common and more likely to be complicated by ophthalmopathy in smokers, in whom the risk of Graves' disease is almost doubled.¹⁸

Pathogenesis

Graves' disease is an autoimmune condition characterized by the presence of circulating IgG oligoclonal autoantibodies directed against the TSH receptor within thyroid tissue (TSHR-Ab). These bind to the extracellular domain of the TSH receptor where they cause activation of intracellular cyclic AMP and thereby mimic the effect of pituitary TSH to stimulate thyroid hormone synthesis and secretion. Increased expression of fibroblast growth factor (FGF) contributes to enlargement of the gland resulting in

TABLE 61.4 Specific patterns of thyroid function tests

Suspected pathology	Specific diagnosis	TSH	T4	T3	TSH response to TRH

Figure 61.1 Scintigraphic appearances. (a) Normal thyroid; (b) Graves' disease with pyramidal lobe.

a diffuse swelling. Antibodies which specifically activate phospholipase A₂ are especially goitrogenic.¹⁹

The expression of CD80 and CD86 by dendritic cells and B cells may trigger Graves' hyperthyroidism by acting to co-stimulate infiltrating T cells.²⁰ These are targeted against antigens such as the thyrotropin receptor, which is presented to them by thyroid cells that express HLA class II molecules in response to interferon- γ production. The presentation of antigen and molecules such as CD40, CD54 and IL-6 by thyroid cells may later exacerbate the autoimmune process.²¹ Cross-reactivity between these thyroidal antigens and antigens in orbital and extra-orbital tissues may explain the close relationship between Graves' disease and both ophthalmopathy and dermatopathy. The thyrotropin receptor is additionally expressed in preadipocytes of orbital fibroblasts and has therefore been suggested as a possible cross-reactive antigen.^{22, 23}

The aetiology of Graves' disease remains unknown. It runs in families and a concordance rate in monozygotic twins of 20% suggests a genetic contribution to its development, albeit with additional contribution from environmental factors responsible for promoting development of the disease. Graves' is well known to be associated with HLA-DR3 and HLA-DQA1*0501 in Caucasians, while HLA-DRB1*0701 is protective.²⁴ Environmental factors linked with the development of disease include life stress and subsequent activation of specific neuroendocrine pathways, female sex, steroids, smoking, dietary iodine intake and immune modulators such as interferon α .²⁵⁻²⁷ Lithium may also promote Graves' hyperthyroidism via its immunologic sequelae.²⁸ Graves' disease has been associated with other diseases mediated by the immune system, including Type 1 diabetes, vitiligo (Figure 61.3), coeliac disease, pernicious anaemia and Addison's disease.

Figure 61.2 Graves' disease. A vascular gland displaying characteristic tortuous, hyperplastic follicles with blunt papillary infolding. The thyrocytes are columnar in outline and there is accentuated marginal vacuolation of stored colloid.

Figure 61.3 Vitiligo in hands of patient with Graves' disease.

Clinical manifestations and natural history

Although Graves' disease can occur rapidly over a few weeks, in most the onset is gradual and insidious. Patients exhibit many of the clinical features discussed above but may in addition have extrathyroidal manifestations such as ophthalmopathy (with exophthalmos and conjunctival oedema) and, rarely, dermatopathy and acropachy.

A diffuse goitre is present in the majority of cases but its absence does not rule out Graves' disease, as the thyroid may be of normal size in around 3%.¹⁵⁻¹⁸ The goitre is usually symmetrical, there may be an overlying palpable thrill and a bruit may often be heard. The thrill and bruit result from the increased blood flow to the thyroid.¹⁵⁻¹⁸

Graves' disease is usually treated with antithyroid medication in the first instance. While adequate therapy is given, the disease may be quiescent, but it can return if compliance diminishes or if drug dosage is inappropriately reduced. As with many autoimmune conditions, Graves' disease is sometimes self-limiting, although this is rare. Around 30% of patients experience lasting remission after treatment with antithyroid drugs.

Extrathyroidal manifestations of Graves' disease

Thyroid eye disease

Ophthalmopathy is common in Graves' disease. It is clinically apparent in approximately 50% of patients and may present prior to the onset of Graves' disease.¹⁸ In 75% of those for whom eye disease is clinically apparent, eye signs appear within a year before or following the diagnosis of hyperthyroidism.¹⁸ Even in the absence of clinical signs, imaging such as MRI has provided evidence of eye involvement in most patients (Figure 61.4). Approximately 90% of patients with thyroid eye disease also have Graves' disease.²⁹ The majority of the remainder have autoimmune hypothyroidism.

The ophthalmopathy seen in Graves' disease is characterized by swelling of the extraocular muscles, proliferation of periorbital fat and late fibrosis leading to muscle tethering.³⁰ The lesions develop due to an accumulation of glycosaminoglycans and a lymphocytic infiltration of the orbital and retro-orbital tissues. Patients who smoke are more likely to suffer eye disease of greater severity than non-smokers and hypothyroidism is an additional potentially exacerbating factor.^{31, 32}

Patients with thyroid eye disease may complain of irritation in the eyes and the feeling of a foreign body. There may be excessive watering, especially in the wind. As the disease progresses, there is sometimes a change in physical appearance with periorbital oedema and/or a staring expression caused by exophthalmos and/or eyelid retraction. Eyelid retraction may give the false impression of proptosis, though both most often coexist. This may be bi- or unilateral and patients can complain of a feeling of pressure behind the eyes. Even in apparent unilateral cases, evidence of bilateral disease may be apparent on imaging. In severe cases the patient cannot close their eyes at night, leading to corneal ulceration and scarring. Apparent nerve palsies are also seen due to infiltration of the extraocular muscles with fat and fibrotic changes.

Figure 61.4 Thyroid eye disease. MRI orbits, showing enlarged extraocular muscles.

Figure 61.5 Patient with thyroid eye disease and optic neuropathy. (a) Pre-corrective surgery and (b) after surgical decompression. Note the upper lid retraction, corneal injection, periorbital fat deposition and proptosis pre-surgery.

Diplopia is noted in a significant proportion of patients and corrective surgery may be required (Figure 61.5).³³

A rapid deterioration in visual acuity and loss of colour vision are ominous signs and may be caused by pressure on the optic nerve by swollen extraocular rectus muscles or sheer stretch of the optic nerve. Urgent treatment is required if permanent visual loss is to be avoided. Patients must also be referred urgently to an ophthalmologist if they develop strabismus or poor eye movement, or corneal ulceration or if their visual acuity is less than 6/18 (Box 61.3).³⁴

BOX 61.3 Urgent referral criteria in thyroid eye disease

Rapid deterioration in visual acuity
 Ocular nerve palsies
 Unacceptable cosmetic appearance
 Visual acuity of less than 6/18
 Decreased colour vision
 Corneal ulceration

The most frequently seen signs of thyroid eye disease include eyelid retraction and periorbital oedema. Lid lag also occurs frequently and in mild cases arises as a consequence of sympathetic overactivity, whereas in more significant instances is the result of Graves' ophthalmopathy. Exophthalmos is seen in up to a third of patients. Compression of the optic nerve at the apex of the orbit is rare but can result in visual loss.

Thyroid eye disease occurs in two phases: a dynamic phase and a quiescent phase. Unfortunately, even when Graves' ophthalmopathy is well-treated and quiescent, patients do not always achieve a return in physical appearance to their pre-morbid state. Mild to moderate thyroid eye disease often requires no treatment and may improve spontaneously. Local discomfort can be managed with artificial tears and elevation of the head of the bed to reduce oedema. Severe ophthalmopathy requires management in a multidisciplinary team with experienced ophthalmologists. High-dose glucocorticoids as well as other immunosuppressive agents and orbital radiotherapy can be used successfully in early and active disease, which will have beneficial effects in approximately two-thirds of patients.^{35, 36} The chimeric anti-CD20 monoclonal antibody Rituximab acts to deplete B-cells and may also be of benefit in thyroid eye disease, though trials are ongoing.^{36, 37} Ocular nerve palsies require treatment from an experienced ophthalmologist, either initially or after failure of glucocorticoid treatment.

Dermopathy

This occurs in 1–2% of patients with Graves' disease, almost always accompanied by severe eye disease.³⁸ Usually occurring over the shins and known as pretibial myxoedema, it may affect other areas of the body.³⁹ Dermopathy in Graves' disease also occurs at sites of trauma, thereby exhibiting the Koebner phenomenon.

The skin appears raised, oedematous, nodular and discoloured with a pink or brownish tinge (Figure 61.6).⁴⁰ It is characterized by a florid lymphocytic infiltrate and a build-up of glycosaminoglycans. Although not usually treated, fluorinated steroids may be used topically with occlusive dressings.³⁹

Acropachy

This very rare condition occurs in less than 1 per 1000 patients. It presents as clubbing of the fingers with subperiosteal new bone formation seen on plain X-ray films.⁴¹ Acropachy arises from glycosaminoglycan accumulation and is seen in association with dermopathy and ophthalmopathy. There is no treatment.

Figure 61.6 Pretibial myxoedema.

Laboratory diagnosis

The routine measurement of TSH-R antibodies for the diagnosis of Graves' disease is increasingly regarded to be both valid and reliable.¹⁶ Anti-TPO antibodies are also commonly measured. Laboratory results otherwise typically identify raised serum fT4 and fT3 with undetectable serum TSH.

KEY POINTS**GRAVES' DISEASE**

- Graves' disease is the most common cause of thyrotoxicosis in iodine-replete populations.
- It is more common in women than men.
- It is an autoimmune condition characterized by the presence of IgG anti-TSH receptor antibodies.
- Antithyroid peroxidase antibodies are present in 75% of patients.
- Ophthalmopathy, dermopathy and acropachy are important extrathyroidal manifestations.
- Antithyroid medication is used in most cases at least initially.

TOXIC MULTINODULAR GOITRE

Nodular thyroid disease predominates in the elderly and surpasses Graves' disease as the most common cause of hyperthyroidism in older persons living within iodine-replete areas.⁴² In regions in which iodine is relatively deficient, toxic nodular thyroid disease is the most common cause of hyperthyroidism.⁴³ A toxic multinodular goitre (MNG) occurs when two or more autonomously functioning thyroid nodules secrete excess thyroid hormone. Its precise cause is not known but may relate to genetic change that occurs within specific nodules and thereby drives clonal expansion.⁴⁴ As a consequence of its long natural history, an elderly patient presenting with a toxic MNG may describe the presence of the goitre many years before the thyrotoxicosis develops.⁴⁵ Exposure to pharmacological doses of iodine, such as those found in contrast media, may also precipitate hyperthyroidism through the Jod Basedow effect.⁴⁶ This is commonly seen in areas of iodine deficiency.

Toxic MNGs are generally observed in an older patient group than those who present with Graves' disease and the degree of thyroid hyperfunction is typically less marked.

For these reasons, the classical clinical symptoms and signs of thyrotoxicosis may not all be present. It is the cardiovascular effects that predominate, including palpitation, AF and other tachyarrhythmias.⁴⁷ Patients with toxic MNG may also report the presence of a long-standing goitre. Compressive symptoms are a possible consequence of the presence of a MNG and include dysphagia to solids and dyspnoea that worsen at night.

KEY POINTS

TOXIC MULTINODULAR GOITRE

- This occurs in older patients.
- Thyroid hyperfunction is less marked than in Graves' disease.
- Cardiovascular symptoms predominate.
- Definitive treatment with radioiodine is required.

SOLITARY TOXIC ADENOMAS (PLUMMER'S DISEASE)

A single toxic adenoma is a benign tumour autonomously secreting sufficient thyroid hormone to suppress pituitary TSH secretion. Solitary adenomas tend to grow to at least 3 cm in diameter prior to causing overt hyperthyroidism.⁴⁸ They are a rare cause of thyrotoxicosis and account for only around 5% of cases.⁴⁸ A mutation in the TSH receptor gene occurs in 20–83% of cases.⁴⁹ Several point mutations of this gene have been identified, mostly in the transmembrane domain. These are somatic and result in TSH receptor activation and consequent autonomous thyroid hormone secretion. Other activating mutations have been identified downstream in the stimulatory G protein pathway linked to cyclic AMP production.^{50, 51}

Subclinical hyperthyroidism, characterized by below-normal serum TSH and normal serum fT4 and fT3 concentrations, is often evident on biochemical testing.⁵² It occurs early in the clinical history of a toxic adenoma as a consequence of negative feedback prompted by TSH receptor activation and the resultant autonomous production of thyroid hormones.⁵³ Patients with a toxic adenoma are often younger than those with a toxic MNG, and present in the fourth or fifth decade. There may be a history of a slowly enlarging neck mass and many will have a palpable nodule. The autonomously functioning tissue may nevertheless be diffuse and a palpable nodule will not therefore be apparent in all patients. The level of thyroid hyperfunction is less than that seen in Graves' disease and signs may thus be less florid.⁵² Radionuclide scanning may be utilized to distinguish a solitary toxic adenoma from toxic MNG and Graves' disease. It typically demonstrates a focus of isotope accumulation with no other visible areas of uptake.

Management of hyperthyroidism

The initial approach to the hyperthyroid patient is to minimize symptoms (often with a beta-adrenergic blocking drug) and to reduce the synthesis of thyroid hormones. Overt hyperthyroidism necessitates effective therapy in all

cases in order to reduce the risk of psychological, cardiovascular and skeletal sequelae. The principles of management are summarized in **Box 61.4**.

BOX 61.4 Principles of management of hyperthyroidism

Minimize symptoms (e.g. with the use of a beta-adrenergic blocking drug)

Treat hyperthyroidism to reduce risk of psychological, cardiovascular and skeletal sequelae:

- Thionamides
- Radioiodine
- Surgical resection

Three modalities of treatment exist: drug therapy, radioiodine treatment and surgery. Their relative indications, advantages and disadvantages are summarized in **Table 61.5**. It has been demonstrated that each of the three treatment modalities is as effective at reducing thyroid hormone concentration, with similar improvements seen in quality of life and patient satisfaction following their use.^{54–56} Treatment selection therefore depends on the underlying aetiology, the preference of the clinician and patient factors. Service considerations often also play a role in determining treatment choice and include cost, local restrictions on the use of radioisotopes and the availability of a skilled surgical team.

Standard practice in Europe has been to favour anti-thyroid medication in patients under 40 years of age, with surgery reserved for patients who relapse.⁵⁷ In contrast, radioiodine therapy is not restricted to use in older patients within the USA and antithyroid drug regimens are consequently not commonplace. Radioiodine is considered first-line therapy in Graves' disease and toxic multinodular goitres yet its use, which is commonly associated with hypothyroidism, is not without controversy.^{2, 32}

A long-term increase in all-cause and vascular mortality after treatment of hyperthyroidism with radioiodine has for instance been described, though this is probably due to an underlying diagnosis of thyrotoxicosis rather than a consequence of radioiodine therapy itself.⁵⁸ Induction of hypothyroidism after radioiodine treatment reduces this risk, perhaps because hypothyroidism is the best marker of reversal of adverse tissue effects. Fears about the development of cancer after radioiodine have not been realized, although Graves' hyperthyroidism itself might be associated with a slight increase in the absolute risk of thyroid cancer.^{59–61}

There is consequently a lack of consensus regarding appropriate thyroid hormone replacement in patients rendered hypothyroid by radioiodine, and some evidence to suggest that antithyroid drugs may be safely used longer term for the management of relapsing and remitting hyperthyroidism.

PHARMACOLOGICAL MANAGEMENT

The thionamides (carbimazole, its active metabolite methimazole [not available in the UK] and propylthiouracil) are the most effective antithyroid drugs and represent the mainstay of drug treatment of thyrotoxicosis.⁵⁷

TABLE 61.5 Specific indications, advantages and disadvantages of treatment modalities used in the management of thyrotoxicosis

They act by blocking the synthesis of T4 and T3 early in their biosynthetic pathway by disrupting the organification and oxidation of iodide through inhibition of the thyroperoxidase enzyme. Propylthiouracil (PTU) additionally acts to inhibit the conversion of T4 to T3 but this is not thought to be of clinical relevance. Thionamides have also been associated with a possible immunomodulatory effect, although this is of doubtful clinical significance given that most patients relapse following drug withdrawal.⁶² Carbimazole can be dosed as a once-daily preparation in order to improve compliance and results in fewer adverse effects than propylthiouracil.⁶³ It is therefore generally given in preference, with propylthiouracil reserved for use in pregnancy, women attempting to conceive or patients who have developed an adverse reaction (other than agranulocytosis) to carbimazole or methimazole.⁶⁴

Dosage

All patients with hyperthyroidism require specialist referral and patients should be commenced on antithyroid

drug treatment while they await further clinical review.⁶⁵ Carbimazole is available as 5 mg and 20 mg tablets and is usually given in a starting dose of 20–30 mg per day in a single dose. Treatment should usually begin at 30 mg in cases of severe disease (fT3 and fT4 levels more than twice the upper limit of the normal reference range). Propylthiouracil is given in divided doses, with a dose of 200 mg approximately equivalent to 20 mg carbimazole. Patients begin to feel an improvement at 10–14 days and fT4 and fT3 values return to normal levels over 4–6 weeks.

Side effects

Side effects are seen in 1–5% of patients taking thionamides and can occur with both carbimazole and PTU (Table 61.6). The most common side effect is pruritic rash, which can usually be managed conservatively. Occasionally, the rash necessitates a change from one drug to the other and cross-reactivity in this context is not typically a problem. Other relatively minor side effects include fever, urticaria and arthralgia.^{57, 66}

TABLE 61.6 Side effects of thionamides

Severity	Side effects
Mild	Pruritic rash Fever Urticaria Arthralgia
Serious	ANCA-associated vasculitis Hepatitis Liver failure Agranulocytosis
A fever and sore throat in a patient taking thionamides requires measurement of full blood count.	

More serious side effects are rare and include development of an antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis (typically associated with PTU) and hepatitis.^{67, 68} Agranulocytosis is a serious side effect and occurs in 0.2–0.5% of patients.⁶⁷ This typically occurs in the first few weeks of treatment but may occur at any point during antithyroid drug therapy since it is an idiosyncratic reaction. It is more common in patients taking high doses. For this reason it is essential that all patients are warned (preferably in writing) of the risk of agranulocytosis and that clear instructions are given to present urgently for a full blood count if they develop a fever or sore throat. The agranulocytosis is usually transient and resolves after thionamide withdrawal.

PTU can also result in fulminant hepatic failure, which can necessitate liver transplantation or lead to death. PTU-related acute liver failure occurs in an estimated 1 in 10 000 adults, although it is more commonly seen in children.⁶⁹ The US Food and Drug Administration has consequently issued a warning relating to the use of PTU, and its first-line use in adults and children is now not recommended unless the patient is in the first trimester of pregnancy, if side effects are reported with carbimazole or methimazole therapy, if radioiodine or surgery is not an option or in some instances of life-threatening thyrotoxicosis.⁷⁰

The development of agranulocytosis, hepatitis or vasculitis is an absolute contraindication to the further use of thionamides.

Graves' disease

In cases of Graves' disease patients may be offered a full course of thionamide therapy in the hope of inducing remission. Treatment should be offered for a period of 12–18 months as shorter courses are associated with higher rates of relapse.^{71, 72} Treatment duration is agreed with the patient at the outset, but at any point medication may be stopped if definitive therapy is preferred. Serum fT4 should be measured regularly, ideally every 4–6 weeks initially, then 8–12 weekly once control is achieved. Drug doses are titrated according to the serum concentration of fT4. Serum TSH may remain suppressed in the medium to long term in patients with Graves' disease due to delayed recovery of thyrotrophs. Most patients require a maintenance dose of 5–10 mg carbimazole and 50–100 mg PTU. Poor compliance should be suspected if larger doses are required.

Treatment efficacy

Remission rates with this regimen are less than 50%, but they may be higher in the elderly.^{55–73} Relapse usually occurs within 3–6 months of thionamide withdrawal, in which case patients should be offered definitive treatment. Efforts to risk-stratify patients for their likelihood of relapse using markers such as goitre size, thyroid suppressibility, HLA status, the presence of TSH-receptor antibody and TSH response to thyrotropin-releasing hormone have been unsuccessful.

On a population basis, increased likelihood of remission is most strongly associated with age and sex.⁷³ Remission occurs in approximately 20% of men, compared to 40% of women, in addition to 33% of those less than 40 years of age compared to 48% of those aged over 40. A small goitre or one that shrinks during therapy also appears related to an increased risk of remission.⁷⁴ Once remission is achieved, cure is likely if the patient remains euthyroid for 6 months, although a slowly increasing proportion relapses with length of time of follow-up. Ninety per cent of relapses occur within 3 years. **Table 61.7** summarizes poor prognostic factors for relapse of medically treated Graves' disease.

Block and replace

Although most clinicians use thionamides alone to treat Graves' disease, some prefer the 'block and replace' regimen. This uses thionamides to block endogenous hormone production completely with hypothyroidism avoided in the long term by supplementing with exogenous thyroxine. The dose of thyroxine is then adjusted to maintain serum TSH within the lower reference range. Advocates of this regime suggest that it requires less monitoring and leads to better compliance. Remission rates are not, however, improved by standard block and replace therapy and there is no substantial evidence for any advantage of this regime.^{75, 76} There is clear evidence of increased adverse effects, some of which are serious and are related to the higher doses of thionamides required.⁷⁵ This regimen is also contraindicated in pregnancy because thionamides cross the placenta more easily than T4, leading to the potential for foetal goitre and hypothyroidism.

Toxic multinodular goitre and toxic adenoma

Thionamides may be used in the short term in order to induce euthyroidism in patients with nodular disease but do not lead to remission or cure of thyrotoxicosis in

TABLE 61.7 Poor prognostic factors for relapse of medically treated Graves' disease

Factor type	Prognostic factor
Demographic	Male gender Age < 40 years
Clinical history	Repeated episodes of relapse Presence of a large goitre
Biochemical	Severe biochemical disease Greatly increased T3:T4 ratio High levels of TSH receptor antibodies

this context. Definitive treatment with radioiodine or surgery is therefore required. As the thyrotoxicosis is usually biochemically less severe than Graves' disease, the starting dose of thionamides may be smaller. If surgery or radioiodine is not appropriate, thionamides can be continued indefinitely.

Adjuncts to antithyroid drugs

Beta-adrenergic blockers are useful adjuncts to thionamides in the management of thyroid hormone excess. They act promptly to reduce symptoms such as tremor, palpitations and tachycardia. Their use is cautioned in the elderly where heart failure may be present. The most commonly used beta-adrenergic blocker is propranolol. Thyrotoxicosis may result in accelerated clearance of propranolol and higher doses of this drug may therefore be required.

Patients who develop AF are at risk of embolic complications. Anticoagulation with warfarin or a novel oral anticoagulant (NOAC) such as rivaroxaban or apixaban should therefore be considered, in accordance with the patient's CHA₂DS₂-VASc score and the specific licence of the NOAC. There have been no controlled trials of the use of anticoagulants in thyrotoxic AF but overwhelming evidence for their efficacy in other settings argues in favour of their use for as long as there are not clear contraindications. There is also no evidence for or against the preferential use of NOACs in this context. Approximately half of those with thyrotoxic AF will revert spontaneously to sinus rhythm and this typically occurs within 3 months of the initiation of antithyroid therapy. For those who remain in AF, joint cardiological management involving specific therapy to restore sinus rhythm may be considered when the patient is euthyroid. Chemical or electrical cardioversion is more likely to restore sinus rhythm in those whose AF is of short duration and in those who have no underlying heart disease.⁷⁷

RADIOIODINE

Radioiodine is increasingly used both as first-line therapy in Graves' disease, for toxic multinodular goitre and in patients with Graves' disease for whom initial treatment with a course of thionamides has failed (**Box 61.5**).³² It may also be used to induce shrinkage of benign goitres and in the management of autonomous thyroid nodules.² Permanent hypothyroidism results in most patients treated with radioiodine, though this may occur many years later. The incidence of hypothyroidism is dose-dependent.⁷⁸

Administration

Radioiodine is administered orally as sodium ¹³¹I in capsule form and can be given in the outpatient department. It is incorporated into thyroid tissue and acts principally through the emission of beta rays with a range of 0.5–2 mm. These penetrate into tissue and result in high absorbed doses of radiation within thyroid tissue while sparing the surrounding anatomy. Lasting thyroid tissue damage results but usually lags with maximum thyroid

ablation occurring over 6 weeks to 4 months. Scintigraphic imaging may be employed following the administration of radioiodine as a result of emitted gamma rays in order to determine its distribution within thyroid tissue and to support dosimetry.

BOX 61.5 Radioiodine treatment

Used in toxic multinodular goitres and Graves' disease
Administered orally as a sodium ¹³¹I capsule
Thyroid tissue damage results from emission of beta rays
Pre-treatment with thionamides and symptomatic relief usually required
Side effects include radiation thyroiditis and exacerbation of ophthalmopathy
Long-term safety is proven but hypothyroidism is common
Contraindicated in pregnancy, women who are breastfeeding and children

There is no national consensus regarding the most appropriate dose of radioiodine. The Royal College of Physicians of London recommend that the dose used should be enough to achieve euthyroidism with an acceptable risk of the subsequent development of hypothyroidism. Most centres will administer a fixed dose of 400–600 MBq, which is large enough to induce cure in the majority of patients.⁷⁹ Some centres give larger doses to men and those with large goitres in whom it is suggested that relative radioiodine resistance may be found. Larger doses may be preferable in the elderly, especially those with concomitant heart disease, to be certain of rapid resolution of hyperthyroidism.⁸⁰

Many investigators have attempted to determine a method for calculating a radioiodine dose sufficient to cure hyperthyroidism without resulting in hypothyroidism. Postulated methods have involved assessment of the target volume mass, calculations of likely isotope uptake and assessment of isotope turnover.⁸¹ These have not, however, been supported by prospective studies and it has been shown that the use of a calculated dose carries no advantages over a fixed dose in terms of outcome, but results in extra cost and inconvenience for the patient as a consequence of the planning required.

National radiation protection policies exist and include measures to avoid contamination of the home or workplace with radioiodine. They include avoidance of close contact with small children, avoiding sharing utensils and the recommendation to sleep alone.

Pre-treatment with antithyroid medication

Symptom relief may be achieved by beta-adrenergic blocking agents used peripherally in patients undergoing radioiodine administration with coexistent AF. Pre-treatment with thionamides (preferably with carbimazole) should be administered unless the hyperthyroidism is very mild and radioiodine administered once biochemical euthyroidism is restored. This is because it may take 3–4 months for radioiodine to induce euthyroidism whereas thionamides act much more quickly.

There may be a temporary exacerbation of hyperthyroidism as the radiation damage causes follicular destruction and ‘dumping’ of preformed thyroid hormone into the circulation.⁸² Thionamides may therefore be restarted temporarily following radioiodine administration in order to reduce the risk of radiation-related thyroiditis causing an exacerbation of hyperthyroidism, particularly in the elderly and those with cardiac disease.⁸³

There is evidence to suggest that use of methimazole and PTU during radioiodine therapy impacts on radioiodine kinetics within the thyroid gland. Whichever thionamide is used, it should thus be discontinued 1 week before radioiodine administration in order to reduce the risk of negative impacts on therapeutic outcomes.^{84, 85} Most clinicians advise restarting thionamides after radioiodine administration, particularly in those with severe disease or who tolerate hyperthyroidism poorly. The antithyroid drug can then be tailed off according to measurements of serum fT4 concentration. In instances in which thionamide therapy is continued during radioiodine administration, success rates are reported to fall from over 90% to under 50%.

Follow-up

In the short term, clinical assessment of the patient should be carried out every 4–6 weeks. In addition to serum TSH, serum fT4 concentration should be measured. Measurement of TSH concentration alone may be misleading as it may be suppressed for many months after treatment and does not necessarily imply that relapse is imminent, especially if the patient is clinically euthyroid and the serum T4 concentration is normal. If biochemical hyperthyroidism persists after a 6-month period, it is likely that a second (and rarely a third) dose of radioiodine will be required. Hypothyroidism commonly results in these patients.

All patients who have received radioiodine require long-term biochemical follow-up. Effectively achieved with a computerized recall system, this is essential as the incidence of hypothyroidism is significant many years after treatment with radioiodine and, eventually, up to 90% may become hypothyroid. Annual measurement of serum TSH is appropriate.

Efficacy

Dependent on the administered dose, 50–70% of patients achieve euthyroidism and shrinkage of goitre around 2 months after therapy.³² Around 15–20% of patients require a second dose 6–12 months after their initial treatment. A small proportion of patients require a third dose. Those treated with low-dose radioiodine, males, those with severe hyperthyroidism and those with a medium to large goitre are less likely to be cured after a single dose of radioiodine.⁸⁶

Side effects and safety

Many patients are concerned about the concept of radiation treatment and perceive that there may be an increased

risk of subsequent cancer. Radioiodine has been used for many years, with well-established efficacy. In terms of cancer, long-term safety has been well demonstrated.^{32, 87, 88} The thyroid appears more sensitive to the effects of radiation in children and adolescents. Consequently, most paediatricians would avoid radioiodine in these cases.

Patients who have received radioiodine therapy may notice a sore throat or neck tenderness. This reflects radiation thyroiditis and is thought to occur in around 1% of cases. Symptoms are usually mild and transient. As a result of thyroid ablation, the main side effect of radioiodine treatment is hypothyroidism, although the percentage of patients who develop this during the first year varies according to the dose of radioiodine used. The risk of hypothyroidism with a dose of 600 MBq is around 60%. After the first year, the annual incidence is around 2–3% and seems to be dose-independent.

Radioiodine may worsen moderate to severe ophthalmopathy, particularly in smokers.^{31, 89} Adjunctive administration of corticosteroids may ameliorate or even prevent the development of ophthalmopathy.²² Most physicians delay administration of radioiodine until moderate or severe eye disease has been stable for 12 months. Those with mild eye disease are given radioiodine alongside a course of steroid prophylaxis.²²

Contraindications

Pregnancy is an absolute contraindication to the use of radioiodine due to the risk of ablating foetal thyroid tissue. A pregnancy test is therefore necessary prior to administration of radioiodine and effective contraception required for 4–6 months after treatment in order to allow for resolution of the effects of transient gonadal radiation. Inadvertent pregnancies require close monitoring, although there is little evidence to suggest that birth defects are increased as a result of exposure to radioiodine during pregnancy. Exposure in early pregnancy is nevertheless associated with a theoretical potential late cancer risk due to foetal irradiation, and exposure after 14 weeks may result in thyroid ablation.

Radioiodine is also contraindicated in women who are lactating, in young children because of fears of increased risk of developing subsequent thyroid carcinoma, and in those who are unable to understand or comply with local radiation protection measures.

Use of radioiodine is associated with worsening of Graves’ ophthalmopathy and its use is therefore relatively contraindicated in this group.⁹⁰ Radioiodine should not be used in patients with active thyroid eye disease, whereas steroid prophylaxis is recommended for patients with clinically apparent but stable eye disease.⁹¹ Prophylactic steroid treatment is otherwise not recommended for patients who do not have evidence of thyroid eye disease because of the low absolute risk of developing eye disease after receiving radioiodine.⁹² Routine steroid prophylaxis has, however, been recommended by consensus statement for smokers given radioiodine treatment, even in the absence of established eye disease, in light of this group’s increased risk of complications with radioiodine.⁹³

Specific applications of radioiodine

Graves' disease

Radioiodine is increasingly regarded as the treatment of choice in Graves' disease. In certain groups of patients, such as young women or those with mild disease, a course of thionamide therapy may be appropriate in an attempt to induce remission. However, in general radioiodine is considered first line, especially in those whom antithyroid medication is unlikely to result in a cure, such as young men.

Some clinicians target the therapeutic ideal of euthyroidism in patients with Graves' disease by using low-dose radioiodine. There are, however, a number of problems with this approach. Firstly, Graves' may recur in the thyroid remnant, resulting in recurrent hyperthyroidism. This uncontrolled hyperthyroidism results in a permanent reduction in bone density. Secondly, subclinical hyperthyroidism is a risk factor for AF. Many clinicians give radioiodine in a dose large enough to attain euthyroidism in the majority and to avoid recurrence, with a consequent greater risk of hypothyroidism. A dose of 4–600 MBq results in euthyroidism in 90% of cases but at the expense of around 70% hypothyroidism over 20 years.

Nodular thyroid disease

Radioiodine is an effective and definitive treatment option in toxic nodular thyroid disease. It can be used as first-line treatment in those who have mild biochemical hyperthyroidism and who tolerate it well. In the elderly, pre-treatment with a thionamide is necessary to rapidly relieve hyperthyroidism prior to administration of radioiodine.

Radioiodine is effective in achieving euthyroidism and, in those with autonomously functioning nodules, hypothyroidism is less common. The autonomously functioning nodule causes TSH suppression, which, in turn, suppresses surrounding thyroid tissue so that radioiodine is then preferentially taken up into the nodule with sparing of the rest of the gland. Radioiodine may also cause shrinking of nodular goitres with a reduction in thyroid size of 45% after 2 years.

Although around 90% are cured, those with large goitres or with severe hyperthyroidism may not achieve a cure with a single dose of radioiodine and a subsequent dose may be necessary after 6 months' treatment with antithyroid medication.

SURGERY

Although most experts agree that surgery has little part to play in the routine management of thyrotoxicosis, there are instances where partial or subtotal thyroidectomy may be regarded to be a safe and effective treatment for thyroid overactivity.

Indications for surgery

Indications for surgery are summarized within [Table 61.8](#) and include patient preference, the presence of a cosmetically unacceptable goitre, severe ophthalmopathy, uncontrolled disease, poor response to antithyroid drugs and presence of a coexisting potentially malignant lesion.

TABLE 61.8 Indications for surgery

Indication	Notes
Patient factors	
Patient fear/rejection of radioiodine	
Radioiodine contraindicated	Pregnancy, breastfeeding mothers
Pregnancy with side effect to thionamides	
Pregnancy with severe uncontrolled disease	Radioiodine contraindicated
Clinical features	
Additional non-functioning nodule	If carcinoma cannot be excluded
Cosmetically unacceptable goitre	Radioiodine causes only slow shrinkage of goitre
Severe uncontrolled ophthalmopathy	Radioiodine may worsen ophthalmopathy
Local compressive symptoms	

Preparation

Thyroid surgery may result in the liberation of pre-formed thyroid hormone, which can lead to 'thyroid storm'. This rare, potentially life-threatening condition carries a mortality of up to 50% and is described in [Table 61.9](#). Thorough preparation is required in order to avoid post-operative thyroid storm and significant cardiovascular complications.

Antithyroid drugs are routinely used prior to operative intervention in order to restore euthyroidism. Pre-operative beta-adrenergic blockade may be required if euthyroidism has not been effectively achieved prior to surgery or if a patient is unable to take antithyroid medication due to serious side effects. Use of beta-adrenergic blockers may confer additional technical advantages for the surgeon by decreasing gland vascularity.

Lugol's iodine had traditionally been used in patients awaiting surgery in an effort to reduce iodide uptake and therefore inhibit thyroid hormone release, as well as reducing the vascularity of the thyroid gland. It is now avoided due both to the unpredictable response to its administration and to its potential for exacerbating, rather than improving, thyrotoxicosis.

Complications

Complications of thyroidectomy are relatively unusual, as there is universal agreement that those who perform such surgery should be experienced and perform it frequently.^{94, 95} In order of importance, potential complications include bleeding, recurrent laryngeal nerve injury, hypocalcaemia secondary to parathyroid hypofunction or hungry bone disease, infection, thyroid storm, keloid formation and seroma ([Box 61.6](#)).

Bleeding into the operative site may result in airway compromise due to the development of a haematoma. Immediate clot evacuation and ligation of bleeding vessels

TABLE 61.9 Features and management of extremes of thyroid dysfunction, myxoedema coma and thyroid storm

Predisposing factors		Features/signs	Treatment	
			General measures	Specific measures
Myxoedema coma	Occurs in elderly patients with hypothyroidism who: <ul style="list-style-type: none"> • have withdrawn thyroxine • have a severe concomitant illness • are inactive, immobile or live in unheated accommodation 	Coma Hypothermia Bradycardia Hyponatraemia Hypoglycaemia Hypotension	<i>Ideally HDU/ITU</i> Treat precipitating illness with antibiotics if necessary Slow rewarming (0.5°C/h) Warm humidified oxygen or ventilation if necessary Monitor and treat arrhythmias Correct hypotension and electrolyte imbalance	T4 300–500µg via NG tube, then 50–100µg daily If no improvement T3 10µg i.v. 8-hourly or 25µg orally Hydrocortisone 50–100mg 6–8-hourly unless hypocortisolism excluded
Thyroid storm	Develops in hyperthyroid patients with acute infection who: <ul style="list-style-type: none"> • are postpartum • have undergone thyroid or non-thyroid surgery • reactive iodine containing contrast agents • withdraw antithyroid medication 	<i>Rare but life-threatening condition, significant mortality (up to 50%)</i> Severe signs of hyperthyroidism Fever/hyperpyrexia Alteration in mental state Tachycardia/tachyarrhythmia Vomiting and diarrhoea Multi-organ failure – cardiac failure, hepatic congestion with hyperbilirubinaemia and jaundice, dehydration and renal failure	<i>Best carried out in ITU</i> Cooling, fluid balance, antibiotics, respiratory support if necessary Correction of electrolyte imbalance Standard antiarrhythmic therapy Anticoagulation if in atrial fibrillation Chlorpromazine if agitated	PTU 300mg 6-hourly via NG tube (PTU blocks T4 to T3 conversion) Potassium iodide 60mg 6-hourly via NG tube (inhibits thyroid hormone release; start 6 hours after PTU). Propranolol 160–180mg in divided doses or by infusion to block adrenergic manifestations Prednisolone 60mg o.d. may also stop T4 to T3 conversion Plasmapheresis may be necessary in refractory cases

BOX 61.6 Complications of surgical thyroid resection

- Bleeding
- Recurrent laryngeal nerve injury
- Hypocalcaemia
- Infection
- Thyroid storm
- Keloid formation
- Seroma

is therefore required. Damage to the recurrent laryngeal nerve is also possible and vocal cords should be checked prior to surgery. Unilateral damage causing some hoarseness usually improves after a few weeks. Bilateral damage is rare but serious, as stridor develops soon after extubation. The ensuing airway obstruction necessitates a tracheostomy.

Damage to the parathyroid glands can occur and may be transient. It can follow a direct insult or an interruption of blood flow to the glands. The frequency and severity of damage increases with the extent of thyroid surgery and also correlates with the incidence of post-operative hypothyroidism. Transient hypocalcaemia may be seen post-operatively and the patient may be symptomatic with signs of neuromuscular excitability such as Chvostek's sign, Trousseau's sign and carpopedal spasm. Hypocalcaemia typically occurs 1–7 days post-surgery and repeated measurement of serum calcium concentration during this

period is therefore mandatory, as is close clinical monitoring of the patient for relevant signs. Mild hypoparathyroidism is managed with oral calcium supplementation but more severe cases require intravenous calcium gluconate.

Effective pre-operative preparation means thyroid storm is now exceedingly rare. It should be managed in the intensive care setting with oxygen, cooling, sedation, PTU and the use of intravenous beta-adrenergic blockers and steroids. Aspirin may exacerbate the condition by causing an increase in free thyroid hormone levels and should be avoided.

Thyroid function in the post-operative setting

The relative degree of thyroid function following thyroidectomy depends on the volume of the thyroid remnant preserved. Thyroid function in the immediate post-operative period should include measurement of fT3, fT4 and TSH. Approximately 20% of patients who are initially hypothyroid will be euthyroid within 3–6 months of surgery. Permanent hypothyroidism tends to become apparent in the first 2 years after surgery. The rate of post-operative hypothyroidism is reported to be in the range of 2–48%, with recurrent hyperthyroidism seen in 0–15% of patients. Measurement of fT3 and fT4 may be necessary in patients who have been managed for post-operative hypothyroidism because their clinical state may not be accurately reflected by serum TSH.

Specific applications of surgery

Graves' disease

In most large centres the surgical treatment of choice in Graves' disease is a total thyroidectomy. In expert hands the recurrence rate with this procedure is less than 4% but at the expense of hypothyroidism, such that patients leave hospital taking levothyroxine therapy.

Nodular thyroid disease

Toxic nodular hyperthyroidism may be treated by thyroid lobectomy or excision of a single hot nodule. The adenomas are often easy to excise and there is very little risk of either recurrence or post-operative hypothyroidism. For patients with a toxic MNG, surgery is appropriate for those with compressive symptoms, such as dysphagia and upper airway obstruction, and for those with a cosmetically unacceptable goitre. Radioiodine may cause shrinkage of the gland and may be preferable in the high-risk patient, although the rate of shrinkage is relatively slow.

KEY POINTS

THYROTOXICOSIS

Clinical features

- Classical symptoms may not be present in the elderly.

Investigations

- Measure fT4, TSH and thyroid autoantibodies in suspected hyperthyroidism. fT3 and ESR may be useful.
- Ultrasound and nuclear medicine scans should be reserved for specialist use.
- Hyperthyroidism due to thyroiditis is often self-limiting. Treat with NSAIDs +/- beta blockers.

Treatment

- Initial management should consist of antithyroid drugs +/- beta blockers and endocrine referral.
- Thionamides: warn patients of side effects. 'Block and replace' or titration regimes may be used.
- Radioiodine: safe and effective. This is the first-line treatment in the elderly and those with cardiac dysfunction.
- Surgery: used in toxic multinodular goitre, compressive symptoms, Graves' disease, eye disease.

Subclinical hyperthyroidism

Subclinical hyperthyroidism is essentially a biochemical diagnosis, though it is increasingly associated with a number of potential complications. Its detection relies on sensitive assays of TSH and it is therefore only in recent years that our understanding of this condition has widened.

AETIOLOGY

The biochemical finding of low TSH with normal fT4 and fT3 may result from an exogenous source, as a consequence of treatment with thyroxine or a raft of other drugs, or from an endogenous pathology. These include nodular thyroid disease, undetected early Graves' disease or non-thyroidal illness. Exogenous subclinical hyperthyroidism is by the far the largest group with over 20% of

patients taking thyroxine having low TSH values on at least one occasion.^{8,96}

COMPLICATIONS

Long-term survival appears to be affected by suppressed TSH, contributing to an increased mortality due to cardiovascular causes.⁹⁷ The transience of TSH reduction in patients with illness or drug therapy suggests that for these individuals subclinical hyperthyroidism is likely to be of little consequence. Potential complications of subclinical hyperthyroidism are therefore likely confined to those in whom TSH suppression reflects a minor degree of thyroid hormone excess.

A specific complication associated with subclinical hyperthyroidism is that of AF, with those aged over 60 years who have an undetectable TSH harbouring a threefold increase in relative risk.⁹⁸ Subclinical disease is also associated with reductions in bone mineral density and increased fracture risk, especially in postmenopausal women.^{99,100}

MANAGEMENT

The management of subclinical hyperthyroidism remains both complex and controversial. The prevailing consensus is that in those with persistent TSH suppression and evidence for underlying thyroid disease antithyroid treatment is warranted, particularly if the subclinical hyperthyroidism is associated with cardiac disease or AF.^{101,102} As these patients are usually elderly, radioiodine is the treatment of choice unless contraindications exist. There does, however, remain a paucity of evidence for a beneficial effect of this therapy in this setting and the results of relevant randomized controlled trials are awaited.

Practically, it is prudent to repeat TFTs on a 6-monthly basis in those who have endogenous subclinical hyperthyroidism where AF and osteoporosis may have been exacerbated by excess thyroid hormone treatment.¹⁰²

KEY POINTS

SUBCLINICAL HYPERTHYROIDISM

Aetiology

- Some causes are related to thyroid disease and its management: thyroxine therapy, previous Graves' hyperthyroidism, Graves' ophthalmopathy, nodular goitre.
- Other causes relate to non-thyroidal illness: any significant illness, therapy with drugs such as glucocorticoids, iodine-containing compounds, pregnancy.

Investigations

- Findings show low TSH with normal fT4 and fT3.

Complications

- AF
- Osteoporosis

Management

- Antithyroid treatment may be warranted

Thyrotoxicosis in the absence of hyperthyroidism

Perhaps confusingly, thyrotoxicosis may present in the absence of hyperthyroidism. In these instances thyrotoxicosis results from thyroid hormone excess originating either from the thyroid gland as a consequence of a destructive lesion or from a source outside the thyroid. The absence of hyperthyroidism refers to thyrotoxicosis occurring despite there being no increased synthesis of thyroid hormones in the thyroid gland. Consequently, a low uptake of radioiodine is seen on scintigraphy.

DESTRUCTIVE THYROIDITIS

Thyroiditis refers to any inflammatory condition of the thyroid. It may be associated with transient thyrotoxicosis during its acute phase as a consequence of disruption to the normal architecture of the thyroid gland, which results in the release of T4 and T3 from the colloid.

Classification of thyroiditis

The classification of thyroiditis is confusing but may be divided into those processes in which pain and tenderness develop, and those that do not have pain as a predominant feature (Table 61.10). Generally, the former rarely result in permanent hypothyroidism but the latter often do. Subacute, painless and postpartum thyroiditis are generally associated with only mild thyrotoxicosis which lasts only a few weeks as a consequence of the restoration of normal thyroid architecture.

Subacute granulomatous/De Quervain's thyroiditis

Clinical features

De Quervain's, giant cell or subacute thyroiditis is an uncommon cause of transient thyrotoxicosis. The typical patient is female and aged between 40 and 60 years.¹⁰³ Presentation is with pain in the region of the thyroid, often (but not always) associated with swelling. This is

associated with systemic symptoms such as fever, dysphagia and malaise. The pain is a striking feature, may radiate to the ear and is worse on turning the head. On examination there is often swelling of either thyroid lobe, which may be extremely painful to palpate. Signs of thyrotoxicosis may be present, such as tachycardia, tremor and irritability. There may also be fever. It can take 8 weeks for pain to resolve and a complete resolution is seen in 6 months.

Investigations

Laboratory tests show raised inflammatory markers, such as erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), and there may be a normocytic normochromic anaemia.¹⁰⁴ Thyroid scintigraphy with ^{99m}Tc or ¹²³I/¹³¹I shows a complete absence of uptake, although this can also occur with thyrotoxicosis factitia and iodine-induced hyperthyroidism. Histology is characteristic and lends the condition its name, with multinucleate giant cells surrounding a central core of colloid. Initial TFTs show thyrotoxicosis with a suppressed TSH and an elevated serum fT4. This reflects destruction of the thyroid follicles by the inflammatory process and release of pre-formed thyroid hormone.

Clinical course

At 12–16 weeks there may be a hypothyroid phase during which the damaged tissue is unable to generate thyroid hormone. Most patients do not require treatment with thyroxine and most are ultimately euthyroid. Rarely, hypothyroidism may be permanent. Initially, thyroid auto-antibodies may be positive but again this is often transient although some retain thyroid autoimmunity for life. The course of subacute thyroiditis is shown in Figure 61.7.

Management

Treatment is supportive. Non-steroidal anti-inflammatory drugs such as aspirin and indomethacin are effective analgesics, while beta-adrenergic blockers are useful if symptomatic in the thyrotoxic phase. Rarely, the severity may necessitate high-dose oral corticosteroids

TABLE 61.10 Classification of thyroiditis

Pain and tenderness	Diagnosis	Subcategories
Yes	Subacute granulomatous thyroiditis	De Quervain's Giant cell thyroiditis
	Infectious thyroiditis	
	Radioiodine-induced thyroiditis	
No	Subacute lymphocytic thyroiditis (silent)	Postpartum thyroiditis Drug-induced thyroiditis
	Chronic lymphocytic thyroiditis	Hashimoto's thyroiditis Postpartum thyroiditis
	Fibrous thyroiditis (Riedel's thyroiditis)	
	Amiodarone-induced thyroiditis	

Figure 61.7 Typical course of subacute thyroiditis.

(e.g. prednisolone 30–40 mg daily) which are extremely effective in reducing the pain and swelling but must be withdrawn slowly over some months if the condition is not to recur.¹⁰⁵

Aetiology

The female preponderance, seasonal incidence, geographical aggregation and raised inflammatory markers have led to a hypothesis of a viral aetiology.¹⁰⁶ Mumps virus, Coxsackie, influenza and adenoviruses have been implicated in the development of the disease although a viral role in the pathogenesis remains obscure.

Silent/painless thyroiditis

Painless thyroiditis can occur in the early stages of autoimmune thyroiditis. This may lead to mild biochemical hyperthyroidism and occasionally to symptomatic thyrotoxicosis. The thyrotoxicosis is generally mild and raised markers of inflammation are rarely found, in contrast to subacute thyroiditis. The thyroid is enlarged in approximately half of all patients and is not painful. Fine-needle aspirate reveals the changes associated with Hashimoto's disease and includes extensive lymphocytic infiltrate with plasma cells rather than multinucleate giant cells. Thyroid autoantibodies are often positive.

The duration of the thyrotoxic phase is around 8 weeks and symptomatic treatment with beta-adrenergic blockers may be required. There then follows a hypothyroid phase that can last for more than 6 months. In most patients, euthyroidism is eventually restored but permanent hypothyroidism is almost certain to develop over time.

Radiation-induced thyroiditis

Administration of large doses of radioiodine may result within 2 weeks in thyroiditis. There is usually a requirement only for simple analgesia and this condition tends to self-resolve within 2 weeks of its onset. Significant pain or swelling may necessitate the use of oral glucocorticoid therapy.

Iodine-induced thyrotoxicosis

Iodide-induced thyrotoxicosis (IIT) results from genetic change that leads to autonomous thyroid hormone production within sufficient numbers of thyrocytes to cause hyperthyroidism in the presence of an increased supply of iodine. This 'Jod Basedow' effect is often seen in patients with toxic MNGs in areas of iodine deficiency. It may also occur in the absence of pre-existing thyroid disease and generally resolves within 6 months. Iodine-containing contrast agents are a common source of excess iodine and confer a 0.3% risk of IIT within iodine-deficient areas.¹⁰⁷

Amiodarone-induced thyrotoxicosis

Use of amiodarone may result in thyrotoxicosis by one of two ways. In patients with pre-existing thyroid disease, the high iodine content of amiodarone may induce thyrotoxicosis.¹⁰⁸ This is termed amiodarone-induced

thyrotoxicosis (AIT) type 1. AIT type 2 arises when a destructive thyroiditis occurs as a consequence of the cytotoxic effect of amiodarone and its metabolite, des-ethylamiodarone. AIT is prevalent in iodine-deficient areas whereas in areas which are iodine-replete, amiodarone-induced hypothyroidism (AIH) predominates.

Withdrawal of amiodarone may result in an improvement for patients with both AIT type 1 and AIT type 2. Oral corticosteroid therapy may restore euthyroidism in those with AIT type 2 while thionamides are effective in AIT type 1. Antithyroid drugs may be given with potassium perchlorate, which inhibits thyroidal iodide uptake and consequently increases sensitivity to thionamide action.

HYPOTHYROIDISM

Definitions

Hypothyroidism refers to the insufficient production and secretion of thyroid hormones from the thyroid gland. It may occur due to a disturbance within the thyroid gland itself (**primary hypothyroidism**) or within the hypothalamic–pituitary–thyroid axis (**secondary hypothyroidism**).¹⁰⁹ The term **myxoedema** is not synonymous with hypothyroidism and refers to the accumulation of glycosaminoglycans occurring in severe hypothyroidism. These hydrophilic substances are deposited within the dermis, leading to induration of the skin and the characteristic facial features of hypothyroidism. The term **hypothyroxinaemia** may be used to refer to low serum fT4 concentrations in the presence of normal levels of TSH (**Box 61.7**).

BOX 61.7 Key definitions in thyroid hormone deficiency (hypothyroidism)

Hypothyroidism	<i>Insufficient production and secretion of thyroid hormone</i>
Primary hypothyroidism	<i>Pathology of the thyroid gland itself</i>
Secondary hypothyroidism	<i>Pathology of the hypothalamic–pituitary–thyroid axis</i>
Myxoedema	<i>Accumulation of glycosaminoglycans in the dermis</i>
Hypothyroxinaemia	<i>Low serum fT4 concentrations in the presence of normal TSH concentrations</i>

Epidemiology

Like hyperthyroidism and other autoimmune conditions, hypothyroidism is more common in women, amongst whom its prevalence is estimated at 2%.¹ This compares to 0.2% of men.¹ Incidence peaks in the 40–50 years age group so that prevalence in women aged over 65 rises to 5–10%.⁹⁷ Juvenile hypothyroidism is nevertheless not uncommon. Neonatal hypothyroidism, which if untreated results in severe intellectual impairment, occurs in around 1 in 4000 births and is routinely screened for in the postnatal period in the UK.¹¹⁰

Aetiology

The causes of hypothyroidism are outlined in [Table 61.11](#). The most common cause in areas replete with iodine is chronic autoimmune hypothyroidism, otherwise termed Hashimoto's thyroiditis.^{111, 112} Hypothyroidism may also be an iatrogenic phenomenon, resulting either from thyroidectomy, use of radioiodine therapy or external beam irradiation of the neck.^{32, 112, 113} Worldwide, the most common cause of hypothyroidism is iodine deficiency.¹¹⁴

Clinical manifestations

Insufficiency of thyroid hormone affects almost every organ system in the body. The effects of hypothyroidism can be broadly categorized into those relating to the generalized slowing of all metabolic processes and those resulting from the tissue accumulation of glycosaminoglycans, as summarized in [Table 61.12](#). Among other features, the slowing of metabolic processes results in fatigue, cold intolerance and weight gain. Characteristic features of hypothyroidism such as coarse dry skin, hair loss and doughy peripheral oedema relate to glycosaminoglycan accumulation. A low threshold for thyroid function testing is necessary, given that few patients have all signs and symptoms of hypothyroidism. There is, however, no consensus for routine screening of thyroid function.

SYMPTOMS

The onset of symptoms may be insidious and go unrecognized, such that severe myxoedema may result. The typical patient complains of lethargy and fatigue, and these complaints, plus the accompanying apathy and listlessness, mean that the ability to work is impaired. There may be a slow increase of weight despite a reduction in appetite and constipation is a common feature. Cold intolerance is typical with the patient wearing multiple layers of clothes at initial consultation.

Menstrual periods may be heavy and a desired conception elusive. Myopathy may cause difficulty in walking upstairs or rising from a chair, and numbness and paraesthesia in the hands may develop as carpal tunnel syndrome results from peripheral oedema. Occasionally, neuropsychiatric complications may result and 'myxoedema madness', though now largely confined to historical literature, was previously described.

SIGNS

There may be a husky voice incorrectly attributed to laryngitis but which actually results from oedema of the vocal cords. Women may complain of dry coarse hair and brittle nails. Peripheral and facial oedema is also seen, as is bradycardia, the presence of a goitre and slow-relaxing tendon reflexes. The rare but life-threatening condition of

TABLE 61.11 Causes of hypothyroidism

Primary			Secondary	
Associated with goitre (TSH raised, T4 low)	Not associated with goitre (TSH raised, T4 low)	Self-limiting	Hypothalamic (TSH low, T4 low)	Pituitary (TSH low, T4 low)
Hashimoto's thyroiditis (chronic thyroiditis)	Atrophic thyroiditis	Transient thyroiditis; e.g. subacute or silent	Congenital; e.g. lack of TRSH	Congenital; e.g. lack of TSH
Iodine deficiency (affects 800 million worldwide)	Iatrogenic; e.g. radioiodine, surgery, neck irradiation	Postpartum thyroiditis	Infiltrative; e.g. sarcoidosis, tuberculosis, primary or metastatic malignancy	Panhypopituitarism; e.g. pituitary tumour, cranial irradiation, infection, inflammation
Inherited defects of biosynthesis	Congenital anomaly; e.g. thyroid agenesis	Iatrogenic; e.g. overtreatment with antithyroid medication	Infective; e.g. encephalitis	
Maternal transmission; e.g. antithyroid agents	Drug-induced; e.g. amiodarone, lithium, iodides, phenylbutazone			

TABLE 61.12 Manifestations of hypothyroidism

	Clinical manifestations					
	General	Skin	Gastrointestinal	Cardiovascular	Reproductive	Neurological
Symptoms	Weakness/fatigue Decreased appetite Weight gain Coarse facial features Cold intolerance Peripheral oedema	Coarse, dry skin Pale skin/flush (peaches and cream) Loss/drying of hair	Decreased appetite Weight gain Constipation	Peripheral oedema	Menorrhagia Ovulatory failure Galactorrhoea	Slow/hoarse speech Intellectual impairment Carpal tunnel syndrome Neuropsychiatric problems
Signs	Characteristic facial features Goitre	Pale, cool skin Peripheral/facial oedema		Bradycardia		Slow-relaxing tendon reflexes Hoarse voice

myxoedema coma can occur in hypothyroidism, particularly in older patients, and can be precipitated by infection, trauma or cold.

Diagnostic evaluation

Thyroid function testing may help support clinical suspicion of hypothyroidism. Low serum fT4 concentration is the hallmark of reduced thyroid function.¹¹⁵ This is usually associated with a raised TSH concentration, though this may be normal or low in secondary hypothyroidism. Concentrations of fT3 tend to be decreased but may be normal. Microsomal antibodies may be significantly raised in cases of autoimmune hypothyroidism. Other non-specific changes are seen, including a normochromic normocytic anaemia and an atherogenic lipid profile consisting of raised serum levels of cholesterol, triglycerides and low-density lipoprotein (LDL) in addition to lowered high-density lipoprotein (HDL). Reduced negative feedback from thyroid hormones and a consequent excess of thyrotropin-releasing hormone stimulates excess production of prolactin from the anterior pituitary gland so that serum levels may be raised. Laboratory investigations and findings are summarized in [Table 61.13](#).

Ultrasound evaluation of the thyroid may provide support in determining the cause of hypothyroidism although should not be performed routinely. Low echogenicity and gross inhomogeneity are seen in autoimmune thyroiditis. Use of colour-flow Doppler may identify greater vascularity in autoimmune thyroiditis than in the atrophic variant of the disease. The identification of nodular tissue should raise suspicion of coexisting adenomas or malignancy.

Specific conditions associated with hypothyroidism

CHRONIC AUTOIMMUNE HYPOTHYROIDISM (HASHIMOTO'S THYROIDITIS)

Seen in 3.5 per 1000 women per year and fewer than 1 per 1000 men per year, this condition is in many respects the archetypal autoimmune disease.¹¹⁶ In addition to

TABLE 61.13 Laboratory investigations in suspected hypothyroidism

Investigation		Results in hypothyroidism	
		Primary	Central
Thyroid function	TSH	↑	↓/↔
	fT4	↓	↓
	fT3	↓/↔	↓/↔
Immunology		Positive thyroid microsomal autoantibodies	
Biochemistry		Raised serum cholesterol, triglycerides, LDL Lowered HDL	
Endocrine		Raised serum prolactin	
Haematology		Normochromic normocytic anaemia	

occurring more commonly in females, it runs in families where Graves' disease may feature along with other autoimmune conditions, such as vitiligo, pernicious anaemia, rheumatoid arthritis and type 1 diabetes mellitus.¹¹² It is more common in older women yet it can occur in infants as young as 2 years of age and it is the major cause of hypothyroidism in children.

The pathogenesis of this condition is well understood.¹¹⁷ Histology reveals diffuse lymphocytic infiltration of the thyroid gland and the presence of circulating thyroid autoantibodies, reflecting the direct cellular injury induced by cytotoxic T-cells and the role of humoral factors.

Although patients have high circulating antibodies to thyroid microsomes and to thyroglobulin, these are not thought to have functional activity. Histologically, the gland is infiltrated with lymphocytes and areas of follicular destruction and fibrosis may be evident.¹¹⁷ Enlarged epithelial cells with oxyphilic changes in the cytoplasm and Askenazy cells are commonly found in this condition ([Figure 61.8](#)).

Initially, the thyroid hypofunction may be subclinical, but it may become overt with a rate of developing hypothyroidism of around 5% per year. A slowly growing goitre may have been found on examination or noted by the patient or a family member.

The typical goitre is moderate in size and smooth. Although both lobes are affected, the gland may appear asymmetrical. The presence of the goitre may predate the development of overt hypothyroidism and, generally, the goitre remains static or may decrease in size. Some patients present without a palpable goitre and are said to have atrophic autoimmune thyroiditis, which is thought to represent the end point of Hashimoto's thyroiditis.¹¹¹

IATROGENIC HYPOTHYROIDISM

This may be seen as a consequence of surgery, treatment with radioactive iodine or external beam radiotherapy, such as that used in the management of head

Figure 61.8 Histology of Hashimoto's thyroiditis. There is a dense interstitial lymphocytic infiltrate, with secondary germinal centre formation, enveloping small colloid-depleted follicles. These are lined with plump cuboidal oxyphil (Askanazy or Hürthle) cells possessing characteristic copious pink granular cytoplasm.

and neck malignancy. Hypothyroidism may occasionally result from overtreatment of hyperthyroidism with antithyroid medication, but with close monitoring this is not common.

Thyroidectomy

Hypothyroidism would become evident in all patients who have undergone total thyroidectomy at around 2–4 weeks without treatment. Thyroid hormone replacement should therefore be commenced in these patients prior to their discharge from hospital. Subtotal thyroidectomy may also result in hypothyroidism, with most patients becoming so within a year.

Radioiodine therapy

The majority of patients treated with 400–600 MBq of radioiodine will develop hypothyroidism.^{18, 113} This may be transient, resulting from radiation thyroiditis some 4–6 weeks after treatment, or permanent. Sustained hypothyroidism may not ensue until months or even years after therapy.

External beam neck irradiation

Radiotherapy given to the neck may result in both hypothyroidism and an increased risk of thyroid malignancy, especially in children and adolescents.¹¹³

For patients who have had more than 25 Gy there may be a slow-onset dose-dependent development of hypothyroidism. Such patients should be carefully monitored for both the hypothyroidism, which can initially be subclinical, and for nodular thyroid disease which may herald a thyroid malignancy.

Tyrosine kinase inhibitor therapy

Small molecular tyrosine kinase inhibitors (TKIs) are used across a spectrum of disorders and have been associated with thyroid dysfunction.^{118, 119} The vascular endothelial growth factor receptor (VEGFR) disruptor sunitinib has, for instance, been linked to both hypothyroidism and thyrotoxicosis. Other TKIs have also been implicated in thyroid dysfunction including Imatinib, which targets the Philadelphia chromosome in chronic myeloid leukaemia, and motesanib, which is used in differentiated thyroid carcinoma.¹²⁰

IODINE DEFICIENCY

Iodine deficiency remains the most common cause of hypothyroidism and goitre worldwide.^{43, 114} Iodine is present in the body in only minute amounts and must therefore be sourced from the diet. When iodine requirements are not met, thyroid hormone synthesis is impaired and goitre follows due to increased secretion of TSH, which is released to maximize utilization of available iodine and acts to stimulate the thyroid. Goitres may be present from young adulthood and can become sufficiently large to cause obstructive symptoms. Other iodine deficiency disorders include mental retardation and neonatal cretinism,

a combination of intellectual impairment, ataxia, coarse facies and deaf mutism. This has a substantial effect on mental development.¹²¹

It is estimated that iodine intake is insufficient in 36.5% of school-age children and 35.2% of the general population worldwide. South-east Asia, Africa and the Western Pacific are the most affected by iodine deficiency whereas the addition of iodine to salt in the USA and, to a lesser extent Europe, results in sufficient dietary intake of iodine for the majority of the population. Mild-to-moderate iodine deficiency is nevertheless recognized in the United Kingdom, where salt iodization is not commonplace.⁴³ Diets high in goitrogens, such as cassava and some soya beans, can exacerbate complications of iodine deficiency.

NEONATAL HYPOTHYROIDISM

This is routinely screened for during the postnatal period in iodine replete regions.¹⁰⁹ It may be caused by inherited defects in thyroid hormone synthesis, transplacental transmission of anti-TSH antibodies causing transient neonatal thyroid underactivity or thyroid gland agenesis and dysgenesis.

CENTRAL HYPOTHYROIDISM

Lack of hypothalamic thyrotropin-releasing hormone or pituitary TSH may lead to hypothyroidism, although central hypothyroidism accounts for less than 1% of all cases of hypothyroidism. The commonest cause is a tumour in the hypothalamic or pituitary region and the surgery or radiotherapy used to treat them.¹²² Such central causes may be distinguished from primary hypothyroidism by a normal or low-serum TSH concentration that is inappropriate given a low serum fT3 and fT4 concentration. Approximately a third of patients with central hypothyroidism display marginal elevation of TSH, which is bio-inactive.

Patients with a pituitary adenoma may have other features of hypopituitarism, such as hypogonadism and hypoadrenalism. These may mask the symptoms of thyroid hormone deficiency. Patients with central hypothyroidism should be referred for specialist consultation.

Management of hypothyroidism

Levothyroxine is the drug of choice for the treatment of hypothyroidism.^{123, 124} It is absorbed from the upper small bowel with approximately 80% efficiency and is a pro-hormone which is deiodinated in peripheral tissues to the active hormone T3. T3 has a tenfold higher affinity than T4 for thyroid hormone receptors. Treatment is provided with the aim of returning the patient to a euthyroid state both clinically as judged from symptoms, and biochemically as judged from serum TSH estimations.

ADMINISTRATION OF LEVOTHYROXINE

At 7 days, the half-life of levothyroxine is long enough to allow for daily or even weekly dosing if compliance is an issue. The average daily dose is around 125 µg but variation exists and typical doses required to achieve

euthyroidism range between 100 µg and 150 µg. In those less than 50 years of age with no evidence of ischaemic heart disease, a moderate dose (1.6 mcg/kg or typically 100 µg) may be started immediately. In older patients, or those with known cardiac disease, a starting dose of 25 µg is prudent due to the risk of exacerbating or precipitating cardiac disease as a consequence of the rise in cardiac output associated with initiation of therapy. Increments of 25 µg can be added every 4–6 weeks until TSH concentrations are within the normal range.

Due to the long half-life of thyroxine, 4–6 weeks should elapse before measuring TSH concentration after initiating therapy or after dose adjustment. Once stable, serum TSH needs to be checked on an annual basis to ensure ongoing compliance.¹⁰⁹

SPECIFIC CONSIDERATIONS WHEN PRESCRIBING THYROXINE

Central hypothyroidism

In those with central hypothyroidism, it is imperative that hypoadrenalism be excluded before initiating thyroxine therapy. An adrenal crisis may be precipitated if hypoadrenalism is not treated before thyroxine therapy is commenced. In central hypothyroidism, the serum TSH concentration is of no value in monitoring therapy, thus dose adjustments should be made on serum fT4 and fT3 concentrations alone, aiming to keep serum fT4 in the upper half of the reference range.

Elderly patients

Thyroxine therapy should be started at a dose of 25–50 µg daily and increased every 4 weeks until stable. Overtreatment, resulting in a suppressed TSH concentration, should be avoided due to the risk of precipitating AF.

Pregnant women

Women need more thyroid hormone during pregnancy and those with pre-existing hypothyroidism cannot increase T4 and T3 secretion in the same manner as women who do not have hypothyroidism. Hypothyroid women need around 40% more thyroxine in pregnancy and the dosage should be increased upon finding of a positive pregnancy test. Thyroid function tests should be monitored using pregnancy and gestation specific reference ranges preferentially. Repeat measurements should be undertaken 4-weekly during the first trimester and once per trimester thereafter. Most international guidelines recommend treating with levothyroxine to keep serum TSH below 2.5 mIU/L prior to and during pregnancy.^{124–126}

T3 THERAPY

A minority of patients feel that their symptoms of hypothyroidism are not controlled on thyroxine therapy despite normal concentrations of TSH and T4. Some choose to take T3 in addition to or instead of thyroxine, although due to its rapid absorption and short half-life it must be taken three times a day and fluctuations in thyroid

hormone levels exist. Current national and international guidance does not recommend the use of T3 monotherapy or T3/T4 combination therapy in the management of hypothyroidism based on the lack of evidence supporting these treatment strategies.^{127, 128} Similarly, the use of desiccated thyroid extract is not advisable.¹²⁹

KEY POINTS

HYPOTHYROIDISM

Clinical features

- Manifestations presented are those of the slowing of metabolic processes and tissue accumulation of glycosaminoglycans.

Investigations

- Low serum T4 and raised TSH is seen in primary hypothyroidism.
- Low serum T4 with normal or suppressed TSH are seen in central hypothyroidism.
- A pro-atherogenic lipid profile and a normochromic normocytic anaemia are seen in chronic disease.

Treatment

- Levothyroxine is the drug treatment of choice.
- A lower starting dose may be required in older patients.
- There is no evidence to suggest an advantage from T3 therapy.

Subclinical hypothyroidism

Subclinical hypothyroidism is a biochemical diagnosis made where a raised TSH is seen in conjunction with a normal fT4 concentration.

EPIDEMIOLOGY

It is common, affecting 7–8% of women and 2–4% of men. The prevalence rises with age to approximately 15% in women over 60.¹³⁰ It is also more common in those with other autoimmune conditions.

AETIOLOGY

Subclinical hypothyroidism may be endogenous or iatrogenic, resulting from either previous radioiodine treatment or surgical resection of the thyroid gland. Around 60% of women with subclinical hypothyroidism have positive antibodies to thyroid peroxidase.¹³¹ Prospective studies have confirmed that those with both positive thyroid autoantibodies and elevated TSH concentrations are at risk of developing overt hypothyroidism at a rate of around 5% per year, although this figure is likely to be greater in older patients.

MANAGEMENT

Given the potential risks to bone and cardiovascular health of overtreatment with thyroxine, there remains controversy as to who should be treated and at what point.

Recent guidelines have highlighted evidence linking raised TSH and cholesterol but otherwise state that data for a clear benefit to treatment are lacking. Many clinicians would opt to treat in the presence of symptoms and serum TSH concentration of greater than 10 mU/L as well as positive antibodies, as a result of the high risk of progression to overt hypothyroidism. For asymptomatic patients with a modestly raised TSH (below 10 mU/L) or with a low or negative titre of microsomal antibodies, retest on a 6-monthly basis is advised.¹³²

KEY POINTS

SUBCLINICAL HYPOTHYROIDISM

Aetiology

- This is an autoimmune condition.
- It is iatrogenic: previous radioiodine treatment, surgical resection.

Investigations

- Raised TSH with normal fT4 and fT3 is seen.

Complications

- These are unclear.
- There is a possible association between raised TSH and cholesterol.

Management

- Best practice is unclear: treat if serum TSH >10 mIU/L or during pregnancy.

THYROID DISEASE IN PREGNANCY

Thyroid dysfunction is relatively common in pregnancy, during which both overt and subclinical disease are associated with adverse outcomes.¹²⁵ Foetal development is dependent on maternal thyroid hormone delivered via the transplacental route until around 18 weeks of gestation, although maternal thyroid hormone transfer continues up to delivery. Thyroid hormones are known to influence foetal size and the maturation of tissues, in addition to uteroplacental development. The foetal brain additionally responds to thyroid hormones from 5 weeks of gestation. Euthyroidism is therefore essential throughout pregnancy in order to minimize risk to the foetus.

Physiological changes to the thyroid axis during pregnancy have been extensively described previously.¹³³ Maternal TSH is seen to decline during the first trimester but resolves to pre-pregnancy levels by the end of gestation. Maternal fT4 concentrations decline throughout pregnancy. Gestation-specific ranges, which are both population- and age-specific, should therefore be used by the clinician caring for a pregnant patient with thyroid disease.

Hyperthyroid states in pregnancy

The immunological changes associated with pregnancy and delivery can affect thyroid status in different ways. Those with pre-existing disease may find symptoms are

aggravated or ameliorated at different times during the pregnancy.

Postpartum, around 5–10% of women develop thyroid dysfunction. The risk is higher in those who have positive thyroid antibodies, Type 1 diabetes mellitus (25%), a family history of thyroid disease or another coexisting autoimmune condition.¹²⁵ Of those who develop postpartum thyroid dysfunction, around one-third have postpartum thyroiditis. The remainder may present with either Graves' disease or Hashimoto's thyroiditis. In those with biochemical and clinical thyrotoxicosis developing later than 3–6 months postpartum, Graves' disease is more likely, and in these cases the hyperthyroidism will be sustained.¹²⁵

Radioisotope uptake measurements are the investigation of choice and can help to distinguish between postpartum thyroiditis and Graves' disease. The distinction is important, as treatment choices differ according to the aetiology of thyroid dysfunction. Those with postpartum thyroiditis will show reduced uptake on scintigraphic scanning whereas those with Graves' disease will show elevated uptake. Breastfeeding should be avoided for 24 hours if ^{99m}Tc is used.

POSTPARTUM THYROIDITIS

This commonly presents with symptoms of thyrotoxicosis at around 12 weeks post delivery, followed by a period of hypothyroidism at around 3–6 months. Histologically, there is a destructive thyroiditis with a florid lymphocytic infiltrate seen at around 16 weeks in those who are antibody-positive. In some women, only the hypothyroid phase is evident and eventually there will be a return to a euthyroid state. Patients may be managed symptomatically with propranolol during the thyrotoxic phase if necessary. Treatment of the hypothyroid phase may be needed in around a third of women and T4 may be necessary for up to 12 months.¹³⁴

Long term, patients who have experienced postpartum thyroiditis are at risk of further episodes in subsequent pregnancies. About 25% of women will develop permanent hypothyroidism, and recurrent postpartum thyroiditis is seen in up to 80% of subsequent pregnancies. Specialist monitoring and annual monitoring of TFTs are essential.

HYPEREMESIS GRAVIDARUM

Transient thyrotoxicosis may be seen in hyperemesis gravidarum. It is likely to arise as a consequence of the shared alpha subunit of beta-HCG and TSH, with high levels of HCG in hyperemesis gravidarum causing stimulation of the TSH receptor. Around 60% of women with hyperemesis gravidarum have a raised serum fT4 concentration with a suppressed serum TSH. Management is supportive and antithyroid medication should be avoided.

Thyrotoxicosis resulting from hyperemesis gravidarum may be distinguished from that occurring as a consequence of Graves' disease by a negative family history, a lack of any other autoimmune illness and negative thyroid

antibodies (anti-TSH-receptor antibodies in particular). Physical signs typically associated with Graves' disease, such as a diffuse goitre, will also be absent.

GRAVES' DISEASE

This accounts for around 90% of cases of thyrotoxicosis observed in pregnancy and around 1 in every 500 women are affected.¹³⁴ Graves' disease may contribute to menstrual irregularities, difficulties in conception and an increased rate of miscarriage. In those who do conceive, the recognition and effective management of Graves' is crucial given that untreated hyperthyroidism is associated with miscarriage, premature labour, low birthweight and pre-eclampsia.

Graves' disease may rarely develop *de novo* in pregnancy but diagnosis may be delayed as signs and symptoms may be wrongly attributed to physiological changes occurring in pregnancy, such as increased metabolic rate, increased cardiac output, heat intolerance and mood changes. Other symptoms may include hyperemesis gravidarum, muscle fatigue and, occasionally, cardiovascular problems such as pregnancy-induced hypertension or high output cardiac failure.

Treatment of thyrotoxicosis in pregnancy seeks to achieve rapid biochemical euthyroidism while alleviating symptoms.^{92, 125, 126} Specific beta-adrenergic blocking agents may be used as adjuncts but the mainstay of treatment is antithyroid medication. Radioiodine cannot be used as it is contraindicated in pregnancy. Propylthiouracil is preferred to carbimazole in the first trimester as it is associated with fewer teratogenic effects. If antithyroid drugs are continued during the second and third trimester, carbimazole remains the drug of choice in view of fears of liver function abnormalities with propylthiouracil treatment. Antithyroid drugs are excreted in breast milk and babies from mothers taking doses of carbimazole of 20 mg daily or more while breastfeeding should have 4-weekly thyroid function testing.

The presence of circulating anti-TSH-receptor antibodies in pregnancy may result in foetal thyrotoxicosis due to transplacental transfer. Current guidance recommends the determination of TSH-receptor antibody concentrations at 20 weeks' gestation and close monitoring of those with significantly raised levels.^{125, 135}

Joint management with the endocrinologist, obstetrician and paediatrician is important as there is a risk of foetal and neonatal thyrotoxicosis indicated by low birthweight, irritability and tachycardia.

Hypothyroid states in pregnancy

Overt hypothyroidism is associated with both anovulation and first trimester abortion. It is therefore unlikely to present at conception or during early pregnancy though it is seen in approximately 0.2–1% of women during the first trimester. If untreated during pregnancy, hypothyroidism confers a two- to threefold increased risk of spontaneous miscarriage, pregnancy-induced hypertension and pre-eclampsia, low birthweight (which is largely

a consequence of prematurity) and perinatal mortality. There is additional data to link maternal hypothyroidism with an increased incidence of neurodevelopmental defects.¹³⁵

OVERT HYPOTHYROIDISM

Pre-conception thyroid hormone replacement may offer protection against early pregnancy hypothyroidism. During pregnancy the requirement for thyroid hormone increases due to weight gain, transfer of T4 to the foetus and raised concentrations of thyroxine binding globulin. Gastrointestinal absorption is also known to decrease. An increased dose of thyroxine may be required as early as 4 weeks' gestation. Treatment should target the prevention of hypothyroidism and it is important patients are counselled prior to or during early pregnancy in order to ensure compliance with therapy. It is prudent to counsel women to double their dose of thyroxine on 2 days each week should they have a positive pregnancy test, given that a routine antenatal visit does not occur until 10–12 weeks of gestation.

Between 40% and 70% of patients will require further dose adjustment even following this empirical dose increase. Most clinicians would measure TFTs around 4–6 weeks' gestation, 4 weeks after any increase in dose of T4 and at least once per trimester. Levothyroxine dosage can be reduced to pre-pregnancy levels 2 weeks after delivery with TFTs reviewed after 6 weeks in order to ensure adequate thyroid hormone replacement. Dose adjustment of levothyroxine should be based on serum TSH as it demonstrates less inter-individual variation than fT4 concentrations. Some authors do, however, advocate the use of fT4 concentrations in light of the key role of T4 in determining foetal brain development. Ingestion of iron supplementation and antacid for gastroesophageal reflux may affect thyroxine absorption and further complicate dosing.

Obstetricians advocate managing pregnancies complicated by hypothyroidism as high risk. As such, aspirin is advised for pre-eclampsia prophylaxis in addition to uterine artery Doppler studies to screen for malplacentalation. Routine observations should be undertaken frequently to assess for pre-eclampsia.

SUBCLINICAL HYPOTHYROIDISM

Rates of subclinical hypothyroidism in pregnancy are dependent on the iodine status of the population.¹³⁶ A recent meta-analysis of studies which included subclinically hypothyroid populations demonstrated a significant increase in risk of pregnancy loss (including miscarriages, stillbirths and perinatal deaths), pre-term delivery (OR 1.3; 95% CI 1.05–1.60), placental abruption (OR 2.16; 95% CI: 1.15–4.06) and breech presentation at term.¹³⁷ Raised serum TSH is also associated with breech presentation, reduced external cephalic version success rate and an increased incidence of neurodevelopmental defects.^{138–141}

There is a paucity of evidence relating to the management of subclinical hypothyroidism either during pregnancy or in those attempting to conceive. Interestingly, treatment

of subclinical hypothyroidism favours increased live birth rates in subjects undergoing assisted conception. Many endocrine professional bodies advocate the use of levothyroxine therapy, ideally prior to conception, given that the risk ratio is highly favourable with the potential risk of hyperthyroidism minimized by regular monitoring of thyroid function. Recent ATA guidelines support treatment only in TPO antibody-positive women but are relatively undecided on the merits of treatment in TPO antibody-negative disease. The American Congress of Obstetricians and Gynecologists does not endorse recommendations for the treatment of subclinical hypothyroidism in pregnancy.

KEY POINTS

THYROID DISEASE IN PREGNANCY

- Joint management with an endocrinologist, obstetrician and a paediatrician is important.
- Hyperemesis may be associated with thyrotoxicosis.
- Graves' disease should be managed with pregnancy – propylthiouracil is preferable to carbimazole.
- TSH should be maintained at <2.5 mIU/L in hypothyroid women.
- Postpartum thyroiditis is common.

EUTHYROID GLANDULAR ENLARGEMENT

Classification

The term 'goitre' refers to a thyroid gland which exceeds the upper limit defined for normal volume. This may simply be described as 18 mL for women and 25 mL for men but assessment of thyroid size should also respect age-specific criteria for normal values. Thyroid enlargement may be diffuse or may result from the presence of one or multiple thyroid nodules. It may additionally occur in the context of euthyroidism, hypothyroidism or hyperthyroidism. This section will review the enlargement of the thyroid gland which commonly occurs in the absence of aberrant hormone concentrations.

Epidemiology

Enlargement of the thyroid gland is common. The Wickham Survey identified the presence of a palpable

goitre in 15% of persons within an iodine-replete region and a visible goitre in 7%, supported by data from the US Framingham study that identified a 5–10% lifetime risk of developing a thyroid nodule.^{6, 142} The prevalence of goitre is closely related to dietary intake of iodine. This is such that, while 35.9% of the 3941 participants without known thyroid disease in the Study of Health in Pomerania had a goitre in its first phase, goitre was significantly rarer in the 5-year follow-up as iodine intake increased.^{143, 144}

The advent of high-resolution ultrasound has led to reported rates of goitre of between 19% and 67% in imaged individuals, even if the gland is normal on palpation. Higher frequencies have been noted in women and the elderly.²

Aetiology

Thyroid enlargement occurring in the absence of thyroid hormone excess or deficiency may be diffuse or nodular. The potential for malignancy is of concern, although thyroid cancer remains rare and accounts for only 1% of all new malignant disease.¹⁴⁵ Papillary and follicular thyroid cancers are together termed differentiated thyroid cancers and represent 72–85% and 10–20% of thyroid cancers respectively.¹⁴⁶ The remainder comprise of follicular (10–20%), medullary (1.7–35%), anaplastic (<1%) and other carcinomas (1–4%). Benign and malignant causes of nodular thyroid enlargement are summarized in [Table 61.14](#).

Risk factors for the development of thyroid cancer include exposure to head and neck irradiation in infancy and childhood.¹⁴⁷ Increased rates of childhood papillary cancer have been noted in Belarus and Ukraine and are thought to reflect the Chernobyl nuclear reactor accident.¹⁴⁸

Women are disproportionately affected by thyroid cancer with data suggesting a prevalence of 1.5%, which compares to 0.5% for men. Conversely, the presence of a thyroid nodule in a man is more likely to represent an underlying carcinoma.^{2, 149} This is explained by the equal rates of thyroid carcinoma for men and women despite a 5–10 times greater prevalence of nodular thyroid disease in females. Those at the extremes of age are also at most risk of harbouring thyroid cancer.¹⁴⁹

Survival rates are favourable with percentage cancer deaths of 0.21% and 0.3% for men and women respectively.¹⁵⁰ The incidence of thyroid cancer is rising rapidly and this is, at least in part, due to increased detection of

TABLE 61.14 Causes of nodular thyroid enlargement

Benign	Malignant	
	Follicular or C-cell origin	Malignancy of other origin
Follicular adenoma	Papillary carcinoma	Thyroid lymphoma
Hürthle cell adenoma	Follicular carcinoma	Malignancy metastatic to the thyroid
Colloid cyst	Hürthle cell carcinoma	
Simple/haemorrhagic cyst	Medullary thyroid carcinoma	
Lymphocytic thyroiditis	Anaplastic carcinoma	
Granulomatous thyroiditis		
Infectious processes		

incidental thyroid cancers.¹⁵⁰ Clinicians must increasingly respond to the challenge of identifying the minority of patients with thyroid cancer who require surgical intervention and additional therapies.

Clinical manifestations

Goitre development is asymptomatic in the majority of cases but is often visible once thyroid volume exceeds 40 mL. Patients may note that they have changed their collar size or stopped wearing necklaces. As many as 30–85% of patients are reported to develop mechanical compression of the trachea and/or the oesophagus but the majority remain asymptomatic.¹⁵¹ In those who do develop obstructive sequelae, the location of the goitre may predict symptomatology. Retrosternal goitres often result in dysphagia, for example, whereas retrotracheal goitres are more commonly associated with dyspnoea.

Diagnostic evaluation

History and physical examination are key to the evaluation of suspected goitre and may suggest thyroid carcinoma in some instances.¹⁴⁹ History should focus on the presence of mechanical symptoms, the temporal nature of thyroid enlargement, the presence of risk factors for malignancy such as previous head and neck irradiation, and family history relevant to a potential hereditary cancer syndrome.

The neck and upper thorax must be assessed on examination and palpation undertaken to determine goitre size and the presence of nodularity. The presence of signs suggestive of excess or insufficient thyroid hormone should be noted, as should evidence of mechanical compression.¹⁵¹

Features which strongly suggest the presence of thyroid carcinoma include rapid enlargement during hormonal therapy, vocal cord paralysis, ipsilateral lymphadenopathy and the presence of a hard, fixed nodule (Table 61.15).^{2, 149} These are, however, absent in the vast majority of cases and thyroid enlargement as a consequence of malignancy is indistinguishable from enlargement of benign aetiology in many cases. There is in addition considerable inter- and intra-observer variation regarding assessment of the size and morphology of the thyroid. A potential consequence is the increase in the use of ultrasound imaging to assess for and characterize thyroid nodularity.

Investigations in thyroid enlargement

LABORATORY INVESTIGATIONS

Recent guidelines published by both the American Thyroid Association (ATA) and the British Thyroid Association (BTA) advocate determination of the serum TSH concentration during the initial evaluation of a patient with a thyroid nodule.^{152, 153} Thyroid function tests must also be utilized to exclude thyroid dysfunction. Raised TSH should result in assessment of fT4 to identify either subclinical or overt hypothyroidism. Similarly, measurement of fT3 and fT4 should be undertaken in the presence of a suppressed TSH in order to delineate overt from subclinical hyperthyroidism or T3 toxicosis.

However, while virtually all patients with thyroid carcinoma are euthyroid, TSH may be suppressed in cases of malignancy. Interestingly, TSH concentration is increasingly recognized as an independent risk factor for thyroid malignancy. In a study of 1500 patients investigated with fine-needle aspiration cytology (FNAC) following presentation with thyroid enlargement, an increased odds ratio for malignancy was noted in those with serum TSH >0.9 mU/L.¹⁵⁴ Subsequent analysis of 843 patients undergoing resection of likely thyroid malignancy confirmed an increased likelihood of thyroid cancer with higher serum TSH concentration.¹⁵⁵ Levels of serum TSH were also found to be greater in patients with advanced malignancy (stage III/IV disease) compared with those with stage I or II disease.¹⁵⁶

Serum levels of thyroglobulin are influenced by the size of a thyroid gland and factors such as iodine intake. Routine assessment of serum thyroglobulin is therefore not recommended for the initial evaluation of thyroid nodules by both the ATA and the BTA as it is neither a sensitive nor a specific diagnostic test in this context.^{152, 153} Serum thyroglobulin measurements either under TSH suppression or stimulated do, however, remain the gold-standard tumour marker in patients with proven thyroid cancer.

There remains considerable controversy over the measurement of other potential serum markers of thyroid malignancy. Antithyroid peroxidase measurements are, for instance, undertaken by more than half of clinicians, yet they are found in approximately 10% of the general population and may reflect a coexistent autoimmunity rather than directly relate to the thyroid nodule.² The immunometric calcitonin assay is a sensitive marker for

TABLE 61.15 Elements suggestive of thyroid carcinoma in a patient's clinical workup

History	Clinical examination	Imaging
Family history	Hard, fixed nodule	Hypoechoogenicity
Male	Vocal cord paralysis	Solid nodule
Extremes of age	Ipsilateral lymphadenopathy	Microcalcification
Head and neck irradiation in infancy/childhood		Irregular margins
Previous radiation exposure		Increased intranodular flow
Compressive symptoms		Increased anterior–posterior dimension
Nodular enlargement during hormonal therapy		Invasion
		Lymphadenopathy

detection of medullary thyroid cancer, albeit with a high false-positive rate as a consequence of heterophilic antibodies. Calcitonin levels of greater than 10 pg/mL are very sensitive for the detection of medullary thyroid cancer and should elicit further investigation.¹⁵⁷ Despite evidence to suggest that use of calcitonin is cost-effective and a useful tool in the evaluation of thyroid nodules, its use is not widely recognized in the US and is more commonplace within Europe.¹⁵⁸

DIAGNOSTIC IMAGING

The imaging modality used in the assessment of thyroid enlargement is at least partly dependent on the clinical scenario. There is a growing array of options for the clinician, including ultrasonography, scintigraphy, computed tomography (CT) scanning, magnetic resonance (MR) imaging and, most recently, positron emission tomography (PET).

Ultrasound

The most widely used imaging modality in the detection and evaluation of thyroid nodules is ultrasonography, which is now recommended routinely in the assessment of goitre by BTA, ETA and ATA guidelines.^{152, 153} This non-invasive technique has the capacity to detect non-palpable nodules, in addition to permitting estimation of the size of goitres and nodules and allowing accurate guidance of fine-needle aspiration biopsy (FNAB).

A number of specific ultrasonographic changes are associated with malignancy, including hypoechogenicity, solid nodules, microcalcifications, irregular margins, increased intranodular flow, increased ratio of anterior/posterior dimensions in transverse and longitudinal views (more tall than wide), the presence of invasion or evidence of regional lymphadenopathy.

There are several retrospective case series that have together indicated a role for ultrasound imaging in reliably detecting malignancy.^{159, 160} Consequently, radiologists may use a US (U) grading system (U1–U5) to predict malignancy and guide clinicians in deciding whether biopsy of a thyroid nodule is required.¹⁵² The U classification system is depicted in **Table 61.16**. Ultrasound findings that represent a benign nodule (U1–U2) are regarded as not requiring FNAB unless the patient has a high risk of malignancy. Those that are equivocal (U3) or show a higher risk of malignancy (U4–U5) should lead to cytological assessment via FNAB.

Elastography may also be utilized and typically identifies diminished compressibility in malignant thyroid nodules.¹⁶¹ Interestingly, neither the number of nodules nor their size is predictive of malignancy. The presence of multiple suspect ultrasonographic findings confers an 83–99% sensitivity and 56–85% specificity for thyroid malignancy.^{161, 162} This high sensitivity may result in unnecessary investigations and intervention for clinically insignificant nodules. The low specificity continues to render ultrasound assessment of thyroid nodules inferior to FNAB for the diagnosis of malignancy.

TABLE 61.16 Ultrasound (U) classification of thyroid nodules

U classification	Nodule type	Ultrasound characteristics
U1	Normal	
U2	Benign	Vascularity, egg shell calcification, cystic change, iso-echoic or mildly hyper-echoic
U3	Indeterminate/ equivocal	Homogenous, hyper-echoic, equivocal echogenic foci, mixed or central vascularity, solid or halo
U4	Suspicious	Solid, hypo-echoic, peripheral calcification, lobulated outline
U5	Malignant	Solid, hypo-echoic, lobulated outline, intranodular vascularity, taller > wide, lymphadenopathy

Thyroid scintigraphy

Scintigraphy is of little value in the differentiation between benign and malignant nodular disease due both to its poor sensitivity and specificity. While this technique permits differentiation between ‘hot’ (functional) and ‘cold’ (non-functional) nodules, most malignant nodules trap isotope less well than normal thyroid tissue and thus appear cold, yet the risk of malignancy in cold nodules is nevertheless as high as 8–25%.¹⁶³ Both the BTA and the ATA have published guidelines stating that scintigraphy has no role in the routine management of the thyroid nodule.^{152, 153}

Other imaging modalities

Use of CT and MRI provides high-resolution three-dimensional imaging of the thyroid gland but affords no advantage over thyroid ultrasound for the detailed assessment of thyroid architecture. They additionally afford little value in the differentiation between benign and malignant lesions.¹⁶⁴ The use of 2-deoxy-2-fluoro-D glucose (FDG-PET) has met with promise but is limited by both cost and availability. For patients with large goitres, flow volume loop assessment may be helpful.¹⁵¹

Suspicious nodules are now not uncommonly identified incidentally during FDG-PET imaging undertaken for a separate indication.¹⁶⁵ Effective workup of patients with incidentally identified focal hypermetabolic thyroid lesions on FDG-PET imaging is crucial, with approximately one-third of identified lesions likely to be malignant.¹⁶⁶

FINE-NEEDLE ASPIRATION BIOPSY

FNAB is the gold-standard investigation in the evaluation of patients presenting with thyroid enlargement and provides both direct and specific information about the pathology of nodules.^{152, 153} This inexpensive and easy-to-learn technique carries a low complication rate and is the preferred diagnostic tool by the majority of thyroidologists. It remains the investigation of choice in the

evaluation of thyroid nodules as advocated in new ATA guidance.¹⁶⁷

Current BTA guidance recommends a combination of US and cytological findings in the diagnosis of thyroid cancer.¹⁵² The BTA and ATA have additionally provided guidance for the classification of cytological aspirates, as summarized in **Table 61.17**.

In summary, under BTA guidance nodules with seemingly benign US characteristics in patients of usual or low risk of thyroid cancer can be discharged from follow-up with no requirement for routine follow-up ultrasound. In instances of benign (Thy2) cytology and benign ultrasound findings there is again no requirement for follow-up ultrasound. Repeat FNAB is, however, required if US findings are suspicious and the initial FNA result is Thy1, or if the previous FNAB result is Thy2.

Cystic lesions which repeatedly yield non-diagnostic aspirates require close observation and, particularly in if the nodule is solid, may necessitate surgical intervention. Surgery may also be offered to patients with benign cytology who belong to a high clinical risk group or who have pressure symptoms or rapid nodular growth.

TABLE 61.17 Cytological classification of fine-needle aspirates and action required

ATA classification (Bethesda System)		
Diagnostic category	Cytological diagnosis	Management
I	Non-diagnostic	Repeat US-guided FNA
II	Benign	Clinical follow-up
III	Atypia/follicular lesion of undetermined significance	Repeat FNA
IV	Suspicious	Surgical hemithyroidectomy
V	Suspicious	Near-total thyroidectomy / surgical hemithyroidectomy
VI	Malignant	Near-total hemithyroidectomy
BTA classification (RCPATH Thy System)		
Diagnostic category	Cytological diagnosis	Management
Thy1	Non-diagnostic	US assessment +/- repeat FNAB
Thy2	Non-neoplastic	Correlate with clinical / US findings
Thy3	Neoplasm possible <i>Thy3a – Atypia (uncategorized)</i> <i>Thy3f – Atypia (possible follicular neoplasm)</i>	Further US +/- repeat FNAB Diagnostic hemithyroidectomy
Thy4	Suspicious of malignancy	Diagnostic hemithyroidectomy
Thy5	Diagnostic of malignancy	Surgical resection

Indeterminate cytology results are common and are reported in 15–30% of FNA specimens. Gender, nodule size and cytological features such as the presence of atypia may improve diagnostic accuracy but overall predictive values remain low. The use of molecular markers in refining the diagnosis of thyroid cancer is a rapidly expanding field and gene expression classifiers and mutation analysis panels are regularly in some US centres.¹⁶⁸ However, there is as yet insufficient evidence to recommend the routine use of molecular markers in the diagnosis of thyroid cancer.¹⁵²

The risk of malignancy is similar in those with multiple thyroid nodules compared with those presenting with a single nodule. Since sonographic characteristics are superior to nodule size in identifying malignancy current ATA and BTA guidance recommends diagnostic ultrasound in those with multinodular thyroids. Fine-needle aspiration should be undertaken in those with suspicious features. If none of the nodules has a suspicious appearance, the likelihood of malignancy is low and it is reasonable to aspirate the largest nodule only.

KEY POINTS

THYROID ENLARGEMENT

AETIOLOGY

- Benign causes include follicular and Hürthle cell adenoma, colloid cyst, infectious processes and thyroiditis.
- Malignant causes include papillary, follicular, Hürthle cell, and anaplastic or medullary thyroid carcinoma.
- Malignancies may be metastatic to the thyroid.

Clinical features suggesting carcinoma in a patient with thyroid enlargement

- Clinical history: rapid tumour growth, vocal cord paralysis, male sex, age <20 or >60 years, history of head or neck irradiation, presence of compressive symptoms, family history of multiple endocrine neoplasia or medullary thyroid carcinoma.
- Examination: firm nodules, fixation to adjacent structures, regional lymphadenopathy.

Investigations

- High-resolution ultrasound is the diagnostic imaging modality of choice.
- Fine-needle aspiration biopsy is required for cytological assessment.

Management

- Cytological diagnosis of Thy1 and Thy2 will require at least one repeat.
- Cytological diagnosis of Thy3, Thy4 or Thy5 will likely necessitate surgical intervention.

Medical management of nodular thyroid disease

NON-TOXIC MULTINODULAR GOITRE

Surgery is the treatment of choice where there is evidence of moderate to severe compressive symptoms, where FNAC

of a dominant nodule is suspicious of malignant or where the patient prefers surgery for cosmetic reasons.

Radioiodine therapy

Medical treatment of goitre previously involved the use of suppressive thyroid hormone but this is now considered outdated.¹⁶⁹ Use of suppressive therapy necessitates acceptance of a state of subclinical hyperthyroidism and consequent increased risk of reduced bone mineral density and cardiovascular disease.⁹⁷ Its discontinuation often also results in the resumption of growth of thyroid nodules or goitres. Contemporary management therefore typically utilizes the administration of radioactive iodine in cases in which a patient has refused surgery or if age, frailty or comorbidities preclude operative intervention.

Reduction in goitre size may be as significant as 60% and may continue for years after treatment, although most shrinkage occurs soon after treatment. Favourable outcomes are more likely in patients with small goitres who are young, have a shorter history of goitre and who receive higher doses of radioiodine.

Approximately 75% of those with the largest goitres will achieve relief from dyspnoea, accompanied by a reported 36% increase in the cross-sectional area of the trachea.¹⁷⁰ These patients may require large doses of radioiodine and may require hospitalization and isolation as a requirement of radiation protection legislation. Alternatively, therapy may be fractionated over a course of a few months.

The use of radioiodine is not, however, without side effects. Hypothyroidism commonly results from its use and is more likely if multiple doses of radioiodine are administered. The prevalence varies according to the amount of radiation exposure, with figures quoted ranging between 8% and 40% at 1–2 years.² While uncommon, radiation thyroiditis may occur in 3–13% of patients and causes neck pain and tenderness. Graves' hyperthyroidism associated with the development of TSH receptor antibodies occurs in up to 5% of patients and is usually transient.

Goitre size may transiently increase following the administration of radioiodine. Some concern has been voiced previously that this might contribute to a deterioration in respiratory function in those with tracheal compression. This fear is not well substantiated within the literature with studies demonstrating only a small decrease in tracheal cross-sectional area after therapy with no increase in upper airways obstruction. The use of prednisolone peri- and post-radioiodine to minimize risks of tracheal compression has been advocated but there is no evidence base for this practice.

Recombinant TSH may be employed as an adjunct to radioiodine therapy.¹⁷¹ Its use in this setting is aimed towards increasing the stimulus for radioiodine uptake into a goitre so as to maximize the effect per dose ratio. Preliminary data relating to the use of this adjuvant treatment are encouraging but evidence for efficacy in volume reduction is not yet available. Consequently, recombinant TSH is not widely used at present.¹⁷²

SOLITARY NON-TOXIC NODULE

Treatment of a solitary toxic nodule is similar to the management of multinodular goitre.¹⁷³ Surgery remains the treatment option of choice in cases of suspected malignancy and for cosmetic effect. Suppressive therapy with thyroid hormones is not recommended for solitary nodules for reasons outlined previously in this chapter.

Radioiodine therapy

Nodules which take up iodine (hot nodules) may be managed with radioiodine. This simple treatment is safe and cost-effective for this purpose, with a single dose delivering a thyroid volume reduction of up to 40%. Hypothyroidism is seen in approximately 10% of patients at 5 years post-radioiodine, although its frequency is higher in those with pre-existing thyroid autoimmunity.

Aspiration

Approximately 10–15% of solitary thyroid nodules are cystic. Many will resolve over time and small cysts of less than 3 mL volume are managed with a conservative expectant approach. Larger cysts should be aspirated with FNAB performed on any residual nodule. Surgery may be considered in these cases as around 10% of large lesions may harbour thyroid cancer. Recurrence rates following aspiration are poor and may be as high as 80%.

THYROID INCIDENTALOMAS

This area of thyroid disease has gained growing importance as a consequence of the increasing recognition of previously unrecognizable thyroid nodules through various imaging modalities. Usually measuring less than 1.5 cm, these incidentalomas are often diagnosed during evaluation for non-diagnostic neck disorders and pose a management quandary for clinicians.^{152, 153}

The Society of Radiologists in Ultrasound recently released a consensus statement which stipulated that highly suspicious ultrasonographic features, such as microcalcifications, should prompt a biopsy in nodules 1 cm or larger, other suspicious features such as solid consistency should prompt biopsy at 1.5 cm or larger and less suspicious appearances such as mixed solid and cystic consistency should be considered only if nodules measure 2 cm or larger.¹⁵⁹ These guidelines have, however, met with controversy as patients undergoing surgery for papillary cancers as small as <1.5 cm have been identified to have distant metastasis.¹⁷⁴ The revised British Thyroid Association Guidelines on the management of thyroid cancer do not take size into consideration when evaluating incidentalomas and suggest FNAB of nodules that are indeterminate or suspicious on ultrasound (U3–U5 categories).¹⁵²

An alternative approach may be to observe small nodules, in the absence of features of malignancy, and to proceed to FNAB for larger or rapidly growing incidentalomas and those with features suggestive of malignancy, such as irregular margins and increased intranodular flow. Most will require US-guided FNAB as they will be

impalpable, and mixed radiological and clinical follow-up is advocated.

CONCLUSIONS

Thyroid dysfunction is common, affecting more than 2% of the population and is usually caused by autoimmune disease. Thyrotoxicosis is most commonly caused by Graves' disease, with other important causes including toxic nodular hyperthyroidism and thyroiditis. The mainstays of treatment of thyrotoxicosis—namely, antithyroid drugs, radioiodine, and surgery—have not changed for more than 60 years, although the evidence base directing treatment choices and modes of administration is improving. Importantly, there is a rapidly increasing evidence base that mild or subclinical hyperthyroidism is associated with serious consequences, especially cardiovascular effects and osteoporosis.

Worldwide iodine deficiency is the most common cause of hypothyroidism, although in developed countries this is usually caused by Hashimoto's thyroiditis, another autoimmune disease. A number of definitive treatment modalities for hyperthyroidism result in permanent hypothyroidism.

Levothyroxine mono-therapy remains the standard of care for patients with hypothyroidism. Significant controversy continues to surround the long-term consequences and need for thyroid hormone replacement therapy in mild subclinical hypothyroidism. The management of thyroid dysfunction in pregnancy requires a coordinated multidisciplinary approach involving endocrinologists and obstetricians.

Thyroid enlargement and nodules affect up to 50% of the population and the challenge is to identify patients harbouring malignancy from the large majority who have benign disease. When thyroid dysfunction is excluded, the use of high-resolution ultrasound and fine-needle aspiration cytology are the most important diagnostic tools in this setting. A multidisciplinary approach involving thyroid surgeons, radiologists, nuclear physicists and endocrinologists are crucial for optimal management approaches in patients presenting with thyroid gland enlargement. If the presence of malignancy is excluded, often a conservative approach can be adopted. Treatment of suspected thyroid cancer usually involves surgery, whereas a conservative approach is usually adopted in those with benign thyroid enlargement. If there is significant compression, surgery or administration of radioiodine to shrink the goitre may be indicated.

FUTURE RESEARCH

Hyperthyroidism

- Investigation of novel and safe ways to modulate the underlying disease process in Graves' disease including immunological and other biological agents
- Further evaluation of the mechanisms of and risk factors for the development of severe side effects of the antithyroid drugs
- Determination of the long-term outcomes following treatment and their dependence on the treatment modalities employed
- Prospective randomized controlled trials assessing the indications for and outcomes following treatment of subclinical hyperthyroidism

Hypothyroidism

- Development of superior biomarkers of euthyroidism to supplement serum TSH measurements

- Mechanistic research on serum triiodothyronine levels, including effects of age and disease status, relationship with tissue concentrations, as well as potential therapeutic targeting
- Long-term outcome clinical trials testing combination therapy with T3/T4 or thyroid extracts
- Development of thyroid hormone analogs with a favourable benefit to risk profile
- Prospective randomized trials assessing the indications for and outcomes following treatment of subclinical hypothyroidism

Nodules

- Refinement of long-term follow-up strategies in patients with benign nodular thyroid disease
- Improvements in diagnostic accuracy of fine-needle aspiration cytology of thyroid nodules
- Identification of useful molecular markers diagnostic of thyroid malignancy
- Investigation of the role of elastography in the diagnosis of thyroid nodules

KEY POINTS

- Both overt and subclinical thyroid dysfunction are of clinical importance.
- Classical symptoms of thyrotoxicosis may not be present in the elderly.
- Levothyroxine is the mainstay of treatment in hypothyroidism with inconclusive evidence to indicate an advantage from T3 therapy.
- Thyroid disease in pregnancy requires a specialist-driven multidisciplinary approach.
- Thyroid cancer is rare but must be considered in cases of euthyroid glandular enlargement.
- High-resolution ultrasound, with or without fine-needle aspiration cytology, is used first-line in the investigation of euthyroid goitre.

MANAGEMENT OF DIFFERENTIATED THYROID CANCER

Hisham M. Mehanna, Kristien Boelaert and Neil Sharma

Introduction	751	Assessment of the outcomes of treatment	754
Investigations	751	Follow-up	754
Treatment	752	References	756

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: thyroid, cancer, carcinoma, management, radioiodine, as well as published guidelines from the British and American Thyroid Associations. Reference lists for selected papers were examined for further sources.

INTRODUCTION

The prognosis of differentiated thyroid cancer (DTC) is excellent for most patients. Patients with Stage I–Stage III disease have a 10-year survival rate of over 98%,¹ but the survival rate drops dramatically for patients with Stage IV disease, especially when gross local invasion or distant metastases are present in patients older than 45 years.

The management of DTC is mainly surgical, with adjuvant radioiodine ablation followed by TSH suppression in some cases. In the past almost all patients received similar treatment with a combination of all three therapeutic modalities. Over the past 5–10 years, however, a more personalized approach to treatment has been introduced. This tailors the specific treatment that a patient receives according to their individual requirements and risk of recurrence. The type and size of their tumour and the presence or absence of aggressive features such as lymph node metastases or aggressive histological features mainly determine stratified treatment. This change in treatment paradigms has also recently extended to the stratification of risk of recurrence following the completion of treatment, leading to variable follow-up requirements.

INVESTIGATIONS

The investigation of a patient with suspected thyroid cancer^{1, 2} has been covered appropriately in [Chapter 59](#).

Briefly, this includes a detailed clinical history, which should in particular elicit a family history of thyroid cancer, previous neck irradiation and a history of Hashimoto's disease (predisposing to lymphoma). The diagnosis will have been obtained using a combination of high-resolution ultrasound scan (USS) and fine-needle aspiration cytology in most cases. Once thyroid cancer is diagnosed, ideally the extent of the disease should be further staged to assess tumour size, invasion of important central structures such as trachea and oesophagus, and the presence of nodal metastases and/or distant metastases ([Table 62.1](#)). This is undertaken using a combination of ultrasound of the neck, CT and/or MRI.

Use of iodinated contrast for CT scanning will impose some restrictions on the use of ablative radioiodine within 2 months of the scan due to the high concentration of iodinated contrast taken up by the thyroid, which may diminish the effectiveness of radioiodine.^{1, 2} However, this is usually not a problem because the treatment period will include surgery and recovery from this in the first instance and in view of more recent evidence indicating that the clearance period for iodine in both thyroidectomized and euthyroid patients is only 4 weeks.³ Importantly, subjects requiring radioiodine ablation are frequently intermediate-risk patients, in whom a small delay in this treatment will have little effect on outcome. Those patients with more aggressive thyroid cancer tend to have non-iodine avid disease or iodine-refractory disease in which case a

TABLE 62.1 TNM classification of thyroid cancer²⁸

Primary tumour	
Tx	Primary tumour cannot be assessed
T0	No evidence of primary tumour
T1	Tumour ≤2 cm in greatest dimension limited to the thyroid
T1a	Tumour ≤1 cm, limited to the thyroid
T1b	Tumour >1 cm but ≤2 cm in greatest dimension, limited to the thyroid
T2	Tumour >2 cm but ≤4 cm in greatest dimension, limited to the thyroid
T3	Tumour > 4 cm limited to the thyroid, or gross extrathyroidal extension invading only strap muscles
T3a	Tumour > 4 cm limited to the thyroid
T3b	Gross extrathyroidal extension invading only strap muscles (sternohyoid, sternothyroid, thyrohyoid, or omohyoid muscles) from a tumour of any size
T4a	Tumour of any size extending beyond the thyroid capsule to invade subcutaneous soft tissues, larynx, trachea, oesophagus or recurrent laryngeal nerve
T4b	Tumour invades prevertebral fascia or encases carotid artery or mediastinal vessels
Regional lymph nodes (cervical or upper mediastinal)	
Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
N1a	Metastases to Level 6/7 nodes unilateral or bilateral
N1b	Metastases to unilateral, bilateral or contralateral cervical (Levels 1, 2, 3, 4 or 5) or retropharyngeal nodes
Distant metastases	
M0	No distant metastases
M1	Distant metastases
Residual tumour	
RX	Cannot assess presence of residual primary tumour
R0	No residual primary tumour
R1	Microscopic residual primary tumour
R2	Macroscopic residual primary tumour

Note: TNM: tumour, node, metastasis.

delay in receiving radioiodine ablation is significant only in that it can increase time to other adjuvant modalities such as external beam radiotherapy.

TREATMENT

Over the past decade, a more evidenced-based approach to treatment and follow-up has been espoused by both the American Thyroid Association² and the British Thyroid Association.¹ This has resulted in the concept of treatment planning tailored to patients' individual needs. The introduction of personalized medicine has also extended to the need for and duration of TSH suppression as well as to follow-up strategies. Where there is no evidence or conflicting evidence, an open and frank approach with the patient is now recommended so that a full discussion of the potential benefits and risks of adjuvant treatment can be undertaken, leading to shared decision-making.

An assessment of both patient and tumour factors before and after surgery helps determine the extent of the thyroidectomy, the need for neck dissection, the need for radioiodine ablation and the requirement for post-treatment TSH suppression. In addition, the intensity of follow-up the patient requires can be predicted.

Extent of thyroidectomy

Thyroidectomy is the mainstay of treatment for thyroid cancers. In recent years there has been a move towards the more conservative hemithyroidectomy rather than total thyroidectomy. This has coincided with a decrease in the indications for radioiodine ablation. Generally speaking, for DTC, a total thyroidectomy is recommended for patients with tumours >4 cm in size and for patients with tumours where there is multifocal disease, bilateral disease, extrathyroidal spread or confirmed nodal or distant metastases. Additional factors that may warrant

bilateral surgery are older age (>55 years), a history of radiation exposure, familial differentiated thyroid cancer, adverse histopathological features and potential difficulties with follow-up.⁴

The evidence for doing a total thyroidectomy rather than a hemithyroidectomy for patients with low-risk papillary thyroid cancer (PTC) of <4 cm with no poor prognostic features is equivocal and conflicting. Careful review of the data indicates that, while there is a decreased risk of recurrence with total thyroidectomy, and while in the long term this may be a more cost-effective approach, the difference is small when compared with more limited surgery.⁵⁻⁷ In these cases one should have a discussion with the patient regarding the benefits and risks of total thyroidectomy vs. hemithyroidectomy.

Patients with follicular thyroid cancer associated with any of the above poor prognostic features should be advised to undergo a total thyroidectomy.

If tumour is found during the operation to be encasing the recurrent laryngeal nerve (RLN), the clinician should aim to preserve the nerve if it was functioning pre-operatively. This may mean a small amount of disease is left on the nerve but this is acceptable in view of the functional detriments of vocal cord palsy, the gain in quality of life and, importantly, the fact that there is no survival benefit to be gained from nerve sacrifice.⁸

Pre-operatively, one should assess the trachea and the oesophagus radiologically, to identify the need for partial tracheal or oesophageal resection in order to achieve macroscopic tumour clearance. This is important because, unlike for RLN involvement, residual disease left at these sites leads to a significant decrease in survival.⁹ Furthermore, careful pre-operative assessment allows determination of the need for input from a cardiothoracic surgeon.

Treatment of papillary thyroid microcarcinoma

Papillary thyroid microcarcinoma (PTMC) is defined as a tumour no greater than 1 cm in maximum diameter. In general this has an excellent prognosis with almost no mortality. A recent meta-analysis,¹⁰ however, indicated that there are at least two types of PTMC – those found incidentally during histological evaluation post-operatively and those that are identified pre-operatively, either incidentally during radiological investigation or because they caused symptoms. Those patients who are diagnosed incidentally on histology have no mortality and almost no recurrence risk and therefore can be considered as cured and can be discharged to their GP. They should, however, undergo annual thyroid function test monitoring since hemithyroidectomy carries a medium- to long-term risk of hypothyroidism.

Those patients with lesions that were identified radiologically may have a slightly higher risk of recurrence. If there are no poor prognostic features (such as aggressive histology, extracapsular spread or lymph node metastasis), these patients can be followed up for 5 years in the

same manner as patients with low-risk DTC and then be discharged to a lower-intensity setting. Any patient who has PTMC with aggressive features should be managed in the same way as a patient with non-low risk papillary thyroid cancer.

Neck dissection

There is no evidence of benefit from doing a prophylactic lateral neck dissection in patients with no overt lateral neck disease.² The evidence for potential benefits from prophylactic central neck dissection is unclear and conflicting, with some studies indicating improved outcomes^{10, 11} while others do not.¹² In addition, some studies show no additional complications from central neck dissection, whereas others have shown that there is considerable added morbidity.¹³⁻¹⁶ There is a suggestion, however, that central neck dissection may be of benefit in tumours >4 cm in size and in tumours with extrathyroidal extension, but the evidence is unclear. Prophylactic central neck dissection is not recommended in patients who have low-risk disease, or have tumours <4 cm in size with classical PTC and no extrathyroidal extension.

Once surgery is completed, TSH suppression should be undertaken with either thyroxine T4 (2 mcg/kg) or with Liothyronine (20 mcgt.d.s.) until the histopathology is available, and a decision can be made as to the need for adjuvant treatment.

Radioiodine ablation

Of all the treatments for thyroid cancer, the practice of radioiodine ablation has undergone the most radical change in recent years. The evidence of the American Thyroid Association Guidelines in 2009 heralded personalized evaluation and decision-making for radioiodine ablation, a decision that should be made at the multidisciplinary team discussion following surgical resection. For radioiodine ablation to be effective, a total thyroidectomy is required, and therefore patients who have had a hemithyroidectomy require a completion thyroidectomy prior to consideration of this treatment.

The benefits of radioiodine ablation have to be weighed carefully against the potential side effects. Positive effects include the possibility of improved survival, reduced recurrence and better monitoring with thyroglobulin in the long term. The downsides, however, include the inconvenience of being in an isolation ward and the requirement not to come into contact with adults and children for 14–25 days following radioiodine ablation. For younger female patients, the implications on pregnancy and breastfeeding must also be considered. Amenorrhoea/oligomenorrhoea may occur for 4–10 months following radioiodine ablation, as the gonadal tissue is exposed to radiation via blood and excretion in urine and faeces. Current recommendations are to defer pregnancy for 6 months (BTA guidelines¹) or 6–12 months (ATA guidelines²) following radioiodine treatment. Breastfeeding should be

discontinued at least 8 weeks prior to radioiodine administration to prevent excessive uptake by lactating breast tissue.¹ Male patients are advised to defer fathering a child for 4 months following treatment.¹

Patients also sometimes complain of dryness of the mouth, swelling of the submandibular glands and feeling tired soon after the treatment. Xerostomia can increase with time. Finally, sperm banking is often offered to men, as infertility is possible.

Patients in whom radioiodine is indicated include those patients with tumours >4 cm or with gross extrathyroidal spread or distant metastasis. These patients will receive an ablative dose of radioiodine followed by a treatment dose. Patients for whom radioiodine is not indicated include those who have unifocal or multifocal tumours <1 cm in size which are histologically classed as papillary or follicular variant, or minimally invasive follicular cancer, with no angioinvasion or extension outside the thyroid capsule.

The difficulty arises in the group of patients who have intermediate features, as data regarding the benefits of radioiodine ablation are sparse. These include patients with tumours 1–4 cm in size. Those patients who have poorer prognostic features could be offered radioiodine ablation. The poor prognostic features include aggressive histology (tall cell or poorly differentiated or diffuse sclerosing PTC), widely invasive follicular thyroid cancer, extracapsular invasion, multiple involved lymph nodes or a high ratio of involved to non-involved nodes and large size of individual nodes that are involved.

Recently, two large randomized controlled trials (RCTs) have shown that a lower dose of 1.1 Mbq is as effective as a higher dose of 3.7 Gbq. The lower dose, however, had fewer side effects.^{17, 18} Patients have to be prepared for radioiodine ablation by either recombinant TSH injection 5 days before treatment or by Levothyroxine withdrawal, which is more prolonged and has greater side effects. An iodine scan is undertaken 2–10 days after the treatment. This allows assessment of radioiodine uptake and whether uptake has occurred in areas outside the neck.

High treatment doses of radioiodine are recommended in patients who have gross residual disease or distant metastases. These patients may require repeat treatments every 6–12 months, especially those with disease not amenable to surgery.

Further details on radioiodine treatment are provided in [Chapter 66](#).

External beam radiotherapy

Patients with gross evidence of local tumour invasion at surgery are candidates for external beam radiotherapy (EBRT), as are those with residual or recurrent tumour that is non-radioiodine avid. Intensity-modulated radiotherapy (IMRT) is the method of choice as it reduces damage to other surrounding tissues¹⁹ and reduces toxicity. There is no clear-cut evidence as to the best timing of EBRT in relation to radioiodine remnant ablation. Detailed information on EBRT is provided in [Chapter 66](#).

ASSESSMENT OF THE OUTCOMES OF TREATMENT

The post-radioiodine scan, carried out between 2 and 10 days after ablation, helps assess the uptake of radioiodine in the thyroid bed, as well as the extent of residual and metastatic disease. However, the main evaluation of success of treatment occurs 9–12 months afterwards. Evidence suggests that stimulated thyroglobulin measurements provide the most sensitive method of detecting recurrent or residual disease. Stimulated thyroglobulin should be undertaken along with high-definition ultrasound of the neck and thyroid gland. Together these are more accurate than undertaking a whole-body radioiodine scan.^{20, 21}

An injection of recombinant TSH 9–12 months after surgery with a measurement of the thyroglobulin and thyroglobulin autoantibodies following this enables an assessment of disease activity. Stimulated thyroglobulin can also be undertaken using thyroxine withdrawal, but this causes more symptoms and takes more time.^{22–24} A stimulated thyroglobulin of <0.5 mcg/L after TSH stimulation has been shown to predict disease-free status with 98–99% accuracy. A stimulated thyroglobulin of >2 mcg/L is highly predictive of persistent disease.^{20, 25–28} It should be noted, however, that stimulated thyroglobulin can only be used in the absence of thyroglobulin antibodies and is most sensitive in patients who have had both total thyroidectomy and radioiodine ablation. Conversely, it can predict absence of recurrence with 95–99% accuracy.^{29, 30}

An unstimulated thyroglobulin of <0.1 mcg/L in the absence of thyroglobulin antibodies and a negative USS has a very high negative predictive value in low-risk patients and can be used as a cost-effective alternative to stimulated thyroglobulin.^{31–33}

CT scanning should be used only if the measurement of serum thyroglobulin is unreliable or when the post-radioiodine ablation scan shows uptake beyond the neck.

FOLLOW-UP

Dynamic risk stratification produces three groups ([Table 62.2](#)): those with an excellent response, those with persistent disease, and those with equivocal or indeterminate response to treatment. Patients with an excellent response are defined as those who have had surgery and radioiodine ablation and in whom the stimulated thyroglobulin is <1 mcg/L, with a negative USS. Patients who have an excellent response can undergo a less stringent follow-up regimen with annual thyroglobulin assessments. Their TSH should be maintained in the low-normal range at 0.3–2.0 mU/L ([Table 62.3](#)). If they are disease-free after 5 years, consideration can be given to following them up in a less intensive setting, such as a nurse-led clinic.^{2, 34–37} It should be noted that the appearance of thyroglobulin antibodies when they were previously absent, or their gradual rise, may indicate evidence of recurrent disease.

Patients with an incomplete response include those with a stimulated thyroglobulin >10 mcg/L or a

TABLE 62.2 Dynamic risk stratification following treatment for thyroid cancer¹

Response	Criteria	Risk stratification	Follow-up
Excellent	<i>All of the following:</i> Suppressed and stimulated Tg <1 mcg/L Neck USS without evidence of disease Cross-sectional and/or nuclear medicine imaging negative (if performed)	High	6-monthly for first year Annually thereafter
Indeterminate	<i>Any of the following:</i> Suppressed Tg <1 mcg/L and stimulated Tg ≥1 and <10 mcg/L Neck USS with non-specific changes or stable sub-1 cm nodes Cross-sectional and/or nuclear medicine imaging with non-specific changes, not completely normal	Intermediate	More frequently depending on individual need
Incomplete	<i>Any of the following:</i> Suppressed Tg ≥1 mcg/L or stimulated Tg ≥10 mcg/L Rising Tg values Persistent or newly identified disease on cross-sectional and/or nuclear medicine imaging	Low	Investigate and more frequently depending on individual need

TABLE 62.3 Grading of TSH suppression¹

Response	TSH suppression (mU/L)
Excellent	0.3–2.0
Indeterminate	0.1–0.5 (for 5–10 years)
Incomplete	<0.1 (indefinitely)

rising thyroglobulin concentration. They may have a neck USS that shows recurrence. If their ultrasound is normal, then they require a CT scan or MRI. In these patients where cross-sectional imaging is negative, a PET-CT scan should be undertaken. If this is still negative, then a ¹³¹I

scan should be undertaken. If there is evidence of surgically resectable disease in these patients, that should be undertaken. If there is no surgically resectable disease, then further radioiodine therapy can be offered. These patients should then have TSH suppression (<0.1 mU/L) indefinitely and should undergo close follow-up.

Patients with an indeterminate or equivocal response (stimulated thyroglobulin 1–10 mcg/L with non-specific changes on neck ultrasound) should be kept under close review with serial thyroglobulin measurements and ultrasound scans to attempt to detect recurrence at an earlier stage. The TSH should be maintained in the range 0.1–0.5 mU/L for at least 5–10 years.

BEST CLINICAL PRACTICE

- ✓ For appropriately selected low-risk patients, hemithyroidectomy may be appropriate surgical management.
- ✓ A small amount of disease may be left on a functioning recurrent laryngeal nerve without compromising survival.
- ✓ Prophylactic central neck dissection should be reserved for high-risk patients.
- ✓ Lateral neck dissection should only be undertaken in patients with overt lateral neck disease.
- ✓ Dynamic risk stratification should be undertaken for all patients who have had total thyroidectomy and radioiodine ablation to guide their follow-up and further management.
- ✓ Radioiodine ablation is indicated for high-risk cases and some selected intermediate-risk cases.

FUTURE RESEARCH

- Molecular profiling of tumours as an aid to risk stratification
- Methods of identifying high-risk radioiodine-resistant tumours early to escalate treatment and reduce recurrence
- The role of the immune response in thyroid cancer and how this may influence lateral neck dissection

KEY POINTS

- Differentiated thyroid cancer is rare but has a rising global incidence.
- Thyroid cancer remains a predominantly surgical disease.
- Personalized treatment based on the patient's individual disease and recurrence risks is now the mainstay.
- Management of all patients with thyroid cancer should be discussed in the context of a multidisciplinary team.

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: medullary thyroid cancer, MEN2, calcitonin and thyroidectomy.

INCIDENCE

Medullary thyroid cancer/carcinoma (MTC) is diagnosed in approximately 1000 people each year in the United States and 25–50 people per year in the UK and it is responsible for 5–10% of paediatric thyroid cancers. In patients with nodular thyroid disease screened for MTC the prevalence is reported as 0.4%–1.8% (see below).

PATHOLOGY

MTC arises from C-cells located in the middle and upper third of the thyroid gland, adjacent to or within thyroid follicles, between the follicular cell basement membrane and the surface epithelium. C-cells are of neural crest origin and produce calcitonin, calcitonin gene-related peptide (CGRP) and carcinoembryonic antigen (CEA).

The physiological role of calcitonin is unclear. In patients with metastatic medullary thyroid cancer, in whom calcitonin levels are grossly elevated, and after total thyroidectomy for benign disease when levels are low, no derangement of calcium homeostasis is apparent.

C-cell hyperplasia

C-cell hyperplasia (CCH) is defined as a multifocal (diffuse or nodular) quantitative increase in C-cells. Two types of CCH are described:

- **neoplastic:** typically nodular and diffuse and indistinguishable from invasive MTC cells
- **reactive/physiological:** typically diffuse, associated with hypercalcaemia, hyperparathyroidism, chronic lymphocytic thyroiditis and follicular thyroid tumours.

Medullary thyroid cancer

MACROSCOPIC

Sporadic tumours are usually solitary (90%) and unilateral. In familial disease, MTC is usually bilateral and multifocal.

CYTOLOGY

Cell morphology is variable, oval/round/spindle-shaped cells may be seen in clusters or as single cells with pleomorphic nuclei and eosinophilic cytoplasm. Eosinophilic extracellular material is amyloid.

Figure 63.1 (a) MTC cytology from fine needle aspiration (b) MTC histology showing strongly positive immunohistochemical staining for calcitonin.

HISTOPATHOLOGY

Variants of classical MTC include papillary, follicular, squamous and oncocytic subtypes. Amyloid is seen in 80% of tumours on immunohistochemistry, and tumour cells stain positive for calcitonin (Figure 63.1), CEA and chromogranin A. Thyroglobulin staining is negative.

MTC is staged as described in the *AJCC Cancer Staging Manual*.¹

HEREDITARY MTC

Genetically determined disease accounts for 25% of MTC cases. The three main clinical variants are all inherited as autosomal dominant disorders with age-related penetrance and variable expression:

- multiple endocrine neoplasia type 2A (MEN 2A): >50% of cases
- multiple endocrine neoplasia type 2B (MEN 2B): 5% of cases
- familial medullary thyroid cancer (FMTC).

The prevalence is estimated at 1 in 30000. MTC is expressed in almost all patients and is usually the first manifestation of the syndrome; the age at onset can be roughly predicted according to the genotype.

Gain of function germline and somatic mutations of the *RET* proto-oncogene (chromosome 10q11.2) are implicated in the pathogenesis of MTC. *RET* encodes a plasma membrane-bound receptor tyrosine kinase that is expressed by thyroid C-cells, cells of the adrenal medulla, autonomic nerve ganglia, colonic ganglia and parathyroid cells.

Germline mutations associated with MEN 2/FMTC are found in 7 of the *RET* gene's 21 exons. The codon mutations correlate with the MTC phenotype.²

The extracellular, codon 634 mutation (found in 85% of MEN 2A cases) induces a dimerization of the *RET* receptor which leads to abnormal cell growth, differentiation defects and cellular transformation. The intracellular, codon 918 mutation found in 95% of cases of MEN 2B is associated with receptor activation in the absence of receptor dimerization by alteration of kinase substrate specificity.

Somatic mutations of *RET*, usually at codon 918, are found in approximately 25% of sporadic MTC and linked with poorer prognosis.

CLINICAL FEATURES OF SPORADIC AND HEREDITARY MTC

Sporadic MTC presents usually in the fourth to sixth decade, MEN2A typically presents in the second or third decades, MEN2B in the first and second decades, and FMTC in the fourth and fifth decades. The sex ratio is almost equal.

A thyroid mass is normally the first indication of disease (>75%), cervical lymphadenopathy is a presenting feature in approximately 40–50% of patients. Around 10% of patients will have distant metastases, and symptoms include diarrhoea (the specific cause of which is unknown), flushing and bone pain. Rarely (<1%), ACTH/CRH production by MTC causes Cushing's syndrome³ and is associated with poor prognosis.

Phaeochromocytoma is most frequently associated with *RET* codon mutations 634 and 918,⁴ occurs in 50% of MEN 2 patients most commonly in the third and fourth decades and may be the presenting feature of MEN 2 in up to 25% of cases.

In patients with MEN 2A, hyperparathyroidism occurs in 20–30% of individuals with *RET* 634 mutations. The hypercalcaemia is often mild. Asymmetric parathyroid gland enlargement is likely and resection of only enlarged glands is recommended.⁵

Rare variants of MEN 2A with specific *RET* mutations are associated with Hirschsprung's disease and cutaneous lichen amyloidosis (brownish plaques of multiple tiny papules, usually in the interscapular area).

In FMTC, the age at onset of MTC is later than is seen in MEN 2A and MEN 2B; the phenotype is less aggressive. MEN 2B has a specific phenotype that may be apparent in infancy and progresses as the patient ages. There is a typical facial appearance with enlarged lips (Figure 63.2). Mucosal ganglioneuromas arise in the digestive tract – associated with abdominal distension, megacolon, constipation and diarrhoea. In infants, the colonic manifestations of MEN 2B may be confused with Hirschsprung's disease. Ganglioneuromas are seen on the conjunctivae, lips and tongue (Figure 63.3).

Figure 63.2 Typical facial phenotype of three unrelated MEN 2B patients.

Figure 63.3 Tongue of an 11-year-old MEN 2B patient showing typical ganglioneuromas.

Other manifestations include skeletal abnormalities such as Marfanoid habitus, joint laxity, pes cavus and pectus excavatum, and markedly thickened corneal nerves. Around 95% of patients have a mutation at codon 918, and 75% of patients are the index case (i.e. *de novo* mutations).

DIAGNOSIS OF MTC

The diagnosis of MTC in most cases will result from the investigation of patients who present with a thyroid or lymph node mass. Fine-needle aspiration cytology (FNAC) will result in a diagnosis in 50% of cases,⁶ and the additional use of calcitonin assay of the fine-needle aspirate has high sensitivity and specificity for MTC diagnosis.⁷ When necessary, targeted core needle biopsy avoids the need for open biopsy.

Routine measurement of basal calcitonin in patients presenting with nodular thyroid disease is recommended

by some, to identify otherwise undetected MTC and lead to the potential benefit of better outcome. Basal hypercalcaemia will be evident in at least 1.5% of screened individuals but approximately 60% of those with a high basal calcitonin do not have MTC. The positive predictive value of an abnormal basal calcitonin greater than 100 pg/mL is 100%.⁸ Recommendations on the use of routine calcitonin screening in patients with nodular thyroid disease in recent draft guidelines of the American Thyroid Association⁹ and British Thyroid Association² (against) are at variance with European Thyroid Association guideline recommendations (in favour).¹⁰

PRE-OPERATIVE INVESTIGATIONS

Calcitonin

Serum calcitonin is a sensitive and accurate marker of MTC. False-positive serum calcitonin levels are recorded in patients with autoimmune thyroid disease, hypercalcaemia, foregut-derived neuroendocrine tumours and renal failure. Normal basal calcitonin levels are higher in neonates and children than adults.¹¹ MTC with normal basal serum calcitonin is described in less than 1% of patients, more often in those with advanced disease.¹²

Basal calcitonin should be measured in all MTC patients prior to surgery. The level of calcitonin is a good indicator of disease extent. Lymph node involvement may be found in patients with calcitonin as low as 10–40 pg/mL; distant metastasis and extra-thyroidal growth can occur with calcitonin levels of 150–400 pg/mL.¹³

In patients with potentially false-positive basal calcitonin levels, or when there is uncertainty about the histological diagnosis, a calcium stimulation test should be performed.¹⁴ Basal calcitonin levels that are false positives (i.e. not MTC) do not respond significantly to calcium stimulation.

Urinary or plasma catecholamines / metanephrines

Biochemical testing for pheochromocytoma (24-hour urine, or plasma for metanephrines and normetanephrines) is mandatory prior to surgery in all patients with a diagnosis of MTC. Pheochromocytoma should be treated before the thyroid disease. Annual biochemical screening for pheochromocytoma is warranted from the age of 11 years in carriers of *RET* codon mutations 918 and 634, and from the age of 16 in the remainder.¹⁵

Calcium

A serum calcium level should be obtained from all patients prior to surgery. Hypercalcaemia and high or inappropriate serum PTH will indicate the need for careful assessment of the parathyroid glands at the time of thyroidectomy and excision of enlarged glands. Age of commencement of screening for primary hyperparathyroidism is recommended as for pheochromocytoma.¹⁵

RET mutation analysis

RET mutation analysis should be performed in all patients diagnosed with MTC. Your 'sporadic' patient may represent the index case of a previously undiagnosed MEN kindred. The prevalence of a germline *RET* mutation in patients with apparently sporadic MTC is reported as 7%.¹⁶

DNA-based testing will identify mutations in more than 95% of individuals with MEN 2A and MEN 2B and in about 85% of individuals with FMTC. When a patient with MTC is identified as carrying a *RET* mutation, genetic screening should be offered to first-degree relatives. Family members identified as gene-positive can be offered therapeutic, risk reduction or prophylactic surgery for MTC (see below).

Ultrasound

Neck ultrasound performed as a part of thyroid workup or to guide FNA can identify bilateral and/or multiple thyroid lesions – suggestive of genetically determined disease, and enlarged or abnormal lymph nodes.

CT/MRI scanning

Cross-sectional imaging of the neck and mediastinum is required to identify tracheal/oesophageal invasion and mediastinal lymphadenopathy (Figure 63.4).

Systemic staging to include lungs, liver and axial skeleton (including bone scintigraphy) is appropriate in patients with extensive neck disease, symptoms of metastatic disease or a calcitonin >500 pg/mL.¹⁷ Positive findings may restrict the extent of neck surgery.

Pre-operative laryngoscopy is essential in patients with proven or suspected MTC.

Staging

For staging of MTC, please refer to Chapter 58.

Figure 63.4 Magnetic resonance image showing bilateral cervical and infrabrachiocephalic lymphadenopathy in a 17-year-old MEN 2B patient following previous thyroidectomy.

SURGERY FOR MTC

The aims of surgery in patients with MTC are to remove all disease in the neck, produce biochemical and clinical cure and minimize the risk of locoregional relapse that might compromise the airway, oesophagus or recurrent laryngeal nerves. This requires total thyroidectomy and lymph node dissection in most patients. Surgery should be performed with the intention to preserve the recurrent laryngeal nerves, superior laryngeal nerves and parathyroid function.

Rationale for lymph node dissection in MTC

Node metastases are common (>75%) in patients with palpable MTC¹⁸ and occur early in the disease. Lymph node involvement may be found when the basal calcitonin level is only minimally above the normal range:¹³ the frequency can be predicted by tumour size and ranges from 17% (pT1) to 100% (pT4).¹⁹ Node metastases in sporadic medullary microcarcinoma (1 cm diameter or less) have been reported to occur in 43% of patients.²⁰

Ipsilateral lateral neck nodes may be involved in over 80% of cases and contralateral lateral nodes in over 50%.²¹ The frequency of ipsilateral and contralateral lateral compartment node involvement reflects the degree of central compartment node positivity.²¹ Skip metastases (negative central and positive lateral or mediastinal compartments)

are found in approximately 20% of patients. Mediastinal node disease is more likely to occur in patients with positive cervical nodes and extra-thyroidal extension; contralateral cervical or mediastinal lymph node involvement predicts an increased risk of distant metastases.²²

The normal recommendation for the treatment of MTC is total thyroidectomy, although sporadic disease is usually unilateral and unifocal (80%). Total thyroidectomy and compartment-orientated node dissection is associated with improved survival and a reduced risk of recurrence.²³ Biochemical cure can be obtained in 95–100% of patients without lymph node metastases, and in 32–45% of patients with lymph node metastases.^{24, 25} When fewer than 10 lymph nodes are involved, an undetectable calcitonin level is observed in 57% of patients.²⁵

A reasonable approach to the primary surgical treatment of MTC without distant metastases includes the following:

- Clinically evident MTC: a minimum of total thyroidectomy and central neck lymph node dissection (levels VI–VII). Therapeutic selective lateral neck dissection should be performed if there is clinical or radiological evidence of nodal disease. Ipsilateral prophylactic selective lateral neck dissection (levels IIa–Vb) is advised if central neck nodes are involved as there is a high risk of lateral neck node disease. In the absence of overt central neck node disease, histological confirmation of node metastasis by intra-operative frozen section should be performed prior to prophylactic lateral neck dissection. Alternatively, a two-stage procedure may be performed. As biochemical cure is unlikely when node metastases are present in more than two lymph node compartments,²⁶ prophylactic bilateral lateral neck dissection is not recommended.
- Incidental MTC >1cm diagnosed at hemithyroidectomy with elevated post-operative basal calcitonin: treat as above.
- Incidental micro MTC <5mm (*RET*-ve) and normal post-operative basal calcitonin: completion thyroidectomy is not required.
- MTC >5mm in diameter when the post-operative basal calcitonin is elevated, or when the basal calcitonin is normal and stimulated calcitonin levels are elevated: total thyroidectomy and central neck dissection.
- After previous surgery and five or fewer lymph nodes removed with calcitonin <1000 pg/mL: central and ipsilateral lateral neck node dissection as above should be considered.
- When pre-operative imaging identifies infrabrachicephalic mediastinal nodal disease and no evidence of distant metastases: mediastinal lymphadenectomy (via a trans-sternal approach) should be performed.

Patients with known distant metastases at diagnosis should be considered for total thyroidectomy and central neck lymph node dissection, and/or resection of enlarged mediastinal nodes to prevent subsequent compromise of the airway, recurrent laryngeal nerves and oesophagus. Survival may be prolonged in patients with disseminated disease.

FOLLOW-UP

Thyroid function and serum calcium should be monitored post-operatively, the former in conjunction with replacement doses of thyroxine to maintain normal TSH levels. After surgery, measurement of calcitonin levels should be delayed as the post-operative fall in levels may be delayed for up to 3 months.²⁷ All patients with MTC require life-long review, and regular monitoring of calcitonin and CEA. Patients with MEN 2 require multidisciplinary follow-up (endocrinology/oncology/surgery) to diagnose, treat and monitor the other components of their syndrome.

PERSISTENT/RECURRENT HYPERCALCAEMIA AND RECURRENT MTC

Historically, patients have undergone less than optimal initial surgery, approximately 50% of patients having less than treatment guidelines recommend. Surgical treatment that is compliant with recognized guidelines is said to result in fewer reoperations and more biochemical cure.²⁸

Residual/recurrent disease is diagnosed on the basis of clinical symptoms, signs or an elevated/rising calcitonin or CEA. Locoregional and distant metastases from MTC occur preferentially within the first 5 years.

When a patient presents with persistent or recurrent hypercalcaemia, there are three key issues for the surgeon:

- Was the initial surgery less than that recommended according to best practice?
- Is the source of calcitonin in the neck (residual thyroid or lymph nodes) or mediastinum and amenable to further surgery?
- Will further surgery result in cure or improved survival?

The fundamental issue is whether residual disease lies within the neck and is remediable by surgery. Reoperation in selected patients can result in normalization of calcitonin in up to 44% of cases. Biochemical cure is most likely to occur in those patients who have previously undergone inadequate first-time surgery and have serum calcitonin ≤1000 pg/ml or five or fewer nodes removed at previous surgery.²⁹

Radiographic evidence of recurrent disease is unlikely when the calcitonin level is at or below 250 pg/mL.²³ In the ‘absence’ of metastases and when first-time neck surgery was less than adequate, reoperation should be considered for what is persistent disease. This will usually require compartment-orientated cervical node dissection. When localization studies identify recurrent locoregional disease after appropriate first-time surgery, reoperative surgery should also be performed. The presence of distant disease should not in isolation preclude surgery. The aim of surgery is not only to cure or significantly reduce disease bulk or symptoms but also to relieve or prevent future compression of the airway and oesophagus as well as involvement of the brachial plexus or recurrent laryngeal nerves.

LOCALIZATION OF PERSISTENT/ RECURRENT MTC

Diagnostic imaging studies in patients with persistent/recurrent hypercalcaemia are used to identify surgically remediable locoregional disease that may put the patient at risk of airway or oesophageal compression. They also provide baseline criteria to facilitate entry of patients into clinical trials, and measurement of responses to systemic therapy.

In patients with elevated calcitonin levels following thyroidectomy, metastases are best detected when serum calcitonin levels are greater than 800 pg/mL. The most efficient detection of metastatic MTC consists of neck ultrasound, chest CT, liver MRI, bone scintigraphy and axial skeleton MRI.³⁰ FDG PET/CT identifies residual/recurrent MTC in patients with progressive disease and suggests poor survival. F-DOPA PET/CT more accurately assesses the extent of residual MTC³¹ with sensitivity of 80%,³² but access to this latter scan is limited in the UK.

OUTCOME AND PROGNOSIS

Reported survival rates at 10 years range from 56%³³ to 96%²⁴ respectively. More than 50% of patients with sporadic MTC will die of their disease. Biochemical cure following surgery is associated with 97.7% survival at 10 years;³⁴ disease-specific survival for patients with micro MTC is reported as 96% at 10 years.³⁵ Children with medullary carcinoma thyroid have 5-year survival rates of 95%. Patients with advanced disease have a median survival of 8 years,³⁶ and a third of patients with systemic symptoms die within 5 years.³⁷

When post-thyroidectomy calcitonin/CEA levels are raised, measurement of doubling times at 6-month intervals predicts outcome. Post-treatment calcitonin/CEA doubling times of less than 1 year³⁸ or more than 2 years³⁹ correlate with worse and better outcomes respectively.

NON-SURGICAL TREATMENT OF MTC

Adjuvant radiotherapy

Adjuvant radiotherapy has been found to be independently associated with a decreased survival although its use is inevitably confined to those patients with a worse prognosis. External beam radiotherapy is reported to reduce local relapse in high-risk patients and in those presenting with more advanced disease. It has not been shown to produce a survival benefit. It should be considered in those patients at high risk of locoregional recurrence.

Targeted biological therapy

The rationale for the use of tyrosine kinase inhibitors arises from the knowledge that nearly all patients with genetically determined MTC and approximately 50% of patients with

sporadic MTC have germline or somatic *RET* mutations respectively. *RET* encodes a receptor for tyrosine kinase. Clinical benefit from treatment of patients with symptomatic progressive/metastatic MTC with Vandetanib and Cabozantinib is seen in more than half the patients, but toxicity is considerable and side effects common.⁴⁰

Diarrhoea can be an extremely distressing symptom of widespread metastatic MTC and is often resistant to treatment with antimotility drugs. Somatostatin analogues may reduce symptoms, and chemoembolization of liver metastases may be effective.⁴¹

PROPHYLACTIC SURGERY FOR HEREDITARY MTC

Children and adolescents identified by *RET* screening to be at risk for the development of medullary thyroid cancer can be treated with prophylactic thyroidectomy before developing the disease. The timing of the intervention and the extent of surgery should be based on the affected codon, the age of the patient and the calcitonin level. Gene carriers with serum calcitonin less than 60 pg/mL who have undergone surgery appear to have intra-thyroidal MTC without evidence of nodal spread.⁴²

The timing of thyroidectomy

Children with *RET* codon 918, 883, mutations (MEN 2B) have the **highest** risk from aggressive MTC – neoplastic transformation of C-cells occurs in the first year of life. Prophylactic thyroidectomy should be performed within the first year of life, preferably in the first 6 months.

Children with a *RET* codon 634 mutation have a **high** risk for MTC – neoplastic transformation of C-cells occurs in the first decade. Prophylactic thyroidectomy should be performed at 5 years of age, or earlier if the calcitonin level is elevated above 40 pg/mL.¹³

Children with other *RET* codon mutations are now recommended to undergo 6-monthly clinical examination, and measurement of serum calcitonin around the age of 5 years. With parents involved in decision-making, thyroidectomy may be delayed until later in childhood or the teenage years if calcitonin levels do not rise above the normal range. Although some national guidelines recommend the use of neck ultrasound in assessment of at-risk patients, it appears to be ineffective in identifying MTC in this patient group.⁴³

The need for and timing of lymph node surgery

In ideal circumstances, risk reduction surgery – total thyroidectomy – should be performed before the onset of MTC thereby reducing the need for lymph node dissection, which is associated in children with an increased risk of hypoparathyroidism and recurrent laryngeal nerve injury. In reality, cases often manifest when it is likely or evident that MTC is already present and occult lymph node metastasis may have occurred.

It has been suggested that children from known kindred with highest-risk mutations (918, 883) should be considered for lymph node dissection at the time of prophylactic thyroidectomy in the first year of life. Because the risk of post-operative hypoparathyroidism is so high in these children, if parathyroid glands cannot be identified or preserved at surgery, it may be appropriate to avoid node dissection.

Children with MEN 2A with a mutation of codon 634 should undergo central neck dissection at the time of prophylactic thyroidectomy if the calcitonin level is greater than 40 pg/ml or when there is evidence of node metastasis on imaging.

KEY POINTS

- Care for adult and paediatric MTC patients should be provided in a tertiary centre and treated according to the recommendations of the specialist MDT.
- All patients with MTC should be offered *RET* gene mutation analysis. If the patient is confirmed to have genetically determined disease, first-degree relatives should be offered genetic screening.
- Risk reduction/prophylactic surgery should be offered to gene carriers prior to the onset of malignant disease.
- All patients with proven or suspected MTC must have undergone biochemical testing to exclude pheochromocytoma prior to neck surgery.
- Patients with MTC and an elevated basal calcitonin should undergo a minimum of total thyroidectomy and central neck lymph node dissection.

Introduction	765	Lymphomas	768
Anaplastic thyroid cancer	765	References	771

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: anaplastic thyroid cancer and thyroid lymphoma.

INTRODUCTION

Apart from both being malignancies of the thyroid gland, the other similarity between anaplastic thyroid cancer and thyroid lymphoma is that for the majority of cases the role of surgery is limited to diagnosis and maintaining an airway. The majority of anaplastic thyroid cancer is advanced at presentation, either locally or distantly or both, and complete resection is rarely possible. In the majority of thyroid lymphomas with the exception of limited stage IE mucosa-associated lymphoid tissue (MALT) surgery is not curative and radiation with or without chemotherapy is the optimal treatment.

ANAPLASTIC THYROID CANCER

Anaplastic thyroid carcinoma (ATC) is at the extreme end of a continuum of dedifferentiation of follicular adenomas and differentiated thyroid cancer (DTC). In contrast to DTC, however, it occurs in older patients (median age 65). The female:male ratio (3:2) still is in favour of female patients but it is relatively more common than DTC in men. Unlike DTC and thyroid lymphoma it is a highly fatal cancer with a median survival of only 3–5 months. Given the appalling survival after diagnosis of the majority of patients with ATC, it is essential in any discussion of treatment that the potential risks and side effects of any treatment are discussed along with a discussion of best supportive care. Fortunately, ATC is

rare in the US, accounting for less than 2% of all thyroid cancers.¹⁻²

Patients usually present with rapid onset of locoregional symptoms in the background of a pre-existing thyroid goitre or mass. In a large review of over 3000 patients an enlarging neck mass occurred in 86%, also change in voice, swallowing and breathing in about a third of patients for each symptom.¹ Local pain was less common (approximately 15%). Extrathyroid extension is usual, local invasion occurring in up to 90% of cases and distant metastases are identified at presentation in 30–50%. Although the lung is the commonest site of metastasis (35%), metastases can occur in any part of the body. Given the aggressive nature of ATC, the UICC/AJCC staging is unique in that all patients are staged as stage IV: Stage IVa (confined to the thyroid), stage IVb (extrathyroid extension) and stage IVc (distant metastatic disease).³ Along with extent of local invasion and presence of metastases, male gender, age above 60 and size of the primary (>5–7 cm) are associated with poorer survival.^{2,4,5}

Imaging for staging should consist of CT head and neck, chest and abdomen and, when available, fluorine-18-labelled deoxyglucose positron emission tomography (FDG-PET) to assess local and distant disease. USS and MRI of the neck and a bone scan may also be of value.⁶ As a third of patients have a change in voice at presentation, assessment of vocal cord function, airway adequacy and intraluminal extension of tumour into the trachea, preferably by fibre-optic endoscopy, is essential. Once initial investigations are complete, stage of the tumour has been assessed and potential surgical

resectability has been determined, the options of treatment which require a multidisciplinary approach with surgical, medical oncology, and radiation oncology opinions along with best supporting care can be discussed with the patient and family.⁷

The morphological appearance of ATC can be very varied but spindle cells are the commonest, and giant cells and cells with squamoid differentiation can also occur. All, however, have numerous and often atypical mitoses.⁸ Extensive necrosis, sometimes with inflammatory infiltrates, is common. The pathogenesis from differentiated thyroid cancer is shown in that 20% or more can coexist with areas of DTC. Surgical resection with negative margins and consequently survival is more likely in cases where ATC is only a small component.⁹ A fine-needle aspiration may be diagnostic but often a core biopsy is required.

Treatment

See [Figure 64.1](#).

SURGERY FOR POTENTIALLY RESECTABLE LOCOREGIONAL DISEASE

No more than 10% of patients have ATC confined to the thyroid; of these, ATC may be found incidentally.⁹ In the majority of other patients, an assessment by an experienced surgeon is essential to assess whether a resection with either negative (R0) or microscopic margins (R1) is possible. In the recent guidelines on the management of ATC by the American Thyroid Association it was clearly stated that: ‘Gross tumor resection, not debulking, is the goal of surgery.’⁷ If the tumour is resectable, a total or near-total thyroidectomy with central and lateral lymph node dissection should probably be performed. Survival for patients with an R0 or R1 resection can result in long-term survival. However, it is important to balance the aggressiveness of the surgery with the quality of life and prognosis of a patient with ATC. An R0 or R1 resection should be performed only if surgical morbidity is minimal. Ablative surgery such as a total laryngectomy should be avoided.^{7, 10} A tracheostomy, however, may be required if the patient is in acute airway distress or stridor.

ADJUVANT THERAPY

Following a successful resection, adjuvant therapy should be considered along the lines described below for unresectable ATC. Although there are no randomized controlled studies in the management of ATC, two population-based studies support the use of multimodality therapy and suggest that survival is improved. A large Surveillance, Epidemiology, and End Results (SEER)-based study of 516 patients found in a multivariate analysis that surgery combined with external beam radiotherapy (EBRT) was an independent predictor of survival.¹¹ In a smaller study from British Columbia, survival was better in patients who had more extensive surgery and had high-dose radiation with or without chemotherapy.¹² That these were

population-based studies is important: a number of single institutional studies also support the use of multimodality therapy compared to mono therapy but they are all subject to bias as there is always an element of case selection with patients with less extensive disease, young age and better performance status potentially receiving more aggressive therapy.^{9, 13–17}

The role of additional therapy after resection of an incidental ATC is uncertain. The ATA working group did not come to a consensus on whether to advise additional therapy in this situation. The role for neoadjuvant therapy for patients with unresectable disease is also uncertain. Although there have been a few reports recommending neoadjuvant therapy, the majority of patients remain unresectable. Rather than planned neoadjuvant therapy, the ATA guidelines recommend combined modality therapy for unresectable disease and, if the disease response is durable and distant metastases do not develop, then consideration of surgical resection.^{7, 18–20}

UNRESECTABLE LOCOREGIONAL DISEASE

Data on outcome when a resection is not possible are mainly from single institutional reports and again subject to case selection bias, but patients with good performance status with no evidence of metastatic disease appear to have a better outcome following high-dose radiation with or without chemotherapy.¹⁴ A response rate of 80% to radiation alone has been reported with suggestion of a dose response with higher doses resulting in a trend to improved survival but not tumour response.²¹ To overcome the rapid growth rate of ATC and potential for tumour cell repopulation after radiation has commenced, the radiation may be hyperfractionated and accelerated with two fractions given a day, so that the overall treatment time is reduced. In addition, chemotherapy may be given concurrently in an attempt at radiation sensitization.²² The most frequently prescribed chemotherapy agent in the past was doxorubicin. In a multimodality approach combining mostly doxorubicin with hyperfractionated radiation, a local control rate of 60% has been reported, but the 2-year survival rate was only 9%.²³ In contrast, the Mayo Clinic experience found no benefit in median survival, although more survived to 1 year (23%) when chemotherapy + radiation was compared with radiation alone (10%).²⁴

Several more recent reports of other agents that are better established as head and neck cancer radiosensitization (cisplatin and taxanes) have suggested encouraging results with concurrent chemoradiation. In a report on 6 patients treated with intensity-modulated radiation therapy (IMRT) and docetaxel all patients had at least a partial response and 4 had a complete response.²⁵ In another report on 10 patients, 5 were alive and free from disease at 32 months with a median survival of 60 months. However, due to either metastatic disease or patient preference, only 10 out of 25 patients with ATC were treated on the protocol.²⁶ In a report of hyperfractionated radiation without chemotherapy the median survival was greater than with

conventional therapy (13.6 vs 10.3 months).²² In contrast in another study, however, a hyperfractionated accelerated protocol with larger fraction size, no survival advantage was reported but there was significant toxicity.²⁷

Typical radiation doses would be hyperfractionated 60–70 Gy in 40–45 fractions over 4–5 weeks or daily fractions such as 60–70 Gy in 30–35 fractions.

Most of the newer studies combining radiation and chemotherapy utilize IMRT. With this technique it is

possible to generate concave dose distributions and narrow margined dose gradients so that normal structures can be spared while complex volumes are treated.^{17, 28, 29} Despite modern radiation techniques, the toxicity from hyperfractionated radiation or concurrent chemoradiation can be significant and enteral nutrition with a feeding tube and growth factor support may be required, especially if large tumour volumes are treated. There has been no comparison of altered fractionation alone

Figure 64.1 Anaplastic thyroid cancer. A 68-year-old man who had a long-standing history of a thyroid nodule that had increased in size. Fine-needle aspiration showed large and spindle cells and necrosis diagnostic of anaplastic thyroid. **(a)** Axial CT scans of his head and neck showed a 4 cm mass. There was no evidence of local invasion or lymph node involvement. **(b)** A PET scan showed uptake at the site of the lesion and nowhere else. He underwent surgical resection. Pathology revealed a 4 cm widely invasive anaplastic thyroid carcinoma. The tumour arose from a well-differentiated papillary carcinoma showing tall cell change but 70% of the total tumour volume was anaplastic carcinoma. There was extensive perineural invasion, and focal angioinvasion. The tumour infiltrated extrathyroidal skeletal muscle. **(c)** He received post-operative radiation therapy using an IMRT technique: 60 Gy in 40 fractions twice daily over 4 weeks was given to the post-operative site and concurrent 44 Gy in 40 fractions to the rest of the thyroid bed and adjacent nodal areas. **(d)** Within 2 months of completing his radiation he developed lung metastases which have progressed on paclitaxel.

compared to chemoradiation with standard or hyperfractionated radiation and the potential benefits remain unanswered especially when more aggressive therapy is associated with increased toxicity.³⁰

There is no consensus whether there is any benefit in high-dose radiation with or without concurrent chemotherapy in patients with limited metastatic disease and otherwise good performance status, but it has been recommended in selected highly motivated patients.^{7, 31} For patients of poor performance status who decline or who would not tolerate high-dose radiation, low-dose radiation may be of palliative benefit in controlling pain and possibly obstructive symptoms.²¹ As noted earlier, radiation can result in an 80% response rate and, although higher doses of radiation resulted in improved survival, the response rate was no better. Palliative doses such as 20 Gy in five fractions (which may be repeated 4–6 weeks later) or 30 Gy in ten fractions may be of benefit in these patients.

METASTATIC DISEASE

In the presence of metastatic ATC, life expectancy is poor and therefore maintaining a good quality of life for as long as possible is imperative. Short 1–2-week courses of radiation as described above may control local symptoms. Unfortunately, ATC is not a chemosensitive disease and the response rates to systemic therapy are generally poor and short-lived. Currently, of the available chemotherapeutic agents the taxanes (paclitaxel or docetaxel), doxorubicin and cisplatin have the greatest clinical effect. Docetaxel (60 mg/m² i.v. every 3 weeks) can stabilize disease for a time and rarely results in a complete response.²⁵ There are several small reports on the use of molecular targeted agents. Antimicrotubular agents and kinase inhibitors occasionally result in a partial response or stable disease but more research is required.^{2, 7, 32} Palliative radiation may be required for bone and lung metastases.³³

KEY POINTS

ANAPLASTIC THYROID CARCINOMA

- Uncommon
- Poor survival (median 3–5 months)
- Best if incidental or R0 resection possible
- Often disseminated at diagnosis
- The role of surgery is for:
 - diagnosis
 - secure airway
 - resect to R0 or R1 if possible
- Local regional control important
- Multimodality treatment: surgery, radiation, chemotherapy
- Not chemosensitive but taxanes and molecular targeted agents show some promise
- Quality of life and palliative care are important
- Treatment guidelines:
 - American Thyroid Association – comprehensive
 - National Comprehensive Cancer Network – limited
 - European Thyroid Association – very limited

LYMPHOMAS

The management of non-Hodgkin lymphoma (NHL) in the thyroid gland is primarily influenced by the acuteness of the presentation, histology and the Ann Arbor stage.⁶ A thyroid presentation occurs in only 1–2% of all patients diagnosed with lymphoma, and these are usually in stage IE (when the thyroid gland alone is involved) or stage IIE (when the cervical or superior mediastinum lymph nodes are involved additionally). The ‘E’ designations indicate that an extranodal organ (the thyroid gland) is involved as a primary site. The principle role for surgery is to establish the diagnosis of lymphoma³⁴ and to ensure a stable airway since thyroid lymphomas often present with a bulky mass with significant compression of the upper aerodigestive tract. A tracheostomy (temporary) may sometimes be necessary for tracheal lumen compromise if the patient presents with stridor. While fine-needle aspirate (FNA) may suggest lymphoma, it may be inadequate for subtyping the histology, in which case either core-needle biopsy or an open biopsy will be required. Optimal pathology interpretation involves immunophenotypic and sometimes special molecular studies, which can be done on cytology specimens if there is good cell yield. Special fixative and fresh tissue are necessary and therefore specific protocols for tissue retrieval and processing are required. If the FNA biopsy is diagnostic and able to subtype the lymphoma accurately, the therapeutic role of surgery is limited³⁴ as most patients are treated with chemotherapy, radiation therapy, or a combination of the two. In most cases a philosophy of functional preservation is followed. The need for the use of chemotherapy and/or radiation therapy is generally not diminished following surgical excision of lymphoma, except in the case of MALT lymphoma where a thyroidectomy if performed may be considered curative if there has been a complete excision.³⁵ However, aggressive surgical approaches that compromise function, including neck dissection and cosmesis, should be avoided.

Staging investigations should include CT scans of neck, chest, abdomen and pelvis and a FDG-PET scan. Thyroid scintigraphy tests with radioactive iodine or ^{99m}Tc are generally unhelpful. Blood work including complete blood count, lactate dehydrogenase (LDH) (which as a tumour marker for lymphoma usually correlates with the disease burden), liver function tests and creatinine should be done. A bone marrow aspirate and biopsy is standard. Approximately 90% will be found to have localized (stage IE or stage IIE) disease.³⁶ Advanced stages (stages III–IV) of lymphoma where there is documented lymphoma outside the thyroid gland and cervical lymph nodes are treated primarily with chemotherapy and will not be discussed further here. In these situations the thyroid involvement is considered secondary spread as part of disseminated lymphoma. For stage I–II presentations in the thyroid, the curative treatment approach involves radiation alone,

or combined modality therapy with chemotherapy followed by consolidation radiation.

Indolent lymphoma

The most common indolent lymphomas in the thyroid are **MALT lymphomas** (also known as extranodal marginal zone lymphomas), with **follicular lymphomas** being second most common;^{36, 37} both are radiation-sensitive diseases. MALT lymphomas present with localized (stage IE–IIE) disease in 90% of cases,^{38, 39, 41} involving the thyroid gland as a nodule or mass, occasionally diffusely enlarging the thyroid gland, usually non-bulky (<5 cm). It is almost always associated with pre-existing Hashimoto's thyroiditis and occasionally other autoimmune diseases which are predisposing conditions to the development of MALT lymphomas.⁴¹ Cervical lymph nodes are involved in 20–30% of cases. Females are more commonly affected than males with a ratio of 3:1.³⁶

Stage I and stage II MALT or follicular lymphomas of the thyroid gland are treated with involved-site radiation therapy (RT), covering the thyroid site and the immediate drainage lymph node regions (zones 3, 4, 5 and 6). If a total thyroidectomy was performed and the MALT lymphoma was localized within the thyroid gland and has been completely excised, no further therapy may be required and the patient should be carefully followed.³⁵ Local treatment is therefore highly successful, resulting in an excellent local control rate exceeding 95% and long-term disease-free survival of >90% for MALT lymphoma,^{38, 39, 41, 42} and 50–60% for follicular lymphoma.^{44, 45} Because of exquisite radiation sensitivity, low to moderate doses (24–30 Gy, fractionated over 2–4 weeks) has been the standard approach.

Aggressive histology lymphoma

Thyroid lymphoma with aggressive histology is the most common, accounting for 65–70% of cases.^{36, 37, 45} It usually presents with a rapidly enlarging mass, sometimes growing to 10 cm or even larger when diagnosed. It can arise *de novo* or from pre-existing indolent lymphoma or Hashimoto's thyroiditis, recognized as histological transformation to aggressive disease with a poorer prognosis. There is a female predominance with typical presenting age of over 65 years.^{37, 46} Cervical lymph nodes are commonly involved (20–50%).^{45, 46} The most frequent histology is diffuse large B-cell lymphoma (DLBCL)³⁷ (Figure 64.2) for which standard therapy has been well established based on phase III clinical trials. Other types of aggressive lymphomas (e.g. T-cell lymphomas) rarely present in the thyroid and the management is based on a

similar philosophy of treatment with combined modality therapy (CMT) and functional preservation.

Despite a presentation at an early stage (IE–IIE), the recognition of the high risk for occult systemic disease mandates the use of systemic immunochemotherapy to achieve the best cure rates.^{37, 45, 46} Patients are treated with CMT, typically the CHOP-R regimen (cyclophosphamide, doxorubicin, vincristine, prednisone and rituximab), with chemotherapy first for 3–6 cycles, followed by moderate dose radiation (30–40 Gy) 3–6 weeks later. In general, a cure rate ranging from 70–85% is achieved, depending on age, tumour burden and other prognostic factors such as performance status and LDH level.^{46, 47} For the typical B-cell lymphomas, the addition of immunotherapy with anti-CD20 antibody (rituximab) in combination with chemotherapy improves the clinical outcome compared with CHOP alone^{48–50} and is considered the standard approach. Because of the moderate radiation doses required (30–40 Gy), short-term toxicity is mild and serious long-term toxicity is rare, particularly with IMRT, with improved ability to further reduce the dose to uninvolved normal tissues. For stage IE patients treated with CMT, the radiation volume can be limited to the primary thyroid disease site, without intentional coverage of the drainage lymph nodes. For stage IIE patients, the coverage should include the thyroid site and the immediate drainage lymph node regions (typically bilateral zones 3, 4, 5 and 6).

Toxicity of treatment

When chemotherapy is required, the principle toxicities depend on the drugs used. For the CHOP-R regimen, the most common toxicities include nausea and vomiting, fatigue, alopecia, mucositis, myelosuppression, increased risk of infections and bleeding, neuropathy (vincristine), infusion-related reactions (rituximab) and prednisone-related side effects. More serious toxicities, such as cardiac failure, are fortunately rare. Standard management protocols including use of pre-medication, cardiac ejection fraction assessment and monitoring, and use of growth factor support minimizes these risks.

The toxicities of radiation therapy are moderate and significantly less severe than for treatments given for thyroid cancer, due to the lower total dose required for lymphoma. Short-term toxicity is mild and serious long-term toxicity is rare in virtually all head and neck tissues irradiated in the lower neck area. Xerostomia is not expected since the treated volume is generally below the level of the salivary glands. There is a significant risk of radiation-induced hypothyroidism (30% risk for a dose of 30–40 Gy).

Figure 64.2 Lymphoma. An 82-year-old woman with a rapidly enlarging thyroid mass, with biopsy (right hemithyroidectomy) showing diffuse large B-cell lymphoma. There was significant residual disease involving the left lobe of the gland, right paratracheal area, and also lymphadenopathy in the left neck. Stage IIAE. Pre-treatment CT scans: **(a)** axial; **(b)** coronal. Treatment was with combined chemotherapy and radiation (CHOP-R \times 6 cycles and 35 Gy) with curative intent. There was complete resolution of the disease 2 years post therapy. Post-treatment CT scans: **(c)** axial; **(d)** coronal.

KEY POINTS

Primary thyroid lymphomas

- Uncommon
- Usually localized
- The role of surgery is for:
 - diagnosis
 - secure airway
- Almost always B-cell lymphomas
- The MALT-type lymphoma has a high cure rate (>90%) with local therapy (surgery or radiation)
- Diffuse large B-cell lymphoma requires combined chemotherapy and radiation with long-term cure in 75% of patients

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: thyroid cancer, recurrence, papillary thyroid cancer and follicular thyroid cancer.

INTRODUCTION

As differentiated thyroid cancer (DTC) becomes increasingly common, so does the challenge of managing patients with post-treatment evidence of recurrent disease. The appropriate management of such patients requires an understanding of the biology of DTC and the concept of recurrence versus persistent disease. Clinicians must also recognize the high potential for morbidity from salvage therapy and balance that against the benefit likely to be gained by their patients. In this chapter we will discuss recurrent DTC and outline an approach to management of this complex problem. The discussion will be limited to the surgical management of locoregional recurrence as systemic therapies for disseminated disease are discussed elsewhere.

RISK GROUP STRATIFICATION

Initial risk stratification systems for differentiated thyroid cancer focused on mortality.¹⁻³ Using these systems, patients can be classified as low, intermediate or high risk of death from disease. However, the majority of patients

will fall into the low- and intermediate-risk groups with few fatalities. In 2009 the American Thyroid Association (ATA) recognized the importance of risk group stratification in recurrence prediction.⁴ They published a system which again stratified patients in to low, intermediate and high risk of recurrence ([Table 65.1](#)).

Initial disease extent and the extent of primary surgical resection are important predictors of locoregional recurrence.⁵ Those patients with advanced local disease or bulky nodal metastases have higher rates of recurrence than those with smaller lesions. Patients who have gross disease following surgery are clearly at high risk of disease progression.

Specific factors associated with locoregional recurrence include macroscopic extrathyroid extension, multiple or large volume nodal metastases, locally invasive disease and aggressive histological subtypes (insular, tall cell or poorly differentiated carcinoma). Other factors which can also predict poor outcome include advanced age, the presence of *BRAF* mutations and Tg doubling time.

A recent publication from the ATA recognized the importance of the status of the neck in predicting locoregional recurrence.⁶ This work, which summarized the

TABLE 65.1 American Thyroid Association risk of recurrence stratification

	Regional metastases	Distant metastases	Extrathyroid extension	Surgical resection	Aggressive pathology	RAI uptake outside thyroid bed	
Low risk	Absent	Absent	Absent	Complete	Absent	Absent	Only low risk if all are true
Intermediate risk	Present	Absent	Microscopic	Complete	Present	Present	Intermediate or high risk if any are true
High risk		Present	Macroscopic	Incomplete			

TABLE 65.2 Level of risk associated with specific nodal metastatic features in papillary thyroid cancer (adapted from Randolph et al⁶)

	Descriptor	Locoregional recurrence rate
Clinically N0 (cN0)	All patients	6%
	Young patients*	0%
	Older patients *	9%
Clinical N1 (cN1)	All patients	13–30%
	All patients*	19–42%
Pathological N1 (pN1)	All patients	7–14%
	All patients*	13%
Specific pN1 descriptors	<5 positive lymph nodes	3%
	>5 positive lymph nodes	19%
	>10 positive lymph nodes	21%
	Extranodal extension	15%

* Denotes that papillary micro carcinomas were excluded from these cohorts.

available literature at the time, demonstrated the importance of size and number of nodal metastases as well as the significance of extranodal extension (Table 65.2).

DEFINITION OF RECURRENCE IN DIFFERENTIATED THYROID CANCER

The approach to managing DTC has become increasingly standardized over the past 50 years.^{4, 7–11} Recognition of the relatively indolent biology of the disease and the role of therapy has led to well-defined international treatment guidelines. However, over the same time period a significant change has taken place in relation to recurrent disease.

In the mid-20th century, clinicians followed their patients with clinical examination including palpation of the neck and visualization of the larynx. Investigations including chest X-rays would soon be surpassed by more advanced imaging including computed tomography (CT) scanning, magnetic resonance imaging (MRI) and ultrasound. Further progress with ever-improving imaging, particularly with the widespread adoption of high-resolution ultrasound, allowed clinicians to subject the central and lateral neck to increasing levels of scrutiny following initial therapy.

During the same period the introduction of serum thyroglobulin (Tg) measurement allowed a biochemical assessment of residual or recurrent tissue of thyroid origin. Improvements in the sensitivity of Tg assays have now allowed the detection of recurrence which is of such small volume that even the most advanced imaging systems cannot identify structural disease. In addition to measuring Tg in patients' serum, when structurally suspicious nodal disease is targeted for biopsy, cytology can be supported with thyroglobulin measurements in fine-needle aspiration biopsy specimens in order to confirm metastatic thyroid cancer.¹²

While our ability to identify biochemical and structural evidence of recurrent disease has improved, so too has our understanding of the biology of DTC. The majority of patients with DTC will have papillary thyroid cancer (PTC). This malignancy has a behaviour which does not conform to that of other head and neck malignancies. Groups who routinely dissect the regional lymph nodes in PTC report high rates (up to 40%) of histologically demonstrable metastatic lymph nodes, despite a lack of pre-operatively identifiable disease.¹³ The more scrutiny such nodal dissections are subjected to, the higher the rate of demonstrable metastasis, with one group showing over 50% of nodal specimens to contain evidence of thyroid tissue in resected lymph node specimens by immunohistochemistry when conventional staining showed no evidence of thyroid cells.¹⁴

Unlike squamous cell carcinoma, however, where the presence of regional lymph node metastases is associated with a halving of survival, the impact of subclinical metastases in PTC has little impact on survival.⁶ Indeed, the impact on recurrence has also been questioned.^{15,16} So small is the perceived impact of occult nodal disease that no major international guideline now supports prophylactic lateral neck dissection in DTC and the tide is turning away from prophylactic central neck dissection also except in high-risk patients.^{7,17}

In understanding recurrent DTC, therefore, the clinician must appreciate some critical distinctions. Structural recurrence which can be suspected based on clinical examination or imaging studies and supported by cytological sampling must be distinguished from biochemical recurrence alone. In addition, when disease is identified following initial therapy, a distinction must be drawn between likely persistent disease in the nodes of an untreated neck and truly recurrent disease which presents within the previously operated field. It should also be recognized that, when unresectable disease is identified either pre-operatively or following surgical exploration, progression of disease in that site presents another separate challenge for the disease management team.

Most recurrences are now detected by biochemical evaluation and/or ultrasound screening. Following initial therapy, a rising Tg tends to be an indication of recurrence which is generally in the lymph nodes of the neck. Although cross-sectional imaging and radioactive iodine (RAI) scans can be used to detect structural recurrence, ultrasound is usually the most convenient modality to assess the regional lymphatics. Positron emission tomography (PET) scanning can be useful, particularly for dedifferentiating cancers which lose their radioactive iodine avidity. Such PET-positive, RAI-negative disease is more aggressive and associated with poor outcome. An outline for considering recurrent thyroid cancer is provided in [Table 65.3](#).

MANAGEMENT OF RECURRENCE

The goals of managing recurrent disease in thyroid cancer should be considered prior to embarking on a course of management. The ultimate goals include removing recurrent disease and preventing further recurrence.¹⁸ When considering these aims, one must also consider the goal of minimizing morbidity and negatively affecting a patient's quality of life. Indeed, if the decision is made to observe potentially recurrent disease, the goal

of management is to prevent disease progression, with a particular focus on invasion of critical structures during follow-up.

Disease recurrence in the central neck may involve the nodal tissue, the thyroid bed or both. Local, thyroid bed recurrence is rare but, when it occurs, the anatomical location of disease presents a significant challenge in terms of surgical resection. Involvement of the recurrent laryngeal nerve (RLN) may be a presenting feature of the recurrence, and invasion of the larynx or trachea should be suspected based upon the relationship between the airway and the site of disease. Airway involvement can be categorized as by Shin et al. into tumour adherent to the perichondrium (stage 1), invading cartilage (stage 2), involving submucosa (stage 3) or involving mucosa (stage 4) ([Figure 65.1](#)).¹⁹

Pre-operative assessment of the airway is critical in managing thyroid cancer recurrence, particularly with regard to assessment of the function of the RLNs. If a tumour involves the oesophagus, unlike in primary disease where a plane can often be dissected between muscle and mucosa, scarring may require full-thickness oesophageal resection which will then mandate appropriate reconstruction with free tissue transfer or gastric pull-up. Following surgery, external beam radiotherapy should be considered as an adjunct as it has been shown to improve rates of local control in patients demonstrating gross extrathyroidal extension.²⁰⁻²³

A contrast should be made between visceral and nodal recurrence in the neck. Isolated nodal recurrence which does not involve the laryngopharyngeal complex should be carefully assessed prior to deciding to operate. Again the function of the RLNs, the size of the lesion and its

Figure 65.1 Shin classification of airway involvement with thyroid cancer.

TABLE 65.3 Types of differentiated thyroid cancer recurrence

Central compartment		Lateral neck		Distant
Thyroid bed	Central compartment lymph nodes	Levels I–V	Retropharyngeal and parapharyngeal nodes	Pulmonary > non-pulmonary metastases
Recurrence involving visceral structures	(Levels VI and VII)			

precise anatomical location should be determined. Small-volume nodal tissue which is distant from the nerve and airway may be safely followed. In contrast, rapidly enlarging nodes or disease in close proximity to the central neck viscera should be treated more aggressively in order to prevent extension into vital structures.

A compartment-orientated approach to a previously unoperated nodal field harbouring recurrence includes a level II–V selective neck dissection for lateral neck disease and levels VI–VII for central neck disease. However, for recurrence within an operated field, such an approach is likely to be associated with high morbidity and a more targeted approach may be reasonable.

Evidence relating to oncological outcomes following surgical therapy for recurrent DTC suggests that a significant number of patients can be ‘cured’. However, the literature is difficult to interpret due to differences in definitions of cure (biochemical versus structural), the inclusion of patients of various risk groups in different studies and the differences in duration of follow-up. Nonetheless, groups report success rates of 25–90% of appropriately selected patients.^{24–30}

For example, research from MD Anderson Cancer Center, USA, found that, of 210 patients with recurrent or persistent PTC who underwent comprehensive central compartment dissection, 71% of pre-operatively Tg positive had no evidence of post-operative disease and 66% had no measurable Tg at last follow-up (median 7.25 years). Those patients who did suffer recurrence were able to be surgically salvaged giving an overall 98% central compartment control rate and 10-year disease-specific survival of 99% for young patients and 78% for older patients. In this surgical series from a tertiary referral cancer centre the rate of hypoparathyroidism was 1% and new RLN palsy was encountered in 2%.²⁷

A group from Ohio State University reported outcomes of 95 patients with recurrent or persistent PTC. They found that 27% of patients achieved a biochemical complete response following lymphadenectomy and 42% achieved a stimulated Tg of <2.0 ng/mL. Even those who did not achieve a complete response did have a significant reduction in Tg following initial and, if required, subsequent surgeries. None of these patients developed distant metastases or died of disease.²⁸

It should be noted, though, that the senior authors of such publications are experienced, high-volume surgeons often working in tertiary referral centres. Such outcomes are unlikely to be achieved in less experienced hands.

Traditional surgical therapy has been the standard of care for structural disease following initial therapy in DTC. However, some groups have adopted an alternative approach including both ethanol and radiofrequency ablation of small-volume recurrences with apparently high rates of success. Although not widely practised, these treatment modalities are particularly attractive for low-risk patients with small nodes in a site amenable to a percutaneous approach.^{31–34}

EVALUATION OF THYROGLOBULIN LEVEL

The introduction of routine Tg monitoring following treatment for DTC has resulted in a paradigm shift in such patients’ management. Small-volume recurrences can now be identified prior to the development of structural disease. The identification of a rising Tg should prompt further imaging. In most circumstances, persistent disease is in the neck and ultrasonography will be the initial imaging modality of choice. If significant structural disease is encountered, surgical excision should be recommended.

If small-volume (<8 mm) suspicious nodes are identified, clinicians should proceed with caution. When one study observed 166 low-risk patients with abnormal lateral neck nodes, only 20% of patients demonstrated progression and 14% regressed.³⁵ Assessment of the potential disease extent and relationship to critical structures should guide further management in this situation. Small-volume nodes which are distant from the RLN may safely be monitored without the need for biopsy or intervention. If a decision is made to pursue such small-volume disease, even in experienced hands, identification of the nodes in question can be challenging and techniques such as charcoal tattooing and intra-operative ultrasound should be considered to aid localization.

When a rising Tg is encountered in the absence of any evidence of structural disease on imaging, surgery is not indicated. The role of RAI in this situation is controversial with some advocating empirical treatment in an attempt to address occult micrometastases. In general, however, this approach is not supported.³⁶

COMPLICATIONS OF TREATMENTS

Rates of complication in the setting of revision surgery, particularly in a previously operated field, are higher than those following initial therapy.³⁷ Although common complications include injury to the RLN and temporary or permanent hypoparathyroidism when re-entering the central neck, revision lateral neck surgery is also associated with high rates of injury to the accessory nerve, the lower division of the facial nerve or the sympathetic trunk. Due to the relatively high rates of complication, the disease management team must develop a balanced approach and incorporate what they consider the best surgical intervention to control disease while minimizing rates of complication.

PRACTICAL TIPS IN THE MANAGEMENT OF RECURRENT THYROID CANCER

The management of recurrent thyroid cancer is complex and surgical intervention may be difficult due to

involvement or proximity of the structures in the central compartment. Thorough evaluation with cross-sectional imaging is very important. The decision about tracheal shave versus sleeve-resection of the trachea will directly depend on the tracheal involvement by recurrent tumour. A majority of the tumours can be easily shaved off the trachea, unless there is a direct submucosal or intra-luminal extension of the disease. The surgeon should be prepared to make these complex decisions intra-operatively for the best oncologic resection of the recurrent tumour.

The nodal recurrence in the central compartment and at level IV may be also a complex surgical undertaking, primarily related to complications of nerve injury and hypoparathyroidism. The operating surgeon should evaluate the extent of the disease and be prepared to manage the patient with a multidisciplinary approach. These patients will require lifetime follow-up.

A sub-centimetre recurrent tumour may be difficult to find and may present a higher risk of injuring the nerve. Generally these patients are secondary references to a cancer centre and involvement of the surgeon, endocrinologist and the multidisciplinary team is very critical. Patients should be warned of the complications of the surgical

procedure and the appropriate decision-making should be undertaken for the best form of treatment. Patients should be informed that the thyroglobulin level may not be normalized after the surgery, or they may recur in the future, either in the same neck, quadrilateral neck or in the superior mediastinum. It is very important to have a best understanding with the patient, their family and the treating physicians. The first principal of surgery should be maintained – *Primum non nocere* – first do no harm.

CONCLUSION

Patients with recurrent differentiated thyroid cancer truly require multidisciplinary team management. Not only a surgeon and endocrinologist but nuclear medicine physician, radiologist, pathologist, cytologist and even oncologist must collaborate for optimal evaluation and overall control of disease. By balancing the risks of treatment against the chance of successful outcome, the disease management team must consider options from observation through limited resection to aggressive surgical therapy on a case-by-case basis.

KEY POINTS

- Recurrent thyroid cancer may be biochemical or structural.
- Careful assessment of recurrence should include cross-sectional imaging and endoscopy.
- Small volume nodal recurrence in areas without critical structures may be suitable for observation.
- Large-volume recurrence in high-risk areas (around the recurrent laryngeal nerve for example) should be managed surgically.
- The potential complications of revision surgery should be carefully weighed against the potential benefits on an individual patient basis.

DIFFERENTIATED THYROID CANCER

There is limited prospective randomized controlled data relating to the management of differentiated thyroid cancer (DTC) as it is an uncommon disease with a long natural history. Many areas of thyroid cancer management remain controversial, including the indications for ablation using radioactive iodine (RAI, also called radioiodine), the optimal administered activity of radioiodine, the degree and duration of thyroid-stimulating hormone (TSH) suppression, as well as indications for external beam radiotherapy and optimal timing for initiation of targeted therapies for the treatment of metastatic disease. The recommendations in this chapter reflect common UK practice and advice from the British Thyroid Association (BTA) and American Thyroid Association (ATA) guidelines.^{1,2}

¹³¹I treatment

Normal thyroid gland tissue and differentiated thyroid cancer can concentrate iodine from the circulation and ¹³¹I (an unsealed radionuclide of iodine) is taken up in the same way as stable iodine in the diet.

In practice, it is very difficult to achieve complete surgical ablation of the thyroid gland and some residual tissue, known as the thyroid remnant, is inevitably present. As a rule, normal thyroid tissue within the remnant

will preferentially take up the iodine compared to thyroid cancer tissue. Hence, if a large remnant is present post-operatively, the post-ablation whole-body radioiodine scan cannot be relied upon to exclude the presence of residual malignancy either locally in the neck or at distant sites as the iodine may be seen in the remnant only. Only when this remnant of normal thyroid tissue is ablated can you reliably expect to see any significant radioiodine uptake in regional and distant sites of differentiated thyroid cancer.

RADIOIODINE REMNANT ABLATION

Radioiodine uptake is usually seen in the thyroid bed following a total or near-total thyroidectomy. ¹³¹I destruction of this residual tissue is called radioiodine remnant ablation (RRA).

RRA aids the detection and earlier treatment of persistent/metastatic disease by destroying normal thyroid tissue; it may destroy microscopic foci of cancer in the thyroid remnant, and aids interpretation of serum thyroglobulin (Tg) measurements during follow-up. Remnant ablation may reduce local recurrence and increase survival,^{3,4} although not all reported series support these findings.⁵⁻⁸

It is important to individualize patient management and to use radioiodine selectively by allocating patients to a risk category post-operatively ([Table 66.1](#)).

TABLE 66.1 Post-operative risk stratification for risk of recurrence of DTC^a

Category of risk	Patient characteristics
Low risk	No local or distant metastases All macroscopic tumour has been resected, i.e. R0 or R1 resection No tumour invasion of locoregional tissues or structures The tumour does not have aggressive histology (tall cell, or columnar cell PTC, diffuse sclerosing PTC, poorly differentiated elements) or angioinvasion
Immediate risk	Microscopic invasion of tumour into the perithyroidal soft tissues (T3) at initial surgery Cervical lymph node metastases (N1a or N1b) Tumour with aggressive histology (tall cell, or columnar cell PTC, diffuse sclerosing PTC, poorly differentiated elements) or angioinvasion
High risk	Extrathyroidal invasion Incomplete macroscopic tumour resection (R2 resection) Distant metastases (M1)

The following is the British Thyroid Association's guidance on the indications for ¹³¹I ablation.¹

- **No indication for ¹³¹I ablation**
These patients are at low risk of recurrence or cancer-specific mortality.
 - Tumour <1 cm unifocal or multifocal, and on histology classical papillary or follicular variant or follicular minimally invasive without angioinvasion and no invasion of thyroid capsule.
- **Definite indications for ¹³¹I ablation**
 - Tumour >4 cm.
 - Any tumour size with gross extrathyroidal extension (pT4).
 - Distant metastases present.
- **Uncertain indications for ¹³¹I ablation**
Patients in this category may or may not derive a benefit from ablation. Factors that may influence the decision on whether to proceed include:
 - large tumour size
 - extrathyroidal extension
 - presence of unfavourable histological cell type (tall cell, or columnar cell papillary thyroid cancer (PTC), diffuse sclerosing PTC, poorly differentiated elements)
 - widely invasive histology
 - multiple metastatic lymph nodes
 - resected metastatic lymph nodes large in size, high ratio of positive to negative nodes, extracapsular nodal involvement.

HIGH VERSUS LOW ADMINISTERED ACTIVITY OF ¹³¹I FOR REMNANT ABLATION

Administered activities of ¹³¹I of 1.1 GBq or 3.7 GBq show similar rates of successful remnant ablation,^{10–13} although

there is a trend towards higher success rates with higher administered activities.

Results from two large multicentre randomized trials^{14, 15} have shown that 1.1 GBq of ¹³¹I was as effective as 3.7 GBq in ablating the thyroid remnant, while adverse events were fewer in the 1.1 GBq group. In these studies all patients had undergone total thyroidectomy and had an R0 (no microscopic residual disease) resection. Most patients were staged pT1 N0 and pT2 N0. One of the trials¹⁴ included patients with pT3 tumours, and patients with N1 disease, who were ablated successfully with 1.1 GBq. A recent meta-analysis found no difference in efficacy between 1.1 GBq and 3.7 GBq.¹⁶

¹³¹I ADMINISTRATION PROCEDURE

Those prescribing radionuclide therapies in the UK must hold an appropriate Administration of Radioactive Substances Advisory Committee (ARSAC) certificate and the treatment must be given in appropriately designed areas.

Radioiodine is administered orally. Although it is available in liquid or capsule formulations, the latter is the preferred format as it is easier and safer to handle.

For successful remnant ablation to be achieved, the TSH level prior to the isotope administration must be elevated to >25–30 mU/L. This stimulates the sodium iodide symporter (membrane protein involved in active transport) and hence radioiodine uptake into thyrocytes. This can be achieved in two ways.

- **Recombinant human TSH injections (rhTSH, Thyrogen™):** These can be administered as an exogenous source of TSH and allow the patient to continue with thyroid hormones throughout the radioisotope treatment period. The benefit with using rhTSH is the avoidance of potential significant physical and psychological symptoms of hypothyroidism resulting from thyroid hormone withdrawal.^{17, 18}
- **Thyroid hormone withdrawal:** If the period between surgery and RRA is expected to be longer than 4 weeks, patients should be commenced on thyroid hormone replacement. If liothyronine is commenced (usual dose 20 mcg tds), this should be withdrawn 14 days prior to radioactive iodine treatment. If levothyroxine is used, it should be substituted with liothyronine starting 28 days prior to radioactive iodine treatment and this is then stopped for the last 14 days prior to treatment. By swapping the thyroid hormones in this way, it is possible to reduce the length of time that the patient is rendered hypothyroid. If ¹³¹I ablation can be performed approximately 4 weeks after surgery, there may be no need for thyroid hormone supplementation to be commenced in the immediate post-operative period but this might be associated with the development of unnecessary hypothyroid symptoms.

The decision whether a patient should receive ¹³¹I remnant ablation after thyroid hormone withdrawal (THW) or after rhTSH injections depends on the current licensed

indications of use for rhTSH, the patient's comorbidities and the local availability of rhTSH injections.

The current licensed indications for rhTSH (Thyrogen™) use are as follows:

- With serum Tg testing with or without radioiodine imaging for the detection of thyroid remnants and well-differentiated thyroid cancer in post-thyroidectomy patients maintained on thyroid hormone suppression therapy (THST). Low-risk patients with well-differentiated thyroid carcinoma who have undetectable serum Tg levels on THST and no rhTSH-stimulated increase of Tg levels may be followed up by assaying rhTSH-stimulated Tg levels.
- For pre-therapeutic stimulation in combination with a range of 1.1–3.7 GBq radioiodine for ablation of thyroid tissue remnants in patients who have undergone a near-total or total thyroidectomy for well-differentiated thyroid cancer and who do not have evidence of distant metastatic thyroid cancer.

Patient factors that would warrant rhTSH use in preference to THW include hypopituitarism, functional metastases causing TSH suppression, severe ischaemic heart disease, previous history of psychiatric disturbance precipitated by hypothyroidism, advanced disease and frailty.

Injections of rhTSH (0.9 mg) are given by deep i.m. injection into the buttock on days 1 and 2 with radioiodine being administered on day 3.

Possible rhTSH side effects include flu-like myalgia, mild nausea and headache. There is also the possibility of stimulating thyroid remnant tissue and metastases, resulting in local symptoms, and consideration should be given to prophylactic corticosteroids before use if residual neck disease or metastases are known to be present.

Serum Tg should be measured immediately prior to ¹³¹I administration if THW preparation is undertaken or ideally on day 5 if rhTSH is used and local facilities are set up to handle radioactive samples.

Patients with pT1-2, N0 with R0 resection should receive 1.1 GBq. For patients with pT3 and/or N1 disease, the final choice of ¹³¹I activity should be decided by the MDT on an individual case basis, taking all prognostic factors into consideration.

¹³¹I therapy doses are usually in the range 3.7–5.5 GBq. Whole-body radioiodine scans are performed 2–10 days after giving radioiodine for ablation or therapy to determine the sites of radioiodine uptake and are more sensitive than diagnostic whole-body scans due to the higher administered activity of radiation used. The addition of SPECT CT to planar gamma camera imaging allows more precise anatomical localization of any iodine uptake demonstrated. The timing of the scan will depend on the administered activity of ¹³¹I, the method of patient preparation (rhTSH versus thyroid hormone withdrawal) and the clinician's choice of the residual activity at which to image the patient.

Physiological ¹³¹I uptake is seen in salivary tissue, genitourinary tract, gastrointestinal tract and sinuses.

Hürthle cell lesions are generally poorly responsive to radioiodine treatment and in particular distant metastases are often resistant to radioiodine therapy.

A pre-ablation radioisotope scan is not routinely indicated, but it may be used to demonstrate the size of thyroid remnant. If a large remnant is seen, consideration of further surgery may be warranted. If further surgery is not appropriate, it may influence the activity of radioiodine that is administered and prompt the prescription of pre-medication with corticosteroids prior to RAI to limit radiation thyroiditis symptoms.

If a preablation scan is performed, a low administered activity of ^{99m}Tc pertechnetate or ¹²³I are preferred to ¹³¹I as they reduce the risk of stunning,^{19,20} which is the term used for the reduction in uptake of the ¹³¹I therapy dose as a result of the pre-treatment diagnostic dose.

Thyroid hormones can be started 1–3 days after radioiodine administration if the patient has been withdrawn from hormones. If the patient has been given rhTSH, they can stay on thyroxine throughout the procedure.

Prior to radioiodine administration, the total body iodine pool should be reduced. A low daily intake of iodine can increase the effective radiation dose achieved with ¹³¹I in the regions of interest.^{21–23} There is little consensus on the degree and the duration of dietary iodine restriction, but duration of the diet is often 1–2 weeks.

Other sources of excess iodine (e.g. iodinated i.v. contrast and amiodarone) should be eliminated before proceeding with ¹³¹I administration.

¹³¹I TOXICITY

- Neck discomfort and swelling may be caused by an inflammatory response in the remnant, residual tumour or involved cervical lymph nodes. This is most likely to be seen when there is a large thyroid remnant present. Discomfort is usually adequately treated with simple analgesics. If the patient has only had a debulking procedure and gross residual thyroid tissue is present, prophylactic corticosteroids are advisable to minimize the pain and swelling associated with the inflammatory response and can be started just prior to RAI administration.
- Patients may experience an altered sense of taste, and nausea (although vomiting is uncommon and prophylactic antiemetics are not routinely indicated).
- Sialadenitis arises due to physiological uptake of ¹³¹I and subsequent excretion from salivary tissue. This can be reduced by encouraging patients to drink liberal quantities of fluids. In the long term, it is possible for intermittent parotid swelling, which may be tender, to develop. This can often be managed by parotid duct massage and the use of post-meal sialogogues if there is no evidence of duct stenosis or calculus.
- Lacrimal gland dysfunction.
- Radiation cystitis. The risk may be reduced by maintaining a high fluid intake following radioiodine administration and during the isolation period.
- Gastritis.
- Bleeding/oedema in metastases.

- Bone marrow suppression. This reaches its peak 4–6 weeks after treatment. It is more likely in those patients who have extensive skeletal metastases or who have received prior external beam radiotherapy or chemotherapy.
- Gonadal tissue is exposed to radiation from radioiodine in the blood, urine and faeces.
- **Male fertility:** a temporary rise in follicle-stimulating hormone (FSH) and a reduction in sperm count may be seen. High cumulative doses (e.g. >14 GBq) may reduce fertility, and consideration should be given to sperm storage in high-risk cases where multiple therapeutic doses of ¹³¹I are expected.²⁴
- **Female fertility:** no significant difference in fertility rate, birth weights or prematurity rates have been documented. Temporary alterations in the menstrual cycle may last for 4–10 months in about a quarter of female patients. Increased risk of miscarriage may persist for up to 1 year following ¹³¹I ablation/therapy.^{25–29} The risk of impaired fertility may be reduced by maintaining a high fluid intake following radioiodine administration and for the duration of the isolation period. This is in order to dilute the urine and therefore reduce concentration of radioactive iodine in the bladder and hence exposure of gonadal tissues.
- If the patient has undergone thyroid hormone withdrawal, constipation is a common symptom of the hypothyroid state so laxatives may help in reducing radiation exposure to gonadal tissue.
- If miliary pulmonary metastases are present, the patient may be at risk of developing pulmonary fibrosis especially if a high cumulative activity of radioiodine is administered. Consideration of pulmonary function test monitoring and corticosteroids immediately before and during treatment may reduce this risk. The data available are, however, fairly limited.³⁰
- An increased risk of leukaemia and second cancers in organs that concentrate ¹³¹I (salivary gland, breast, bladder, colon) is seen, with the risk being highest with high cumulative activities of radioiodine, i.e. greater than 18.5 GBq, and after external beam radiotherapy. The risk of leukaemia is lower than reported in earlier series due to deliberate attempts to limit the total body dose and to increase the interval between radioiodine administrations, whereas the risk of second solid malignancy might be higher than previously thought.^{31, 32}
- Good hydration, frequent micturition and regular bowel activity will help reduce the level of whole-body radiation.

Consideration should be given to the use of high-dose corticosteroids before radioiodine if there is bulky neck disease or metastatic disease.

RADIATION PROTECTION ISSUES

Before the administration of ¹³¹I, pregnancy and lactation must be excluded. Following the administration of ¹³¹I, pregnancy must be avoided for 6 months and male patients must avoid fathering a child for 4 months.³³

During the patient's stay in the isolation room, visiting of family and friends must be restricted to non-pregnant adults. Visiting options vary between centres but often entail no direct entry into the patient's room, with visitors needing to stay in a designated area outside the room.

The patient's clothing must be washed separately on their return home, unless it is heavily soiled, when storage on the hospital site or disposal may be needed. The method of transport home may be determined by the patient's residual activity. For example, short-distance travel in a private family vehicle, unoccupied by children, may allow discharge home with a higher residual activity than a longer journey via public transport where exposure to other members of the public, particularly children, may occur. Once at home, the patient must double-flush the toilet, use separate cutlery and crockery, sleep alone, and restrict the time with and extend the distance between them and their contacts. The duration of the restrictions is individualized for each patient and is longer for prolonged and close contact with children and pregnant women than with non-pregnant adults. Timing of a patient's return to work will depend on the type of work undertaken, the work environment and the surrounding work personnel involved. The patient will be given dates on discharge home which advise how long radiation protection restrictions need to be followed for adults and a second longer date for children and pregnant (or potentially pregnant) women

TSH LEVEL

Following total thyroidectomy, thyroxine is required both to replace thyroid hormones no longer produced endogenously and to suppress TSH levels. The dosage tends therefore to be larger than that used for replacement purposes following thyroidectomy for a benign aetiology.

Thyroxine in these larger doses prevents the pituitary from being stimulated to produce TSH and hence prevents stimulation of any remaining thyroid tissue, whether normal or malignant, with the intention of reducing the risk of recurrence, tumour progression and death.

The degree of suppression has not been tested in prospective studies and, due to concerns regarding the effects of prolonged suprathreshold thyroxine doses in low-risk cases, there has been a recent move to relax the degree of TSH suppression in low-risk cases, aiming for a TSH within the lower part of the normal range.

The BTA Guidelines 2014 recommend the following:¹

- Patients who have not received RRA do not require TSH suppression and the serum TSH should be maintained in the low–normal range.
- Following initial treatment with total thyroidectomy and RRA, and before evaluation of the patient's response to treatment after 9–12 months, TSH should be suppressed to below 0.1 mU/L in all patients.
- In patients with an excellent response to treatment for thyroid cancer, the serum TSH should be maintained in the low–normal range.

- In patients who have an indeterminate response, it is recommended that the goal of TSH suppressive therapy be adjusted to maintain serum TSH concentrations between 0.1 mU/L and 0.5 mU/L for 5–10 years.
- In patients with an incomplete response to treatment for thyroid cancer, the serum TSH should be suppressed below 0.1 mU/L indefinitely in the absence of specific contraindications.

When TSH is being suppressed, the free T4 (fT4) level is often seen to be above the upper limit of the normal range. Moderate elevation does not commonly result in symptoms or signs of ‘hyperthyroidism’.

Thyroxine is taken once daily, usually in the morning, and on an empty stomach. A number of medications can interfere with the absorption of thyroxine, so it is advisable to leave a 2-hour gap between taking thyroxine and other medications, such as calcium supplements, antacids, iron and multivitamins.

THYROGLOBULIN

Thyroglobulin is a glycosylated protein which is a key substrate for biosynthesis and storage of thyroid hormones. It is secreted by normal and cancerous thyroid cells and its release is TSH-dependent. The diagnostic sensitivity of Tg is increased when the TSH level is elevated. The Tg level may be undetectable in 20% of cases in the presence of isolated lymph node metastases if it is measured while the patient is on TSH suppression therapy. The serum Tg level is more sensitive than ¹³¹I whole-body scan (WBS) in detecting recurrent or metastatic disease.

Thyroglobulin autoantibodies (TgAb) interfere with the ability to accurately measure and follow Tg trends. The prevalence of thyroglobulin antibodies is higher in patients with differentiated thyroid cancer (DTC) than in the general population (up to 25% versus 10%).³⁴ There is evidence that measuring TgAb levels and trends is of value in monitoring patients with thyroid cancer if the Tg cannot be relied upon in the presence of the autoantibodies; a rising trend in TgAb levels may indicate disease relapse in a patient.^{35–39}

In order to interpret the serum Tg level, it is necessary to know the TSH level and TgAb level.

Serum thyroglobulin is not useful as a diagnostic test pre-operatively because Tg is a product of normal thyroid tissue and can be markedly elevated by inflammatory

thyroid diseases. It is therefore not specifically a serum tumour marker; however, if elevated in a patient who has previously been rendered athyroid by surgery and radioiodine ablation, it may indicate recurrent or metastatic differentiated tumour.

A serum Tg which starts rising over time while on suppressive thyroxine therapy is highly suggestive of tumour recurrence and needs further investigation. There is no need to measure Tg under TSH stimulation if the basal serum Tg is already detectable.^{40–45}

FOLLOW-UP

There is some variation in practice relating to the timing and modalities used for assessing success of thyroid remnant ablation. Whole-body radionuclide imaging has largely been superseded by neck ultrasound and stimulated Tg assessment in many centres. Cervical ultrasound is a sensitive method for detection of residual disease in the thyroid bed or cervical lymph nodes. It is essential for the ultrasound to be performed by a highly skilled operator with knowledge of thyroid cancer behaviour and not as a routine investigation by a general ultrasonographer.

Diagnostic ¹³¹I or ¹²³I scans can, however, provide useful information on the effectiveness of ablation and the need for further ¹³¹I if uptake was seen outside the neck on the post-ablation whole-body scan and can be considered for patients with thyroglobulin antibodies.

A follow-up neck ultrasound scan and stimulated Tg should ideally be performed 9–12 months following ablation.¹ The results from these two investigations will be used to allocate patients to a treatment response group. This process is ‘dynamic risk stratification’ (Table 66.2).^{46–48}

For low-risk cases, if initial follow-up serum Tg is undetectable under TSH stimulation conditions, subsequent long-term follow-up Tg assessments can be performed under TSH suppression conditions.⁴⁹

If the follow-up neck ultrasound scan and stimulated Tg are within normal limits, the patient is kept on clinical follow-up with Tg monitoring. If the scan or the Tg is abnormal, a decision needs to be made on further management. This may be surgery if localized disease is identified in the thyroid bed or cervical lymph nodes or ¹³¹I therapy. The usual administered activity of ¹³¹I in this setting is 5.5 GBq¹ and this too will be followed up with repeat imaging and Tg assessment to assess response.

TABLE 66.2 Dynamic risk stratification: definitions of response to initial therapy of DTC (9–12 months after total thyroidectomy with R0 resection and subsequent RRA) (Adapted from American Thyroid Association^{46, 47})

Excellent response	Indeterminate response	Incomplete response
<p>All of the following are present:</p> <ul style="list-style-type: none"> • Suppressed and stimulated Tg <1 µg/L • Neck ultrasound without evidence of disease • Cross-sectional and/or nuclear medicine imaging negative 	<p>Any of the following are present:</p> <ul style="list-style-type: none"> • Suppressed Tg <1 µg/L and stimulated Tg ≥1 and <10 µg/L • Neck ultrasound with non-specific changes or stable subcentimetre lymph nodes • Cross-sectional and/or nuclear medicine imaging with non-specific changes, although not completely normal 	<p>Any of the following are present:</p> <ul style="list-style-type: none"> • Suppressed Tg ≥1 µg/L or stimulated Tg ≥10 µg/L • Rising Tg values • Persistent or newly identified disease on cross-sectional and/or nuclear medicine imaging

The TSH stimulated Tg level may remain detectable at low levels after ^{131}I ablation. This could represent residual/recurrent cancer but in the majority of cases represents thyroid remnant. An expectant policy in low-risk cases is recommended with repeat TSH-stimulated Tg assessment at 6–12 month intervals. In many cases, repeat assessments will reveal a gradual decline in stimulated Tg to the point of no detection, when routine follow-up should then be commenced.

Thyroglobulin-positive, imaging negative disease

This is a not uncommon scenario seen in the follow-up of patients with differentiated thyroid cancer and there is uncertainty regarding optimal management.

When Tg is detectable, additional investigations aiming to localize the disease recurrence and offer specific therapy (in particular, surgical resection of the disease wherever possible) are indicated.

A possible imaging strategy is as follows:

1. Neck ultrasound/MRI of neck and mediastinum – the thyroid bed, cervical and mediastinal nodes are the most common sites of recurrence for PTC.
If negative:
2. CT lungs – to look for micronodular lung metastases. Remember the potential for iodinated intravenous contrast to inhibit subsequent radioiodine uptake.
If negative:
3. $^{99\text{m}}\text{Tc}$ isotope bone scan. MRI spine is more sensitive and may be considered if the bone scan is equivocal and the patient has localized symptoms. *If negative, consider proceeding with:*
4. ^{18}F FDG-PET/CT imaging. TSH stimulation prior to positron emission tomography (PET) imaging has shown increased sensitivity in some studies.^{50, 51} Patients with positive FDG-PET imaging have a reduced 3-year survival compared with those who are FDG-PET scan-negative. If PET imaging is positive, ^{131}I imaging is typically negative and the patient is radioiodine refractory. This is often referred to as the ‘flip flop’ phenomenon.

If imaging fails to identify sites of disease, there are two main approaches:

- continued monitoring until repeat imaging demonstrates recurrent disease or the patient becomes symptomatic
- empirical ^{131}I therapy.^{52, 53}

The decision on whether to proceed with an empirical dose of ^{131}I needs to be made, bearing in mind the risk category of the patient and the rate of Tg rise. It is uncertain whether empirical ^{131}I treatment is beneficial in patients with raised serum Tg, compared to active surveillance. There is no evidence from randomized controlled trials for or against empirical ^{131}I . Proponents argue that a

high proportion of patients will have positive post-therapy scans and/or thyroglobulin response and some may achieve cure. Opponents argue that some of these patients have minimal disease and hence radioiodine is unlikely to improve survival and that treatment is associated with acute toxicity. A meta-analysis showed that 50% of post-therapy scans will be positive and of these positive cases 60% will also show a fall in Tg.

Recurrent or metastatic disease

Between 5% and 20% of patients with papillary thyroid cancer relapse in the thyroid bed or cervical nodes, and surgery is the treatment of choice for such locoregional recurrence. Ideally, complete resection is recommended but, if this is not feasible, debulking is beneficial as this will facilitate greater radioiodine uptake in a smaller volume of disease. Distant metastases develop in 10–20% with pulmonary and bone accounting for the majority. If the patient has radioiodine-avid disease, repeated doses of radioiodine are indicated provided there is evidence of symptomatic, radiological or biochemical response.

Remission can be achieved in about two-thirds of patients with neck recurrence and one-third of those with distant metastases. Remission is more likely when a limited tumour burden is present.^{54, 55}

Prognosis depends on the distribution and number of metastatic sites, tumour burden (microscopic foci are more likely to respond) and age at the time of diagnosis of metastases.^{56, 57} If tumour takes up ^{131}I , then long-term survival is possible. The preferred treatment is repeated doses of ^{131}I with administered activities ranging between 3.7 GBq and 5.5 GBq at 6–12-month intervals.

Fixed administered activities of ^{131}I are generally used, but dosimetrically calculated activities are used in some centres.⁵⁸ There is no maximum limit to the cumulative administered activity of ^{131}I that can be used in the treatment of a patient with persistent disease. Normal bone marrow function is needed and reductions in the administered activity are required in the presence of renal impairment.

Extensive bony metastases are generally not curable by ^{131}I alone. For solitary or a limited number of bone metastases, external beam radiotherapy, resection or embolization with or without post-operative external beam irradiation may be associated with increased survival. Other potential treatments include thermal ablation and cement injection.

External beam radiotherapy

The use and role of radiotherapy in differentiated thyroid cancer is debated due to conflicting results in published series. There are no randomized controlled trials and the retrospective reviews often extend over several decades, resulting in considerable variation in extent of surgery and accuracy of staging investigations. Problems with selection bias are also encountered, as well as inappropriately short follow-up for a disease with a long natural history.

The published data are also often lacking with regards to the radiotherapy techniques and doses used, the acute and late toxicity and study end points. The long natural history of the disease means that drawing conclusions from any treatment intervention is difficult.^{59–61}

External beam radiotherapy (EBRT) is infrequently used but the main indications are:

- gross local invasion with significant gross macroscopic residual
- residual or recurrent neck disease that fails to concentrate iodine and that is not amenable to surgery
- palliation of inoperable metastatic disease.

The area treated (target volume) generally includes the thyroid bed (in particular the tracheo-oesophageal groove) and draining lymph nodes (perithyroidal lymph nodes in the central compartment, paratracheal, pretracheal, superior mediastinum and cervical lymph nodes) in papillary and oncocyctic follicular (Hürthle cell) cancers. Draining lymph nodes do not need to be irradiated in non-oncocyctic follicular thyroid cancer unless there is confirmed nodal involvement.

Technical difficulties arise due to the irregular shape of the areas requiring treatment and their proximity to the spinal cord, which is more sensitive to the effects of radiotherapy than tumour tissue and is therefore a dose-limiting structure. Without careful attention to radiotherapy planning and delivery, the patient is at risk of radiation myelopathy. The anatomical relationship between the target area and the spinal cord makes it difficult to deliver a homogenous dose to the areas at risk with conventional radiotherapy techniques.

Intensity-modulated radiotherapy (IMRT) allows a better radiation dose distribution to the tumour while reducing the dose to radiosensitive organs close to the target areas.

During radiotherapy the patient is treated supine. Due to the proximity of the area for treatment to critical structures and the need to deliver treatment accurately and precisely over a number of weeks, an immobilization shell is required to keep the patient in a reproducible position.

The most common acute toxicities seen with external beam radiotherapy in this situation are mucositis with associated odynophagia, skin erythema, skin desquamation and laryngitis. If level I and II cervical lymph node areas need irradiating, taste changes, xerostomia and accelerated dental decay and a small risk of osteoradionecrosis of the mandible can arise.

It is possible that radiotherapy may reduce the uptake of radioiodine into residual thyroid tissue and therefore consideration should be given to administering radioiodine therapy before external beam radiotherapy. However, in practice, there may be a significant delay before the patient can be admitted to the isolation room for RRA and for some patients it may be advisable to proceed with external beam radiotherapy rather than delay both treatment modalities.

Targeted therapies

The principal indication for targeted treatments is progressive, symptomatic disease, refractory to conventional treatments. Efficacy for increased progression-free survival (PFS), but not overall survival, has been demonstrated for several agents. The agents demonstrating the most activity and clinical benefit to date are sorafenib and lenvatinib. A randomized phase 3 trial of sorafenib versus placebo resulted in a PFS benefit of 5 months for patients on sorafenib over those on placebo (10.8 versus 5.8 months; $p < 0.0001$).⁶² Studies continue to evaluate the role of molecular profiling in determination of the most appropriate targeted agent.

Targeted therapy agents are administered orally and have a different toxicity profile compared to conventional chemotherapy. The common toxicities are:

- hypertension
- hand–foot skin reaction (palmar–plantar erythrodysesthesia) and rash
- diarrhoea, constitutional symptoms such as anorexia and weight loss
- cardiac ischaemia
- increased risk of bleeding
- alopecia.

These agents should only be prescribed by a specialist and patients need to be closely observed especially during the initial weeks of therapy in order to detect early signs of toxicity. There is a high incidence of toxicity which will require treatment breaks and dose reductions.

Targeted therapy is a rapidly evolving area and information on current clinical trial activity can be found at the websites listed in ‘Key points’ below.

Chemotherapy

There are no data to support the use of adjuvant chemotherapy in the management of differentiated thyroid cancer and it is also not routinely used in the management of locally recurrent or metastatic disease. Its use has largely been superseded by targeted therapies. Published studies of chemotherapy have usually only included small numbers of patients and have often had a mixture of histological tumour types within the study population.

Doxorubicin is the most extensively studied agent in advanced thyroid cancer and the most frequently used drug, with a partial response rate of approximately 20–30% reported.^{64–66} There is no clear evidence, however, that its use increases survival. Doxorubicin in combination with cisplatin has demonstrated a higher response rate but with additional toxicity and no improvement in outcome.

Childhood

Thyroid nodules are more likely to be malignant in children. Papillary carcinoma is the most common differentiated thyroid cancer seen, with 30–40% being

multifocal; 40–90% of patients are found to have involved cervical nodes at initial surgery.

Differentiated thyroid cancer tends to behave more aggressively in children younger than 10 years of age and the chance of recurrence is also higher.^{67–70}

¹³¹I ablation is generally indicated for all children and adolescents with differentiated thyroid cancers >1 cm following total thyroidectomy, and selective neck dissection is recommended for children with positive nodes. The dynamic risk stratification model has not been specifically validated in the setting of paediatric differentiated thyroid cancer but the same general principles should be considered when deciding on the pros and cons of radioiodine remnant ablation.

At presentation, 10–20% have lung metastases, while bone metastases are rare (<1%). Fewer than 10% will die as a result of their disease.

Management of differentiated thyroid cancer during pregnancy

If differentiated thyroid cancer is diagnosed during pregnancy, it is essential to consider the risk to both mother and foetus of both the cancer treatment options and the continuation of the pregnancy. Thyroid cancer discovered during pregnancy does not behave more aggressively than that diagnosed in a similar aged group of non-pregnant women. Women of childbearing age with thyroid cancer generally have an excellent prognosis, similar to that of non-pregnant women.

Thyroidectomy in the first trimester of pregnancy is associated with a very high risk of miscarriage, but it may be performed safely in the second trimester. Alternatively, surgery can be deferred until after the baby is delivered provided the patient is monitored and the thyroid cancer lesion remains stable. Suppressing doses of thyroxine are safe in pregnancy and may be considered until surgery is possible. The dosage of thyroxine will need to be increased during pregnancy.⁷¹ Termination of pregnancy is rarely indicated.

It is advisable to stop breastfeeding at least 8 weeks and preferably 8 weeks prior to ¹³¹I.

Follow-up

Frequency and type of follow-up depends on an individual's risk of recurrence.¹

Patients who have undergone hemithyroidectomy for a low-risk cancer do not require TSH suppression.

Once the thyroid remnant has been ablated and following dynamic risk stratification the frequency of attendance will be decided in each case individually:

- Patients with excellent response should be followed 6-monthly for the first year, and annually thereafter.
- Patients with indeterminate or incomplete response should be followed up more frequently depending on individual need.

Follow-up should be lifelong for the following reasons:

- The disease has a long natural history.
- Late recurrences can occur, which can be successfully treated with a view to cure or long-term survival.
- The consequences of supraphysiological levothyroxine replacement (such as atrial fibrillation and osteoporosis) need monitoring, especially as the patient ages.
- Late side effects of ¹³¹I treatment may develop.

Clinical trials

A list of websites where information on current clinical trials can be found is given in 'Key points' below.

MEDULLARY THYROID CARCINOMA

Surgery is the main modality of treatment for this disease and monitoring of serum calcitonin post-operatively is important in establishing whether biochemical control has been achieved.^{72, 73} The calcitonin level of many patients, however, remains elevated after surgery and it is frequently difficult to locate the site of residual disease and determine whether it is local or at a distant site. Blood samples taken for calcitonin must be immediately stored in ice since rapid degradation occurs at room temperature and may give falsely low results. Carcinoembryonic antigen (CEA) is also commonly raised and can similarly be used to monitor progress and response to therapeutic intervention.

It is presumed that rendering a patient calcitonin-negative will give them an improved chance of long-term survival and cure. Many patients with a raised calcitonin level remain well with an excellent performance status for many years, whereas others become symptomatic over a much shorter interval. In a retrospective review of 65 patients,⁷⁴ calcitonin doubling time during follow-up was a significant predictor of survival in both univariate and multivariate analyses. A calcitonin doubling time greater than 2 years was associated with long-term survival, whereas patients with a doubling time of less than 6 months all died as a result of their medullary thyroid cancer. An online calcitonin and CEA doubling-time calculator can be found on the American Thyroid Association website (<https://www.thyroid.org>).

External beam radiotherapy

Due to a lack of prospective studies, the role of adjuvant radiotherapy to the thyroid bed and cervical nodes remains uncertain.^{75–77} It is difficult to compare published series due to considerable differences in radiotherapy dose fractionation and eligibility criteria, and the relative rarity of the disease means that recruitment has been over very long periods of time. Reported series also often fail to report the associated toxicity and impact on quality of life of any treatment intervention.

Radiotherapy may be indicated in the following situations:

- post-operatively, when the disease was locally advanced at presentation and a macroscopic clearance has not been achieved
- multiple involved lymph nodes, especially if extracapsular spread is present
- bulky inoperable tumours
- palliation of distant metastases (e.g. bone).

Routine adjuvant radiotherapy in the post-operative setting has not been shown to improve survival.

METASTATIC MEDULLARY THYROID CANCER

Many patients' survival can be measured in years and, even in the presence of significant disease bulk, quality of life can often be good.

Distant metastases frequently involve the liver, lungs and the skeleton and may first come to light when the serum calcitonin level rises significantly. Occasionally, the first sign of the development of distant metastases may be when the patient starts to experience diarrhoea as a result of excess peptide release or symptoms related to excess hormone production. As well as experiencing frequent loose bowel actions often with urgency, wheezing and flushing are also possible. Cushing's syndrome may also rarely occur. These symptoms may respond to somatostatin analogue therapy (e.g. octreotide). Chemotherapy is rarely helpful and has largely been superseded by targeted therapies.

There is no curative treatment option. Treatment interventions are therefore usually reserved until the patient becomes symptomatic and/or develops significant radiological progression with accelerated calcitonin doubling times rather than at first presentation of asymptomatic radiologically diagnosed metastases or raised tumour markers.

Unlabelled somatostatin analogue therapy for diarrhoea

Diarrhoea can be a challenging symptom for some patients and, in the first instance, is usually managed with loperamide and/or codeine. If these agents fail, consideration can be given to the use of somatostatin analogue agents.

Somatostatin receptors can be found on medullary thyroid cancer cells and therefore blocking these receptors can result in a decrease in the amount of peptide and calcitonin released. However, a significant decrease in tumour mass is not seen and the aim of treatment is an improvement in symptoms – diarrhoea and flushing and quality of life. Unfortunately, any recorded benefits often seem to be short-lived.

If a patient responds favourably to a twice or three times daily subcutaneous administration of octreotide, a synthetic somatostatin analogue, with a reduction in diarrhoea frequency or severity, then they can be commenced on a monthly depot preparation. With prolonged use, there is a risk of

tachyphylaxis developing with loss of symptomatic benefit. However, if symptom control deteriorates, it is important to consider if disease progression is the cause before attributing the change to tachyphylaxis. Octreotide and lanreotide have a different spectrum of somatostatin receptor blockade. Side effects of the somatostatin analogues include gastrointestinal disturbances, such as anorexia, nausea, vomiting, abdominal pain, flatulence, diarrhoea and steatorrhoea, and rarely with long-term use gallstones may occur. Abnormalities of glucose metabolism may also occur. Local reactions at the site of administration may be seen and rotation of the injection site is recommended.

Targeted radiolabelled therapies

Once metastatic disease has been established, imaging with ^{123}I metaiodobenzylguanidine (mIBG) or ^{111}In octreotide may demonstrate selective uptake at sites of known tumour relapse, thereby opening up the possibility of using similar agents as targeted radiolabelled therapies.

As medullary thyroid cancer is not derived from follicular cells, it does not accumulate radioiodine.

METAIODOBENZYLGUANIDINE (mIBG) THERAPY

Metaiodobenzylguanidine is a guanethidine derivative, structurally similar to noradrenaline. It is transported into neuroendocrine tumour cells by monoamine transport proteins and may be useful as a therapy in a small number of cases.

Approximately 30–40% of medullary thyroid cancers concentrate ^{131}I -mIBG, but histological tumour characteristics that reliably predict isotope uptake and hence suitability for therapy have not yet been defined.

Prior to treatment, care must be taken to prevent the use of drugs that may interfere with the uptake and retention of mIBG. The following are some examples, but not an exhaustive list: tricyclic antidepressants, phenothiazines, calcium channel blockers, salbutamol and opioids. Administered activities of ^{131}I -mIBG vary and treatment is often given at 2–3-month intervals for three cycles, depending on the patient's tolerance and the benefits observed.

The treatment is given in an isotope isolation room by intravenous infusion usually over a 1–2 hour period through a lead-shielded infusion system. Frequent blood pressure monitoring is required during the infusion and for a period of time afterwards, as unstable blood pressure can result. In practice, this is usually managed by slowing or interrupting the infusion, but in the case of a hypertensive crisis, intravenous alpha and beta blockers such as phenolamine boluses and an esmolol infusion may be required. These drugs should be prescribed in advance and should be available at the time of the mIBG administration.

Prophylactic antiemetics, such as ondansetron, are indicated prior to the infusion and should be continued for 72 hours afterwards. It is advisable to insert two cannulae to allow simultaneous i.v. fluids to be given to ensure good hydration in case the patient is unable to take adequate fluids orally as a result of nausea. It is possible that the

patient may experience diarrhoea, wheezing and flushing related to peptide and hormone release from the tumour. The patient remains in the isolation room for several days and will follow similar radiation protection procedures as described above under 'Differentiated thyroid cancer'.

Whole-body gamma camera imaging is performed preferably with SPECT CT just before the patient is discharged home to demonstrate the distribution and intensity of isotope uptake.

A full blood count (FBC) should be checked weekly for 6 weeks afterwards as myelosuppression, particularly thrombocytopenia, can occur. This is more likely if there is widespread bone marrow involvement or if the patient has received chemotherapy.

Response to treatment can be assessed in terms of symptom improvement, decreasing calcitonin levels or tumour regression on imaging. It is the former, however, which tends to dictate management decisions. Up to 60% of patients may derive symptom benefit and 30–80% may achieve disease stabilization. However, these data are derived from small series.^{78–80} mIBG is traditionally reserved until patients become symptomatic from metastatic disease and it is unknown whether its use earlier in the natural history of the disease may be beneficial.

RADIOLABELLED SOMATOSTATIN ANALOGUE THERAPY

Somatostatin receptor imaging is reported to have a sensitivity of 50–70% in localizing medullary thyroid tumour.^{81, 82}

Somatostatin analogues bound to ⁹⁰Yttrium or ¹⁷⁷Lutetium can therefore be used as therapy in those patients who demonstrate sufficient somatostatin analogue uptake within sites of tumour when compared to background physiological uptake. A subjective benefit may be seen after one or two treatments and this may be associated with a reduction in calcitonin/CEA and tumour stabilization. It is important to realize that a formal radiological assessment of response can be misleading. Often, overall tumour size remains static on cross-sectional imaging, even in the presence of significant radioisotope uptake, symptomatic response and biochemical response. Toxicity includes myelosuppression and nephrotoxicity. Pre-treatment with an amino acid infusion reduces binding of the somatostatin analogue to the renal tubules and hence reduces renal damage.

Other targeted therapies

Various vascular endothelial growth factors (VEGFs) and VEGF receptors (VEGFRs) are often overexpressed in MTC, both in tumour cells and in the supporting vascular endothelium.

Two agents are now licensed for the treatment of symptomatic inoperable locally advanced or metastatic medullary thyroid cancer:

- vandetanib^{83–85} (Caprelsa™) which targets *RET*, epidermal growth factor receptors (EGFRs) and VEGFR

- cabozantinib⁸⁶ (Cometriq™) which targets *RET*, c-Met and VEGFR.

These agents have shown the potential to provide high rates of disease control (partial response and stable disease) with durable responses and a highly statistically significant improvement in PFS. These treatments are given orally on a daily basis for as long as tumour control persists.

Common acute toxicities include:

- photosensitivity
- palmar plantar syndrome, rash
- prolonged QTc interval and risk of sudden death
- hypertension
- fatigue, reduced appetite, diarrhoea, nausea, vomiting
- corneal deposits
- proteinuria, nephrolithiasis.

Short-term toxicity can be significant and often requires dose reductions or treatment withdrawal. Treatment should only be initiated by a specialist and close monitoring is required. Long-term toxicity needs to be investigated further and includes concerns over the potential for skin malignancy to develop.

Chemotherapy

This is rarely used now that targeted therapies have become available but it might rarely be considered for rapidly progressive and symptomatic metastatic disease.

There are no randomized controlled trials and no significant survival benefit has ever been demonstrated.

As medullary thyroid cancer is a neuroendocrine tumour (NET), chemotherapy regimens with activity in other NETs, such as carcinoids, have been suggested, such as 5-fluorouracil and streptozocin.

Clinical trials

A list of websites where information on current clinical trials can be found is given in 'Key points' below.

ANAPLASTIC THYROID CANCER

Patients with anaplastic thyroid cancer (ATC) have a very poor prognosis, with the median survival being 6 months from symptom onset.^{87–89}

External beam radiotherapy

This tumour is the least radiosensitive of the thyroid tumours. Tumour response tends to be partial even with high doses and the majority of patients still die as a result of locally progressive disease. It is also very important to appreciate that patients may spend a very significant proportion of their remaining lives undergoing treatment and recovering from its significant toxicity.

Attempts have been made to improve response to treatment by intensifying the radiotherapy regimen by hyperfractionation (delivering more than the standard one fraction of radiotherapy per day) or by shortening the time period over which it is delivered (accelerated radiotherapy) and combining this with chemotherapy.^{90–93} This intensification has in some series resulted in improved response rates but at the cost of increased toxicity and no increase in overall survival.⁹⁴

Chemotherapy

There is no definitive evidence to demonstrate prolonged survival or improved quality of life for ATC patients treated with systemic therapy. Tumour regression can, however, be induced in some patients. Risks and potential

benefits must be carefully considered in each case. The agents with the greatest clinical activity in metastatic ATC are the taxanes (paclitaxel or docetaxel), the anthracycline doxorubicin, and the platins (carboplatin and cisplatin).

Fosbretabulin, a prodrug of the antimicrotubule-disrupting agent combretastatin was assessed in the randomized phase II functional assessment of cancer therapy (FACT) trial. Unfortunately, the study closed prematurely due to slow patient recruitment but stable disease was seen in 27% with a median survival of 4.7 months and 23% of patients surviving 1 year.⁹⁵

Clinical trials

A list of websites where information on current clinical trials can be found is given in ‘Key points’ below.

KEY POINTS

- Decisions on radioiodine remnant ablation should be individualized taking into account both patient and tumour factors.
- Administered activity of radioiodine in the ablation setting is dependent on the risk category.
- Recombinant human TSH should be used where possible in the radioiodine ablation setting to avoid hypothyroidism and reduced quality of life caused by thyroid hormone withdrawal.
- Degree and duration of long-term TSH suppression depends on the dynamic risk stratification outcome.
- Metastatic thyroid cancer may be low volume, slowly progressive and asymptomatic in many cases and an active surveillance approach is appropriate during this time.
- Information on current clinical trials can be found at the following websites:

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: thyroidectomy, thyroid surgery, thyroid lobectomy, total thyroidectomy, recurrent laryngeal nerve, thyroid cancer.

There is lack of substantive high-level evidence due to the intrinsic nature of the chapter. In most areas the evidence is at most level 2.

HISTORY OF THYROIDECTOMY

The first recorded thyroidectomy was attributed to Abdul Kasan Kelebis Abis in Baghdad in AD 500. The first in Europe was performed in Spain by another Arabic physician Abu Al-Qasim (El-Zahra 936–1013) and its record published in his book *Al-Tasrif* in AD 952.

In 1646 the first thyroidectomy using scalpels was performed. However the patient, a 10-year-old, died and the surgeon was imprisoned. During the subsequent two centuries surgery for the thyroid gland was hazardous due to the inability to adequately control bleeding, and the lack of antiseptics and anaesthesia. Most patients died and this surgery was extremely unpopular and even condemned by prominent physicians and surgeons. The mortality rate from thyroid surgery by 1850 was about 40%.

During the first part of the 19th century advances were made in the understanding of the function of the thyroid gland and the role of iodine. Two Swiss physicians, Johan Straub and Francois Coindet, recommended the use of iodine to reduce the size and vascularity of goitres before surgery was undertaken.

The second half of the century saw two crucial developments that helped to usher in a new era of thyroid

surgery: the discovery of anaesthesia and the introduction of antiseptics by Joseph Lister meant that surgery became much safer. These developments coincided with the arrival of Theodor Kocher and Albert Theodor Billroth.

Albert Theodor Billroth (1829–1894), one of the most prominent surgeons of his time, reduced his thyroidectomy mortality rate from 40% to 8% thanks to anaesthesia and antiseptics. However, thyroid surgery will always be associated with Theodor Kocher (1841–1917). While he was Chair of Surgery in Bern, he performed more than 5000 thyroidectomies. He was extremely meticulous and paid close attention to haemostasis. He was the first surgeon to systematically ligate the inferior thyroid artery, which reduced significantly the risk of haemorrhage. His mortality rate plummeted from 12.6% in 1870 to 0.2% in 1898. He introduced the collar incision, preserved the strap muscles whenever possible and pioneered anaesthesia and antiseptics for thyroid surgery. However, by removing the entire thyroid gland, many patients were left severely hypothyroid and Kocher described this as *chachexia struma priva*. This prompted him to study the physiology, pathology and surgery of the thyroid gland in great detail, which in 1909 earned him the Nobel Prize. It was from then on that he was acknowledged as the 'father of modern thyroid surgery'.

William S. Halsted (1852–1922) brought the Kocher surgical philosophy to the USA. He also introduced anti-sepsis and developed a new set of haemostats, which together with his meticulous technique made thyroid surgery very safe. Halsted also introduced the first residency programme at the John Hopkins Hospital in Baltimore where he was made Professor of Surgery. From this programme, many famous future thyroid surgeons were trained including Charles Horace Mayo, Frank Lahey and George Crile.

Further refinements to thyroid surgery were introduced by Thomas Peel Dunhill, Jan Mikuliz, Wolfler, Eugene Gley and Harold Floss who first introduced the use of motion pictures to teach thyroid surgery.

Thyroidectomy is now a common procedure with rates increasing year-on-year.¹ In contrast to early results, complications related to thyroidectomy are now uncommon, with the highest volume surgeons reporting the lowest risk of morbidity.²

Despite all of these developments, the principles of Kocher's surgical philosophy with meticulous surgical technique and exemplary attention to detail continue to serve as the cornerstone of thyroid surgery.^{3,4}

SURGICAL CONCEPTS

- **Total lobectomy (TL):** the removal of the one lobe, often performed with a thyroid isthmusectomy.
- **Thyroid isthmusectomy (TI):** the excision of the thyroid isthmus, often with the pyramidal lobe of the gland, a procedure that should be reserved for nodules in the isthmus which measure no more than 4 cm in diameter and do not encroach significantly on either lobe.
- **Subtotal thyroidectomy (ST):** the bilateral excision of more than one half of the thyroid gland on each side together with the isthmus. This technique is currently not recommended.
- **Near-total thyroidectomy or Dunhill's thyroidectomy (NTT):** the excision of 90% of the gland, leaving a small remnant of tissue on one side at the level of the Berry's ligament.
- **Total thyroidectomy (TT):** the excision of the entire thyroid gland.

Partial lobectomy, subtotal lobectomy and nodulectomy are confusing terms and are best avoided.

INDICATIONS AND EXTENT OF SURGERY

Thyroidectomy is a benchmark procedure for surgeons, and a thorough understanding of the indications for surgery results in the ability to select the most appropriate primary operation, which is critical to maintaining excellent outcomes. When selecting an appropriate thyroid procedure, the surgeon must first consider whether the surgery is for benign disease, malignancy or diagnostic purposes.

Excision of a nodule from the thyroid gland or 'nodulectomy' has been abandoned. The reasons for this include the bloody nature of the operation itself, but more importantly the high rates of recurrence of benign or malignant disease following surgery. Not only are recurrence rates high, but re-operative surgery for recurrence typically involves unacceptably high risks to both the recurrent laryngeal nerve (RLN) and the parathyroid glands. In addition, for malignant disease, unacceptable oncological outcomes have been associated with less than total thyroid lobectomy.

For most purposes, then, the complete removal of one entire thyroid lobe should be considered the minimum thyroid surgery performed by the modern surgeon.⁵

SURGERY FOR BENIGN DISEASE

Patients without evidence of malignancy may be considered for surgery either due to benign nodular thyroid disease causing compression or cosmetic concerns, or in the setting of hyperthyroidism.

Non-toxic multinodular goitres

In the event that nodular disease has resulted in compression of the trachea or oesophagus, surgical decompression should be considered. Pre-operative assessment is crucial. The surgeon must not only consider the site of compression, but the entire gland, as some patients will have bilateral multinodular disease.⁶

In patients with a single nodule which has enlarged sufficiently to cause compression, TL alone may be sufficient to relieve symptoms, while preventing the need for contralateral tracheoesophageal groove dissection, and therefore eliminating the chance of permanent hypoparathyroidism and bilateral vocal cord palsy. Post-surgical surveillance of the remaining thyroid remnant will be required, as will regular thyroid function tests as up to a third of patients will develop hypothyroidism during long-term follow-up.⁷ The need for later thyroid hormone replacement is more common in those with a raised pre-operative thyroid-stimulating hormone level or thyroiditis.⁸

For those patients with bilateral multinodular goitre (MNG), TT is the operation of choice.⁹ This removes all nodules and minimizes the chance of recurrence.

ST should only be considered in healthcare settings where an adequate supply of exogenous thyroid hormone cannot be ensured, and functioning thyroid tissue is preserved to maintain endocrine function.

Thyrotoxicosis

The choice of surgery for patients with hyperthyroidism will be related to the pre-operative findings in the gland as a whole. Analysis suggests that surgery for Graves' disease is successful, with total thyroidectomy the preferred option.¹⁰

For those patients with an autonomously functioning solitary nodule, TL alone may suffice. For those patients with multinodular disease or global glandular dysfunction (e.g. Graves' disease), TT should be recommended. Such an approach again reduces the chance of recurrent hyperthyroidism, and the need for reoperative surgery. Patients considered for such surgery must understand that they will require lifelong hormone supplementation.

'DIAGNOSTIC' SURGERY

This term is controversial but just under 30% of patients investigated for thyroid malignancy will have an indeterminate pre-operative diagnosis.¹¹ In this setting, each patient should be considered on an individual basis.

Those patients with uninodular disease, which would be adequately treated with TL alone in the setting of malignancy, should undergo TL.^{12, 13} Those with multinodular disease should be considered for TT for ipsilateral diagnostic purposes and also to prevent the need for lifelong serial assessment of contralateral nodules.

Patients who have uninodular disease but are likely to require completion thyroidectomy in the event of a malignant diagnosis can be offered either diagnostic TL with completion thyroidectomy as a staged procedure, TT up front, or TL with on-table frozen section analysis with immediate completion if malignancy is confirmed.

Each approach has advantages and disadvantages. Clinicians must assess each case, including the clinical, biochemical, ultrasonographic and cytological features in order to make an individualized decision. A number of statistical models are available to assist in predicting the risk of malignancy within an individual thyroid nodule, which can be used in the clinical setting to aid decision-making and informed consent.¹⁴

SURGERY FOR MALIGNANT DISEASE

Many patients who undergo surgery for thyroid nodules do so with a biopsy-proven malignant lesion.¹⁵

For patients with T3 and above differentiated thyroid cancers (DTC), medullary carcinoma of the thyroid, poorly differentiated thyroid cancer, multinodular glands, multifocal cancer, evidence of extrathyroidal extension or overt nodal metastases, the majority of authors agree that TT is the procedure of choice.¹⁶⁻²⁰

Patients with disease limited to the isthmus may have a TI lesion²¹ but for the majority of patients with uninodular DTC, without extra thyroid extension or metastases, TL results in oncological outcomes equal to TT.^{22, 23}

When considering the extent of surgery for thyroid cancer, the surgeon, endocrinologist, nuclear medicine physician and patient must all agree to the proposed treatment plan. Bear in mind that it is rare for a patient with DTC to die of disease following appropriate primary therapy, so a balance between maximizing outcome while minimizing morbidity must be achieved in every case.

CONSENT

The consent for thyroidectomy should include the explanation of the procedure, its rationale and the options of alternative treatments relevant to the condition. The potential complications should be discussed and should include the risks of general anaesthesia, scarring, infection, haemorrhage, injury to the external branch of the superior laryngeal nerve (EBSLN) and to the RLN, hypocalcaemia and hypothyroidism. In cases of large retrosternal goitre or invasive thyroid carcinoma, the risks of airway obstruction with the potential need for tracheostomy should also be discussed. If extensive intrathoracic goitre requires sternal split or lateral thoracotomy, all relevant complications such as injury to pleura and pneumothorax, pneumonia, and injury to phrenic nerves and the pericardium should be discussed.^{8, 24, 25}

PRE-OPERATIVE CONSIDERATIONS

1. Evidence of clinical examination, cytological or histopathological analysis and adequate imaging should be available.
2. Laryngeal examination and pre-operative voice assessment with fibre-optic laryngoscopy should be performed on all patients.²⁶
3. Patients should be euthyroid; in thyrotoxic patients adequate precautions should be taken to avoid the possibility of a thyroid storm.
4. Patients should be adequately consented.
5. Patients undergoing general anaesthesia should have a north-facing endotracheal tube so it does not interfere with the surgical field.
6. Local anaesthetic should be considered to help haemostasis while raising the flaps and to aid analgesia in the post-operative period.
7. Neuromonitoring and surgical aids such as loops, microscope, fine bipolar forceps, ligaclips and energy devices should be encouraged to facilitate surgery.
8. Mild hypotensive anaesthesia should be used but reversed before the procedure is completed.

SURGICAL TECHNIQUE FOR STANDARD THYROIDECTOMY

Position The patient should be in a supine position, with a soft shoulder support and a soft head ring to allow maximum extension of the neck and aid stabilization of the head during surgery ([Figure 67.1](#)).

Incision and incision planning

The classical Kocher collar incision consists of a transverse cervical incision in a skin crease placed halfway between the cricoid cartilage and the sternal notch. There is no one-size-fits-all rule for the incision placement, but the following aspects should be considered ([Figure 67.2](#)).

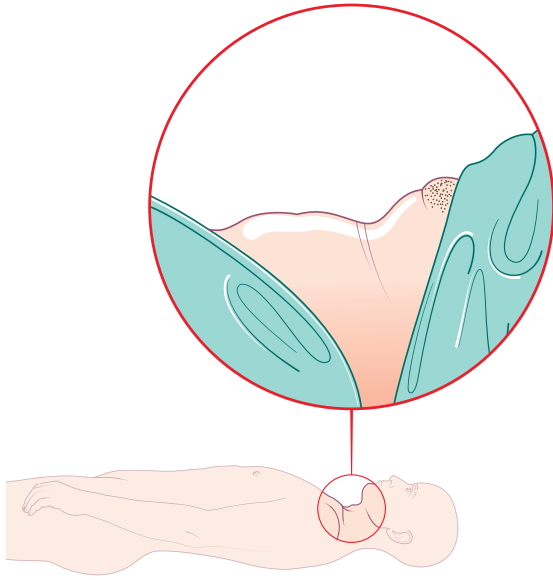

Figure 67.1 Position of patient undergoing thyroidectomy, demonstrating the supine posture with neck extension.

- **Access:** The incision must be of adequate length to provide sufficient access to the superior, inferior and lateral aspects of the thyroid to ensure a safe dissection. Many surgeons prefer an incision as small as 3 cm and use retraction to move the incision in relation to the gland, exposing the areas of interest in sequence.
- **Cosmesis:** To avoid unnecessary attention drawn to the wound, it should be symmetrical across the midline. By placing the incision in a deep skin crease, the end result will be excellent, and in many cases this will outweigh the need for a small incision: it may be more cosmetically appealing to make a longer incision placed in a skin crease than a short incision between creases.
- **Secondary movement:** When planning the incision, breast size should be considered. In women with large breasts, significant inferior movement of the scar will occur over time. In this case, placing an incision higher in the neck will prevent the scar from migrating to an unsightly position in the presternal area.
- **Future procedures:** Particularly in high-risk patients with extrathyroid extension, for example, the surgeon should bear in mind the possibility that future access to the central and lateral neck may be required. An incision above the level of the cricoid cartilage can easily be extended along a skin crease to the level of the trapezius in order to access all levels of the neck if required at a later date. The modified extended Kocher incision is particularly helpful in this setting.²⁷

Approach

Following the skin incision the tissues should be divided through the subcutaneous fat and the platysma. Traditionally, flaps are raised in the immediate subplatysmal plane up to a level above the thyroid cartilage and down to the suprasternal notch. The anterior jugular

Figure 67.2 Typical Kocher incision 6 months after thyroidectomy.

Figure 67.3 Subplatysmal flaps elevated.

veins should be identified and protected during this dissection as damage to these vessels during the early dissection can result in significant post-operative haemorrhage. The extent of dissection should be tailored to the gland in question. The exposure required for a small atrophic gland will be significantly less than for a retrosternal goitre (Figure 67.3).

When an extensive dissection is required, flaps should be raised over the sternomastoids, and indeed the muscle can be dissected from its fascial envelope to improve access to the lateral aspect of the gland. The most inferior tendinous insertions of the sternomastoid muscles are connected by ligamentous fibres which can be divided to improve access to an intrathoracic goitre.

Incision of the cervical fascia

The investing cervical fascia is then incised in the midline and opened to the level of the thyroid cartilage and to the level of the sternal notch. Care should be taken to identify any communicating vessels crossing the midline ([Figure 67.4](#)).

Thyroid isthmus (TI)

The TI is identified once the cervical investing fascia has been opened. In cases of performing a TL only, it can be divided early to help the mobilization of the gland or can be dealt with at the end of the procedure. The timing of the division will depend on the experience of the surgeon.

Division of the strap muscles

This is often necessary, especially in cases of large glands. This allows access and better visualization of the vascular pedicles, particularly the superior pedicles. Either the sternothyroid and/or the sternohyoid muscles can be divided. They should be divided in the upper third as this will prevent injury to the ansa cervicalis, which enters the muscles in their inferior aspect ([Figure 67.5](#)).

Dissection proceeds on one side initially. The sternohyoid should be separated from the sternothyroid and the medial aspect of the carotid sheath, with the ansa cervicalis identified laterally.

Lateral retraction of the sternohyoid muscle allows access to the sternothyroid muscle. This should again be grasped with atraumatic forceps. Medial traction on the thyroid gland allows dissection of the muscle from the surface of the gland. Attention should be paid to this plane, which is elevated close to the muscle. Evidence of extrathyroid extension at this point should alert the surgeon to the advanced local stage and will alter the

approach to the gland. If extrathyroid extension into the straps is evident, the muscle should be excised by dividing above and below the gland.

Identification and division of the vascular pedicles

This is an essential step in thyroidectomy. Individual vessels should be carefully dissected, identified, ligated and divided. This is best done with a curved dissector such as a Lahey or a Mixer dissector. This will allow adequate haemostasis, reducing the risk of post-operative haemorrhage, and will reduce the risk of injury to the superior laryngeal nerve and of leaving large glandular remnants that invariably exist between the vessels.

The superior pole

Management of the superior pole is critical to achieving total removal of the thyroid lobe. Great care should be taken to identify and control the multiple vessels, which fan out from the superior pedicle to insert on the gland.

Traditional descriptions of identifying the superior thyroid artery and dividing distant to the gland should be discouraged as they increase the potential for damage to the EBSLN as it crosses to innervate the cricothyroid muscle. Instead, these vessels should be taken close to the gland, ensuring that the entire superior pole is dissected ([Figure 67.6](#)).

Some authors now consider identification of the EBSLN mandatory in all procedures. Most, however, prefer to take care to stay close to the gland rather than exploring the area to formally identify the nerve.

Having started the mobilization, the next step is identification of the superior parathyroid gland (PTG). This will be found adjacent to the posterior capsule of

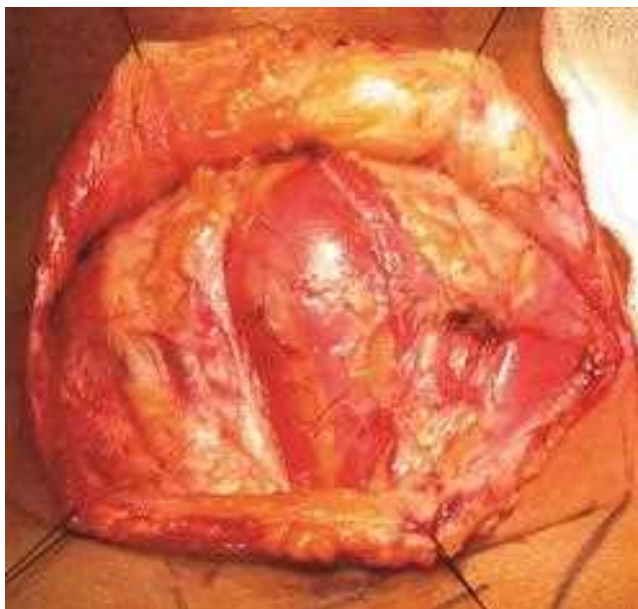

Figure 67.4 Incision cervical fascia, demonstrating the exposure of the thyroid isthmus.

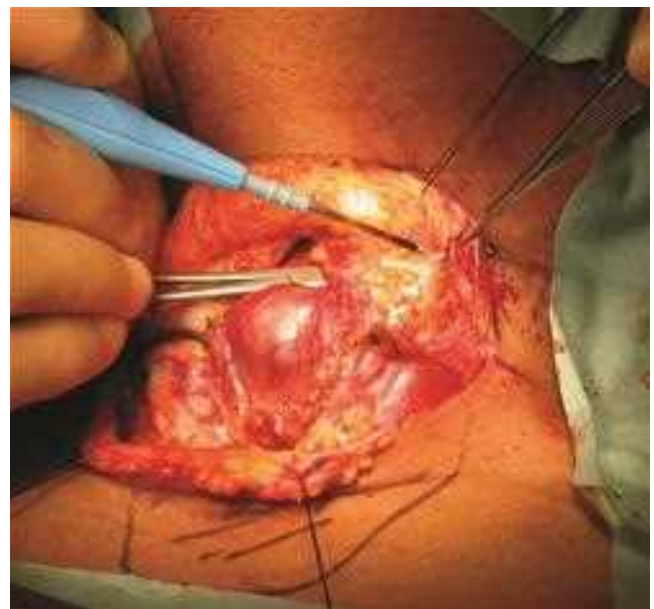

Figure 67.5 Division of the strap muscles using monopolar cutting diathermy.

Figure 67.6 Identification, dissection and division of the superior vascular pedicle vessels.

the superior pole. The blood supply must be maintained, and the gland dissected off the thyroid in order to maintain function.

The lateral aspect

With the superior pole mobilized, attention can be turned to the lateral aspect of the gland. The surface of the gland is identified and dissected from the strap muscles. The dissection is done using a combination of sharp and blunt dissection to expose the whole length of the gland. At the lateral aspect of the gland the middle thyroid veins are ligated and divided to allow delivery of the gland and access to the paratracheal areas.

The fascia surrounding the gland is dissected and the thyroid is slowly mobilized, allowing visualization of the trachesophageal groove (**Figure 67.7**).

The inferior pole

With the superior and medial aspects of the gland mobilized, attention can be turned to the inferior pole.

Figure 67.7 Mobilization of the lateral aspect of the gland.

By identifying the trachea, a safe plane of dissection can be developed which allows the inferior pole to be dissected from the trachea without jeopardizing the RLN.

External branch superior laryngeal nerve

The EBSLN should be identified whenever possible during the dissection of the superior pole.^{28–30} This is done at the sternothyrolaryngeal or Joll's triangle, which is delineated by the superior thyroid pedicle and upper lobe of the gland, the cricothyroid muscle and the lower edge of the thyroid cartilage (**Figure 67.8**).

Recurrent laryngeal nerve

The position of the RLN varies depending on the side, as previously described in the anatomy section. Although most RLNs are single, up to 30% of nerves can branch before entering the larynx and this may lead to higher risk of injury (**Figure 67.9**).^{31, 32}

- **Lateral approach:** The nerve is usually identified in the Beahrs triangle in the lower lateral part the neck. This triangle is defined by the inferior thyroid artery superiorly, the trachea medially and the common carotid artery laterally. This is safest way of identifying the recurrent laryngeal nerve (**Figure 67.10**).³³
- **Superior approach:** The nerve can be identified at the level of the cricothyroid junction at its entry into the larynx. This approach can be very useful in cancer patients with extensive nodal disease, reoperative surgery, when other approaches have failed and when considering a non-recurrent laryngeal nerve. Once the nerve is identified, it should be dissected in a caudal direction, tunnelling the tissue surrounding the nerve with a mosquito fine-tip dissector (toboggan technique). The tissue above the tunnel is then diathermized with bipolar diathermy and divided (**Figure 67.11**).³³

Figure 67.8 Identification of the SLN in the Joll's triangle.

Figure 67.9 RLN demonstrating two extralaryngeal branches.

Figure 67.10 Identification of the RLN using a standard lateral approach.

Figure 67.11 Identification of the RLN at the cricothyroid joint using a superior approach.

- **Inferior approach:** In large goitres or in revision surgery, an inferior approach can be used. This allows identification of the nerve in a virgin site (Figure 67.12).³³

In every thyroidectomy, an attempt should be made to identify the nerve. Without this attention to detail, injury rates can be unacceptably high. Having identified the nerve, there is no need for it to be traced for any great distance. With experience, the surgeon will come to recognize the importance of the relationship between Berry's ligament and the nerve. In patients with a low Berry's ligament, which sits posterior on the trachea, the nerve will be in close proximity to the gland at this crucial point. In these cases the nerve must be carefully traced and the gland mobilized off the nerve. When Berry's ligament is high, the nerve is often quite laterally placed in comparison, and minimal dissection will be required. This minimizes the chance of inadvertent injury.

Around 2% of RLNs are non-recurrent and this is almost always present on the right. Pre-operative imaging

Figure 67.12 Identification of the RLN at the apex of the Behr's triangle using an inferior approach.

Figure 67.13 Non-RLN arising directly from the right vagus nerve.

which identifies situs inversus, or more commonly a retroesophageal subclavian artery, may raise the index of suspicion. If the RLN cannot be identified in the traditional position, the surgeon must consider the possibility of a non-recurrent nerve. This structure will be running inferomedially from the vagus nerve and will be wide in comparison to a normal RLN (Figure 67.13).

RLN MONITORING

Recent technological advances have allowed surgeons to assess the integrity of the recurrent laryngeal nerve during thyroidectomy. Proponents of these techniques highlight the potential reduction in rates of iatrogenic injury and find the nerve monitor useful in the training of junior surgeons. Those who oppose the routine use of nerve monitors cite increases in operative time and cost as well as the lack of clear evidence of overall patient benefit. The topic remains controversial, and it is covered in detail elsewhere.

Figure 67.14 Typical position of the parathyroid glands once the right thyroid lobe has been mobilized, demonstrating the superior parathyroid gland in a superior-lateral position and the inferior parathyroid gland in an anterior-inferior position with the RLN crossing from a caudal to cranial position.

Management of the parathyroid glands

The parathyroid glands should be identified whenever possible. The position of the glands can be variable and 25% of the glands may not be in the position that the surgeon expects them to be (Figure 67.14). When the thyroid gland has been mobilized, the superior parathyroid gland should fall in a posterior position of the nerve and the inferior parathyroid gland in an anterior one. Once identified, the tissue handling needs to be very precise and delicate so the glands can be dissected with their blood supply preserved.

The superior glands are relatively uniform in their position. The inferior glands are traditionally described as ventral to the RLN in the region of the inferior thyroid artery. However, it is not uncommon for these glands to

be aberrant in position, and lie somewhere between the level of the cricoid to the thymus. Traditionally, 1% of parathyroids have been considered to be intrathyroidal, although with careful scrutiny of resected thyroid tissue this may be an underestimate.

Parathyroid glands rely on their blood supply to function, and it is critical that their nutrient vessels are preserved. The glands should be gently dissected from the thyroid, taking care not to cause traction or diathermy injury to their blood supply. In the event that a parathyroid is excised, or is considered non-viable, a sample should be sent for frozen section analysis and, on confirmation, the gland should be divided into around 12 pieces for implantation into a muscle. Often the sternomastoid muscle is used due to its convenience, although this view has recently been challenged.³⁴

Berry's ligament

At this level the recurrent laryngeal nerve is at greatest risk. The ligament is dissected using fine and judicious bipolar diathermy. The blades of the bipolar should be resting on the thyroid gland and away from the nerve. Once the diathermy has been performed, the ligament is divided with a size 15 blade scalpel. This provides the best accuracy and reduces the risk of injury. It is important to note that the ligament is often very vascular and its thickness variable. It is therefore often necessary to dissect and divide the ligament in several steps until the perichondrium of the trachea is reached (Figure 67.15).

Pyramidal lobe

The pyramidal lobe should always be identified, dissected and excised together with the thyroidectomy specimen.

Having delivered the thyroid from Berry's ligament, the gland should be dissected off the anterior tracheal wall towards the midline. Great care should be taken at this

point to identify any pyramidal tissue. If this is left behind, it will be evident on post-operative imaging and may result in the need for adjuvant RAI, or sampling to exclude the possibility of local recurrence. The pyramidal lobe tends to be a central structure, although it is not always immediately in the midline. It extends in the direction of the thyroglossal tract towards the hyoid, and should be divided as superiorly as possible (Figure 67.16).

Closure

1. **Wound wash.** Once the thyroidectomy is completed, the wound is washed with water or normal saline. Iodine-based solutions are best avoided, especially when performing surgery for thyroid cancer, as this may interfere with subsequent radioiodine ablation.
2. **Haemostasis.** Haemostasis is essential. To check for any bleeding points, the wound must be clean of clots. When this has been done, a Valsalva manoeuvre should be used at least twice to check for any bleeding.

Figure 67.16 Dissection of the pyramidal lobe.

Figure 67.15 Management of the Berry's ligament using careful bipolar coagulation of the fine vessels followed by division of the ligament with a size 15 scalpel.

Figure 67.17 Post-operative appearance of a thyroid bed after total thyroidectomy, demonstrating the trachea, larynx, RLNs and parathyroid gland.

3. **Check the RLNs and parathyroid glands.** Once haemostasis is completed, the RLNs and the parathyroid glands should be checked to ensure that they are intact anatomically. If neuromonitoring is used, an EMG signal should be obtained and recorded (Figures 67.17 and 67.18).
4. **Drainage.** The need for drains should be considered on an individual patient basis. Many prospective, randomized trials have shown that drains do not reduce haematomas or seroma rates. Despite this, some units use suction drains, particularly when a significant dissection has resulted in a large dead space or the patient uses anticoagulation.³⁵
5. **Subcutaneous tissues and skin closure.** The wound is closed in layers. The strap muscles should be approximated with an absorbable suture. Many surgeons now advocate only one suture to prevent trachea–cutaneous adhesion, while maintaining a connection between the deep central neck and the more superficial planes. The theory is that this may prevent the development of high lymphovascular pressure in the perilaryngeal

Figure 67.18 Specimen of a total thyroidectomy for thyroid cancer.

tissue in the event of a hematoma, thereby reducing the risk of airway oedema and respiratory obstruction.

The platysma should then be re-approximated using an absorbable suture. The skin should then be closed with meticulous attention to detail to optimize wound healing. The technique (interrupted nylon, staples, subcuticular sutures, skin glue, etc.) is less important than the need to be precise and treat the skin edges with respect. The ideal closure will allow easy reopening in the event of haematoma.

POST-OPERATIVE CARE

- **Position.** Patients should be nursed head up in a 45 degree position for the first 4 hours before they can start mobilizing.
- **Venous thromboembolism (VTE) prophylaxis.** Patients undergoing thyroid surgery should have adequate VTE prophylaxis. As a general rule, anticoagulant VTE prophylactic agents should be commenced 24 hours from the procedure and continued until the patient is discharged.
- **Nursing.** Patients should be monitored in an adequate post-operative care facility or ward. An adequate pathway of monitoring and enhanced recovery should be instigated in all units dealing with thyroid surgery. Suture or staple removal forceps should be available at the bedside.
- **Steroid therapy.** The use of intravenous steroid therapy in the first 24 hours is a valuable adjunct to analgesia as an antiemetic and in one randomized controlled trial has shown to reduce the rate of RLN neuropraxia.³⁶
- **Antibiotic prophylaxis.** This is not usually necessary. In complex cases with extensive dissection, ETE involving the airway structures or lateral neck dissection, prophylactic antibiotics up to three doses in 24 hours should be considered.
- **Analgesia.** Adequate analgesia is imperative. Opiates are preferred to non-steroidal analgesics to minimize the risk of post-operative bleeding.
- **Resume oral intake.** Patients can resume oral intake as soon as they are fully awake and have a normal diet 4 hours from completion of the procedure.
- **Mobilization.** Early mobilization should be encouraged.
- **Drain removal.** Monitoring of drainage volume should be every 8 hours. If the volume is less than 20 mL at 24 hours or 10 mL at 8 hours, the drain may be removed.
- **Removal of sutures or staples** – most surgeons use either staples or subcuticular sutures. Staples can be removed as early as 36 hours from completion of the procedure, and edges reinforced with Steri-Strip™ tapes for 7–10 days. This will ensure adequate healing and optimal cosmesis.
- **Calcium management.** This is addressed in Chapter 79 on the prevention and management of complications.
- **Post-operative vocal cord check.** A post-operative vocal cord check should be done as soon as possible after the surgery if RLN injury is suspected. If there is no suspicion of RLN injury, a post-operative vocal cord check can be done in the first post-operative appointment.²⁶

KEY EVIDENCE

- Essential pre-operative investigations for thyroid surgery include clinical examination, thyroid function test, thyroid antibodies, ultrasound-guided FNAC, pre-operative voice assessment with fibre-optic laryngoscopy and, for established malignancy, appropriate cross-sectional imaging investigations.
- Thyroid lobectomy is the minimum procedure acceptable except for those nodules located in the isthmus or pyramidal lobe.
- During thyroidectomy the recurrent laryngeal nerves and parathyroid glands should be identified and preserved unless there is pre-operative evidence of involvement with locally invasive thyroid cancer.

KEY POINTS

- Evidence of clinical examination, FNAC, core needle biopsy and adequate imaging USS, CT or MRI should be available.
- Laryngeal examination and pre-operative voice assessment with fibre-optic laryngoscopy should be performed in all patients undergoing thyroid surgery.
- Patients should be euthyroid or in cases of thyrotoxicosis in which the thyroid function is abnormal adequate precautions should be taken to avoid the possibility of a thyroid storm.
- Patients should be adequately consented.
- Patient undergoing general anaesthesia should have a north-facing endotracheal tube so it does not interfere with the surgical field.
- Local anaesthetic should be considered pre-operatively to help haemostasis while raising the flaps and to aid analgesia in the post-operative period.
- Nerve monitoring should be used whenever possible.
- Surgical aids such as loops, microscope, fine bipolar forceps, ligaclips and harmonic knives are very useful and should be encouraged to facilitate surgery.
- Mild hypotensive anaesthesia should be used but reversed before the procedure is completed.
- Adequate incision and approach should be employed for the extent of the procedure.
- Surgery is the mainstay of thyroid cancer treatment and total thyroidectomy should be performed in the majority of patients.
- Level VI selective or central compartment neck dissection should be performed whenever indicated.
- Careful tissue handling is paramount as the thyroid gland is one of the most vascular glands in the body.
- The RLN should always be identified and preserved.
- The EBSLN should be identified whenever possible. This may only be possible in up to 60% of cases due to the position of the nerve in relation to the superior thyroid pedicle.
- Parathyroid glands should be identified and preserved whenever possible. If, however, a parathyroid gland is removed during surgery or its blood supply is lost, frozen section should be used to confirm the nature of the tissue and, if positive, the gland should be reimplanted in a pocket made in the sternocleidomastoid muscle.

Advanced thyroid cancer.....	805	Surgery for distant disease	809
Extrathyroidal spread.....	805	References	810

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: well-differentiated thyroid cancer, advanced thyroid cancer, extrathyroidal spread, nodal disease, laryngotracheal invasion, oesophageal invasion and recurrent laryngeal nerve invasion.

Key evidence has come from the British Thyroid Association guidelines for the management of well-differentiated thyroid cancer, the American Thyroid Association guidelines for the management of well-differentiated thyroid cancer and the American Head and Neck Society Consensus statement.

INTRODUCTION

In the majority of cases, differentiated thyroid cancer (DTC) carries an excellent prognosis and behaves in an indolent manner.¹⁻³ However, in advanced disease, including direct spread beyond the thyroid capsule or extranodal spread, surgical management is challenging with higher associated morbidity and mortality.^{1,4} Surgery is well accepted as the primary modality of treatment of both primary and recurrent DTC although adjunctive therapies play an important role.^{3,5} Awareness of poor prognostic features pre-, intra- and post-operatively can aid in appropriate surgical planning and decision-making and there is a move towards patient-specific risk stratification in management strategy.⁴ Treatment planning should be patient-centred and be made within the context of a multidisciplinary team setting (MDT).³ When treating patients with advanced thyroid cancer, decision-making is the most important part of management, as often a balance must be struck between achieving clear margins and the potential morbidity of surgical intervention. Patients with residual thyroid cancer may survive for many years and be minimally symptomatic. As such, in DTC, leaving microscopic and sometimes macroscopic disease behind to preserve function may be the most appropriate course of action.

ADVANCED THYROID CANCER

Surgical management of advanced thyroid cancer includes:

- direct disease extension beyond the thyroid capsule (extrathyroidal spread)
- recurrent or residual disease in the thyroid bed and neck
- extracapsular nodal disease
- surgery for distant metastasis.

EXTRATHYROIDAL SPREAD

Spread of disease beyond the thyroid capsule into surrounding tissues represents a poor prognostic sign with significant potential for increased post-operative morbidity and early mortality.⁶ Extrathyroidal extension (ETE) can be present at some level in up to 25% of patients and occurs in papillary and follicular disease with equal frequency although papillary thyroid cancer has a much greater incidence and is therefore more likely to be encountered.^{2,6-10} Extrathyroidal spread can range from minimal extension into surrounding strap muscles and fat (T3) to invasion of the laryngobronchial tree and prevertebral muscles (T4a/b).

Extrathyroidal spread occurs most commonly in those with other risk factors for adverse prognosis.^{9, 11–12}

Residual and unrecognized disease is likely to represent the most common manifestation leading to local recurrence and macroscopic disease clearance is associated with higher survival.^{2, 13} As such, early recognition of extrathyroidal spread with appropriate pre-operative planning is likely to minimize the risk of inadvertently leaving residual disease. Patient factors that increase the risk of extracapsular spread mirror the risk factors for detecting malignancy in a thyroid nodule and include extremes of age at presentation, size of primary tumour (>4 cm), advanced nodal disease or clinical evidence of distant metastases.^{8–9, 11} Presentation with features of upper aerodigestive tract invasion including voice change, recurrent laryngeal nerve palsy, stridor and dysphagia should alert the surgeon to the need for careful clinical assessment of the aerodigestive tract including flexible laryngoscopy to assess vocal fold function as well as bronchoscopy and oesophagoscopy if directed clinically.¹⁴ In addition, patients with suspected aerodigestive tract invasion should have analysis of pre-operative imaging by a radiologist with a special interest in head and neck radiology, preferably within the context of the MDT such that surgery can be planned with the patient fully informed.

Histological factors that should alert the surgeon to a higher risk of ETE include poorly differentiated and unencapsulated histological subtypes associated with more aggressive disease such as diffuse sclerosing, solid and tall cell types.⁹

Once identified pre-operatively, management planning should be discussed in detail with the patient such that the appropriate resection boundaries and the morbidity associated with obtaining completely clear margins can be adequately understood.³ The operative skills, experience and repertoire of the surgeon are important factors when obtaining clear surgical margins in patients with cancer spread beyond the thyroid capsule.^{14–16}

Involvement of non-vital structures around the thyroid bed

The greatest chance of cure is obtained through macroscopic removal of disease with clear margins. This is the case primarily and for residual or recurrent disease where there is direct spread from the thyroid gland. Predicting extrathyroidal spread is important but not always possible and subtle involvement of local structures are often not identified on imaging.² If extrathyroidal spread involves the strap muscles or surrounding lympho-fatty tissue where en-bloc excision leads to little added morbidity, it is generally accepted that these structures should be excised as far as the disease progresses.^{3, 17}

Involvement of the recurrent laryngeal nerve

In locally advanced thyroid cancer, the recurrent laryngeal nerve (RLN) can be involved to a greater or lesser

extent in up to 60% of cases by direct cancer spread from the gland or by paratracheal lymph nodes.⁶ RLN involvement can range from tumour abutting the nerve to partial or total encasement and direct invasion.¹⁸ Evidence that nerve and functional voice preservation can be achieved without compromising local recurrence has led many to adopt a nerve-preserving technique, although large-scale trial data supporting this are not available.^{17–19} Further, some studies suggest RLN function can return after tumour has been peeled off the nerve, even when extensively dissected.²⁰ RLN involvement, in the presence of a still-functioning nerve, is not usually possible to predict on radiological grounds. Most patients with RLN involvement or encasement have no predictive features. Where a pre-existing, ipsilateral cord palsy exists in the context of an encased nerve, most would advocate nerve excision.¹⁷ In a functional ipsilateral vocal cord, with solitary RLN involvement, some would advocate removal as the balance of morbidity from a unilateral RLN palsy may outweigh the risk of leaving disease behind. Others, however, would aim to preserve the nerve while removing macroscopic disease on the basis that adjuvant treatment would be employed to reduce the risk of local recurrence.^{17–19} Decisions such as these should be patient-specific. Where both RLNs are involved and functional pre-operatively, a more difficult decision has to be made, but most would advocate RLN preservation to avoid tracheostomy. The British Thyroid Association (BTA) recommends leaving one or both nerves in situ regardless of macroscopic disease and relying on non-surgical post-operative treatment modalities to achieve local control.³ In addition, RLN monitoring is widely used in thyroid surgery and may aid intra-operative decision-making regarding nerve preservation.²¹ This may be particularly helpful in the presence of an apparently functional nerve where nerve signal has been lost.²² There is debate, however, on the ability of intra-operative nerve monitoring to predict voice outcome following thyroid surgery and large-scale prospective studies are needed to evaluate this further.^{23, 24}

Where resection of the recurrent laryngeal nerve is anticipated, such as in the context of a pre-existing vocal fold paralysis, there is some evidence albeit from small studies that primary re-anastomosis of the RLN may improve voice outcome.²⁵ Such repair may involve end-to-end or cable graft repair. The skills of the operating surgeon may be a factor in whether this is achievable and donor nerve morbidity must be taken into account.

Involvement of the trachea and larynx

Oesophageal and pharyngeal involvement is rare in isolation, and normally occurs in association with involvement of the laryngobronchial tree.² When disease recurs, it is most likely to do so locally (70%).²⁶ Up to 50% of death from DCT is from direct invasion of the airway. The prognosis for those with locoregional recurrence is better than those with distal disease, however, and where locoregional control can be achieved, death is more likely from distant metastasis.²⁷ Treatment should therefore be directed towards macroscopic, local disease clearance.

Again, where resection is being considered, patient and tumour factors should be at the forefront of the decision-making process. Whether tumour breaches the inner lumen of the airway is the key to surgical planning and all patients with suspected airway invasion should undergo thorough pre-operative evaluation. Clinically, laryngoscopy and bronchoscopy should be performed if luminal spread is suspected. Imaging in the form of contrast-enhanced CT is specific if not particularly sensitive in detecting both tracheal and laryngeal invasion and MRI may add further information regarding laryngeal cartilage invasion.²⁸ Depending on the skills of the surgeon, the extent of resection may mandate involvement of other specialities or onward referral to tertiary care.

Where macroscopic disease invades the outer layers of the laryngobronchial tree, most agree it is acceptable to shave cartilage as far as macroscopic disease is seen and treat post-operatively with ¹³¹I and/or external beam radiotherapy (ERBT).^{29, 30} In tracheal invasion, local control rates as high as 95% have been reported when adopting such strategies, even with high rates of microscopically involved margins.³¹ It is likely that

post-surgical, adjuvant treatment reduces recurrence and improves survival in these circumstances.^{29, 32} Where macroscopic disease excision necessitates entering the lumen of the airway, formal resection and reconstruction should be considered.^{29, 33} Although this is likely to increase surgical morbidity from anastomotic breakdown, laryngo-tracheal stenosis and tracheostomy dependence, revision surgery for residual or recurrent disease is likely to be very challenging and carry significantly higher morbidity.^{34–36} Options for segmental tracheal and laryngeal resection can be seen in [Figures 68.1–68.4](#).³⁷

As with tracheal involvement, where the outer layers of the larynx are involved, macroscopic resection of disease with preservation of the larynx is likely to achieve good rates of local control. Where disease spreads through the cartilage, consideration of partial or total laryngectomy should be made as leaving behind macroscopic disease is associated with a high risk of recurrence, regardless of post-operative treatment, and salvage surgery is again likely to involve high morbidity.¹⁷ Often laryngeal preservation can be achieved, however, with good functional and local outcomes.³⁸ Again decisions should be made

Figure 68.1 Options for tracheal resection and repair. A small defect can be closed primarily and a larger defect reconstructed with a local muscle flap.

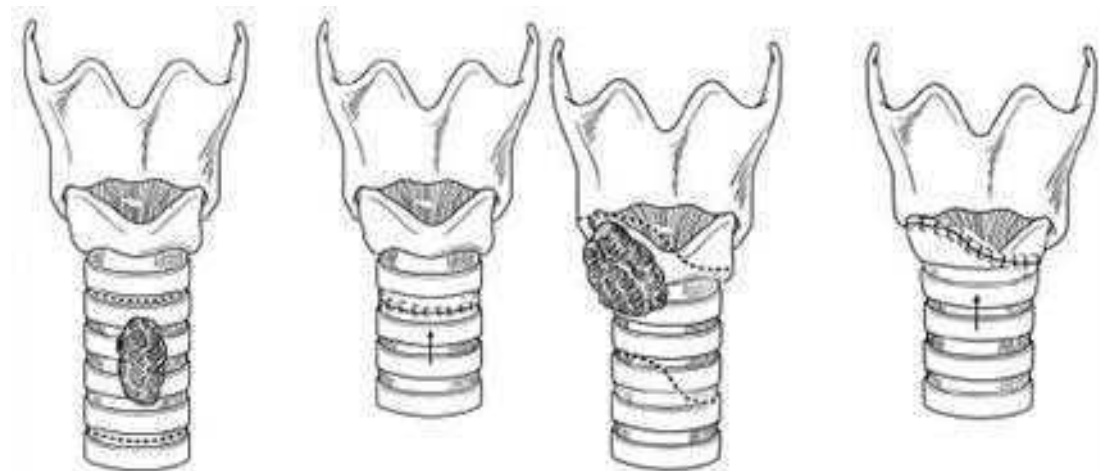

Figure 68.2 Segmental tracheal resection – with an end-to-end primary anastomosis and a stepped closure involving partial resection of the cricoid cartilage.

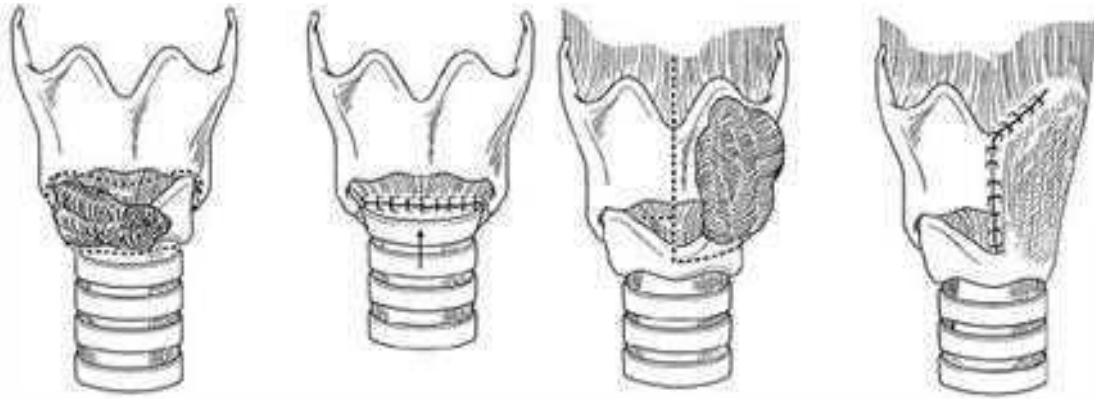

Figure 68.3 Total cricoid resection – with trachea to cricothyroid membrane anastomosis and vertical hemilaryngectomy.

Figure 68.4 Total laryngectomy – for advanced disease extending across the midline.

with the patient at the centre of the discussion and including surgeons with the appropriate skill mix to complete the procedure.³⁹

Involvement of the pharynx and oesophagus

Pharyngeal and oesophageal invasion are rare in thyroid cancer and most commonly occur from direct primary tumour extension rather than extranodal disease in the central compartment.³⁶ A history of true dysphagia should prompt a thorough evaluation of the aerodigestive tract although in most cases involvement is asymptomatic. This is in part because intra-luminal involvement is rare with extension most frequently involving the muscularis layer in isolation without submucosal or mucosal spread.¹⁰ As such, endoscopic examination of the pharynx and oesophagus is often not predictive. As involvement is most likely due to direct spread, the position of the primary within the thyroid may give an important clue to the presence of invasion. MRI scanning is both sensitive and specific at predicting invasion and should be performed whenever invasion is suspected.⁴⁰

Surgery to the pharynx and oesophagus will be dictated by the extent of involvement but should follow the principals of macroscopic disease resection. Where the lumen is breached, segmental resection is required which may be repairable by layered closure or by direct reanastomosis.¹⁷ More extensive defects may require myofascial or myocutaneous reconstruction from pedicled local flaps, free microvascular tissue transfer or gastric pull-up procedures.

Involvement of the vascular compartment

Although rare, vascular involvement occurs and every effort should be made to recognize involvement in the pre-operative phase.⁴¹ Both the internal jugular vein (IJV) and common carotid artery can be involved by direct primary tumour spread although IJV compression and thrombosis is more commonly caused by extensive nodal disease.⁴² Again, it is patients with high risk features who are more likely to present with vascular involvement. Clinical signs of arterial involvement are often minimal but major venous involvement should be suspected in the presence of facial flushing, oedema, venous congestion and unexplained headaches or vascular events. Where vascular involvement is suspected, extensive pre-operative evaluation should be performed as there is significant potential for morbidity and mortality if the IJV and or carotid has to be resected.¹⁷ Imaging should be directed towards assessment of resectability and, if so, what structures would need repair. Combination imaging including ultrasound Doppler, MRI, MRA and CT angiography may be sufficient to evaluate intra-luminal involvement and distinguish thrombus from intra-luminal tumour.⁴² Formal angiography may be required, however, in particular to assess the arterial supply to the circle of Willis if arterial resection is contemplated.

Ipsilateral IJV involvement can be resected with no recourse to reconstruction of the venous system. There is consensus, however, that in bilateral IJV resection, reconstruction with autologous vein graft should be considered, due to the significant morbidity associated with bilateral IJV excision.^{17, 43} Most authors consider a completely encased carotid to be akin to inoperable disease although cases of carotid resection and are reported.⁴²

Encasement up to 270 degrees is usually amenable to resection assuming the artery itself is not directly invaded. Where an attempt to resect disease that is advanced to that extent is being considered, careful consideration of the surgical morbidity and the likelihood of improving survival should be undertaken.

SURGERY FOR RECURRENT DISEASE: LOCOREGIONAL RECURRENCE

As with primary disease, recurrent disease should be managed surgically where possible and with curative intent.^{13,3} Local disease recurrence is most often seen in the thyroid bed with the central and lateral neck compartment less commonly affected. Patients with high-risk features are more likely to die from their disease and as such the case for surgical intervention for recurrent local disease is more clear cut.³ In those with low-volume or low-risk disease, however, close clinical observation may be a better strategy.³ Consideration should be paid to the position of the recurrence prior to any attempt at surgical excision as well as ¹³¹I uptake status. Patients with locoregional recurrence have a better prognosis than those with distant disease, a reflection of the fact that recurrent disease is most likely enlarging residual disease rather than loss of disease control and that all modalities of treatment are still available. Where resection is undertaken, a complete clearance of the central compartment should be performed with invasion into local structures managed as previously discussed.¹⁷

Where disease recurs in the lymphatics, the central and lateral compartments are most commonly affected and disease can be confined to the nodes themselves or spread extranodally into the free tissue spaces of the neck. Where nodal compartments are macroscopically affected, the aim should be to clear all affected levels in their entirety, avoiding ‘berry picking’ at all times. In the lateral compartment clearing levels IIa to IV with level Vb if affected is considered the treatment of choice.¹ Where extranodal extension affects other structures such as the vascular

compartment or neural structures, consideration of the balance between morbidity and increased survival should be made on a case-by-case basis.

Where nodal disease recurs in previously dissected nodal levels, a comprehensive dissection of the lateral neck should be considered in patients with high-risk disease. In previously operated levels, this may involve excision of the residual node, affected local structures and scar tissue only. Again, a watchful waiting strategy may be adopted for those with low-risk recurrent disease.³ Non-surgical treatments should be explored with ¹³¹I uptake status as well as the possibility of EBRT for patients not amenable to surgery.

SURGERY FOR DISTANT DISEASE

Distant metastatic spread carries a poor prognosis, in part a representation of the disease process itself and in part due to the limitation of treatment modalities available, particularly surgery.⁴⁴ Distant spread is most common to the lung followed by bone, soft tissues and brain.⁴⁵ Although metastasis reduces life expectancy by 50%, the disease can progress slowly and may be relatively asymptomatic.⁴⁴ For many patients with distant metastases, including to mediastinum and lung, surgery is not considered an option and an assessment should be made as to whether metastases uptake iodine.³ In these situations ¹³¹I may be the treatment of choice with or without EBRT. For isolated or limited bony metastases in accessible places where morbidity is low, surgery may be considered, especially as ¹³¹I is relatively ineffective at treating these lesions.⁴⁶ Selection should be on a case-by-case basis and multimodal treatment considered. Pain, weight-bearing positions, risk to neuronal structures and risk of other treatment modalities such as EBRT should be considered prior to or instead of surgery. Surgery may be considered first-line treatment for isolated cerebral metastases in patients with good performance status as greater long-term survival has been demonstrated.^{3,47,48} Surgery for cerebral metastasis should be considered regardless of ¹³¹I uptake and a decision made in conjunction with a neurosurgical team.

FUTURE RESEARCH

- ▶ Imaging modalities for the detection of early recurrence or residual disease
- ▶ Centralization of data and patients with advanced disease for the purpose of audit and research
- ▶ Randomized trials in the surgical management of locoregional recurrence and distant disease
- ▶ Biomarkers to predict subtypes more likely to recur
- ▶ Surgical technology to aid in monitoring intra-operative nerve function

KEY POINTS

- Where possible, individual patient and tumour factors (risk stratification) should be included in decision-making.
- Management should be patient-centred and made within the context of the MDT with consideration of non-surgical treatment where appropriate.
- Assessment and anticipation of advanced disease allows management decisions to be made in advance of surgery.
- Microscopic residual disease may not adversely affect long-term survival.
- A balance must be struck between extent of planned excision and associated morbidity, particularly when there is involvement of the upper aerodigestive tract.

INTRODUCTION

The principles for safe thyroid surgery were laid down by Kocher at the beginning of the 20th century. Until recently there has been little change to the technique he described, an approach to thyroidectomy that conferred him Nobel laureate in 1909. His incision is still eponymously used although this rarely reflects the incision that he performed.

The site of incision and scar is often a significant focus of patient anxiety when considering surgery. Studies have revealed that 71% of patients surveyed in a thyroid clinic would prefer not to have a neck scar given a choice, a view independent of sex and skin colour. Furthermore, validated scar assessments reveal that professionals rate the aesthetics of a scar more favourably when compared to patients.¹

Until further advances in medical research permit an incision that is truly scarless, techniques will continue to evolve to minimize scarring. This will facilitate safe surgery through a smaller and cosmetically more desirable incision or for the incision to be placed at a site where the scar is unobtrusive and invisible.

MINIMALLY INVASIVE THYROIDECTOMY

Technological developments of the endoscope and energy sealing devices provided essential prerequisites to develop small incision thyroidectomy techniques. These are known

by several euphemisms: minimally invasive video-assisted thyroidectomy (MIVAT) or Miccoli technique, minimally invasive thyroidectomy (MIT), endoscopic-assisted thyroidectomy (EAT) and, finally, the Henry technique. Endoscopic-assisted thyroidectomy more accurately describes these techniques in practice.

Paolo Miccoli in Pisa and Jean-François Henry in Marseille largely pioneered the techniques of minimal invasive thyroidectomy.

Miccoli technique

Miccoli described the open method (gas-less), where a 2–3 cm midline incision facilitates endoscopic dissection of the superior pole and its delivery into the neck. Dissection of the lower pole and completion thyroidectomy is then done in a conventional manner once the thyroid is delivered through the incision. It has the disadvantage of requiring both two competent assistants and video stacks. Nonetheless, it avoids the potential complications of insufflation and it is possible to perform a total thyroidectomy through a single incision.

Excellent visualization of structures such as the recurrent, external laryngeal nerves and the parathyroids is obtained. Its limitation, as in all minimal invasive techniques, is the size and nature of the lesion for which the technique is suitable. This equates to approximately 8% of a UK surgeon's practice.¹ Volume outcome data would indicate that only surgeons with a large thyroid practice would have sufficient numbers to hone and maintain the skills required to adopt this technique both safely and

responsibly. A steep learning curve exists requiring over 50 cases before a surgeon obtains expert status.² This on a background where 86% of the British Association of Endocrine and Thyroid Surgeons (BAETS) membership perform fewer than 50 thyroidectomies a year³ is indicative of why few surgeons have adopted this technique in the UK.

MIVAT permits solitary nodules of 3 cm to be safely removed. Highly experienced and skilled surgeons in the technique have extended its application to selected Graves' and cancer patients. It is wise to avoid its use in patients with a history of thyroiditis, cancer or previous surgery. It is recommended that total thyroid lobe volume should not exceed 20 mL with nodules up to 3 cm being suitable, equating to a volume of 14 mL.

In the author's experience, if the small incision necessitates excessive traction (which it does), this can predispose to hyperpigmentation and hypertrophy of the scar. This is clearly undesirable given the reason for using this technique in the first place. Long-term cosmetic analysis of scars is therefore essential for adequate evaluation of minimally invasive techniques. **Figure 69.1** shows the Miccoli instrumentation.

Henry technique

Virtually synchronous to the advent of Miccoli's technique was the insufflation method largely pioneered by Jean-François Henry in Marseille. This relies on the creation of three lateral ports along the anterior border of sternomastoid, two 3 mm ports for instrumentation and a 1 cm port for introduction of the insufflator endoscope. CO₂ at a pressure of 8 mmHg facilitates working space and achieves a bloodless field in which to dissect. It requires

Figure 69.1 The Miccoli range of instruments (gas-less) technique inclusive of suction dissectors, spatulas and specially designed retractors. A 30 degree 4 mm endoscope is used.

an assistant to hold and manipulate the endoscope while dissection proceeds with the other port instruments.

Dissection takes place completely within the neck and delivery of the thyroid lobe once completed is through the endoscope port. Indications for the technique replicate that of Miccoli. A total thyroidectomy is not possible by this method. Technically it is much more challenging than the Miccoli method and, while lending itself very well to parathyroidectomy, it has not been widely adopted for thyroid surgery. **Figure 69.2** shows the Henry instrumentation.

Minimally invasive thyroidectomy – the evidence base

There have been many peer-reviewed publications and even meta-analyses on minimally invasive thyroidectomy. The meta-analysis of Radford contained only five studies with a low degree of freedom and study heterogeneity. It also included a series from Miccoli, the pioneer of the technique. The analysis of 318 patients concluded that complications were no higher and supported superior cosmetic outcomes at the expense of operative time. Scar cosmesis was studied in the early post-operative period only and validated scar assessment methods were not used.⁴

The literature gives clear guidance on the indications, methodology, safety and learning curves. It has been less clear on volume outcome metrics. The latter will assume greater prominence with the advent of revalidation and surgical outcomes being placed in the public domain. Long-term prospective cohort studies comparing conventional and MIT are regrettably lacking. However, a personal communication with JFH has suggested there may be little or no difference in scar satisfaction after 18 months once full healing has taken place.

Figure 69.2 The range of instruments available for the Henry (gas) technique. Three ports are used and operative space is created by CO₂ insufflation.

Despite these reservations there is nonetheless a patient demand for this procedure. In the highly skilled such as Miccoli and Henry with high volume practices there is undoubtedly a niche for this technique. It is particularly attractive to those patients who have a tendency to hypertrophic scarring and possible keloid, although in the author's experience true keloid is very rare in thyroidectomy scars. However, because of the technical difficulty of achieving competency, steep learning curves and a regular supply of suitable cases, a large volume thyroid practice is essential. For this reason very few centres in the UK perform truly minimally invasive thyroidectomy.

SCARLESS IN THE NECK TECHNIQUES

Despite advances conferred by minimally invasive techniques they nonetheless have the disadvantage of leaving a scar in the neck. Although other endoscopic techniques have been employed, including a facelift approach,⁵ the desire to avoid an incision in the head and neck has led to infraclavicular innovations. It is important that emphasis is placed on scarless in the neck rather than minimally invasive because the latter would not be an accurate description of any infraclavicular method.

Transaxillary and breast techniques were pioneered in the Far East particularly by Japanese and Korean surgeons. The cultural desire to avoid a scar in the neck from the negative feng shui in having a horizontal scar in the neck (denoting death) has been a significant driving force behind these innovations. Although technically demanding, the published literature shows that lobectomy or total thyroidectomy can be achieved safely.⁶ These techniques are known as the axillo-bilateral-breast approach (ABBA) and bilateral axillo-breast approach (BABA) respectively.

There is not surprisingly a steep learning curve and a requirement to have a competent assistant working with 2D operative view in a confined operative space. Both gasless and insufflation techniques have been used, the latter potentially being complicated by hypercarbia, which can be a serious sequela of insufflation techniques.⁷

With the introduction of the da Vinci telerobot in the late 1990s, the next logical iteration was for this new technology to be used for thyroidectomy.

ROBOTIC-ASSISTED THYROIDECTOMY (RAT)

NASA had long considered the dilemma that would arise if an astronaut became ill in space. The concept of remote or 'tele' robotics was therefore spawned. The Ministry of Defence also declared an interest in developing the concept of bringing surgical expertise to the front line without placing the surgeon in danger. Patents for the technology were ultimately acquired and a system for commercial use developed by Intuitive (Sunnyvale, California).

The da Vinci telerobotic technology makes remote operating a reality with the feasibility of transatlantic surgery being published by Marescaux and colleagues in 2001.⁸

In head and neck surgery, pioneering work in the USA by Weinstein and colleagues in Philadelphia has led to robotics becoming the gold standard for the treatment of oropharyngeal tumours. In the UK, adoption has been frustratingly slow but this will change and a bright future is predicted for telerobotics in this domain of head and neck surgery.

The da Vinci system has also been used for both thyroid⁹ and parathyroid¹⁰ surgery. Lobe and colleagues published a lobectomy using the da Vinci with insufflation in 2005.¹¹ The present transaxillary technique, however, has been pioneered by Chung and other Korean surgeons.^{6, 9, 12, 13} In 2013, Korean surgeons had experience in excess of 3000 patients. For reasons to be elaborated upon later, establishment of RAT has been tardy elsewhere in the world.

Chung and colleagues working at the Yonsei University in Seoul have published data on feasibility and learning curves supporting a superior cosmetic outcome and better post-operative swallow.^{14, 15} They have also published data supporting its safe use in patients with papillary thyroid cancer. Noteworthy is that the mean size of tumour excised was only 8mm and therefore fits into a microcarcinoma category.¹⁶ Further studies are required before conclusions can be made with regard to safety in treating thyroid cancer.

A recent meta-analysis¹⁷ supports its safety compared with conventional thyroidectomy (CT). Complications including cord palsy and hypocalcaemia rates were shown to be no different in this analysis. This study, however, has a low degree of freedom and high heterogeneity. There was also a heavy weighting of publications from pioneering units in Korea. Further prospective cohort studies are required before general conclusions can be made about the safety of RAT. There is inherent publication bias as complications of RAT tend not to get published.

Da Vinci telerobotics system

The da Vinci is a master-slave robot that has undergone five iterations from Standard, Xi to SP machines. The system consists of three components: the surgeon console, cart and video stack containing camera control units (charge-coupled devices, CCDs) and other hardware. As a master-slave device, movements of the robotic arms are controlled by the surgeon sitting remotely in the console.

The surgical cart engages with the patient through a process termed 'docking'. The cart has four arms, one holding an endoscopic camera with other arms being used for surgical instruments. In practice this equates to instruments in the right and left hands with fourth arm instrumentation serving as a surgical retractor or assistant.

Endoscopes are 8mm or 12mm and, unlike standard endoscopes that give a 2D view, images seen with the da Vinci are in 3D. This is brought about by the endoscope casing containing two endoscopes thereby replicating a truly 3D surgical experience. This gives the surgeon a

depth of field dimension to the operative field. The endoscope can be moved to alter magnification and also moved in various planes to avoid line of sight conflicts that accompany standard endoscopic methods.

Movement of instruments within the hand of a surgeon are restricted by anatomical limitations brought about by evolution. The human hand is able to adduct, abduct, supinate, pronate, flex and extend through a defined range of movements. This limitation is apparent during standard suturing and it limits what a surgeon can achieve in confined spaces where visualization is limited. These anatomical restrictions are overcome by the Endowristed capability of robotic instrumentation.

Robotic instruments are capable of moving through an arc of 270 degrees in both clockwise and anticlockwise directions. Clever algorithms within the system are finally able to remove natural human tremor, a process termed 'tremor-filtration'. Finally, motion-scaling permits the range of movement of instruments in the operative field to be scaled so that movements of the hands at the console can lead to smaller or larger movements at the patient interface. In essence this gives the surgeon 7 degrees of freedom and confers a capability of being equally dextrous with dominant and non-dominant hands.

The CCDs are able to transmit images of each endoscope to the right or left eyes when seen through the viewing binoculars. This replicates a truly 3D surgical experience. The Si has a screen resolution of 1080, a 30% improvement in quality compared to 720 in the S and 480 in the standard machines.

Fine control of the instrument jaws is brought about by movement of thumb with index and middle fingers that are inserted through the rings of the hand control, as shown in [Figure 69.3](#).

Figure 69.3 The operating surgeon at the console controlling the robotic arms and instruments by the hand cradle.

Infrared sensors in the console stop any movement of the robotic instruments once the surgeon moves his head from the console as a safety measure. The development of dual consoles, bolt-on simulators and telestration aid both training and proctorship of robotic surgery.

Ethical considerations

The da Vinci is now routinely used for hemithyroidectomy, lobectomy, total thyroidectomy and level VI central compartment dissection. More recently, applications have extended to lateral compartment neck dissection through the axillary approach.¹⁸

A review of published literature from South East Asia shows that the majority of patients undergoing robotic surgery have had relatively small nodules, with the mean size of cancerous nodule removed 8 mm. Although median nodule size would have been more appropriate, it is clear that surgery is being undertaken on patients with small volume pathology. This has been confirmed by personal communication from several surgeons who have visited Korea.

A different healthcare system in association with screening of the thyroid, a variance in reimbursement tariff for robotic compared to conventional approaches (by a factor of five) combined with a national psyche for avoiding a neck scar have combined to create the perfect environment for advancing robotic thyroid surgery in Korea.

Ethical, safety and economic factors need to be considered before the introduction of new technology and surgical techniques. Surgeons practise in an environment of scrutiny with a medicolegal dimension that appears insatiable. However, without the adoption of innovation, advances which improve patient care will be stifled. The history of surgery abounds with examples of innovations that were initially resisted – some quite vehemently – anaesthesia, antiseptics, caps, gowns, gloves and even 'keyhole' surgical techniques to name but few. The environment in which RAT takes place in the Far East may not necessarily translate to a western European population. The body habits of patients, cultural perception to neck scars and the health system in which doctors operate are very different.

The author received training in robotic surgery in 2007 before publication of RAT. To innovate and learn RAT unassisted has been a long and arduous journey involving cadaveric dissection in Paris, Strasbourg and Geneva. Furthermore, ethical permission was sought and finally granted after two submissions. Funding for prospective evaluation studies was obtained for the initial 50 patients. Obtaining recognition from private companies to recognize robotic head and neck surgery was another hurdle that had to be negotiated for fee-paying patients. Finally, peer perception of RAT had to be negotiated and addressed as we all work in an environment where to be considered maverick and an outlier confers professional risk.

There are thyroid-specific and generic considerations for RAT. My personal view is that RAT is suitable for hemithyroidectomy of nodules or nodular pathology of up to 6 cm and a total thyroidectomy, provided the

Figure 69.4 Keloid scarring on the upper arm following vaccination – a patient typically who may have valid reasons for avoiding a visible neck scar.

contralateral lobe is ‘near’ normal. I would counsel avoidance for cancer other than for microcarcinoma in the young and for Graves’ disease. It is an attractive option for patients having a history of hypertrophic scarring (Figure 69.4) or those simply expressing a personal preference to avoid neck scarring. The approach should be avoided in obese patients with a BMI over 30, those with degenerative shoulder pathology and those with other significant comorbidity placing them in an ASA category greater than 2. The ideal patient, therefore, would be a thin, narrow-chested female with a thyroid nodule of up to 4 cm. Nodules of greater than 4 cm can be removed but are technically more challenging. Large cystic nodules can also be made suitable by aspiration at the time of surgery.

Consent

As for all surgery, informed consent should take place. It is my opinion that all consent but particularly RAT should be performed by the consultant. The literature supports that RAT is as safe as conventional surgery with the same risk of bleeding, infection, vocal cord palsy and parathyroid dysfunction. RAT, however, has the additional rare potential complication of brachial plexus dysfunction. The operation achieves the objective of translocation of an incision from neck to axilla at the expense of an increased operative time. The inpatient stay and time off work are identical.

Reservation of RAT regarding airway obstruction from a bleed is often a concern quite reasonably raised. It may come as a surprise that airway obstruction will not occur following a bleed from RAT simply because the potential space for a bleed to disseminate is so capacious compared to conventional thyroidectomy. In this respect it is safer

than CT, although this would not be a cogent argument for the routine introduction of RAT.

Operative set-up

PRE-OPERATIVE CONSIDERATIONS

Teamwork is essential in the pre-operative preparation of the patient. On the arm of the side of surgery no identification bracelet, lines, blood pressure cuffs or ECG leads must be placed. I routinely use laryngeal nerve monitoring.

It is very important to mark the 5–6 cm axillary incision while the patient is awake, with the back of the patient’s hand touching the central portion of the forehead, a position which I describe as an extended salute (Figure 69.5). In my experience this is the only technique that successfully identifies the best site for the incision. Otherwise, part of the incision can migrate to the upper arm or onto the anterolateral chest wall. I often extend the incision superiorly in a curvilinear fashion so it sits in a natural crease, which reduces tension and a tendency towards a hypertrophic and pigmented scarring. The axilla is not an environment well suited for healing because of its damp anaerobic nature but, with experience and correct planning, the incision heals well and becomes invisible (Figure 69.6).

At induction the patient is routinely given i.v. Augmentin and 4 mg Dexamethasone.

THEATRE SET-UP

Prior to transfer of the patient to the operating table it is important that all three components of the da Vinci are appropriately positioned. The cart is placed on the opposite side of the operating table (Figure 69.7) and is draped

Figure 69.5 Marking of the incision immediately prior to surgery. This is of fundamental importance and is a vital component of pre-operative planning.

Figure 69.6 The same patient as in Figure 69.5, showing the axillary scar 9 months following surgery.

Figure 69.7 The cart is docked at right angles to the operating table, on the opposite side to the incision.

and correctly positioned before the patient is moved onto the operating table, thereby being ready for docking.

Contrary to CT, a shoulder roll is not placed under the shoulders as this has a tendency to overextend the neck and move the superior pole away from the robotic instruments. I place the patient's head and shoulders under a pillow so that there is adequate and comfortable support in a subtle 'sniffing the morning air' position. The head of the table is then dropped by about 20 degrees to widen the angle between the arm and the chest.

A special arm rest supports the arm, which is abducted and flexed with the forearm pronated so that the back of the hand rests on the central portion of the forehead. I stabilize this position with a Velcro coin attached to the hand and forehead. This movement has the effect of elevating and externally rotating the clavicle so that the distance between the incision site and thyroid gland is shortened.

The positioning of the arm in this way is a modification to Chung's method where the arm is fully extended over the head. This puts the brachial plexus at risk and should never be used in my opinion. I have had no problems since I modified Chung's method of arm positioning.

Once completed, the incision site is infiltrated with 2% Xylocaine and 1:200 000 adrenaline. Skin preparation and draping then take place while the surgeon scrubs.

The operation

PREPARATION OF THE ROBOTIC FIELD

The area to be dissected extends from the thyroid cartilage to sternal notch in a subcutaneous plane. The superior and inferior extent of the axillary incision is level with the thyroid and sternal notches respectively. An imaginary line in a horizontal plane connects the two with the area to be dissected being trapezoid-shaped.

Dissection extends medially in the subfascial and subcutaneous planes above pectoralis major and over the clavicle. The natural dehiscence between the sternal and clavicular heads of the sternomastoid is entered to get to the plane of the strap muscles. Dissection then extends under the strap muscles to access the thyroid gland. The surgical planes are then developed as in a standard CT. The lower insertion of the sternothyroid into the back of the manubrium and first rib is divided as is its superior attachment to the thyroid cartilage; this allows full access to superior pole structures. I routinely divide the omohyoid muscle as it extends over the internal jugular vein. Once the strap muscles have been separated off the thyroid gland to approximately a third of the contralateral thyroid lobe, dissection is complete. A modified retractor is then inserted (Chung, Koppersmith, Modena or Imperial) and the robot docked.

DOCKING

The cart is docked at right angles to the operating table (Figure 69.7). All four arms can be placed through a single axillary incision or the fourth arm can be inserted through a periareolar incision. The last incision has little morbidity and the scar is invisible once it has healed.

The 30 degree down 12mm stereoscopic endoscope is placed at an angle of 220 degrees and is inserted low laterally, extending high and upwards medially towards the thyroid gland. The fourth arm can then be placed under the endoscope, which functions as the assistant. Finally, the first and third arms, which carry the instruments for dissection and haemostasis, are positioned. The fourth assistant arm holds the 8 mm Prograsp, while the first and third arms hold a combination of 5 mm Maryland, DeBakey and Harmonic shears.

THE PROCEDURE

It is my preference to identify the recurrent laryngeal nerve and parathyroid glands first by using Maryland and DeBakey forceps. Once these have been clearly defined, I then swap the DeBakey for the Harmonic shears. The shears use old CS14 harmonic technology that will

seal and transect vessels of up to 3 mm, which is adequate for RAT. As with all energy sealing devices, care must be taken when using this instrument close to the nerve.

Standard technique is to divide the superior pole vessels, identify the external branch of the superior laryngeal nerve then dissect the thyroid off the trachea and divide the isthmus as in a standard lobectomy. For a total thyroidectomy the approach is to divide the superior pole vessels first then dissect the thyroid off the trachea to help mobilize the remaining lobe. The inferior pole vessels and middle thyroid vein are then divided before identification and careful dissection of the nerve off the thyroid gland. This part of the operation often involves repositioning of the retractor, which has a tendency to slip. If a subtotal thyroidectomy is to be avoided, the contralateral thyroid lobe is required to be near normal in my opinion.

As in all thyroid surgery, haemostasis should be meticulous and a reversed Valsalva in the presence of normotension must be adhered to before closure. As in conventional surgery, I do not insert a drain and have found this to be unproblematic.

Closure of the incision is with 4-0 subcuticular Vicryl Rapide and Dermabond. An anterior chest wall compression dressing is applied overnight and patients are advised

to wear a sports bra or vest for 2 weeks to provide light compression to the anterior chest wall. I routinely give antibiotics for 7 days. Follow-up is at 2 weeks, then 3, 6, 12 and 18 months as all patients are in a prospective study for long-term RAT evaluation.

CONCLUSION

RAT is an exciting technological development in thyroidectomy. It is here to stay but presently will have niche indications. It is not for every surgeon, hospital or patient in its present state of technological development.

Economically it is difficult to justify and lack of competition in the robotic market is hindering the expansion of robotic surgery. Training, proctorship and credentialing are factors of vital and fundamental importance to guarantee safety.

The use of RAT is technically challenging with a steep learning curve. It is still in an evaluation phase and incorporation of patients into long-term studies will assist this process. Robotic technology must be used sensibly, responsibly and ethically to ensure patient safety.

KEY POINTS

- The evidence base for minimal invasive and scarless in the neck techniques for thyroid surgery are outlines.
- This is an evolving field that will witness the indications, applications and approach for remote thyroid surgery change with advances in robotic technology.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: goitre, goitre, retrosternal, thyroidectomy, mediastinal, thyroid, intrathoracic. There are no randomized controlled trials comparing treatments for the enlarged thyroid. Evidence to support statements made in the chapter are level 2b at best.

INTRODUCTION

The term 'goitre' derives its etymological origins from the Latin 'gutter' meaning throat.¹ Today goitre can be used to describe any thyroid considered to be larger than normal. Prior to widespread salt iodination, Gerber found the average thyroid weight in women over 50 years was 80–90g and in men 55–75g.² The same study found 30 years after salt iodination the average thyroid weight reduced by approximately half. Pankow et al. reported that the average weight of thyroids in men aged 20–29 years was 16.4g and 14.4g for women, suggesting that subjects spending their entire life under the influence of iodinated salt are likely to have a smaller thyroid.³ The upper limit of the normal thyroid gland in the iodine-replete population is considered to be 20g.^{4,5}

In 1994, the World Health Organization (WHO) defined goitre as any palpably enlarged thyroid.⁶ A number of geographically different radiographical studies in iodine-replete regions found the upper limit of the impalpable thyroid to be approximately 15 cm³ in men and 12 cm³ in women.^{7–9}

In this chapter we discuss the clinical and radiological assessment and management of the enlarged thyroid. This includes both retrosternal goitre and goitre without intra-thoracic extension.

TERMINOLOGY

The Swiss anatomist Haller first described the finding of a thyroid with intra-thoracic extension in 1749.¹⁰ The first report describing removal of such a thyroid was by

Klein in 1820.¹¹ Intra-thoracic, secondary intra-thoracic, substernal and cervicomediastinal are all terms that have been used synonymously with retrosternal. Up to ten definitions for these are found in the literature with the most commonly used being either (i) any goitre which extends below the thoracic inlet (with the patient in the surgical position) or (ii) any goitre where more than 50% of the gland is below the thoracic inlet.^{12–21} Primary intra-thoracic goitre is a distinct entity and describes a thyroid mass that originates from ectopic thyroid tissue in the mediastinum, rather than from cervical thyroid tissue.²²

Large goitres without intra-thoracic extension comprise a group without a clear definition in terms of volume or weight. One study of 813 goitres divided patient groups by weight of gland after thyroidectomy and defined the huge goitre as heavier than 400g.²³

AETIOLOGY

Crile attributed goitre with intra-thoracic extension to neck musculature obstructing extra-thoracic growth and directing the goitre downwards.¹⁴ In 1934, Lahey and Swinton discussed the potential role of negative intra-thoracic pressure and downward traction from swallowing.²⁴ These goitres tend to extend into the anterior mediastinum with only 10–15% growing into the posterior mediastinum.²⁵ The majority of these tend to be right-sided due to the great vessels impeding extension into the left thorax.²⁶ Primary intra-thoracic goitre is due to an abnormality of embryologic migration. A key point is that goitres with intra-thoracic

extension still derive their blood supply from the superior and inferior thyroid arteries, while primary intra-thoracic goitre is supplied by intra-thoracic vessels.^{27,28}

In accordance with the variation in terminology describing goitre with intra-thoracic extension, the incidence described in the literature varies from 0.2–45%.^{16,29} Using one of the most common definitions (where the majority of the goitre lies below the thoracic inlet) the incidence is up to 20%.^{16,25,30} Primary intra-thoracic goitre represents less than 1% of all goitres and up to 12% of all mediastinal tumours.³¹

CLINICAL PRESENTATION

In goitre without intra-thoracic extension, the most common presenting symptom is an anterior neck mass. Compressive symptoms (dysphagia, cough, dyspnea, wheeze, stridor) occur in up to 17% of patients and are associated with increasing size of goitre.^{32–34} In benign disease recurrent laryngeal nerve palsy at presentation is rare (0.7%).³⁵

The goitre with intra-thoracic extension often presents without any palpable, or a barely palpable, neck mass with the majority of the thyroid bulk being in the chest.^{1,36} Approximately 40% of these can be asymptomatic. The most common presenting symptoms are secondary to airway compression, with acute distress occurring in up to 20%, followed by dysphagia.^{16,37,38} Less common presentations include superior vena cava syndrome (venous distention of neck and chest wall, dyspnoea, facial oedema, upper limb oedema, plethora, cyanosis, papilloedema, cough, confusion), which can also lead to the development of downward oesophageal varices.^{39–42} Pemberton's sign (facial congestion and cyanosis while elevating both arms) indicates increased thoracic inlet pressure due to a retrosternal mass.⁴³ Horner's syndrome due to direct compression of the sympathetic chain, chylothorax due to thoracic duct compression and transient ischaemic attacks secondary to thyrocervical steal have also been reported.^{44–46}

Figure 70.1 Incidental plain chest X-ray abnormality suggesting a mediastinal mass due to primary intra-thoracic goitre.

Primary intra-thoracic goitre presents either as an incidental finding or with compressive symptoms similar to goitre with intra-thoracic extension.^{28,31}

INVESTIGATIONS

Biochemical assessment of thyroid function is necessary for management of all goitres. The majority are euthyroid, particularly goitres with intra-thoracic extension (80%).^{1,16,39,47} Up to 30% may have suppressed serum TSH levels without raised thyroid hormone levels (subclinical thyrotoxicosis).⁴⁸

Ultrasound is highly sensitive and specific for evaluating morphology and measuring volume of accessible, extra-thoracic goitre.^{49,50} It cannot evaluate intra-thoracic goitre, except as an occasional adjunct in transluminal endobronchial fine-needle aspiration to aid pre-operative diagnosis of posterior mediastinal goitre.⁵¹ CT remains the best imaging modality when evaluating the extent of intra-thoracic extension. As a basic rule, if it is not possible to palpate the distal extent of a thyroid goitre, a CT scan is necessary to assess its intra-thoracic extent.

CT allows assessment of the full inferior extent of the intra-thoracic goitre, as well as the shape and position of the goitre in terms of the mediastinal compartment.⁵² A number of studies have examined CT findings as predictors of whether a thoracic approach is needed. Although CT is not a definitive predictor, it is more likely a sternotomy will be required if the goitre extends below the level of the aortic arch or there is evidence of extra-thyroid extension suggesting malignancy.^{52–55} The risk of malignancy in goitres with intra-thoracic extension has been reported to be up to 11%.^{39,56} Factors that increase the likelihood of requiring a lateral thoracotomy are a goitre extending into the posterior mediastinum or a primary intrathoracic goitre that is primarily right-sided.⁵²

Scintigraphy plays no role in the pre-operative evaluation of the biochemically euthyroid patient.⁵⁷ Indeed, intra-thoracic goitres often demonstrate limited iodine avidity despite their size (Figures 70.1–70.4).

Figure 70.2 Confirmation of the mass as a likely primary intrathoracic goitre on parasagittal MR image.

Figure 70.3 ^{123}I image demonstrating reduced iodine avidity often demonstrated by primary intrathoracic goitre (blue arrow demonstrates thyroid uptake in the neck; white arrow demonstrates uptake in the intrathoracic portion).

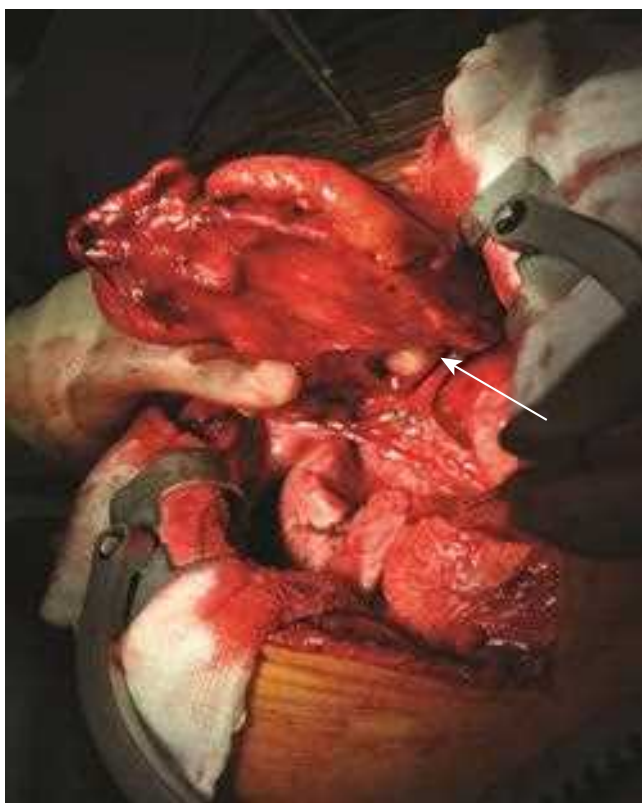

Figure 70.4 Removing the intra-thoracic goitre from the chest cavity preserving the innominate vein (arrow).

Objective assessment of respiratory compromise secondary to retrosternal goitre is difficult. The most common test performed is flow loop spirometry.⁵⁸ Obstruction secondary to goitre theoretically produces flow volume

loops characterized by plateaus of flow during both forced inspiration and expiration.⁵⁹ However, studies have found that flow volume loop results correlate poorly with goitre weight, extent of tracheal narrowing or patient-reported symptoms.^{60–63}

MANAGEMENT

When assessing the need for thyroidectomy in a patient with an enlarged thyroid and particularly retrosternal goitre, two questions need to be asked. First, will the patient benefit from the procedure and second are the surgical risks outweighed by the potential surgical benefits? The American Thyroid Association guidelines suggest that in the absence of lower airway disease, a patient will gain from retrosternal thyroidectomy from a respiratory perspective if the trachea is compressed by 35% or greater on axial CT imaging preoperatively.^{64, 65} However, the American literature shows us that patients with retrosternal goitre are older, have more comorbidities, and a 73% increased risk of death during admission.⁶⁶

In addition, patients undergoing sternotomy have a 25% risk of respiratory complications compared to a 2% risk for those who undergo a cervical approach only and the risk of deep sternal infection is cited as 1–5%, with sternal dehiscence carrying a 50% mortality rate.

A significant body of thyroid surgeons will cite the risk of spontaneous intragoitre haemorrhage leading to acute respiratory embarrassment as a reason to perform retrosternal thyroidectomy. However, Hsu tells us that in a retrospective group of patients presenting to the intensive care unit of Singapore General Hospital over a 15 year period with acute respiratory distress caused by mediastinal mass, only 1 of 19 was due to retrosternal goitre and this patient made a full recovery following surgery whilst admitted.⁶⁷ Perhaps therefore this risk, although real, is over exaggerated.

When assessing patients with retrosternal goitre therefore, it is important to remember that the majority comprise an older more frail patient subgroup.

NON-SURGICAL MANAGEMENT

No intervention

In the asymptomatic, euthyroid, benign goitre without intra-thoracic extension a conservative approach is appropriate.⁶⁸ A Scandinavian study followed up 261 patients with euthyroid goitre over 10 years.⁶⁹ Of these patients 21.8% required surgery due to worsening symptoms, 1.9% were diagnosed with carcinoma over the 10-year period and 5% developed thyrotoxicosis. Three patients died of their disease (two after developing anaplastic carcinoma and one with aggressive papillary carcinoma).

An operative approach is advocated by some as the only option to avoid the risks associated with bleeding or continued growth.^{39, 70, 71} One of the largest series of thyroidectomies published included 1153 goitres with intra-thoracic extension or primary intra-thoracic goitre.

This found that they were at a higher risk of post-operative complications compared to goitres without intra-thoracic extension.⁷²

Radioiodine therapy

In symptomatic patients who refuse or are unfit for surgery, radioiodine (¹³¹I) therapy remains an option. This has been used in the treatment of hyperthyroidism for over six decades.⁷³ Conventional ¹³¹I has been shown to reduce non-toxic goitre size by approximately 30–45% after 1–2 years in around 80% of patients.^{74–77} The effect does diminish with increasing goitre size and approximately 10% of goitres will continue to grow.⁷⁴ In a small series conventional ¹³¹I does appear to have the same effect on the intra-thoracic portion of goitres as the extra-thoracic portion.⁷⁸ Goitres causing compressive symptoms should not be considered for ¹³¹I as it can induce an acute increase in size.⁷³ Other adverse effects of ¹³¹I include radiation-induced thyroiditis, transient hyperthyroidism and long-term hypothyroidism (up to 58%).⁷³ The long-term risk of thyroidal or extra-thyroidal malignancy does not appear significant but is not definitively known.^{79–82} Recombinant human TSH-augmented ¹³¹I has been demonstrated to improve radioiodine uptake and increase volume reduction by 33–56% compared to conventional ¹³¹I therapy.^{83–85}

SURGERY

Anaesthetic considerations

Traditionally, the two primary anaesthetic concerns related to massive goitre were intubation difficulty and problems extubating due to tracheomalacia. A number of series have been published detailing the rate of difficulty intubating and/or the need for tracheostomy in patients with goitre.^{86, 87} These suggest that the majority of patients with huge goitres with or without intra-thoracic extension can be intubated successfully using i.v. induction or awake fiberoptic intubation. In a report from an endemic goitre region, the rate of tracheostomy was not increased in goitres weighing >400g compared to those <400g.²³ As might be expected, there is a significant increase in the proportion of difficult intubations in huge goitres. Tracheomalacia is also reported to be a rare occurrence in iodine-replete regions (<1%) though it may be more common in endemic goitre regions (up to 33%) in the huge goitre with or without intra-thoracic extension.^{23, 86, 88, 89} Treatment options for this include prolonged intubation, placement of supporting sutures, tracheal stenting and tracheostomy.^{23, 42}

Another concern is sudden, post-induction cardiorespiratory collapse, which has been described in patients with mediastinal masses.⁹⁰ Cardiopulmonary bypass is the necessary option in this situation. The risk of requiring this may be more common in posterior mediastinal goitre and in those with extremely low tracheal compression where prophylactic tracheostomy is not beneficial.^{91, 92}

Surgical considerations

The patient is consented ideally prior to the day of surgery. The aims of the operation should have been clarified by the operating surgeon and understood by both parties. Any imaging performed should be available in theatre. The important things to note on imaging are whether the thyroid extends into the posterior mediastinum, whether it extends behind the oesophagus and whether it extends between the trachea and oesophagus. Other significant factors include evidence of extra-thyroidal extension, and evidence of oesophageal or tracheal invasion. Careful study of the CT scan is necessary as tracheal invasion may be subtle but may make goitre delivery extremely difficult (Figures 70.5 and 70.6).

With retrosternal disease the likely necessity for cardiothoracic input should be identified pre-operatively. The overwhelming majority of retrosternal goitres are deliverable through a collar incision. However, it is foolhardy to perform such procedures in units where

Figure 70.5 Axial CT scan of the chest demonstrating early invasion of the tracheal wall (arrowed) from a poorly differentiated thyroid cancer in the 10 o'clock position.

Figure 70.6 Tracheoscopic confirmation of the CT findings.

cardiothoracic expertise is not available. Cardiothoracic input is necessary in primary intrathoracic goitre and occasionally in malignant thyroid disease where the tumour has extended beyond the boundaries of the thyroid within the chest. In the latter instance the benefit of resection should be carefully discussed with the patient pre-operatively because often the patient has comorbidities and the procedure is palliative rather than curative, so a careful risk–benefit analysis should be considered. Rarely, thoracic access is necessary due to patient proportion. A short, obese patient may provide limited access through the neck to the thyroid. The majority of these patients have incidental retrosternal glands, which begs the question: just because the thyroid is retrosternal, will its removal confer significant benefit to the patient?

Extension of the goitre to the level of the carina has previously predicted the need for sternotomy.^{13, 14} Thyroid weight greater than 800g has also been linked with the need for an extra-cervical approach, but this is a post-operative finding.^{13, 15} The choice of which extra-cervical approach to take depends on whether access to either hemithorax or mediastinum is required.

In the infrequent situation where greater exposure is required, the option for a partial upper median sternotomy, anterior thoracotomy in the second or third space or video-assisted thoracoscopic approach may be sought. Given that the majority of thyroid masses lie anterior to the innominate vein, a median sternotomy or partial upper median sternotomy provides ideal exposure to the mass and bilaterally towards the pleura. In posterior mediastinal goitre a lateral thoracotomy may be considered. If there is asymmetry to the retrosternal extension, entering via the side with the majority of the mass is appropriate, although the aortic arch can limit access on the left, especially if there is suggested involvement of posterior mediastinal structures such as the trachea. In this situation a right-sided posterolateral thoracotomy is the incisional choice. In the rare situation that there is lateral extension into the upper thorax, a Dartvelle approach (Figure 70.7) would provide better control of the subclavian vessels, though this may limit exposure in the neck. Additionally, the use of video-assisted

Figure 70.7 Dartvelle approach.

thoracoscopic surgery (VATS) has aided the excision of retrosternal goitres.

The patient is positioned 30° semi-supine with the right side slightly elevated. A double lumen tube allows for lung isolation. The possible approaches include a lateral camera position with medial utility ports allowing for retraction and dissection, or a subxiphoid camera position which can allow for visualization of both hemithoracic cavities. This approach provides good visualization from below and of the phrenic nerves, internal mammary vessels and great vessels. The mass is removed through the cervical incision. The subxiphoid approach limits visualization of the posterior mediastinum as the pericardium lies in the way.

Surgical procedure

A collar incision is made, normally extended to the membranous insertion of the sternomastoid muscles. A superior subplatysmal flap is raised and the flap extended laterally beyond the bodies of the sternomastoid muscles. In virtually every case, once the linea alba is divided to gain access to the thyroid isthmus, the strap muscles are divided. This is best performed superiorly as innervation of the straps is from inferior to superior.

The key to successful delivery of the retrosternal gland is to achieve mobility without excessive blood loss. A plane is therefore developed laterally between the thyroid lobe and the carotid sheath which may lie lateral to the cervical component of the gland, or anterior or posterior to the gland. An anteriorly placed carotid does not preclude thoracic delivery as lateral retraction will still enable delivery in the majority of cases. While the surgeon develops the plane, keeping on the gland surface, it is possible to assess the initial intra-thoracic extent of the gland, and indeed sometimes reach a finger to the inferior extent of the gland.

The next step is to devascularize the lobe. The superior thyroid pedicle is identified in the normal manner, retracted laterally from the cricothyroid muscle, to minimize risk of damage to the external branch of the superior laryngeal nerve, and divided vessel by vessel. The superior vessels are generally far larger in retrosternal glands so there is an increased need for ties or Ligaclips®. Once the pedicle is ligated, the mobility of the lobe is increased. Further blunt dissection laterally improves mobility further. This can be facilitated by placing a gauze swab on the lobe and digitally retracting the lobe out of the chest, the swab reducing slippage. A finger gently slid down the lobe into the mediastinum will give an indication of the extent of intra-thoracic extension. Using these manoeuvres, the lobe can often simply be delivered from the chest. This becomes more difficult if the thyroid is particularly firm or if the central isthmus portion of the gland is enlarged pushing the trachea away from the manubrium as this reduces the potential of swinging the enlarged lobe in a superomedial direction during extra-thoracic passage. In this circumstance it is often useful to palpate for the plane between the trachea and the lobe below the isthmus so that retraction from the chest can be performed both medially and laterally on the lobe.

Figure 70.8 Axial MR demonstrating huge goitre with right posterior mediastinal component.

The search for the recurrent laryngeal nerve is generally performed once the lobe has been delivered from the chest as the nerve will lie deep to the lobe. However, in posterior mediastinal goitre this is not always the case and the nerve can lie anterior to the retrosternal portion. In this instance, therefore, the nerve needs identifying prior to lobe delivery (**Figures 70.8** and **70.9**). Continuous vagal nerve monitoring if available is a great advantage in such cases.

On completion of the operation the strap muscles are restored and often a drain is inserted to reduce the risk of haematoma formation in the mediastinal space.

Figure 70.9 Delivery of right posterior mediastinal goitre through a cervical incision. The recurrent laryngeal nerve lies anterior to the goitre (arrow).

In a study comparing morbidity of surgery for goitres with and without intra-thoracic extension Pieracci, Fahey and others found that those with intra-thoracic extension experienced significantly higher rates of recurrent laryngeal nerve injury (2.1%), post-operative bleeding (2.2%) and deep-vein thrombosis (0.5%).^{68, 93–95} Multiple series suggest there is not necessarily a higher risk of permanent post-operative hypoparathyroidism following surgery for goitres with intra-thoracic extension.^{68, 94, 96} Increasing size or weight of thyroid alone does not appear to be associated with an increased risk of intra-operative surgical complications.^{23, 97–99}

KEY POINTS

- Surgery is performed on the enlarged thyroid to relieve obstructive symptoms, to manage thyroid overactivity, and to manage thyroid cancer or suspicious goitres.
- Pre-operatively the goitre should be assessed for function and extension. If the distal extent cannot be manually palpated, or if the goitre is an incidental intra-thoracic or retrosternal presentation, three-dimensional imaging should be obtained pre-operatively.
- Pre-operatively, the surgeon needs to know the extent of thyroid extension, whether the trachea or bronchi are compressed, and the relationship of the gland to the retro-oesophagus, and retropharyngotracheal area, beware the gland passing between the trachea and oesophagus. A significant isthmic retrosternal goitre is harder to deliver through the neck, and a patient's thoracic proportions should be considered.
- Surgeons should carefully assess imaging, paying particular attention to the integrity of the tracheal wall as tracheal invasion may be subtle.
- Surgery on large goitres, particularly with retrosternal extension, should involve an experienced thyroid anaesthetist.
- The thyroid will be deliverable through a collar incision in virtually every case but, if there is evidence of extra-thyroidal extension or primary intra-thoracic goitre, cardiothoracics should be alerted.
- When performing retrosternal thyroid surgery, the first part of the operation involves mobilizing the portion of the gland in the neck to facilitate thoracic delivery. During this phase it is not normally necessary to look for the nerve (except in posterior mediastinal presentation). Delivery is simplified by splitting the straps, dividing the isthmus, dealing with the upper pole, and digital dissection often both medial and lateral to the thoracic component at the level of the thoracic inlet.
- Retrosternal thyroid surgery should only be performed in a centre with cardiothoracic availability.
- In posterior mediastinal goitre be vigilant for the recurrent laryngeal nerve passing anterior to the thoracic portion of the goitre.
- When dissecting in the presumed tracheo-oesophageal groove, it is often worth inserting an oesophageal bougie to accurately locate the oesophagus and avoid mucosal transgression.
- Tracheomalacia is vanishingly rare in a first world economy but, if encountered, it will normally respond to extended intubation post-operatively.

CLINICAL EVALUATION OF HYPERCALCAEMIA

Mo Aye and Thozhukat Sathyapalan

Introduction	827	Laboratory evaluation	828
Interpretation of serum calcium	827	References	832
Clinical evaluation.....	828		

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: hypercalcaemia, parathyroid hormone, primary hyperparathyroidism, familial hypocalciuric hypercalcaemia and hypercalcaemia of malignancy.

INTRODUCTION

Since the advent of the automated serum biochemistry analyser in the 1970s, mild to moderate hypercalcaemia has become a common incidental finding in clinical practice. Very high serum calcium (more than 3 mmol/L, 12 mg/dL), however, remains uncommon. Whenever hypercalcaemia is confirmed, a definitive diagnosis needs to be established. Primary hyperparathyroidism (PHPT) and malignancy are the two commonest causes of hypercalcaemia and account for more than 90% of cases.¹ Initial evaluation should be directed at distinguishing between the two.

INTERPRETATION OF SERUM CALCIUM

Before any further investigation, it is essential to make sure that the apparent hypercalcaemia is not a false-positive laboratory test result. Biologically relevant hypercalcaemia is due to an elevated ionized ('free') calcium concentration. Most standard laboratories measure total calcium rather than ionized calcium. Up to 45% of serum calcium is bound to protein, principally albumin. Increased protein binding can result in apparent elevation in serum total calcium concentration without any rise in the ionized calcium.

This phenomenon is called 'pseudohypercalcaemia'. It may occur in those with hyperalbuminaemia from severe dehydration. Rarely, calcium-binding paraproteins in multiple myeloma present with pseudohypercalcaemia. Conversely, when albumin is low as in chronic illness, severe malnutrition or liver disease, serum total calcium may appear to be falsely low although ionized calcium is normal. If a laboratory is able to measure ionized calcium reliably, it would be preferable to measure it directly in clinical situations where serum albumin may be high or low.

Most laboratories will correct measured serum total calcium with respect to albumin, assuming normal albumin to be 40 g/L:

$$[\text{Ca}]_{\text{adjusted}} = [\text{Ca}]_{\text{total}} + \{0.02 \times (40 \text{ g/L} - [\text{Alb}]_{\text{serum}})\}$$

where:

$[\text{Ca}]_{\text{adjusted}}$: adjusted serum calcium, in mmol/L

$[\text{Ca}]_{\text{total}}$: measured serum total calcium, in mmol/L

$[\text{Alb}]_{\text{serum}}$: measured serum albumin concentration, in g/L.

With US units measuring calcium in mg/dL and albumin in g/dL, the correction formula is:

$$[\text{Ca}]_{\text{adjusted}} = [\text{Ca}]_{\text{total}} + \{0.8 \times (4 \text{ g/dL} - [\text{Alb}]_{\text{serum}})\}$$

A single, unexpected serum calcium reading should be repeated to confirm the diagnosis. If hypercalcaemia is detected in association with dehydration, calcium should be retested after correction of dehydration. Where cumulative results are available, previous calcium results should be reviewed to see if hypercalcaemia is acute or chronic. Chronic, stable, asymptomatic hypercalcaemia is likely to be benign, the commonest cause being PHPT. Familial hypocalciuric hypercalcaemia (FHH), an inherited condition characterized by a loss of function mutation of the calcium-sensing receptor (CaSR), may also present as chronic asymptomatic hypercalcaemia.

The degree of hypercalcaemia also may be useful diagnostically. Primary hyperparathyroidism usually presents with borderline or mild hypercalcaemia (serum calcium concentration often below 2.75 mmol/L, 11 mg/dL). Values above 3.25 mmol/L (13 mg/dL) are unusual in primary hyperparathyroidism, although they do occur, and are more common in patients with malignancy-associated hypercalcaemia.

CLINICAL EVALUATION

Mild to moderate hypercalcaemia is usually asymptomatic. Signs and symptoms of hypercalcaemia are non-specific and similar regardless of the cause. These include constitutional symptoms such as weakness, lethargy, intellectual weariness and depression.² Very severe hypercalcaemia both contributes to and is exacerbated by dehydration. Additional features should be sought in the clinical presentation to help uncover the underlying cause of hypercalcaemia.

An adult with asymptomatic hypercalcaemia probably has PHPT. Clinical features which favour this diagnosis include chronicity, modest elevation in serum calcium levels, slow or no progression of hypercalcaemia over time, normal physical examination and lack of obvious alternative diagnoses. Established end-organ damage such as osteoporotic fragility fractures, declining renal function and kidney stones may be surrogate features of chronicity and their presence may provide some reassurance that the underlying cause of hypercalcaemia is not neoplastic.

PHPT typically occurs in middle-aged or older women. A finding of high calcium in a patient outside this demographic group should prompt consideration of causes other than PHPT. Younger patients with hypercalcaemia may have a familial cause. Parathyroid cancer should be suspected in young men presenting with PTH-driven hypercalcaemia.

Although hypercalcaemia can be the first manifestation of malignancy, in most patients with malignancy-associated hypercalcaemia, the disease is not occult. Typically, features of underlying disease would have brought the patient to medical attention; hypercalcaemia is detected as an additional finding during further investigations. Rapidly progressive or very high serum calcium concentrations should raise concerns about malignancy. Breast, lung, colon and prostate cancers are the commonest solid organ tumours with skeletal metastases.³

TABLE 71.1 Causes of hypercalcaemia

Parathyroid hormone dependent

- I. Primary hyperparathyroidism
 - a. Solitary or multiple adenomas
 - b. Parathyroid hyperplasia
 - c. Parathyroid cancer
- II. Tertiary hyperparathyroidism (end-stage renal failure)
- III. Ectopic PTH secretion (very rare)
- IV. Multiple endocrine neoplasia – MEN 1 and 2a
- V. Inactivating mutations in CaSR or G proteins: familial hypocalciuric hypercalcaemia (FHH)
- VI. Lithium therapy (alteration in CaSR function)

Parathyroid hormone independent

- I. Neoplastic
 - a. Osteolytic skeletal metastases
 - b. Multiple myeloma
 - c. Paraneoplastic syndrome (PTHrP mediated)
- II. Chronic granulomatous disease (e.g. sarcoidosis)
- III. Endocrine disorders
 - a. Hyperthyroidism
 - b. Acromegaly
 - c. Hypoadrenalism
- IV. Medications
 - a. Thiazide diuretics
 - b. Hypervitaminosis A or D
 - c. Theophylline
 - d. Teriparatide (human recombinant PTH 1-34)
- V. Excessive calcium intake
 - a. Milk-alkali syndrome
 - b. Total parenteral nutrition
- VI. Miscellaneous
 - a. Immobilization
 - b. Metaphyseal chondrodysplasia
 - c. Congenital lactase deficiency

Clinical evaluation should include an enquiry about weight loss, change in bowel habit, examination of the respiratory system, breast examination in women and prostate examination in men. Multiple myeloma may present with hypercalcaemia alone.

Dietary calcium intake and medications (prescription and non-prescription drugs, herbal preparations, calcium and vitamin supplements) are important to diagnose drug-induced hypercalcaemia (Table 71.1). If possible, any medication that may be causing hypercalcaemia should be discontinued. With the exception of vitamin D excess, hypercalcaemia is generally mild in drug-induced hypercalcaemia. Diagnoses are not mutually exclusive. It is possible for thiazide diuretics to accentuate or unmask mild or incipient PHPT.

LABORATORY EVALUATION

Once hypercalcaemia has been confirmed, the next step should be to determine whether this elevation is PTH-driven. PTH mediates hypercalcaemia both in PHPT and FHH. All other causes of hypercalcaemia suppress PTH (Table 71.2).

TABLE 71.2 Differential diagnosis of hypercalcaemia

Condition	Total adjusted serum calcium	Ionized serum calcium	Phosphate	Parathyroid hormone (PTH)	Urinary calcium excretion	Vitamin D	Comments
Pseudohypercalcaemia	↑	↔	↔	↔	↔	↔	May occur in presence of calcium-binding proteins other than albumin (e.g. in myeloma)
Primary hyperparathyroidism (PHPT)	↑	↑	↔ or ↓	↑ or high-normal	High-normal or ↑	↔ or ↓	Usually mild to moderate. More common in postmenopausal women. May be hereditary, e.g. MEN 1 and 2a
Familial hypocalciuric hypercalcaemia (FHH)	↑	↑	↔ or ↓	↑	Ca: creatinine excretion ratio <0.01	↔	Autosomal dominant. Usually presents with asymptomatic hypercalcaemia
Osteolytic skeletal metastases	↑↑	↑↑	↔ or ↑	↓↓	↑ but routine measurement not needed	↔	May present with very high calcium level, often over a short duration. Clinical features of primary solid organ tumour usually predominates
Multiple myeloma	↑	↑	↔ or ↑	↓	↔ or ↑	↔	Hypercalcaemia may be the first presenting clinical feature. Usually has normal alkaline phosphatase
Paraneoplastic syndrome	↑	↑	↔ or ↑	↓	↔ or ↑	↔	Raised PTHrP. Features of malignancy may predominate
Vitamin D excess (oral ingestion, granulomatous disease, lymphoma)	↑	↑	↑ or ↔	↓	↔ or ↑	↔ or ↑	1,25-DHCC raised in granulomatous disease and lymphoma

Serum parathyroid hormone (PTH)

ELEVATED OR MID- TO HIGH-NORMAL PTH

Hypercalcaemia with elevated PTH is likely to be PTH-driven. Elevated PTH in the setting of hypercalcaemia is most likely to be due to PHPT.⁴ For reasons which are not clear, PHPT also appears to be more common in cancer patients than in the general population.^{5, 6} PTH should still be measured even in patients with known malignancy who present with elevated calcium. Confirmation of PHPT in this situation could obviate a psychologically distressing and ultimately futile search for metastatic or paraneoplastic disease.

Parathyroid hormone levels should be interpreted in context. Physiologically, once hypercalcaemia is established, production of PTH from the parathyroid glands should be switched off. A PTH level within the upper half of the reference range despite hypercalcaemia is 'inappropriately elevated'; this picture is still consistent with PTH-driven hypercalcaemia and hence with the diagnosis of PHPT. It should also be noted that PTH levels rise with age. In a younger individual (age <45 years), the normative range is lower and narrower. PHPT in a young individual may show a PTH value that is within normal range for the population.⁷

However, with a PTH level within the upper end of the normative range, other diagnoses such as FHH should also be considered. PTH levels may be influenced by pre-analytic factors related to collection, storage and transit.⁸ PTH should be repeated when the test results appear equivocal.

In chronic kidney disease, there is complex interplay of regulatory hormones (PTH, calcitriol and fibroblast growth factor 23 (FGF-23)). The characteristic biochemical picture is elevated PTH in response to high phosphate, low calcitriol (1,25 dihydroxycholecalciferol), with or without low serum calcium. Hypercalcaemia is relatively rare until relatively later stages of chronic kidney disease (estimated glomerular filtration rate <30 mL/min/1.73 m² BSA). Hypercalcaemia in this situation may occur as a progression of compensatory ('appropriate') parathyroid hyperplasia to an autonomous overactivity of parathyroid glands. This is known as tertiary hyperparathyroidism. The diagnosis is relatively straightforward since the emerging trend would be well documented in a patient with progressive renal decline; most patients who develop tertiary hyperparathyroidism also have end-stage renal failure. Hypercalcaemia may be absent in those patients if they are on haemodialysis.

Hypercalcaemia may also be seen in patients with adynamic bone disease, a form of chronic kidney disease mineral bone disorder (CKD-MBD) characterized by low bone turnover. In such patients, calcium elevation results from failure of the bone to take up calcium after an oral calcium load, such as calcium carbonate to treat hyperphosphataemia.⁹ PTH in adynamic bone disease is only modestly elevated, typically (<11 pmol/L, 110 pg/mL) and may appear disproportionately low relative to the degree of renal dysfunction.

Following renal transplantation, the parathyroid hyperplasia subsides over a period of months to years. Sometimes, hypercalcaemia develops after successful renal transplantation as calcitriol production is restored before parathyroid hyperplasia has subsided completely.

SUPPRESSED PTH

PTH-independent causes should be considered if the PTH is low or within the lower half of the reference range. Serum intact PTH levels below 2.2 pmol/L (20 pg/mL) are highly suggestive of a non-PTH related cause.

Malignancy should be suspected if the hypercalcaemia is of short duration and especially if the calcium level is very high (>3 mmol/L). More often than not, the primary tumour is a solid organ tumour and the patient may present with clinical features attributable to the primary cancer. Hypercalcaemia may arise from direct lytic metastases from non-small cell lung cancer, breast cancer, renal cell carcinoma and gastrointestinal tumours. Skeletal symptoms such as bone pain and pathological fractures may be present. It is recognized, however, that hypercalcaemia and the extent of skeletal metastases are poorly correlated.¹⁰

In the absence of overt skeletal metastases, humoral hypercalcaemia of malignancy may arise from the action of tumour-derived humoral factors, such as PTH-related protein (PTHrP). PTHrP-related hypercalcaemia has been described in association with solid organ tumours, particularly squamous cell carcinoma of the lung and skin, head and neck tumours and renal cell carcinoma. PTHrP does not react with PTH assays. Humoral hypercalcaemia is accompanied by suppressed PTH levels on standard second- and third-generation PTH assays. Measurement of PTHrP is seldom justified in clinical practice as the underlying malignancy should be self-evident. Levels of PTH and 1,25DHCC are both suppressed appropriately.¹¹

Hypercalcaemia occurs in as many as 30% of patients with multiple myeloma.¹⁰ Anaemia, bicytopenia or pancytopenia may be accompanied by reversal of albumin-globulin ratio and impaired renal function. Alkaline phosphatase usually remains normal as osteoclastic bone resorption in myeloma is not accompanied by osteoblastic attempts at bone formation. A number of cytokines have been implicated, including tumour necrosis factor α (TNF- α), transforming growth factor β (TGF- β), interleukin-1 and leukaemia inhibitory factor. In the past, these humoral agents were collectively covered under a generic

term 'osteoclast activating factor'. Elevated PTHrP has also been described in myeloma patients.

24-hour urinary calcium and urine calcium/creatinine excretion ratio

Urinary calcium should be measured routinely in suspected PHPT. The 2013 Fourth International Workshop consensus criteria lists calcium excretion of more than 10 mmol/day (400 mg/day) as one of the criteria for considering surgery in asymptomatic PHPT.

Familial hypocalciuric hypercalcaemia is rare in the general population but it is clinically important because the biochemical picture is indistinguishable from PHPT except for hypocalciuria.¹² The 24-hour urinary calcium is typically less than 5 mmol/day (200 mg/day) in FHH. Calculating urinary calcium/creatinine (Ca/Cr) excretion ratio is preferable to simply measuring 24-hour urinary calcium for excluding FHH. The ratio is calculated using paired serum and urinary calcium and creatinine samples, using the following formula:

$$\text{Ca/Cr excretion ratio} = \frac{\text{Urine calcium} \left(\frac{\text{mmol/L}}{\text{L}} \right) \times \text{Plasma creatinine} \left(\frac{\mu\text{mol}}{\text{L}} \right) / 1000}{\text{Plasma calcium} \left(\frac{\text{mmol/L}}{\text{L}} \right) \times \text{Urine creatinine} \left(\frac{\text{mmol}}{\text{L}} \right)}$$

The Ca/Cr excretion ratio is less than 0.01 in approximately 80% of patients with FHH. In PHPT, the Ca/Cr excretion ratio is typically greater than 0.02.

When evaluating patients with apparent hypocalciuria, other factors which may cause hypocalciuria should also be considered and eliminated. These include vitamin D deficiency (<30 nmol/L, <12 ng/mL), very low calcium intake, treatment with thiazide drugs and lithium therapy.

In FHH, there may be a family history of hypercalcaemia as FHH follows an autosomal dominant pattern of inheritance. Patients with FHH have few, if any symptoms. Hypercalcaemia tends to be modest. PTH itself may be high-normal or just modestly elevated. Serum magnesium levels may also be raised. Hypocalciuric hypercalcaemia may be acquired as an autoimmune disorder and may be associated with antithyroid, antigliadin or anti-endomyseal antibodies.

Vitamin D metabolites

Except in cases of obvious humoral hypercalcaemia of malignancy, serum vitamin D should be performed routinely in non-PTH dependent hypercalcaemia. An elevated 25-hydroxycholecalciferol [25(OH)D] is indicative of excessive ingestion of vitamin D. There is no agreement on the level of 25(OH)D at which hypercalcaemia typically occurs. Many experts define vitamin D intoxication as a value greater than 375 nmol/L (150 ng/mL).¹³

Parathyroid hormone catalyses the conversion of 25(OH)D to 1,25 dihydroxycholecalciferol (1,25-DHCC). With long-standing PHPT, it is common for the substrate 25(OH)D to become depleted. Serum calcium may drift lower with coexisting vitamin D deficiency with the true extent of hypercalcaemia being revealed only after vitamin D deficiency has been corrected.

Measurement of 1,25-DHCC is not required routinely but should be considered if the cause of hypercalcaemia is unclear. Extra-renal conversion of 25(OH)D to 1,25-DHCC occurs in granulomatous diseases and in lymphoma. A chest X-ray to look for malignancy or sarcoidosis may be helpful. Most patients with sarcoidosis or lymphoma generally have clinically evident pulmonary and extrapulmonary manifestations. In the absence of such clinical involvement, a thorough search for occult pulmonary, renal, hepatic, ocular and bone marrow granulomas is indicated.

PTH-independent hypercalcaemia associated with normal or low vitamin D metabolites may result from unsuspected stimulation of bone resorption (as in multiple myeloma, thyrotoxicosis, prolonged immobility, hypervitaminosis A), or unrecognized high calcium intake especially in the face of milk-alkali syndrome.

Serum phosphate

Parathyroid hormone is phosphaturic. A low phosphate level may occur in PHPT and in PTHrP-driven humoral hypercalcaemia. Vitamin D increases reabsorption of phosphate from renal tubules. Hypercalcaemia which occurs in association with vitamin D excess or in granulomatous diseases is associated with high or high-normal phosphate levels. Phosphate levels are variable in FHH.

Diagnostic imaging

Evidence of osteitis fibrosa on a bone film is very specific for primary hyperparathyroidism but is only seen in about 5% of cases. Radiographs of the skeleton are no longer recommended in view of the rarity of radiologically detectable bone disease. There is no role for high-resolution neck ultrasound, computed tomography or technetium ^{99m}Tc sestamibi (MIBI) scintigraphy in routine evaluation of suspected PHPT. These tests are useful only for pre-operative localization of confirmed disease.

Tests of other endocrine diseases

In most situations, hypercalcaemia occurring in association with other endocrine diseases is an ancillary finding. The clinical presentation is usually dominated by signs and symptoms of the underlying endocrine condition.

THYROID FUNCTION TESTS

Mild hypercalcaemia occurs in 15–20% of patients with thyrotoxicosis.¹⁴ Hypercalcaemia persisting after control of thyrotoxicosis should be evaluated on its own merits, as there may be concomitant hyperparathyroidism.

EVALUATION OF ADRENAL FUNCTION

Hypercalcaemia is an occasional finding in adrenal insufficiency.¹⁵ Possible contributory factors are: increased bone resorption, ECF volume contraction, haemoconcentration and increased proximal tubular reabsorption of calcium. Cortisol administration reverses hypercalcaemia within days. Again, persistence of hypercalcaemia despite treatment should prompt evaluation. Hypercalcaemia has also been described in central hypoadrenalism due to hypophysitis.¹⁶

EXCLUSION OF PHAEOCHROMOCYTOMA

PHPT occurs as part of multiple endocrine neoplasia (MEN 2a). Rarely, hypercalcaemia can be a feature of pheochromocytoma itself due to humoral production of PTHrP.

Miscellaneous conditions

Other less common causes of hypercalcaemia due to increased bone resorption include Paget's disease of the bone, especially if the patient is immobilized, administration of oestrogen or a selective-oestrogen receptor modifier (SERM) to patients with breast cancer who have extensive skeletal metastases¹⁷ and hypervitaminosis A (ingestion of more than 50000IU daily).¹⁸ Retinoic acid causes a dose-dependent increase in bone resorption, resulting in overall incidence of hypercalcaemia of approximately 30%.^{19, 20} Theophylline toxicity has been associated with mild hypercalcaemia.²¹ In Jansen-type metaphyseal chondrodysplasia, a rare form of dwarfism, mutations in PTH or PTHrP receptor genes result in continuous activation of the receptor even with low PTH levels of PTH secretion.²² The clinical picture is that of asymptomatic but significant hypercalcaemia with low phosphate and normal or low PTH.

KEY POINTS

- Primary hyperparathyroidism and malignancy are the two commonest causes of hypercalcaemia.
- Once hypercalcaemia is confirmed, the next step is to determine whether this elevation is parathyroid hormone driven by measuring parathyroid hormone.
- Parathyroid hormone levels will be raised or inappropriately normal in primary hyperparathyroidism and suppressed in malignancy related hypercalcaemia.
- In patients with familial hypocalciuric hypercalcaemia the urine calcium creatinine excretion ratio is typically less than 0.01.

Invasive localization techniques	838		

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: hyperparathyroidism, localization, invasive, non-invasive, imaging, intra-operative and sestamibi.

INTRODUCTION

Primary hyperparathyroidism (PHPT) is the commonest cause of hypercalcaemia in the outpatient population. Over the last decade the advent of improved pre-operative imaging, intra-operative PTH monitoring (IOPTH) techniques and radioguided surgery has resulted in the development of various techniques of 'minimal access parathyroidectomy'. These have succeeded the classic 'four-gland bilateral exploration', with better outcomes.^{1,2} Primary hyperparathyroidism is usually caused by a solitary adenoma (80–85%), hyperplasia (10–15%), double adenoma (2–5%) or parathyroid carcinoma (<1%).³

Pre-operative localization studies are useful in determining the appropriate surgical technique and approach; they should not be used as a diagnostic tool or as a factor to decide the need to operate and should be ordered only after a decision has been made to operate. Information gained contributes to reduced surgical time, reduced hospital stay, less risk of permanent hypoparathyroidism and use of local/regional anaesthesia.⁴

Several modalities can be used to image the parathyroid gland and can be categorized into:

- **non-invasive studies:** radiology/sonography-based imaging, nuclear medicine imaging
- **invasive techniques:** selective venous sampling (SVS), parathyroid arteriography, fine-needle aspiration.

NON-INVASIVE LOCALIZATION STUDIES

Ultrasonography

The neck is scanned with the patient in the supine position and head slightly extended to simulate the position during surgery. Usually sonography is performed with a 10 MHz or a higher transducer to provide gray scale and colour Doppler imaging in the transverse and longitudinal planes. Ultrasound (US) provides detailed anatomical information of the gland and structures adjacent to it. Techniques can be utilized to aid identification of enlarged parathyroid glands, which include rotating the neck away from the side being examined, gentle compression of the neck and asking the patient to swallow during the scanning.

The results are highly operator-dependent with sensitivity and specificity of US imaging in the ranges 51–96% and 90–98% respectively.^{4–6} The sensitivity of glands >500 mg is 86% compared with 75% for glands <500 mg.⁷ Factors that reduce the sensitivity of US are a background of concomitant multinodular thyroid, parathyroid hyperplasia and multiple adenomas. There seems to be no difference in US detection of adenomas due to serum calcium and PTH values.⁸

Attention is focused on the area posterior and inferior to the thyroid gland, medial to the carotid sheath and the tracheo-oesophageal groove. The superior parathyroid

glands are less commonly ectopic as compared to the inferior pair. Up to 20% of PAs are found at ectopic sites. The usual sites are the retro-oesophageal, retro- or paratracheal, superior mediastinum, within the carotid sheath, thymus tissue and adjacent to the hyoid bone. Scanning should be extended to the retromandibular area superiorly down to the clavicle/suprasternal notch if not found in the usual sites.

The classic enlarged parathyroid adenoma is greater than 1cm and typically a homogeneously hypoechoic, ovoid, well-margined, extrathyroidal solid lesion with a fat or connective tissue plane separating it from the thyroid gland. Parathyroid adenomas are typically highly vascular lesions, which on colour Doppler sonography reveal a peripheral vascular arc arising from a vascular pedicle on the superior or inferior pole of the adenoma (Figure 72.1). In comparison, normal lymph nodes have a central echogenic fatty hilum surrounded by hypoechogenic cortex with small hilar vessels and are typically kidney-shaped.

Larger adenomas may be multilobed, pear-shaped or complex with cystic/solid components. Other structures in the vicinity which may mimic PA are the oesophagus and the longus colli muscle. They are recognized on US imaging by identifying the striated muscles, position and their elongated structures. Parathyroid carcinomas may show cystic degeneration, calcification, heterogeneity with local invasion and local lymphadenopathy. Intra-thyroidal adenomas (Figure 72.2) may mimic thyroid nodules whereas thyroid nodules may appear like parathyroid adenomas (Figure 72.3). In Hashimoto's thyroiditis central compartment lymphadenopathy may make it difficult to identify parathyroid adenomas due to similar features.⁹

US-guided fine-needle aspiration and rapid PTH assay can help differentiate an adenoma from a lymph node, and it is utilized especially to evaluate patients before revision surgery.¹⁰ If all four parathyroid glands are enlarged on ultrasound, the diagnosis may be PT hyperplasia; the glands may appear asymmetrically enlarged and individual hyperplastic glands may be difficult to distinguish from an adenoma. The advantages and disadvantages of US scanning are listed in Table 72.1.

Figure 72.1 Colour Doppler sonography reveals a peripheral vascular arc arising from a vascular pedicle on adenoma.

Figure 72.2 Intra-thyroidal adenoma.

Figure 72.3 Multinodular goitre with parathyroid adenoma.

TABLE 72.1 Ultrasonography for parathyroid adenomas

Advantages	Pitfalls
Inexpensive	Operator-dependent
No radiation exposure	Ectopic or intra-thyroid adenomas missed
Non-invasive	Limited value in retro-oesophageal, paratracheal and mediastinal adenomas
Helpful in fine-needle biopsy	Difficult to differentiate between small adenomas and lymph nodes

For best results and interpretation of parathyroid sonography, well-trained and experienced personnel with a specialist interest are essential and lead to successful localization of the parathyroid adenomas in the surgical field.

Imaging using radioactive tracers

SESTAMIBI SCINTIGRAPHY

^{99m}Tc sestamibi was originally used for diagnostic cardiology and was accidentally found to be concentrating in parathyroid adenoma tissue.¹¹

TABLE 72.2 Predictive factors for sestamibi scan

Positive	Negative
High oxyphil content (>20%)	Thyroid nodules
Vitamin D deficiency	Multigland disease
High PTH levels	Adenomas <600 mg
High calcium levels	Calcium channel blockers

Sestamibi diffuses passively through cell membranes and accumulates almost exclusively in mitochondria. High mitochondria content in oxyphilic cells in parathyroid adenomas is considered to be the reason for the excessive tissue uptake in PHPT.¹² A meta-analysis of 35 ultrasound and 14 sestamibi-SPECT studies had a pooled sensitivity of 76.1% and 78.9% respectively.¹³

Factors influencing sestamibi imaging include the following and are summarized in [Table 72.2](#):

- **Calcium:** A higher calcium level is more likely to be observed in patients with positive sestamibi scans. In a study of 102 patients, a positive sestamibi scan was found in over 95% of patients with calcium over 11.3 mg/dL.¹⁴ Other studies suggested that the severity of hyperparathyroidism has an influence on sestamibi scans, with positive scans in 64% of asymptomatic patients, in 83% with nephrolithiasis and in 100% of patients with severe bone involvement.¹⁵
- **PTH:** A high PTH level was directly related to the uptake ratio and positive scans, with almost 100% sensitivity when the PTH levels exceed 200 pg/mL.¹⁶ This was not replicated by others¹⁷ and PTH levels do not allow selection of candidates for pre-operative scanning.¹⁸
- **Vitamin D deficiency:** In a study of 421 patients with low cholecalciferol levels, positive scans were more

likely in those who were vitamin D-deficient than in those with normal vitamin D.¹⁹

- **Calcium channel blockers:** The use of these interferes with the sestamibi uptake by parathyroid cells and reduces the sensitivity of ^{99m}Tc-MIBI parathyroid SPECT.²⁰
- **Oxyphil content:** Adenomas with >20% oxyphil cell content are associated with a positive scan while small adenomas (<600 mg) and low oxyphil cells (<20%) are likely to give negative results.²¹
- **Multigland disease:** In a study of 123 patients, none of the 15 patients with multigland disease were identified pre-operatively. It is a major shortcoming of sestamibi scanning in identifying multigland disease.²²
- **Thyroid disease:** In the presence of thyroid nodules, the sensitivity of sestamibi scanning is low (92% vs 53%).²³ However, a large retrospective study did not find any difference.²⁴

Sestamibi scintigraphy is the imaging of choice for pre-operative localization of parathyroid adenomas. ^{99m}Tc sestamibi is taken up by the mitochondria of the salivary, thyroid and parathyroid tissue. In parathyroid adenomas the mitochondria-rich oxyphil cells retain the radiotracer for longer than in thyroid tissue.²⁵ It is a functional scan and provides limited anatomical details.

The patient should be positioned as on the operating table with a sandbag under the shoulders under the gamma camera. Dual phase planer images are taken 10 minutes after injection of ^{99m}Tc sestamibi and again 2 hours later to identify a focus of retained radiotracer consistent with a hyperfunctioning parathyroid gland. It is better at picking up mediastinal ectopic glands not identified in ultrasound imaging ([Figure 72.4](#)). It is also used to identify adenomas during radioguided surgery. The combination of sestamibi scans with 3-dimensional (SPECT) imaging, fusion with

Figure 72.4 Sestamibi scan showing ectopic parathyroid in the mediastinum.

computed tomography (MIBI-SPECT-CT) and thyroid subtraction scans helps obtain better results.

SPECT

Sestamibi–single-photon emission computed tomography (SPECT-MIBI) provides multidimensional higher-resolution images, which helps to detect glands deep in the neck and improves detection of ectopic glands, hence aiding focused surgical techniques. Various studies have shown that SPECT (92–98%) improves the sensitivity of abnormal parathyroid gland in comparison to sestamibi scintigraphy (71–79%).^{26,27} Its sensitivity to identify multigland disease is, however, limited (Figure 72.5).

SPECT-CT FUSION

The addition of an integrated SPECT-CT scanner combines the gamma camera with a multidetector CT (Figure 72.6). The SPECT provides the functional information while the CT provides the anatomical information which facilitates surgical exploration.²⁸ A study using SPECT-CT revealed the exact position of the abnormal gland in 102 out of 116 patients (88%), while CT or SPECT-MIBI alone was predictive in 65% and 55% respectively.²⁹

SUBTRACTION THYROID SCAN

Dual isotope subtraction scintigraphy is useful in identifying abnormal parathyroid glands in the presence of thyroid pathology. The patient is given a radiotracer which accumulates in thyroid and parathyroid (sestamibi) followed by a thyroid-specific radiotracer (radioiodine ^{123}I or technetium pertechnetate ($^{99\text{m}}\text{Tc}$ pertechnetate)).³⁰

After taking images of both radiotracers, computer software is used to subtract the thyroid element from the combined thyroid parathyroid (sestamibi) image, revealing the parathyroid area (Figure 72.7). The limitation of this technique is that the image quality can be compromised due to motion artefact.

COMPUTED TOMOGRAPHY (CT)

Axial contrast-enhanced fine cuts (2.5–3 mm) through the neck will help localize PAs in 46–87% of cases,^{31,32} allowing accurate imaging for focused surgical techniques. This modality is available in most hospitals but it is a costly procedure with exposure to radiation. On routine use, studies have not found any advantage over ultrasound in identifying abnormal parathyroid glands. It is helpful in identifying ectopic glands in the mediastinum or

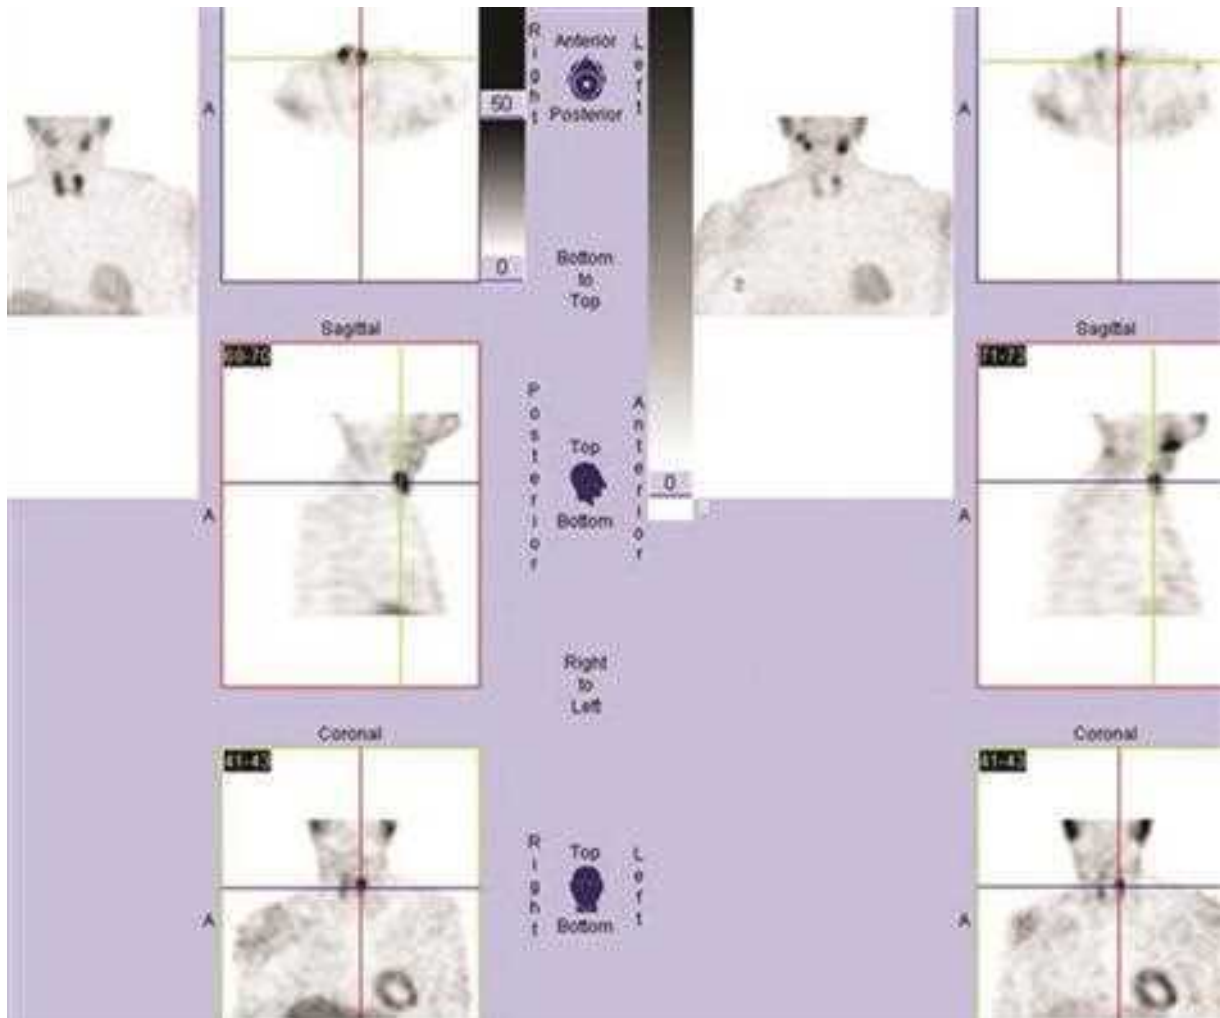

Figure 72.5 SPECT-MIBI.

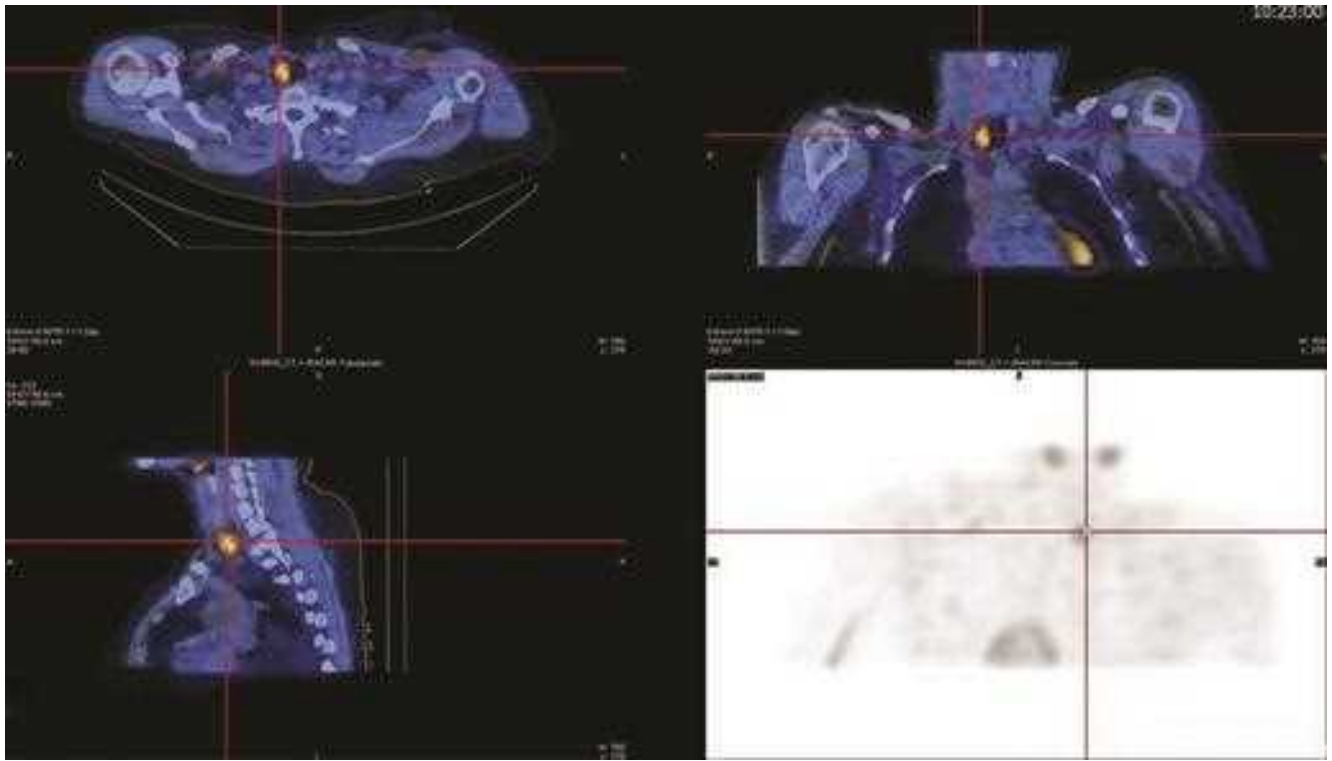

Figure 72.6 MIBI-SPECT-CT.

Figure 72.7 Dual isotope: Sestamibi/iodine 123, subtraction study.

trachea-oesophageal groove, especially in patients with a prior failed neck exploration and distorted tissue planes.³³

Four-dimensional computed tomography (4D-CT) techniques utilize the characteristic of rapid contrast uptake and washout of parathyroid adenomas. The name is derived from an added dimension from the rapid changes of perfusion of contrast over time to 3D-CT. It provides both anatomical and functional data about the abnormal parathyroid glands. The image protocol for 4D-CT scans initially consists of an unenhanced scan followed by an intravenous bolus of non-ionic contrast (2 mL/kg with a maximum of 120 mL at 4 mL/second). Triple-phase 1.5 mm axial scans are repeated from the angle of the mandible to the carina at 30, 60 and 90 seconds after the administration of contrast.

Information from 4D-CT helps to localize ectopic glands (in the deep neck, mediastinum or laterally within the carotid sheath) or intra-thyroid parathyroid adenomas. Prior to the intravenous administration of contrast material, parathyroid adenomas demonstrate attenuation similar to that of muscle. Parathyroid adenomas tend to be hypervascular structures with variable contrast enhancement and early washout. A hypervascular soft-tissue mass near the expected location of the parathyroid glands is considered to represent a parathyroid adenoma (Figure 72.8). Ectopic glands may be seen, most commonly within the mediastinum. This helps to improve pre-operative planning in revision surgery in a scarred field with poor tissue planes and thus reduces operative morbidity.^{34–36}

MAGNETIC RESONANCE IMAGING (MRI)

This modality is less commonly used than ultrasound and sestamibi scans for pre-operative localization but is still useful for evaluation of abnormal parathyroid glands due to its excellent anatomic detail. For revision surgery, it provides a non-invasive, radiation-free modality to localize abnormal parathyroid tissue. The reported sensitivity of MRI for abnormal parathyroid tissue ranges from 74% to 88%^{37, 38} and images are not degraded by streak artefacts from surgical clips or previous surgery. However, compared to CT scans, MRI appears especially useful in detecting ectopic mediastinal glands, with sensitivities exceeding 80%.³⁹ Parathyroid adenomas are identified as soft-tissue masses in the expected location of the

Figure 72.8 4D CT scan. (Courtesy: Dr F. Riffat.)

parathyroid glands. The most common tissue characteristics are intermediate to low T1-weighted images and high signal intensity on T2-weighted images.⁴⁰ The accuracy of MRI imaging of parathyroid disease is reduced in concomitant thyroid disease, which is present in up to 40% of patients with hyperparathyroidism.⁴¹

POSITRON EMISSION TOMOGRAPHY AND CT (PET-CT)

Studies of FDG-PET do not confirm that it is as good an imaging technique as MIBI and ultrasound for abnormal parathyroid glands.⁴² In patients with initial diagnosis of hyperparathyroidism, the sensitivity of PET-CT for detection and localization of parathyroid adenomas is not as promising as previously thought.⁴³ While performance was better in secondary hyperparathyroidism, we believe that PET-CT cannot be recommended for PHPT localization although it may be useful for patients in whom other imaging modalities have failed to find the abnormal parathyroid gland.⁴⁴

INVASIVE LOCALIZATION TECHNIQUES

Selective venous sampling

Selective venous sampling (SVS) is the most common invasive modality used for parathyroid localization and the accuracy is much better than large venous sampling. In patients with suspected residual parathyroid adenomas after unsuccessful surgery or in those where non-invasive methods are negative or conflicting, invasive localization techniques may be helpful. In these situations, SVS has a sensitivity of 75% compared to sestamibi (65%) or ultrasound (50%).⁴⁵ A 1.5–2-fold increase in PTH levels allows for identification of side (left vs. right) and region (cervical vs. thoracic). False positive results in SVS can be attributed to post-operative changes in venous flow due to ligatures or scarring.

Factors that need to be considered with SVS include costs, expertise, radiation exposure and risks such as haematoma at catheter site, adverse reactions to contrast material and vascular accidents. With intact PTH assays, the sensitivity of SVS has been reported as high as 98%⁴⁶ and can be considered as the gold standard in patients with persistent or recurrent hyperparathyroidism and unhelpful non-invasive localization techniques.

Parathyroid arteriography

Selective arteriography was performed to localize adenomas in the past when other non-invasive techniques were not available, with varying results. Due to the risk of central venous system complications associated with this technique, it is rarely used. There may be limited benefit in post-operative patients with altered venous or fascial anatomy due to surgical sequelae.

Fine-needle aspiration

For revision surgery, CT or ultrasound-guided fine-needle aspiration (FNA) can be helpful in distinguishing parathyroid from non-parathyroid tissue.^{47, 48} Testing the sample for PTH levels is more sensitive than cytology as thyroid follicular cells may look similar to parathyroid tissue.

COMPLEX CLINICAL SETTINGS

Localization techniques in multigland disease patients such as multiple endocrine neoplasia (MEN) type 1, familial HPT, secondary or tertiary hyperparathyroidism are less accurate. Often the dominant hyperactive parathyroid(s) is prominent and other less active ones may be suppressed in the background. **Figure 72.9** shows the parathyroid localization flow charts for surgery in hyperparathyroidism used at the University of California, San Francisco.⁴⁹

In a systematic review of more than 20 000 cases of solitary adenomas (SA), multiple gland hyperplasia disease (MGHD) and double adenomas (DA), ^{99m}Tc-sestamibi and

ultrasound were 88.44% and 78.55% sensitive, respectively, for SA, 44.46% and 34.86% for MGHD, and 29.95% and 16.20% for DA.⁵⁰

In minimal access parathyroidectomy one of the challenges is to identify the posteriorly placed superior adenoma. This not uncommonly placed in the trachea-oesophageal groove, retro-oesophageal area or adherent to the lateral oesophageal wall. It may erroneously be interpreted as an inferior gland in planar sestamibi scans but better identified in SPECT scans. Standard 10 Mhz ultrasound probes may give negative results in these cases due to poor penetration in glands placed in a deep plane.⁵¹

Hyperparathyroidism in pregnancy could limit the choices of imaging modalities. The first choice would be to try ultrasonography alone and consider surgery only in severe hyperparathyroidism with renal and/or bony complications. Ultrasound-guided FNA with PTH aspiration directly from the gland may be useful for confirmation.⁵² If the need for further imaging is necessary, MRI and low-dose sestamibi with radiation shielding to the embryo may help.^{53, 54} Mild or moderate presentations are best deferred until pregnancy is over.

KEY POINTS

- Minimal access, minimally invasive parathyroidectomy is now producing cure rates equal to the traditional four-gland bilateral exploration.
- This requires good localization studies, and non-invasive techniques such as ultrasound with sestamibi scans are quite often adequate to give satisfactory information to perform a focused surgical procedure as a day case.
- Invasive techniques are best reserved for revision surgery and negative imaging studies.
- The final choice of the pre-operative localization studies depends on local expertise, choice and final surgical outcomes.

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: hypercalcaemia, parathyroidectomy, primary hyperparathyroidism, cinacalcet. Further relevant articles were obtained by manual screening of the reference lists of selected papers and contemporary textbooks.

CLASSIFICATION OF HYPERPARATHYROIDISM

Hyperparathyroidism literally means excess secretion of parathyroid hormone (PTH). In isolation, the term 'hyperparathyroidism' is of little value in informing clinical practice. For instance, hyperparathyroidism may occur as the result of autonomous hypersecretion of PTH causing hypercalcaemia; conversely physiologically appropriate hypersecretion of PTH may be seen in conditions where hypocalcaemia prevails. Thus the classification of hyperparathyroidism into primary, secondary and tertiary allows an aetiology-based approach to management. Typical biochemical features of primary, secondary and tertiary hyperparathyroidism are shown in [Table 73.1](#).

Depending on specific underlying causes of secondary and susceptibility to tertiary, specific biochemical features will differ. This chapter will focus on the management of primary hyperparathyroidism (PHPT). Because secondary hyperparathyroidism (SHPT) has underlying medical causes, management of the range of conditions causing SHPT (e.g. vitamin D deficiency and chronic renal impairment) is beyond the scope of this chapter.

INTRODUCTION TO PRIMARY HYPERPARATHYROIDISM

PHPT represents a biochemical syndrome of inappropriate or unregulated hypersecretion of parathyroid hormone (PTH) by one or more of the four parathyroid glands in the absence of a recognized stimulus, leading to hypercalcaemia. Most cases are sporadic and caused by a single parathyroid adenoma (85–95%) or multigland disease (5–10%), with parathyroid carcinoma accounting for <1%.¹

CHANGING CLINICAL PRESENTATION OF PHPT

PHPT was previously considered a relatively rare disorder, with clinical manifestations dominated by renal and/or bone disease. However, in modern times the diagnosis is most frequently recognized coincidentally on biochemical testing in patients evaluated for unrelated complaints. The annual incidence of PHPT is around 20 cases per 100 000, although the prevalence does vary depending on the populations studied and detection methods used.^{2, 3}

TABLE 73.1 Biochemical features of primary, secondary and tertiary hyperparathyroidism

	Primary	Secondary	Tertiary
PTH	↑/↑↑	↑↑	↑↑↑
Calcium	↑	↓	↑/↑↑
Phosphate	↓/→	↓ – vitamin D deficiency ↑ – renal failure	↓/↑
Alkaline phosphatase	→/↑	→/↑	↑
Notes		Biochemistry differs according to underlying cause	

Classical skeletal complications (osteitis fibrosa cystica) are present in less than 5% of newly presenting patients and the incidence of renal stones has fallen to around 15–20%.⁴ The latter, however, is still the most common complication of PHPT. More diffuse calcification may also be seen in the renal parenchyma (nephrocalcinosis) in association with hypercalciuria and a decline in renal function may be seen with long-standing PHPT.

Neuromuscular manifestations tend to be vague and include fatigue and subjective weakness, as opposed to a definable myopathy. Reduction in neurocognitive function that sometimes ameliorates following successful parathyroidectomy has been described.⁵ Psychological and psychiatric symptoms are not in isolation regarded as indications for parathyroidectomy, however.⁶

Peptic ulcer disease and pancreatitis are associations of classical primary hyperparathyroidism. Pancreatitis is rarely seen nowadays because most PHPT is ‘mild’. Peptic ulcer disease may be seen in patients who have PHPT in association with multiple endocrine neoplasia syndrome type 1 (MEN-1). Cardiovascular risk is increased in PHPT, particularly with respect to increased vascular stiffness.⁷ There is an increased incidence of hypertension with PHPT, although the underlying mechanisms are not fully understood. Results of a number of recent studies suggest parathyroidectomy in hypertensive patients reduces systolic and diastolic blood pressure.^{8,9}

WHAT ARE THE INDICATIONS FOR PARATHYROIDECTOMY?

Parathyroidectomy is the only curative treatment for PHPT, with first-time cure rates exceeding 95% of cases.¹⁰ In symptomatic patients or those with evidence of end-organ disease, such as low bone mineral density (BMD) or kidney stones, cohort studies have demonstrated that after successful parathyroidectomy BMD improves substantially and the incidence of kidney stones declines; cognitive function may improve and cardiovascular disease rates and premature death also appear to decrease.^{11–14} For these reasons, if no contraindications exist, all patients with symptomatic PHPT or in whom there is evidence of end-organ disease should receive parathyroidectomy.

ASYMPTOMATIC PHPT

The clinical profile of PHPT has shifted from a symptomatic disorder with hypercalcaemia-related symptoms, kidney stones and overt bone disease to a symptomatically more mild condition, and there remains controversy concerning surgical intervention in patients with no clear clinical features. Some clinicians believe ‘asymptomatic’ patients with no complications can be managed non-surgically, while others believe virtually all patients with biochemical evidence of PHPT, irrespective of how mild, should undergo parathyroidectomy as there may be ‘insidious’ elements to chronic mild PHPT.¹⁵

IS ASYMPTOMATIC PHPT BENIGN?

Consequences of untreated asymptomatic PHPT

Developing robust clinical guidelines for the management of asymptomatic PHPT requires a clear understanding of the natural history of the disease. However, large-scale high-quality data in this area are lacking. A prospective study published in 1999 reported no significant change in serum calcium concentration, urinary calcium excretion and BMD after 10 years in 52 patients with asymptomatic PHPT who did not undergo parathyroidectomy.¹⁶ The same group published 15-years follow-up data in the same cohort of patients, reporting a small but significant increase in serum calcium concentration compared to baseline, along with a 10% decline in BMD at one or more sites, although lumbar spine BMD remained unchanged.¹⁷ In addition, there was progression of PHPT in 37% of patients over the 15 years of observation, to the point that criteria for surgery were met.

In a recent well-characterized cohort of 904 untreated patients with mild PHPT (median follow-up 4.7 years), serum calcium did not rise in the group but there was a significant rise in PTH concentration over the follow-up duration.¹⁸ There was progression of PHPT in 121 patients (13%) and 26 (3%) underwent parathyroidectomy for progressive disease during the follow-up period. Baseline age (higher) and PTH concentration were markers for disease progression.¹⁸

Impact of asymptomatic PHPT on BMD and fracture risk

A small number of studies have prospectively examined bone density changes in treated and untreated asymptomatic PHPT. Studies have generally been short term over 1–2 years. A meta-analysis of such studies has shown small but significant loss of bone density in untreated PHPT, ranging from 0.6% to 1.0% per year.¹⁹ Following parathyroidectomy, there was a rise in bone density, broadly similar to that observed in patients with mild PHPT who did not undergo parathyroidectomy but who were treated with antiresorptive medical therapies.¹⁹

In a randomized controlled trial of parathyroidectomy versus observation, 28 patients followed up without surgery were found to have a loss of BMD at the femoral neck (-0.4% per year) and total hip (-0.6% per year), but not at the spine or forearm.²⁰ In 25 patients managed surgically, following parathyroidectomy there was an increase in BMD of the spine, femoral neck, total hip and forearm. Similar findings were reported in two randomized controlled trials comprising 191 patients²¹ and 50 patients²² with asymptomatic PHPT randomized to surgery or observation. The trial of 191 patients reported a significant increase in BMD compared to baseline at the lumbar spine following surgery, with a similar trend at the femoral neck.²¹ BMD remained stable in the observation group. At 1 year, the second trial observed a statistically significant change in lumbar spine and total hip BMD between the parathyroidectomy and observation groups.²² There was no difference in distal radius BMD between the two groups.

In the prospective study of the natural history of asymptomatic PHPT over 15 years, a 10% decline in BMD at one or more sites was observed in patients managed without surgery, although lumbar spine BMD remained unchanged.¹⁷ In patients who underwent parathyroidectomy, there was post-surgical improvement in BMD at all sites (lumbar spine, femoral neck and distal radius). BMD increased and remained above the 10% line for 15 years after surgery.

There are no controlled studies on the risk of fracture in asymptomatic PHPT patients. However, cohort and population studies suggest that fracture risk is increased up to 10 years before diagnosis and treatment of PHPT (relative risk up to 1.8), suggesting fracture risk may be increased in undiagnosed, asymptomatic PHPT patients.^{13, 23} The impact of surgery on this potential increased fracture risk remains unclear.

Impact of asymptomatic PHPT on cardiovascular morbidity and mortality

Population and cohort studies have demonstrated that both serum calcium and PTH are independent risk factors for coronary artery disease in subjects *without* PHPT.^{24, 25} A number of studies suggest patients with moderate to severe PHPT may have an increased risk of coronary artery disease that appears to decrease after successful parathyroidectomy.^{26, 27} However, a small randomized study of 49 patients with mild PHPT demonstrated no significant differences in echocardiographic features at 2 years in untreated and parathyroidectomy patients.²⁸

Increased peripheral vascular resistance is an independent marker of cardiovascular risk. A small number of studies have reported increased vascular stiffness in patients with mild PHPT.^{29, 30} One study demonstrated that 15% of the variance in the difference between the second and first systolic peaks in the pressure waveform of the radial artery was uniquely accounted for by the presence of PHPT.³⁰ Interestingly there was a strong positive correlation between PTH and arterial stiffness and PHPT

was a stronger predictor of arterial stiffness than traditional risk factors such as age, smoking and hypertension. This suggests that mild asymptomatic PHPT may represent a prominent risk factor for arterial stiffness, which in turn is a predictor of early cardiovascular pathology. The effect of successful parathyroidectomy on arterial stiffness is unknown.

A matched cohort study, using hospital episode statistics and mortality data, demonstrated that patients with mild PHPT had significantly worse cardiovascular outcomes, in terms of mortality and non-fatal events.¹⁸ The risk of other comorbidities was also increased. These adverse outcomes were subsequently shown to be linked to high baseline PTH concentration but not baseline calcium.³¹

Mild PHPT and risk of malignancy

An almost twofold increased incidence of malignant tumours has been reported in patients with PHPT compared with matched controls.^{32, 33} However, bias may be present due to a number of factors: some patients may have endocrine tumour syndromes that have PHPT as a feature; in addition, an underlying malignancy is often a prompt for biochemical testing during which incidental PHPT might be detected, and patients with hypercalcaemia detected unexpectedly are likely to undergo detailed assessments for underlying malignancy.³⁴ Long-term follow-up of patients with mild PHPT has also demonstrated a significant increased risk of malignancy compared to controls (hazard ratio and cardiac index: HR 2.18, CI 1.80–2.65).³⁵

Impact of asymptomatic PHPT on neurocognitive function/quality of life

Neurological and neuropsychiatric symptoms have been described in classical PHPT,^{36, 37} but it is less clear to what extent they are present (and are reversible) in milder forms of PHPT seen commonly today. Neurological and neuropsychiatric symptoms are especially difficult to define and investigate in mild PHPT. Some studies have demonstrated improvements in quality of life (QOL),^{38–40} but others have not.^{41, 42} Potential reasons for the inconsistent results include the observational nature of many of the studies, small sample sizes, the inclusion of subjects with symptomatic hyperparathyroidism, lack of appropriate control groups and testing at short intervals after parathyroidectomy.⁶

A number of randomized studies of surgery versus observation have been conducted in patients with mild PHPT that addressed aspects of neuropsychiatric function. In 53 patients randomized to surgery or observation, QOL scores measured using the SF-36 general health survey showed significant decline in five of the nine domains (social functioning, physical problem, emotional problem, energy and health perception) in patients followed up without surgery, but in only one of the nine domains (physical function) in the patients who had parathyroidectomy.²⁰

These findings suggest a modest measurable benefit of parathyroidectomy in social and emotional role function. Psychological function as assessed by the Symptom Checklist-90 (SCL-90) scale did not change significantly in either group, except for a decline in anxiety and phobia in patients who had surgery in comparison with those who did not. More recently, in a cohort of 191 patients with mild PHPT randomized to medical observation or surgery, significantly lower QOL and more psychological symptoms were found compared with age- and sex-matched healthy subjects.²¹ Both groups were similar at baseline, and no clinically significant changes in these parameters were seen during the 2-year observation period. Another randomized controlled trial of surgery versus observation in 50 patients assessed QOL and psychosocial well-being using Short Form health survey SF-36 and SCL-90 at baseline and after 1 year of follow-up.²² A modest but significant beneficial effect on QOL (bodily pain, general health, vitality and mental health) was observed in the parathyroidectomy group compared with observation group. One study demonstrated increased anxiety and depression at baseline that did respond positively to parathyroidectomy.⁴³

Overall, the findings of these studies are inconsistent and the available data remain incomplete on the precise nature and reversibility of neuropsychological symptoms following surgery for mild PHPT. However, some of the data support a modest beneficial effect of parathyroidectomy on QOL and psychological functioning.^{6, 43}

Impact of asymptomatic PHPT on survival

A number of large population-based cohort studies have demonstrated that patients with PHPT appear to be at risk of premature death,^{44, 45} with a 50% increase in mortality, predominantly due to cardiovascular disease. However, these data were not specifically derived from asymptomatic patients. A study that examined outcome in an unselected cohort of patients with predominantly uncomplicated, asymptomatic PHPT⁴⁶ found overall survival was not reduced, compared to age- and gender-matched controls. Although patients in the highest quartile of serum calcium levels had significantly worse survival than patients in the three lower quartiles, even in this group, compared to age- and gender-matched controls, there was only a trend towards reduced survival in the patients who did not undergo surgery. Based on these data, the authors concluded that the current practice of observing patients with uncomplicated mild PHPT does not compromise survival. However, a recent matched cohort study from Scotland found all-cause mortality was increased in patients with mild primary hyperparathyroidism, demonstrating a hazard ratio of 2.24 (CI 1.99–2.51), incorporating an increase in cardiovascular deaths (HR 2.67 [CI 2.21–3.23]) and cancer deaths (2.69 [CI 2.16–3.56]).³⁵ Cumulative survival was not linked to baseline calcium, but higher PTH concentrations at baseline did predict worse survival outcome.³¹

Thresholds for surgery in asymptomatic PHPT

Parathyroidectomy is the only cure for PHPT and should be recommended in all patients with symptomatic PHPT or evidence of end-organ damage such as low BMD or kidney stones. However, considerable controversy exists regarding the need for surgery in asymptomatic patients.⁴⁷ Emerging data on the natural history of asymptomatic PHPT have demonstrated that the chronic course of the disease may not be as benign as once considered.¹⁵ A small but significant fall in BMD over many years, particularly at sites rich in cortical bone, can also be anticipated after 15 years of observation.¹⁷ In addition, a number of randomized controlled trials of parathyroidectomy versus observation in patients with asymptomatic PHPT have demonstrated improvements in BMD, neurocognitive function and QOL.^{20–22} Recent epidemiological data on adverse long-term outcomes in patients with mild untreated PHPT have caused a drift towards a lower threshold for parathyroidectomy. The National Institutes of Health (NIH) have developed consensus guidelines, most recently updated in 2009,⁴⁸ giving specific indications for when surgery is recommended in patients with asymptomatic PHPT (**Box 73.1**).

BOX 73.1 National Institutes of Health consensus guidelines for surgery in asymptomatic PHPT

- Age < 50
- Serum calcium > 0.25 mmol/L above upper limit of normal
- Renal
 - A. Creatinine clearance < 60 c/min
 - B. 24-h urine for calcium > 400 mg/d (> 10 mmol/d)
 - C. Presence of nephrolithiasis or nephrocalcinosis by X-ray, ultrasound, or CT
- Bone mineral density (by DXA):
 - A. BMD by DXA: T-score < -2.5 at lumbar spine, total hip, femoral neck, or distal 1/3 radius
 - B. Vertebral fracture by X-ray, CT, MRI, or VFA
- Medical follow-up undesired or impractical

(Adapted from Bilezikian 2014)

The consensus guidelines also recommend a structured conservative follow-up protocol for patients who do not fulfil the guidelines for surgery (**Box 73.2**) and advice regarding hydration status and symptom recognition. It is in this situation that the potential benefits of a permanent cure need to be balanced against the risks of surgery. A particular concern is that mild disease will progress to disease fulfilling surgical criteria at a time when the patient's fitness for surgery has decreased.

BOX 73.2 Monitoring protocol for patients with asymptomatic PHPT (eGFR: estimated glomerular filtration rate)

Serum calcium annually
eGFR, annually; serum creatinine, annually. If renal stones suspected, 24-h biochemical stone profile, renal imaging by X-ray, ultrasound, or CT
Every 1–2 years (3 sites), X-ray or VFA of spine if clinically indicated (e.g., height loss, back pain)

(Adapted from Bilezikian 2014)

These guidelines do not overtly encompass the most recent epidemiological data and, on balance, making an individualized assessment of pros and cons of parathyroidectomy in individual patients is the authors' preferred stance.³⁴

MEDICAL MANAGEMENT OF PHPT WITHOUT SURGERY

Although surgery is the only cure for PHPT, medical treatments can be considered for patients who do not fulfil criteria for surgery or those who are unsuitable for or decline surgery. Bisphosphonates and hormone replacement therapy (HRT) are treatment options for those individuals with PHPT for whom the primary goal is skeletal protection, while the calcimimetic cinacalcet effectively lowers serum calcium and PTH levels in PHPT; however, there is a dearth of data demonstrating positive end-organ outcomes.⁴⁹

Intravenous and oral bisphosphonates may cause a transient reduction in serum calcium, but these are not effective in maintaining lower serum calcium levels in patients with PHPT in the long term.³ However, they can prove useful in managing the bone disease associated with PHPT. Alendronate is the most extensively studied bisphosphonate in PHPT and has been shown to significantly increase BMD in the lumbar spine and femoral neck in patients treated for up to 2 years.^{3, 50, 51} The findings of these studies suggest that bisphosphonates, in particular alendronate, may be useful in the treatment of bone disease associated with PHPT when parathyroidectomy is not recommended or possible. However, there are no data demonstrating that BMD changes reflect a reduced fracture risk. In one meta-analysis there was a similar positive effect on BMD with bisphosphonates compared to parathyroidectomy in patients with mild PHPT.¹⁹ Quantitatively similar effects have also been demonstrated with HRT.¹⁹

Extracellular ionized calcium regulates PTH secretion via the calcium-sensing receptor (CaSR). Stimulation of the CaSR results in inhibition of PTH gene transcription, reduced PTH secretion and reduced parathyroid cell proliferation. Cinacalcet is an orally active calcimimetic, which acts by modifying the CaSR, causing downstream (calcium-like) effects without having true calcium effects peripherally. By mimicking the action of extracellular calcium on the CaSR, cinacalcet blocks PTH secretion. Studies in humans have demonstrated that cinacalcet lowers PTH levels and improves calcium/phosphate homeostasis in patients with primary and secondary hyperparathyroidism.^{52, 53} A double-blind, randomized, placebo-controlled study reported normalization of serum calcium in 73% of patients treated with cinacalcet, compared with 5% of placebo-treated patients.⁵³ PTH decreased by 7.6% in the cinacalcet group, but increased by 7.7% in the placebo group. There were no significant differences in 24-hour urinary calcium levels between the cinacalcet- and placebo-treated patients. Hip and forearm BMD

were in the osteopaenic range and remained unchanged throughout the study in both groups. An open-label extension of this study was recently reported, in which 45 subjects from both groups were treated with 30 mg or 50 mg of cinacalcet twice daily for up to 4.5 years.⁴⁹ Cinacalcet normalized serum calcium in all patients, and maintained eucalcaemia for the duration of the study. Plasma PTH levels reduced substantially, especially in the latter years, but did not normalize. Mean BMD remained in the normal range (Z-scores of -1 to +1) for the length of the study, with no improvements in BMD observed when expressed as mean change from parent study baseline at the spine, wrist, femoral neck and total femur. A review of studies on the use of cinacalcet in PHPT has confirmed these findings, reporting that cinacalcet effectively lowers serum calcium and PTH levels but does not alter bone turnover or increase BMD.⁵⁴

Despite cinacalcet's beneficial effects on serum calcium and PTH levels in patients with PHPT, there are no data supporting beneficial effects on hard clinical endpoints of fractures (or changes in bone density), kidney stones or cardiovascular disease. QOL has been assessed in a study of 17 patients with persistent PHPT after parathyroidectomy or with contraindications to parathyroidectomy that were treated with cinacalcet,⁵⁵ using the SF-36 and Medical Outcomes Study (MOS) Cognitive Functioning scales, the authors found that cinacalcet treatment was associated with improved functional status and well-being in patients with intractable PHPT. The improvements in the Physical Component Summary and Mental Component Summary scores were comparable with the improvements observed in patients with PHPT following parathyroidectomy. This was a small trial, and the results need corroborating in larger studies. In 2008 cinacalcet was approved by the European Commission for the treatment of hypercalcaemia in patients with PHPT for whom parathyroidectomy is indicated on the basis of serum calcium levels but in whom parathyroidectomy is not clinically appropriate or is contraindicated. However, its high cost and lack of data showing improvements in BMD mean that cinacalcet cannot presently be advocated as an alternative to parathyroidectomy.

CONCLUSION

Parathyroidectomy offers the only potential cure for PHPT and should be recommended in all patients with symptomatic PHPT or with evidence of end-organ damage, where there is no obvious contraindication. However, considerable controversy exists regarding the need for surgery in asymptomatic patients. Recently published guidelines have outlined criteria for surgery in the management of asymptomatic PHPT, recommending structured follow-up for patients who do not fulfil these criteria. However, emerging data on the natural history of asymptomatic PHPT have demonstrated that the chronic course of the disease may not be as benign as once considered, with

significantly worse cardiovascular outcomes in terms of mortality and non-fatal events, as well as significantly increased risk of malignancy. This has led some clinicians to propose that virtually all patients with biochemical evidence of PHPT, irrespective of how mild, should undergo parathyroidectomy.

Presently there is no alternative medical therapy to parathyroidectomy that has proven efficacy in managing all aspects of PHPT. Alendronate has beneficial effects on BMD but has not been shown to reduce fracture risk or significantly lower serum calcium, while cinacalcet normalizes serum calcium but does not alter BMD.

Despite the high success rate, low morbidity and convenience of modern parathyroidectomy, patients need to be assessed on a case-by-case basis and important clinical considerations need to be balanced to determine whether parathyroidectomy is the best option for individual patients with mild asymptomatic PHPT (Box 73.3).

BOX 73.3 Factors influencing management of patients with mild PHPT

Favours conservative management

Old age
Short life expectancy
High operative risk
Patient preference
Initial low fracture risk

Favours parathyroidectomy

Young age
Long life expectancy
Low operative risk
Patient preference
Risk of worsening bone disease
Risk of worsening renal function
Neuropsychiatric features
Cardiovascular risk*
High baseline PTH*

(Adapted from Gittoes & Cooper 2010³⁴ and incorporating more recent data* from Yu et al. 2011³⁵)

KEY POINTS

- PHPT is caused by inappropriate/unregulated hypersecretion of parathyroid hormone by one or more of the four parathyroid glands.
- The clinical profile of PHPT has shifted to a symptomatically more mild condition.
- Skeletal complications, renal stones, neuromuscular manifestations, peptic ulcer disease and pancreatitis are now rarely seen in the context of PHPT.
- Parathyroidectomy is the only curative treatment for PHPT, and if no contraindications exist should be performed in all patients with symptoms or end-organ disease.
- Medical treatments can improve bone mineral density and normalize serum calcium, but have not been shown to improve long-term outcomes.
- Asymptomatic PHPT may have clinical sequelae, and specific indications exist for when surgery is recommended.
- Structured follow up is required for patients with asymptomatic PHPT who do not fulfil criteria for surgery.

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: recurrent, persistent, hyperparathyroidism and re-operation and localization.

'The second hardest decision in surgery is when to operate; the hardest decision is when to reoperate.'

Dr Claude H. Organ Jr, MD (1926–2005)

INTRODUCTION

Patients requiring reoperative surgery pose a significant clinical challenge for a number of reasons. Someone has already failed to cure the hyperparathyroidism, suggesting that this case is not 'straightforward'. That 'someone' could be a very good parathyroid surgeon – you or me. This heightens the likelihood of it being difficult and, if you were the surgeon who failed in the first place, it is challenging to encourage the patient to maintain their faith in you. Furthermore, the operative field is going to be more treacherous and so one needs all the help one can get to minimize complications and maximize success. When faced with this clinical challenge, it is wise to have a pre-determined strategy.¹

DEFINITIONS

Persistent hyperparathyroidism (HPT) is defined as the development of hypercalcaemia within 6 months of the first parathyroid operation, whereas hypercalcaemia presenting after an interval of 6 months is termed recurrent HPT.

It is important to understand this distinction because it will give clues to help derive a successful outcome at the next operation, see [Boxes 74.1](#) and [74.2](#).

INCIDENCE

How common is failure? Percentages for bilateral neck exploration and targeted surgery are the same in published data and national disease registries, with a failure rate in the order of 5%.²

REASONS FOR FAILURE

In two landmark publications investigating the reasons for failed parathyroidectomy from California ($n = 102$)³ and Uppsala, Sweden ($n = 69$),⁴ the percentage of distribution between persistent and recurrent disease is remarkably similar. Most (76%) reoperative surgery is for persistent disease. The main causes for failure are shown in [Table 74.1](#). While cause of the majority of the failures were classified as 'ectopia', most ectopic tumours were in the neck in the classically recognized locations such as paraoesophageal and intrathyroidic.

Recurrent disease is very rare. In the Uppsala series it accounted for only 13 cases over 20 years. Most patients had hyperplasia and nearly all of them (89%) were diagnosed to have multiple endocrine neoplasia type 1 (MEN 1).

BOX 74.1 Clue number 1

Persistent HPT is a consequence of inadequate first-time surgery whereas recurrent HPT is a result of the underlying disease process.

BOX 74.2 Clue number 2

If no gland or a normal gland was excised at the original operation, then it is highly likely that the patient has single gland disease (**Table 74.2**).¹³

TABLE 74.1 Causes of failure in first-time parathyroidectomy³

Cause	%	Number
Tumour in ectopic position	53	54
Incomplete resection of multiple abnormal glands	37	38
Tumour in normal position (missed at previous operation)	7	7
Re-growth of partially resected tumour	3	3

TABLE 74.2 The outcome at the first operation is a guide to the underlying pathology¹³

First operation	Underlying pathology	(%)
No gland or normal gland excised	SGD	84
	MGD	11
	Unknown	5
Pathological gland excised	MGD	90
	Regrowth of partially resected adenoma	10

SGD, single gland disease; MGD, multiple gland disease.

Sporadic adenoma as a cause of recurrent disease was exceptionally rare in this series. Of the four cases, one had seeding at the time of the first operation, one recurred at 2 years after a partial resection and only two true second adenomas presented at 8 and 16 years after the first parathyroidectomy.

Another important factor contributing to success at the first operation is the experience of the surgeon. Preventable operative failures are more common in low volume (fewer than 50 cases per year) hospitals.⁵

MEN 1

Recurrent HPT is an inevitable outcome of surgery, even when performed to the highest standard, in patients with MEN 1.⁶ There are a number of surgical options for patients with MEN-HPT (see **Chapter 77**) with recurrence rates reported to vary from 11% at 6 years⁷ to 63% at 10 years.⁸ National Registry data such as those from Scandinavia and the United Kingdom paint a worse picture than the published data, with persistent hypercalcaemia

rates of 25% reported in Scandinavia and 17% in the UK.^{9, 10}

STEPS TO SUCCESS**Step 1: Confirm the diagnosis**

The clinician should start at the beginning in terms of establishing a biochemical diagnosis of HPT (see **Chapter 72**). Particular attention should be given to ensuring that there is no evidence of renal insufficiency, vitamin D deficiency, and familial hypercalcaemic hypocalciuria or paraneoplastic hypercalcaemia.

Step 2: Does the patient need further surgery?

Reoperation should only be considered if the patient has symptomatic hypercalcaemia or when there is evidence of progressive disease (nephrolithiasis or bone disease). The decision about whether to operate is determined by balancing the severity of the disease with the risks of surgery. The main complications of reoperative parathyroidectomy are hypoparathyroidism and recurrent laryngeal nerve injury. Both of these are more common in redo surgery. Hypoparathyroidism (2–20%)¹¹ is more common due to the increased rate of multiple gland disease and the fact that normal glands may have been removed at the first operation. RLN injury is more common (up to 6%)^{4, 12} owing to the scarred operative field.

In addition, unlike first-time surgery, the decision to reoperate may be influenced by a successful localization result that would both facilitate a targeted approach and increase the likelihood of a successful outcome.

Step 3: Research

There is a need to thoroughly sift through all the evidence from the previous attempt to cure the patient. You might have to be prepared to be cynical about the operation note – is what was written an accurate reflection of what was done? If possible, a conversation with the previous surgeon may be helpful, more so if it was in the recent past. The aim is to try to identify clues that describe the boundaries of the previous exploration in order to establish the region(s) where scar tissue will be worst.

In the histopathology report, if parathyroid glands were removed, were they normal or abnormal? Take note not only of the histology but also the weight of the resected specimen.

Review all of the previous localization studies. It is worth while viewing the images **yourself** as sometimes a surgeon will be prepared to place more emphasis than the radiologist on an indeterminate finding.

Step 4: Localization

Parathyroid localization (see **Chapter 72**) is an essential step in reoperative surgery. The goal is to be able to perform a limited operative procedure targeted according to

the localization results in order to minimize risk to both recurrent laryngeal nerves. As stated, it may be that a decision about whether to proceed with surgery is taken once the results of the localization are known.

^{99m}Tc sestamibi (MIBI) scintigraphy and ultrasound are requested first. Non-invasive localization studies have become more successful in recent times compared with 20 years ago.¹⁴ MIBI can be complemented with SPECT-CT coregistration to provide a three-dimensional image. Any lesions identified on ultrasound can be considered for aspiration for PTH. If these modalities are positive, it is reasonable to proceed to surgery.¹³ Cross-sectional imaging with MRI or CT would be the next mode of imaging. Four-dimensional computed tomography is an emerging technique that explores the changes in perfusion of contrast over time to provide a new 'dimension'. Results have been promising for reoperative parathyroidectomy.¹⁵

As each localization studies fails, so the available procedures become more invasive. Angiography either by digital subtraction or conventional methods is the next technique to consider. In expert hands impressive results can be achieved.¹⁶ However, these invasive studies can be associated with significant morbidity.¹⁷ Selective venous sampling (SVS) of all patent superior, middle and inferior thyroid, thymic, brachiocephalic and vertebral veins (as well as a peripheral sample) attempts to 'regionalize' the tumour rather than precisely locate it. A gradient of at least twofold is considered significant.¹⁸ Ligation of veins at the time of the first operation can lead to anomalous venous draining and give misleading results. Many Units use SVS in combination with angiography.

The Uppsala group has published the impact of localization on their practice.¹⁹ Few patients underwent surgery before 1980. Between 1980 and 1990 localization was undertaken in one-third of patients, more between 1990 and 2000 (75%) and in all patients after 2000. Localization has had a profound impact on the ability to perform a targeted approach; 66% underwent bilateral neck exploration between 1962 and 1989, whereas since 1990 no fewer than 73% underwent a unilateral neck exploration.

Step 5: Surgery

PREPARATION

Reoperative parathyroid surgery is a difficult procedure and should be undertaken only by surgeons experienced in this field. The surgeon should be familiar with the anatomical variants that are a consequence of either embryology or migration of a pathological gland. Vocal cord examination by nasoendoscopy is mandatory. The patient must be thoroughly consented to the risk of complications including permanent and temporary nerve injury, haematoma/return to theatre as well as failure to find the abnormal gland(s).

OPERATION

The surgical strategy is influenced by the clues from previous surgery and the outcome of the localization

TABLE 74.3 Surgical strategy in reoperative parathyroidectomy

Expected pathology	Strategy
Solitary abnormal gland	Focused approach
Multiple glands	Bilateral approach
Carcinoma/parathyromatosis	En-bloc resection

studies (Table 74.3). It is advisable to set aside plenty of time in theatre to undertake the case and make sure that you have good assistance. The site of the surgical incision should be through the previous incision. Consider asking your radiologist to place a mark on the skin over the site of the presumed adenoma or perform an ultrasound in the operating room yourself. Obviously, if the localization places the gland in the mediastinum, then midline sternotomy, thoracotomy or thoracoscopy should be considered, especially if the tumour does not appear to be intra-thymic such that a cervical approach is contraindicated.

The surgical approach to the deeper structures in the neck will be influenced by the previous operation and the localization result. For example, if the first-time operation was unilateral (targeted/minimally invasive) and the localization study identifies the gland to the contralateral side, a traditional midline approach will suffice. But if the previous operation was a bilateral exploration and/or the localization result is ipsilateral to the previous operation, then a lateral approach should be adopted. This is achieved by dissecting between the lateral edge of the sternohyoid (strap) muscle and the medial edge of the sternocleidomastoid muscle. In this area the tendon of omohyoid is encountered and divided. Immediately deep to this tendon is the middle thyroid vein (if not already divided) as it drains into the internal jugular vein. The carotid sheath is carefully retracted laterally and the tracheo-oesophageal groove is explored. The intention is to identify the recurrent laryngeal nerve (RLN) in previously unexplored territory and this is most likely to be in a caudal direction. Consideration should be given towards using the nerve monitor. A positional statement by the European Society of Endocrine Surgeons on modern techniques in parathyroid surgery did not recommend the routine use of neuromonitoring in first-time neck exploration but stated that it may be of value in reoperative surgery.²⁰

Once the RLN has been located, a careful search for the abnormal gland is made. For the inferior gland, incise the strap lateral to the midline and follow the surface of the thyroid towards the thyrothymic ligament. For the superior gland, the intersection of the RLN with the inferior thyroid artery is the key area to start looking (see Chapter 77). Intra-operative ultrasound scanning (IOUS) has been reported to be helpful in identifying abnormal glands (normal glands are not identified) and results in shorter operative time in the hands of enthusiasts.¹⁴ If an abnormal gland cannot be located, blind thyroid lobectomy should not be undertaken owing to

the rarity of the intra-thyroidal adenoma,²¹ unless confirmed by IOUS.¹⁴

Once a gland has been located and excised, both frozen section and intra-operative PTH (ioPTH) assay will provide clues to success. The key information from the pathologist is to confirm that the excised tissue is 'parathyroid'. Localization tells you where to start and ioPTH tells you when to stop! While the literature is not unanimous, most evidence is that ioPTH helps to decide when the operation can be terminated and is an accurate predictor of cure.^{19, 22} There is no real evidence, however, that it increases the success rate.

POST-OPERATION

As with all parathyroid surgery, the patient should be closely monitored for the development of a wound haematoma. Results from the UK national audit suggest that the rate of haematoma in redo parathyroidectomy more than doubles compared with first-time surgery (1.2% vs 0.5%).¹⁰ Attention is also given towards the complications of RLN injury and hypocalcaemia. Post-operative nasoendoscopy should be undertaken routinely. The rate of permanent hypoparathyroidism (see Step 2) is between 5% and 11% in most series.^{12, 14} A protocol for managing this complication should be written and available in the medical record. A suggested algorithm is shown in [Table 74.4](#).

The serum calcium will provide biochemical evidence of surgical success. In expert centres success rates of over 95% are reported.^{3, 19}

THE FUTURE

There are two reasons why some surgeons fear that reoperative surgery may become more common.

1. **Focused surgery** – does it lead to higher failure rates? The increased success of pre-operative parathyroid localization and the widespread adoption of ioPTH assay has led to an explosion in the use of a focused approach to first-time parathyroidectomy.²³ Critics of this approach are concerned that ioPTH is inaccurate in determining complete excision among patients with multiple gland disease.^{24, 25} In a recent review of 845 cases of focused parathyroidectomy using ioPTH, with a failure rate of 2.9%, the main cause of operative failure was the inability of the surgeon to find the abnormal gland, not the failure to diagnose multiglandular disease.²⁶ In other words, the most common cause of failed parathyroidectomy remains the surgeon, and experience counts.²⁷
2. **Mild disease.** A study that looked at outcomes in patients with double negative parathyroid localization found an alarmingly high rate of persistent hyperparathyroidism (13.3%).²⁸ It is telling that the median weight of adenoma was small (350 mg). Parathyroid localization is less reliable with smaller tumours²⁹ although ioPTH assay remains a valuable tool in patients with milder HPT.³⁰ Either the threshold for parathyroidectomy is being set too low or the wrong surgeon is undertaking this surgery.

TABLE 74.4 Algorithm for managing hypocalcaemia

Corrected plasma calcium mmol/L (mg/dL)	Symptomatic	Asymptomatic
>2.15 (8.6)	Milk	nil
2.00–2.15 (8.0–8.5)	Calcichew 1 g b.d.	nil
1.90–2.00 (7.6–8.4)	Calcichew 1 g t.d.s. 1-alfacalcidol 1 µg o.d.	Calcichew 1 g t.d.s.
1.80–1.90 (7.2–7.5)	Calcichew 1 g t.d.s. 1-alfacalcidol 1 µg b.d.	Calcichew 1 g t.d.s. 1-alfacalcidol 1 µg b.d.
<1.80 (<7.2)	Tetany: 10–30 mL i.v. calcium gluconate over 10–15 min*	Calcichew 1 g t.d.s. 1-alfacalcidol 1 µg t.d.s.

b.d., twice daily; t.d.s., three times per day; i.v., intravenous
* The cannula must be carefully sited to avoid extravasation.

KEY POINTS

- Reoperative parathyroidectomy is a challenging situation.
- The steps to success include careful pre-operative research and a skilled operative technique.
- Localization is mandatory and should be successful prior to contemplating a reoperation. ioPTH assay and neuromonitoring may be useful tools.
- There is a case for centralizing these cases in expert centres but, as with most other aspects of surgery; it is better to get it right the first time.

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: parathyroid and cancer, hypercalcaemia, parathyroid and tumour.

INTRODUCTION

Parathyroid carcinoma (PAC) is a rare cause of primary hyperparathyroidism which presents with clinical manifestations of severe hypercalcaemia. It was first described in 1904 by Swiss surgeon Fritz de Quervain who reported a non-functioning metastatic PAC, and Sainton and Millot were the first to describe a functioning metastatic PAC in 1933. Around 90% of PACs are functional and may present with a palpable neck mass which invades locally. Skeletal and renal complications are commonly present at presentation. Surgery remains the only effective treatment for primary tumours where en bloc resection is key. Medical therapies are critical for controlling hypercalcaemia. Germ-line DNA testing for the *HRPT2* mutation should be considered for patients who present with PAC.

INCIDENCE AND NATURAL HISTORY

PAC is a very rare malignancy accounting for less than 1% of cases of primary hyperparathyroidism in Europe and the United States, and up to 5% in Japan.¹⁻³ According to the Surveillance, Epidemiology and End Results

cancer registry data, the annual incidence is 5.73 per 10 000 million. This represents a prevalence of 0.005% of all cancers.⁴

PAC occurs equally in males and females, unlike parathyroid adenomas, which have a female preponderance (3–4:1).² PACs present mostly in the fourth to fifth decades of life, which is a decade earlier than their benign counterpart. However, the age of diagnosis is in the range of 23–90 years old. There is no racial predisposition in PAC, whereas benign parathyroid tumours more commonly occur in the Western population.

PAC generally runs a slow but progressive course. Less than 8% of patients have lymph node or distant metastases at initial presentation. The mean time to recurrence is generally within 2–5 years of operation and takes the form of locoregional or cervical node involvement (30%), lung metastases (40%), liver secondaries (10%), or bone or brain deposits. Failure of treatment can result in death from hypercalcaemic-related end-organ damage within 14 months. In general, however, PAC tends to have a relatively indolent course because of the tumour's low malignant potential, with a 5-year survival of 86% and a 10-year survival of 35–79%.^{2,4,5} A significant proportion of patients (25%) will be diagnosed with PAC after initial surgical treatment following review of histopathology or after developing metastatic disease.

AETIOLOGY AND MOLECULAR PATHWAYS

The pathogenesis of PAC is poorly understood with few known environmental or genetic causative agents. Animal models show that parathyroid glands are histologically resistant to X-ray damage at doses less than 5 Gy, but doses of 5–25 Gy cause oedema and hyperaemia, and higher doses cause severe damage with hyperplasia, cyst and adenoma formation and carcinoma.⁶ Head and neck irradiation has been associated with the development of PAC.⁷

PAC has also been reported in patients with secondary and tertiary hyperparathyroidism.⁸ End-stage renal failure can promote clonal expansion of cells within the parathyroid hyperplasia that progresses to parathyroid carcinoma. Chronic hypercalcaemia alone in the setting of renal failure has been postulated as a possible trigger for the development of PAC,⁹ although the association is weak. An increased risk of PAC has also been associated with multiple endocrine neoplasia type 1 (MEN 1) and with autosomal dominant familial isolated hyperparathyroidism, which is due to mutations in the tumour suppressor genes *MEN1* and *CDC73* or the calcium-sensing receptor (*CaSR*) gene, resulting in the formation of one or more parathyroid adenomas.²

Interestingly, several oncogenes and tumour suppressor genes have been linked to PAC. Cyclin D1 or *PRAD1* (parathyroid adenoma 1) is an oncogene involved in cell cycle regulation and is located on chromosome 11q13.¹⁰ It is overexpressed in 91% of PAC specimens and up to 61% of benign parathyroid tumours,¹¹ but the exact mechanism of carcinogenesis remains unclear. PAC also lacks the retinoblastoma tumour suppressor gene on chromosome 13.^{12, 13} Retinoblastoma protein prevents excessive cell growth by inhibiting cell cycle progression, and hence its absence results in dysregulation of cell growth.

The *HRPT2* gene, which encodes the parafibromin protein, has attracted much attention in PAC. Most of the data on the genetics involved in this rare disease are derived from studying inherited disorders of primary hyperparathyroidism such as hereditary hyperparathyroidism-jaw tumour syndrome (HPT-JT). HPT-JT is an autosomal dominant disease characterized by fibromas of the maxilla and mandible and tumours of the parathyroid. In this condition 30% of the parathyroid tumours are PACs.² HPT-JT is associated with an inactivating germ-line mutation of the *HRPT2* gene on chromosome 1q25-q32. This is a tumour suppressor gene encoding the protein parafibromin which has anti-proliferative properties. However, it is also defective in sporadic PAC,¹⁴ and parafibromin expression is decreased or absent in PAC, which may have significant implications for diagnosis and management. Kim and colleagues¹⁵ showed that the loss of parafibromin expression was 94.4% specific for the diagnosis of PAC, and recurrences and metastases only occurred in cases with a loss of parafibromin. Moreover, it has been found that *HRPT2* gene mutation results in the upregulation of up to four proteins including histone H1 and H2,

E-cadherin and amyloid BA4 precursor protein (APP).¹⁶ Histone proteins are involved in gene repair mechanisms. E-cadherin is involved in cell–cell adhesion, and loss of function contributes to tumorigenesis by increased proliferation, invasion and metastasis. Its upregulation is indicative of the cell's loss of function in cell adhesion. APP is a functional neuronal receptor but its upregulation in PAC is of uncertain significance. Staining for these proteins provides a diagnostic marker for PAC.

CLINICAL PRESENTATION

To treat PAC effectively, the clinician should have a high index of suspicion prior to initial surgery so that an appropriate operative approach may be undertaken. This requires an awareness of the differences in presentation between primary hyperparathyroidism due to benign disease and cancer. Patients with PAC are typically younger than those with benign causes of hyperparathyroidism (fourth to fifth decades).¹⁷ PAC occurs equally in both genders. Since 90% of PAC are functioning tumours, most manifest with symptoms similar to benign hyperparathyroidism, namely weakness, fatigue, anxiety and depression, bone pain, renal stones, abdominal pain, peptic ulcer disease and pancreatitis. However, bone disease and renal involvement are far more common in parathyroid malignancy, occurring in up to 80–90% of patients with PAC^{18, 19} and the presence of both is strongly predictive of malignancy. Bone disease includes bone pain, osteopenia, osteoporosis, pathological fractures, osteitis fibrosa cystica, 'salt and pepper' skull and subperiosteal bone resorption. Renal involvement includes ureteric calculi, nephrocalcinosis or renal impairment. Acute pancreatitis, peptic ulceration and hypercalcaemic crisis occur in 12–18% of patients with PAC. These symptoms usually occur before local invasion by the tumour.

Around 50–70% of patients with PAC present with a palpable neck mass.^{2, 20} This is extremely uncommon in benign disease, and can be associated with evidence of local invasion including recurrent laryngeal nerve palsy and dysphagia. Non-functioning tumours do not present with symptoms of hypercalcaemia and therefore are more likely to present with a palpable neck mass.

Serum calcium and parathyroid hormone are elevated in PAC, but the average calcium is much higher in PAC than in benign causes of hyperparathyroidism.^{2, 18} Most patients with parathyroid adenomas have serum calcium levels within 1 mg/dL above the upper limit of normal; patients with PAC have serum calcium in excess of 3.5 mmol/L (14 mg/dL) and serum parathyroid hormone levels 10–15-fold greater than the normal range. A parathyroid hormone level 10 times the upper limit of normal carries a positive predictive value of 81% for PAC.²¹

Imaging of PAC differs to that for parathyroid adenomas due to a greater emphasis on the detection of locoregional tumour infiltration and distant metastasis. Neck ultrasound is a non-invasive and sensitive study for the detection of enlarged parathyroid glands. PAC are typically large (>15 mm), hypoechoic, lobulated, irregular lesions.²²

Ultrasound has been shown to have a high accuracy in detecting parathyroid lesions 1 cm or larger.²³ Infiltration and calcification seen on ultrasound have a high positive predictive value for identifying parathyroid malignancy.²⁴ A meta-analysis of pre-operative localization techniques found that ultrasound had a sensitivity of 76% and a positive predictive value (PPV) of 93%.²⁵ Ultrasound can also be used to guide fine-needle aspiration (FNA) biopsy of neck lymphadenopathy, but FNA of the primary lesion should be avoided to prevent disruption of the primary tumour.²⁶ FNA is not useful in distinguishing benign from malignant parathyroid disease.²

^{99m}Tc sestamibi scintigraphy is useful for localizing primary, recurrent and metastatic disease and to confirm ultrasonographic localization. The radiolabelled isotope has a particular affinity for parathyroid mitochondria.²⁰ It cannot, however, discriminate benign from malignant disease. Sestamibi has a high sensitivity of 79% and a PPV of 91% and continues to be the most useful imaging modality in benign and malignant causes of hyperparathyroidism.²⁵

Four-dimensional computed tomography (4D CT) is increasingly used for parathyroid localization in hyperparathyroidism, particularly when ultrasound and sestamibi imaging are negative or indeterminate (Figure 75.1). It has a sensitivity and specificity of 82% and 92% respectively for the localization of parathyroid adenomas.^{27, 28} Parathyroid glands have unique angiographic and perfusion characteristics²⁹ including a 'blush' following intra-arterial contrast used to distinguish abnormal parathyroid tissue. 4D CT uses non-contrast imaging to differentiate thyroid from parathyroid tissue, as well as an early post-contrast phase to determine a hypervascular gland, and a delayed post-contrast scan to detect altered enhancement or abnormal contrast retention.³⁰ However, 4D CT delivers a significant radiation dose despite dose reduction techniques (20–40 mGy per phase of imaging) and no study has elucidated its importance in PAC diagnosis or localization. Its use may be supported in determining infiltration pre-operatively if PAC is suspected and in reoperative surgery.

In circumstances of recurrence, ¹⁸F-FDG PET CT has been used to detect locoregional recurrence or distant metastases.³¹ MRI may also be useful for mediastinal recurrence.³²

Figure 75.1 Neck CT axial image depicting large right parathyroid mass that proved to be a PAC causing tracheal deviation.

OPERATIVE FINDINGS AND SURGERY

Surgical resection is the main therapeutic modality for PAC, even in the presence of metastatic disease. Treatment of hypercalcaemia and correction of renal dysfunction is often necessary prior to surgical intervention. Hydration with saline, correction of electrolyte imbalance, diuretics and bisphosphonates are useful to optimize the patient's condition prior to surgery.

PAC can be difficult to diagnose intra-operatively but usually appears as a large, firm, grey-white mass with adherence to adjacent tissue and is often greater than 3 cm in maximal diameter (Figure 75.2). Parathyroid adenomas, in contrast, are smaller, softer and are reddish-brown or tan in colour.^{3, 33} En bloc resection involves carefully removing the parathyroid lesion and resecting all adherent tissues with grossly clear margins. This will typically involve ipsilateral thyroid lobectomy and the adjacent level 6 lymphatic component. This approach frequently requires autotransplantation of the ipsilateral parathyroid gland where it appears macroscopically normal as well as cervical thymectomy. It is important not to rupture the capsule, as this increases the risk of seeding and recurrence.³⁴ PAC can also involve the overlying strap muscles, trachea, oesophagus and recurrent laryngeal nerve. In order to provide the best chance of cure these structures may require en bloc resection.^{34, 35} Recurrent laryngeal nerve involvement is suspected pre-operatively if the patient has a hoarse voice and warrants resection in cases where its function is lost due to tumour infiltration or where it is involved circumferentially by malignancy. Sacrifice of a normally functioning nerve is generally not

Figure 75.2 Resection specimen of parathyroid carcinoma removed en bloc with adjacent thyroid tissue. The parathyroid carcinoma is adherent to the thyroid. (Photo courtesy of Prof Anthony Gill, Dept of Anatomical Pathology, Royal North Shore Hospital, Sydney Australia.)

required unless its preservation results in gross residual tumour remaining in the thyroid bed. Lymph node involvement is uncommon, occurring in only up to 8% of patients, and as a result comprehensive lymphadenectomy is usually not necessary except in the local area, level 6. Prophylactic modified radical neck dissection does not improve survival and is not typically performed at the primary surgical procedure. It may be of greater utility in reoperative cases.

In at least 25% of initial presentations PAC is diagnosed after primary surgery on histopathology or with the development of distant metastases.³⁶ In patients with PAC who undergo routine parathyroidectomy because cancer is not suspected, 50% or more will develop local recurrence.^{7,33} The mean time for recurrence in this population is 41 months and the mean disease-free survival time is 62 months.⁷ Conversely, if detected before or during operation, then local recurrence rates are 10–33% and long-term survival improves significantly.⁷

The main issue of controversy is the management of PAC diagnosed after initial surgery on histology. O'Neill and colleagues³⁷ found that subsequent unilateral hemithyroidectomy and lymphadenectomy did not reveal any residual disease and therefore further radical surgery may not be warranted. This is supported by Fujimoto and colleagues³⁸ who recommended post-operative follow-up at 3-month intervals for PAC that had minimal invasion and low malignant potential as these tumours did not necessarily locally recur. Alternatively, it has been suggested that aggressive histopathological features of extensive capsular and vascular spread should prompt re-exploration and completion of resection.³⁹

After initial resection, all patients require immediate monitoring and lifelong surveillance. In the early post-operative period, temporary hypocalcaemia may occur due to secondary uptake of calcium into bones (hungry bone syndrome) which requires treatment with supplemental calcium and vitamin D. PTH levels should also be checked post-operatively to ensure curative resection. Thereafter, PTH and corrected serum calcium are monitored every 3 months.³² If these increase, sites of recurrence should be evaluated with sestamibi scintigraphy and anatomical imaging. If these imaging studies are inconclusive, selective venous catheterization and PTH measurement are recommended to regionalize the recurrence.⁴⁰

Recurrence is most often locoregional and occurs within 2–3 years of the initial operation.^{19, 34} For recurrent locoregional disease, cervical and/or mediastinal re-exploration with wide resection including thymectomy are indicated.^{32, 34} Pre-operative vocal cord examination should be performed prior to reoperative surgery.³⁴ A reoperative neck is challenging due to scar tissue and distorted anatomical planes, but various techniques have been described to aid in re-resection. These include injection of methylene blue dye, which is selectively taken up by parathyroid tissue,^{41, 42} or intravenous injection of technetium-99m 1 hour pre-operatively and subsequent use of the gamma probe intra-operatively to localize the recurrence.⁴³ The low incidence of PAC makes evaluation of these modalities difficult, but extrapolation of

the experience with benign parathyroid disease suggests that methylene blue dye and the gamma probe offer little advantage to the experienced parathyroid surgeon. Intra-operative PTH testing, however, is useful in confirming resection of the target lesion.^{43, 44}

Even for distant PAC metastasis, resection is advocated to provide palliative control of hypercalcaemia, which can be debilitating and life-threatening. Where possible, even small metastatic deposits should be considered for resection. The most common sites of distant metastatic PAC spread are to the lungs, liver and bone, and up to 30% of patients already have metastases at initial presentation.^{45, 46} Radical resections which have provided symptomatic relief include liver or pulmonary wedge resections, bone and cerebral metastasis resections, and oesophageal resection with gastric transposition.^{47–51}

HRPT2 germ-line DNA testing should be considered for patients presenting with apparently sporadic PAC. It is unclear whether genetic testing should be offered to at-risk relatives, but monitoring serum calcium levels offers a simple alternative to definitive DNA diagnosis.¹⁴

HISTOPATHOLOGY AND DIAGNOSIS

Schantz and Castleman⁵² developed a set of criteria for the histopathologic diagnosis of PAC in 1973. These included the presence of a fibrous capsule or fibrous trabeculae, rosette-like cellular architecture, presence of mitotic figures, and capsular or vascular invasion. Stojadinovic and colleagues⁵³ added the presence of adjacent skeletal muscle invasion by tumour. This study found capsular and vascular invasion in 92% and 81% of PAC specimens respectively, and 19% had perineural invasion. However, the histological criteria are often equivocal and hence the World Health Organization (WHO) defined PAC in 2004 as those parathyroid lesions displaying vascular invasion, perineural space invasion, capsular penetration with growth into adjacent tissues and/or metastases (**Figure 75.3**).⁵⁴ While the presence of fibrosis is common, it was not consistent and not considered pathognomonic of PAC, and the trabecular growth only occurs in a minority of cases, with rosette formation a rare finding. In addition, the presence of coagulative necrosis, macronucleoli and mitotic activity greater than 5 mitoses per 50 high-power field is a diagnostic pathologic triad that reflects a high risk of malignant versus benign behaviour. A proliferation marker ki-67 greater than 5% is suggestive of malignancy.

There is generally no accepted staging system for PAC. Tumours tend to be classified as localized when confined to the parathyroid and local soft tissues or metastatic when distant metastases occur.

Since not all PACs exhibit the above diagnostic histopathologic criteria, markers have been sought to distinguish benign from malignant tumours. These include immunohistochemistry markers for ki-67, bcl2, cyclin D1, Rb, CaSR, although false negatives with these arose owing to the rarity of PAC.⁵⁵ The *HRPT2* tumour suppressor gene encodes the protein parafibromin. As mentioned previously, parafibromin is involved in apoptosis, inhibits G1 to S phase

Figure 75.3 Histological section of parathyroid carcinoma invading into adjacent thyroid tissue. The presence of unequivocal invasive growth is the basis of the WHO 2004 criteria for the diagnosis of parathyroid carcinoma (H&E, original magnification $\times 100$). (Photo courtesy of Prof Anthony Gill, Dept of Anatomical Pathology, Royal North Shore Hospital, Sydney Australia.)

of the cell cycle, regulates the wingless type (Wnt) pathway, and regulates growth factor expression.⁵⁶ Loss of the protein parafibromin will therefore increase cellular proliferation. It has been found that 77% of all PAC harbour mutations in the *HRPT2* gene^{14, 57} in contrast to benign adenomata where the mutation is demonstrated in less than 1%.⁵⁸ Demonstration of the *HRPT2* mutation is therefore relatively specific for PAC. Tumours with inactivation of *HRPT2* will show loss of parafibromin staining on immunohistochemistry.^{55, 59} The absence of nuclear staining for parafibromin is diagnostic of PAC or an HPT-JT-related tumour and is a useful adjunct to the traditional histological criteria for malignancy.⁵⁶ Another molecular marker called protein gene product (PGP 9.5) is used to complement parafibromin in the immunohistochemistry process, and this is upregulated in the majority of PAC.⁵⁵

MEDICAL THERAPY

Hypercalcaemia

Medical control of hypercalcaemia is important pre-operatively and also in cases of inoperable PAC. Hypercalcaemic crisis is a medical emergency and requires prompt intervention.³⁴ Aggressive fluid resuscitation with isotonic saline is required as patients become severely dehydrated due to nephrogenic diabetes insipidus and associated nausea and vomiting. Loop diuretics such as frusemide increase urinary calcium excretion and are effective once the patient is euvolaemic. Bisphosphonates (e.g. pamidronate, clodronate, etidronate) inhibit osteoclast-mediated bone resorption and cause apoptosis of osteoclasts and are critical in reducing serum calcium in PAC.⁶⁰ Intravenous pamidronate is infused slowly at a dosage of 60–90 mg and decreases calcium in 2–4 days.²

The effect has a duration of 1–3 weeks but efficacy reduces with time.

Calcimimetic agents (e.g. cinacalcet) increase the sensitivity of parathyroid cells to the suppressive effects of high extracellular calcium by binding to calcium-sensing receptors on parathyroid cells.^{2, 60} Cinacalcet is an oral agent given 30–60 mg daily with a rapid onset of action that reduces calcium within 48 hours and is generally well tolerated.

Other useful agents in PAC include calcitonin and plicamycin. Calcitonin inhibits osteoclast bone resorption and increases urinary excretion of calcium. Calcitonin can be used in conjunction with corticosteroids, which in isolation are useful in reducing hypercalcaemia.⁶¹ Plicamycin is an antineoplastic antibiotic that transiently inhibits bone resorption but has toxic effects on the liver, kidneys and bone marrow. Gallium nitrate, octreotide and haemodialysis can also be used to reduce hypercalcaemia.^{2, 34, 62}

Chemotherapy

Chemotherapeutic agents do not offer significant benefit to patients with PAC. There is no standard chemotherapy regime for PAC as there are no randomized trials to support its use. Several case studies involving the use of dacarbazine, fluorouracil, cyclophosphamide, methotrexate and doxorubicin^{63, 64} have shown some success.

Radiotherapy

PAC has historically been considered radioresistant.^{7, 34} However, the Mayo Clinic reports disease-free survival of 60 months in four patients who received post-operative radiotherapy⁶⁵ and this is supported by the MD Anderson experience of a lower local recurrence rate from 77% to 17% with adjuvant radiation.³⁵ Other case reports support findings that PAC may be a radiosensitive tumour.^{66, 67} Given the lack of strong evidence for the routine use of external beam radiotherapy in PAC, it seems prudent to incorporate it when surgical options have been exhausted.

PROGNOSIS

PAC is generally a slow-growing cancer and the median overall survival is 14.3 years but can range from 1 month to more than 20 years.^{4, 46, 68} Overall survival ranges from 85% at 5 years to 35–79% at 10 years.² As there is no widely accepted adjuvant therapy, complete surgical resection remains the mainstay of cure for both primary and recurrent disease.⁴⁰ En bloc resection results in 10–30% local recurrence and 90% long-term survival rates; incomplete resection results in a 50% recurrence rate and a mortality rate of 46%.⁷ Other negative prognostic indicators include lymph node or distant metastases and non-functioning tumours. Tumour size is not a prognostic indicator.^{46, 68} There is currently no prognostic staging system. Mortality from functional PAC is due to end-organ failure (e.g. renal failure) from uncontrolled hypercalcaemia.^{39, 40}

Overall, PAC is a rare, slowly progressive malignancy, which requires medical control of hypercalcaemia, surgical resection and long-term follow-up. It is best managed in a multidisciplinary setting with clinicians experienced

in the management of parathyroid disease. Expert histological assessment is critical as is an understanding of the genetic associations this rare cancer exhibits.

KEY POINTS

- Parathyroid cancer is a rare cause of primary hyperparathyroidism and typically presents with marked hypercalcaemia with corrected serum calcium greater than 14 mg/dL or 3.5 mmol/L.
- Parathyroid cancers typically present in the fourth to fifth decades of life and are distributed equally between males and females.
- Pre-operative treatment requires correction of metabolic and electrolyte disturbances with saline hydration, loop diuretics, bisphosphonates and calcimimetics.
- Surgery is the mainstay of treatment and the only curative modality.
- The surgical approach should incorporate four-gland parathyroid exploration with en-bloc resection of the tumour and involved structures to achieve complete removal.
- Mutations of the *HRPT2* tumour suppressor gene are strongly associated with the hyperparathyroidism-jaw tumour syndrome and parathyroid cancers.
- Parathyroid cancer is generally a slowly progressive malignancy with a 10-year disease-specific survival of 49–77%.
- Immunohistochemical staining for parafibromin and PGP 9.5 are useful adjuncts to histological diagnosis of parathyroid cancer.

BILATERAL PARATHYROID EXPLORATION

R. James A. England and Nick McIvor

Introduction	865	The operation of bilateral parathyroid exploration.....	868
When to perform bilateral parathyroid exploration.....	865	References	871

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: bilateral exploration, four-gland exploration and parathyroid.

INTRODUCTION

Primary hyperparathyroidism (HPT) is only curable surgically. It is a common endocrine condition with approximately 100 000 new cases diagnosed annually in the United States.¹ Traditionally, the operative procedure of choice involves a search for all four parathyroid glands and the selective removal of any gland(s) judged enlarged by visual inspection. The principles of bilateral parathyroid exploration (BPE) have remained unchanged since their first description by Felix Mandl in 1926.²

More recently, improved localization techniques and the use of intra-operative parathyroid hormone level monitoring have led to a shift away from BPE towards more focused surgery, the often-labelled minimally invasive parathyroidectomy (MIP). This procedure enables ambulatory parathyroidectomy and parathyroidectomy under sedation or local anaesthesia. However, most parathyroid surgeons agree that MIP is only feasible for single-gland disease.

The traditional four gland exploration is therefore mainly for patients with suspected multigland disease, negative imaging and patients undergoing revision surgery. The significant incidence of such patients demands that a parathyroid surgeon has the ability to perform the traditional operation.

This chapter discusses the situations in which BPE is generally the preferred surgical option and the operative steps of BPE.

WHEN TO PERFORM BILATERAL PARATHYROID EXPLORATION

Cases where bilateral parathyroid exploration may be performed fall into four broad groups:

- suspected multigland disease
- parathyroid cancer
- failed pre-operative localization
- failed MIP.

Suspected multigland disease

Approximately 15% of primary HPT patients and all those with secondary HPT have multigland disease. Those with primary HPT having multigland disease include those with double adenoma, non-familial hyperplasia, and familial HPT.

PRIMARY HPT – DOUBLE ADENOMA / PRIMARY HYPERPLASIA

There is some debate as to whether double adenoma is a distinct entity. Some argue that double adenomas are rare and the distinction between adenoma and asymmetrical hyperplasia is difficult pathologically.³ Hyperplasia can be localized within a gland and asymmetrical between glands.

It is not surprising therefore that there is poor correlation between surgeons and pathologists and even among pathologists themselves when interpreting hyperfunctioning glands.⁴

Clonal studies confirm that adenomas are monoclonal whereas hyperplastic glands and normal glands are polyclonal.⁵ However, the likelihood of monoclonal growth occurring simultaneously in two separate glands should be low. Increased proliferative activity is reported in normal glands of some double adenoma patients, suggesting adenomas may arise in a background of hyperplasia.⁶ Furthermore, clonal studies have confirmed monoclonal growth occurring within hyperplastic glands in both primary hyperplasia and renal hyperparathyroidism.^{6–8} Thus the concept of double adenoma is supportable albeit probably in a setting of asymmetrical hyperplasia. The question remains as to how long a patient should be observed after removal of double adenomas to exclude the possibility of recurrence and/or diagnosis of hyperplasia. An interval of 5 years has been recommended.³

In primary HPT, therefore, the surgeon needs to know that double adenoma/primary hyperplasia exists, that imaging is unreliable in this situation,^{9,10} and that a small proportion of patients undergoing MIP will require BPE.

PRIMARY HPT – FAMILIAL

Familial HPT comprises approximately 10–20% of all HPT presentations is discussed further in other chapters.

The hereditary syndromes, most frequently caused by mutations within specific genes, include multiple endocrine neoplasia (MEN) familial HPT and non-MEN familial HPT. MEN HPT occurs in MEN 1 and MEN 2A. Non-MEN HPT includes familial hypocalciuric hypercalcaemia (FHH) and neonatal severe hyperparathyroidism caused by heterozygous and homozygous calcium-sensing receptor gene mutations respectively. Also included is familial isolated HPT for which no specific genetic mutation has thus far been identified, and hyperparathyroidism-jaw tumour syndrome (HPT-JT).¹¹

A familial syndrome should be suspected in young patients (teens, 20s), those with a family history of HPT, and those with a previous history or family history of medullary carcinoma, pheochromocytoma, insulinoma, carcinoid or pituitary tumour. Familial syndromes exist in an autosomal dominant pattern.

Traditional BPE is the procedure of choice in most of these patients with the exception of FHH, which requires no treatment.

MEN familial HPT

MEN 1 HPT MEN 1 is relatively rare, occurring in approximately 1 in 30 000 people. The *MEN1* gene, identified in 1997, is the only gene known to be associated with the syndrome.¹² Primary hyperparathyroidism is the most common clinical manifestation of multiple endocrine neoplasia type 1.² It represents approximately 2–4% of all PHPT, making it the most common form of inherited HPT.

Clinically evident disease is present in 95% of carriers by 25 years of age, with all being affected by 50.¹³ The severity of the condition mandates surgery is performed in most cases but the type of procedure performed varies. The aim of surgery has to be to control HPT, minimize HPT recurrence and avoid hypoparathyroidism. Because of the genetic nature of the condition, removal of only enlarged glands at surgery is not practised because recurrence rates are too high.

Currently, two surgical approaches tend to be practised: subtotal parathyroidectomy removing at least 3–3.5 glands, and total parathyroidectomy with autotransplantation. In both procedures transcervical thymectomy is advised as the thymus often contains ectopic and/or supernumerary parathyroid glands and may develop thymic carcinoids.¹⁴

Subtotal parathyroidectomy generally involves the removal of the three largest glands and part of the fourth, maintaining approximately 50g of parathyroid tissue. In 20% of cases all four glands cannot be found and in this situation a three-gland parathyroidectomy is performed. Large series with long-term follow-up are sparse, but persistent HPT rates range from 0% to 33%, recurrence rates from 0% to 51% and hypoparathyroidism rates from 0% to 27%.^{15–19}

Total parathyroidectomy aims to remove all functioning parathyroid tissue. Hypoparathyroidism is then avoided by reimplantation of approximately 50mg of autologous parathyroid tissue harvested from the most macroscopically normal of the parathyroid glands removed.

The optimum surgical approach is debatable. A cohort study from the Netherlands concluded that the most effective surgical approach involved subtotal parathyroidectomy (SPTX) with bilateral transcervical thymectomy. This was because persistence/recurrence was statistically more frequent when thymectomy was not performed, but permanent hypoparathyroidism was much more likely following total parathyroidectomy (TPTX). However, due to the rarity of the condition, a sample size of 73 patients undergoing a variety of surgical procedures in a non-randomized fashion makes it hard to draw firm conclusions.²⁰ The conclusions obtained correlated with those from a previous meta-analysis searching Medline, Embase and Cochrane from 1966 to 2008 which resulted in the analysis of 12 studies comparing SPTX with TPTX. The analysis concluded that <SPTX (defined as <three gland resection) should not be performed because of the high risk of persistent and recurrent disease. Also TPTX carried too high a risk of permanent hypoparathyroidism (67%). Once again, more caution should be observed, no RCTs were found and all data was retrospective. In addition, follow-up periods varied and the study group was from the same institution as the more recent Netherlands study.²¹

MEN 2A HPT The MEN 2A subtype constitutes 70–80% of cases of MEN 2. In MEN 2A the overriding concern is to manage medullary thyroid cancer (MTC) in a timely fashion, ideally operating on the patient prior to

malignant transformation, but after diagnosis or exclusion of pheochromocytoma. MEN 2A hyperparathyroidism occurs in approximately 20–30% of MEN 2A patients and is generally mild or asymptomatic.²² In the majority of cases, hyperplasia occurs prior to adenoma formation although at surgery a single adenoma may be found.²³ It tends to occur in the third decade of life, but generally before the age of 39.²⁴ Although hyperparathyroidism is associated with various *RET* codon mutations, it tends to occur primarily in association with the exon 11 codon 634 mutation, which accounts for 85% of patients with MEN 2A.²⁵

Recommended surgery depends on whether the neck has previously been operated on as is frequently the case to manage/avoid medullary thyroid cancer. In the unoperated neck with diagnosed PHPT in MEN 2A, ATA guidelines suggest removal of either enlarged glands only, a 3–3.5-gland parathyroidectomy (subtotal) or total parathyroidectomy, all with forearm autograft. For patients who develop PHPT after thyroid surgery it is recommended that parathyroid surgery is directed by pre-operative imaging, again with forearm autograft unless a functioning graft already exists. Patients are controlled medically if there is a high risk of surgical mortality, recurrent disease after previous surgeries or limited life expectancy. All recommendations are grade C.²⁶ It is felt that the optimal surgical intervention should be individualized as the condition is mild and, indeed, often asymptomatic, and most series have significant numbers of permanent hyper- and permanent hypoparathyroid patients.^{27, 28}

Non-MEN familial HPT

Severe neonatal hyperparathyroidism This is a very rare but life-threatening disease in neonates demanding urgent management. Total parathyroidectomy via BPE following medical stabilization with biphosphonate therapy is usually required within the first few months of life. The morbidity of permanent hypoparathyroidism has encouraged surgeons to autotransplant parathyroid tissue, with variable success.²⁹

Hyperparathyroidism-jaw tumour syndrome HPT-JT is a rare autosomal dominant familial cancer syndrome. The condition comprises primary HPT, ossifying tumours of the maxilla and mandible and less commonly renal cysts and/or uterine tumours.³⁰ HPT is the commonest feature of this disease. In affected individuals HPT occurs in approximately 80% of cases. The HPT occurs at a young age (mean 32 years), and it has a high incidence of severe hypercalcaemia and 15% malignancy rate. Treatment comprises a protocol similar to the management of MEN 2A, where only macroscopically enlarged glands are removed, although all glands should be found and assessed because of the high cancer rate. Some advocate total parathyroidectomy to negate the cancer risk.³¹ If a likely cancer diagnosis is made at surgery, then en bloc resection of tumour, ipsilateral thyroid lobe and adjacent involved tissue is performed.

SECONDARY/TERTIARY HPT

Parathyroid surgery in renal failure

With decreasing renal function there is an associated decrease in renal 1-alpha hydroxylase activity, with a resultant drop in calcitriol or vitamin D3 synthesis. This in turn decreases the stimulation of the vitamin D receptor on parathyroid cells, causing an increased production of PTH and secondary HPT.³² This leads to extraskeletal calcification and cardiac disease, causing an increased risk of cardiovascular morbidity and mortality. Indeed, dialysis patients on multivariate analysis have a 30 times greater risk of cardiovascular mortality than the general population.³³

Renal failure patients are treated to normalize biochemical parameters, minimize bone disease and prevent extraskeletal calcium deposition. Nephrologists use serum calcium, phosphate, vitamin D and PTH levels as surrogate markers of disease severity. Treatment involves replacing serum vitamin D and restricting phosphate in the diet; vitamin D replacement in renal failure patients has been shown to reduce the risk of mortality, particularly cardiac related mortality.³⁴ If phosphate restriction proves insufficiently effective, phosphate binders such as calcium acetate and aluminium hydroxide are prescribed. In addition, calcimimetic agents such as cinacalcet may be used. Its implementation has led to a reduction in fracture risk, hospitalization rates for cardiovascular disease and requirement of parathyroid surgery.³⁵
